Table 1: Part-of-speech tagging with Universal Tags: This table shows test results on 5 languages at different target runtimes. Each row's best results are in **boldface**, where ties in accuracy are broken in favor of faster models. Superscript k indicates that the accuracy is significantly different from the k-CRF (paired permutation test, $p < 0.05$) and this superscript is in blue/red if the accuracy is higher/lower than the k-CRF. In all cases, we find a VoCRF (underlined) that is about as accurate as the 2-CRF (i.e., not significantly less accurate) and far faster, since the 2-CRF has $\lvert\overline{\mathcal{W}}\rvert = 4913$. Fig. 1 plots the Pareto frontiers.

(x_{t-1}, x_{t+1}). We use special boundary symbols for tokens at positions beyond the start or end of the sentence.

- Prefixes and suffixes of x_t, up to 4 characters long, that occur ≥ 5 times in the training data.
- Indicators for whether x_t is all caps, is lowercase, or has a digit.
- Word shape of x_t, which maps the token string into the following character classes (uppercase, lowercase, number) with punctuation unmodified (e.g., VoCRF-like $\Rightarrow$ AaAAA-aaaa, $5,432.10 $\Rightarrow$ $8,888.88).

For efficiency, we hash these properties into 2^{22} bins. The $\boldsymbol{f}^{(1)}$ features are obtained by conjoining these bins with y_t (Weinberger et al., 2009): e.g., there is a feature that returns 0 unless $y_t = \textsf{NOUN}$, in which case it counts the number of bin 1234567's properties that $(\boldsymbol{x}, t)$ has. (The $\boldsymbol{f}^{(2)}$ features are not hashed.)

Results: Our results are presented in Fig. 1 and Table 1. We highlight two key points: (i) Across *all languages* we learned a tagger about as accurate as a 2-CRF, but much faster. (ii) The size of the set $\overline{\mathcal{W}}$ required is highly language-dependent. For many languages, learning a full k-CRF is wasteful; our method resolves this problem.

In each language, the fastest "good" VoCRF is rather faster than the fastest "good" k-CRF (where "good" means statistically indistinguishable from the 2-CRF). These two systems are underlined; the underlined VoCRF systems are smaller than the underlined k-CRF systems (for the 5 languages respectively) by factors of 1.9, 6.4, 3.4, 1.9, and 2.9. In every language, we learn a VoCRF with $\lvert\overline{\mathcal{W}}\rvert \leq 850$ that is not significantly worse than a 2-CRF with $\lvert\overline{\mathcal{W}}\rvert = 17^3 = 4913$.

We also notice an interesting language-dependent effect, whereby certain languages require a small number of tag strings in order to perform well. For example, Hindi has a competitive model that ignores the previous tag y_{t-1} unless it is in $\{\textsf{NOUN}, \textsf{VERB}, \textsf{ADP}, \textsf{PROPN}\}$: thus the stationary features are 17 unigrams plus 4×17 bigrams, for a total of $\lvert\overline{\mathcal{W}}\rvert = 85$. At the other extreme, the Slavic languages Slovenian and Bulgarian seem to require more expressive models over the tag space, remembering as many as 98 useful left-context histories (unigrams and bigrams) for the current tag. An interesting direction for future research would be to determine which morpho-syntactic properties of a language tend to increase the complexity of tagging.

6 Conclusion

We presented a structured sparsity approach for structure learning in VoCRFs, which achieves the accuracy of higher-order CRFs at a fraction of the runtime. Additionally, we derive an asymptotically faster algorithm for the gradients necessary to train a VoCRF than prior work. Our method provides an effective speed-accuracy tradeoff for POS tagging across five languages—confirming that significant speed-ups are possible with little-to-no loss in accuracy.

Abstract

Deep neural networks have achieved remarkable results across many language processing tasks, however these methods are highly sensitive to noise and adversarial attacks. We present a regularization based method for limiting network sensitivity to its inputs, inspired by ideas from computer vision, thus learning models that are more robust. Empirical evaluation over a range of sentiment datasets with a convolutional neural network shows that, compared to a baseline model and the dropout method, our method achieves superior performance over noisy inputs and out-of-domain data.[1]

1 Introduction

Deep learning has achieved state-of-the-art results across a range of computer vision (Krizhevsky et al., 2012), speech recognition (Graves et al., 2013) and natural language processing tasks (Bahdanau et al., 2015; Kalchbrenner et al., 2014; Yih et al., 2014; Bitvai and Cohn, 2015). However, deep models are often overconfident for noisy test instances, making them susceptible to adversarial attacks (Nguyen et al., 2015; Tabacof and Valle, 2016). Goodfellow et al. (2014) argued that the primary cause of neural networks' vulnerability to adversarial perturbation is their linear nature, due to neural models being intentionally designed to behave in a mostly linear manner to facilitate optimization. Fawzi et al. (2015) provided a theoretical framework for analyzing the robustness of classifiers to adversarial perturbations, and also showed linear models are usually not robust to adversarial noise.

In this work, we present a regularization method which makes deep learning models more robust to noise, inspired by Rifai et al. (2011). The intuition behind the approach is to stabilize predictions by minimizing the ability of features to perturb predictions, based on high-order derivatives. Rifai et al. (2011) introduced contractive auto-encoders based on similar ideas, using the Frobenius norm of the Jacobian matrix as a penalty term to extract robust features. Further, Gu and Rigazio (2014) introduced deep contractive networks, generalizing this idea to a feed-forward neural network. Also related, Martens (2010) investigated a second-order optimization method based on Hessian-free approach for training deep auto-encoders. Where our proposed approach differs is that we train models using first-order derivatives of the training loss as part of a regularization term, necessitating second-order derivatives for computing the gradient. We empirically demonstrate the effectiveness of the model over text corpora with increasing amounts of artificial masking noise, using a range of sentiment analysis datasets (Pang and Lee, 2008) with a convolutional neural network model (Kim, 2014). In this, we show that our method is superior to dropout (Srivastava et al., 2014) and a baseline method using MAP training.

2 Training for Robustness

Our method introduces a regularization term during training to ensure model robustness. We develop our approach based on a general class of parametric mod-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1979–1985,
Austin, Texas, November 1-5, 2016.

els, with the following structure. Let $\mathbf{x}$ be the input, which is a sequence of (discrete) words, represented by a fixed-size vector of continuous values, $\mathbf{h}$. A transfer function takes $\mathbf{h}$ as input and produces an output distribution, $\mathbf{y}_{\text{pred}}$. Training proceeds using stochastic gradient descent to minimize a loss function L, measuring the difference between $\mathbf{y}_{\text{pred}}$ and the truth $\mathbf{y}_{\text{true}}$.

The purpose of our work is to learn neural models which are more robust to strange or invalid inputs. When small perturbations are applied on $\mathbf{x}$, we want the prediction $\mathbf{y}_{\text{pred}}$ to remain stable. Text can be highly variable, allowing for the same information to be conveyed with different word choice, different syntactic structures, typographical errors, stylistic changes, etc. This is a particular problem in transfer learning scenarios such as domain adaptation, where the inputs in distinct domains are drawn from related, but different, distributions. A good model should be robust to these kinds of small changes to the input, and produce reliable and stable predictions.

Next we discuss methods for learning models which are robust to variations in the input, before providing details of the neural network model used in our experimental evaluation.

2.1 Conventional Regularization and Dropout

Conventional methods for learning robust models include l_1 and l_2 regularization (Ng, 2004), and dropout (Srivastava et al., 2014). In fact, Wager et al. (2013) showed that the dropout regularizer is first-order equivalent to an l_2 regularizer applied after scaling the features. Dropout is also equivalent to "Follow the Perturbed Leader" (FPL) which perturbs exponential numbers of experts by noise and then predicts with the expert of minimum perturbed loss for online learning robustness (van Erven et al., 2014). Given its popularity in deep learning, we take dropout to be a strong baseline in our evaluation.

The key idea behind dropout is to randomly zero out units, along with their connections, from the network during training, thus limiting the extent of co-adaptation between units. We apply dropout on the representation vector $\mathbf{h}$, denoted $\hat{\mathbf{h}} = \text{dropout}_\beta(\mathbf{h})$, where β is the dropout rate. Similarly to our proposed method, training with dropout requires gradient based search for the minimizer of the loss L.

We also use dropout to generate noise in the test data as part of our experimental simulations, as we will discuss later.

2.2 Robust Regularization

Our method is inspired by the work on adversarial training in computer vision (Goodfellow et al., 2014). In image recognition tasks, small distortions that are indiscernible to humans can significantly distort the predictions of neural networks (Szegedy et al., 2014). An intuitive explanation of our regularization method is, when noise is applied to the data, the variation of the output is kept lower than the noise. We adapt this idea from Rifai et al. (2011) and develop the Jacobian regularization method.

The proposed regularization method works as follows. Conventional training seeks to minimise the difference between $\mathbf{y}_{\text{true}}$ and $\mathbf{y}_{\text{pred}}$. However, in order to make our model robust against noise, we also want to minimize the variation of the output when noise is applied to the input. This is to say, when perturbations are applied to the input, there should be as little perturbation in the output as possible. Formally, the perturbations of output can be written as $\mathbf{p}_{\text{y}} = \text{M}(\mathbf{x}+\mathbf{p}_{\text{x}}) - \text{M}(\mathbf{x})$, where $\mathbf{x}$ is the input, $\mathbf{p}_{\text{x}}$ is the vector of perturbations applied to $\mathbf{x}$, M expresses the trained model, $\mathbf{p}_{\text{y}}$ is the vector of perturbations generated by the model, and the output distribution $\mathbf{y} = \text{M}(\mathbf{x})$. Therefore

$$\lim_{\mathbf{p_x}\to\mathbf{0}} \mathbf{p_y} = \lim_{\mathbf{p_x}\to\mathbf{0}} \big(\text{M}(\mathbf{x}+\mathbf{p}_{\text{x}}) - \text{M}(\mathbf{x})\big) = \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \cdot \mathbf{p_x},$$

$$\text{and} \quad \text{distance}\left(\lim_{\mathbf{p_x}\to\mathbf{0}} \mathbf{p}_{\text{y}}/\mathbf{p}_{\text{x}}, \mathbf{0}\right) = \left\| \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right\|_F .$$

In other words, minimising local noise sensitivity is equivalent to minimising the Frobenius norm of the Jacobean matrix of partial derivatives of the model outputs *wrt* its inputs.

To minimize the effect of perturbation noise, our method involves an additional term in the loss function, in the form of the derivative of loss L with respect to hidden layer $\mathbf{h}$. Note that while in principle we could consider robustness to perturbations in the input $\mathbf{x}$, the discrete nature of $\mathbf{x}$ adds additional mathematical complications, and thus we defer this setting for future work. Combining the elements, the new loss function can be expressed as

$$\mathscr{L} = L + \lambda \cdot \left\| \frac{\partial L}{\partial \mathbf{h}} \right\|_2 , \tag{1}$$

where λ is a weight term, and $\mathrm{distance}$ takes the form of the l_2 norm. The training objective in Equation (1) supports gradient optimization, but note that it requires the calculation of second-order derivatives of L during back propagation, arising from the $\partial L/\partial \mathbf{h}$ term. Henceforth we refer to this method as **robust regularization**.

2.3 Convolutional Network

For the purposes of this paper, we focus exclusively on convolutional neural networks (CNNs), but stress that the method is compatible with other neural architectures and other types of parametric models (not just deep neural networks). The CNN used in this research is based on the model proposed by Kim (2014), and is outlined below.

Let S be the sentence, consisting of n words $\{w_1, w_2, \cdots, w_n\}$. A look-up table is applied to S, made up of word vectors $\mathbf{e}_{\mathrm{i}} \in \mathbb{R}^m$ corresponding to each word w_i, where m is the word vector dimensionality. Thus, sentence S can be represented as a matrix $\mathbf{E}_{\mathrm{S}} \in \mathbb{R}^{m \times n}$ by concatenating the word vectors $\mathbf{E}_{\mathrm{S}} = \bigoplus_{i=1}^{n} \mathbf{e}_{\mathrm{w_i}}$.

A convolutional layer combined with a number of wide convolutional filters is applied to $\mathbf{E}_{\mathrm{S}}$. Specifically, the k-th convolutional filter operator filter_k involves a weight vector $\mathbf{w}_{\mathrm{k}} \in \mathbb{R}^{m \times t}$, which works on every t_k-sized window of $\mathbf{E}_{\mathrm{S}}$, and is accompanied by a bias term $b \in \mathbb{R}$. The filter operator is followed by the non-linear function $\mathscr{F}$, a rectified linear unit, ReLU, followed by a max-pooling operation, to generate a hidden activation $h_k = \mathrm{MaxPooling}(\mathscr{F}(\mathrm{filter}_k(\mathbf{E}_{\mathrm{S}}; \mathbf{w}_{\mathrm{k}}, b))$. Multiple filters with different window sizes are used to learn different local properties of the sentence. We concatenate all the hidden activations h_k to form a hidden layer $\mathbf{h}$, with size equal to the number of filters. Details of parameter settings can be found in Section 3.2.

The feature vector $\mathbf{h}$ is fed into a final $\mathrm{softmax}$ layer with a linear transform to generate a probability distribution over labels

$$\mathbf{y}_{\mathrm{pred}} = \mathrm{softmax}(\mathbf{w} \cdot \mathbf{h} + \mathbf{b}),$$

where $\mathbf{w}$ and $\mathbf{b}$ are parameters. Finally, the model minimizes the loss of the cross-entropy between the ground-truth and the model prediction, $L = \mathrm{CrossEntropy}(\mathbf{y}_{\mathrm{true}}, \mathbf{y}_{\mathrm{pred}})$, for which we use stochastic gradient descent.

3 Datasets and Experimental Setups

We experiment on the following datasets,[2] following Kim (2014):

- MR: Sentence polarity dataset (Pang and Lee, 2008)[3]
- Subj: Subjectivity dataset (Pang and Lee, 2005)[3]
- CR: Customer review dataset (Hu and Liu, 2004)[4]
- SST: Stanford Sentiment Treebank, using the 3-class configuration (Socher et al., 2013)[5]

In each case, we evaluate using classification accuracy.

3.1 Noisifying the Data

Different to conventional evaluation, we corrupt the test data with noise in order to evaluate the robustness of our model. We assume that when dealing with short text such as Twitter posts, it is common to see unknown words due to typos, abbreviations and sociolinguistic marking of different types (Han and Baldwin, 2011; Eisenstein, 2013). To simulate this, we apply word-level dropout noise to each document, by randomly replacing words by a unique sentinel symbol.[6] This is applied to each word with probability $\alpha \in \{0, 0.1, 0.2, 0.3\}$.

We also experimented with adding different levels of Gaussian noise to the sentence embeddings $\mathbf{E}_{\mathrm{S}}$, but found the results to be largely consistent with those for word dropout noise, and therefore we have omitted these results from the paper.

To directly test the robustness under a more realistic setting, we additionally perform cross-domain evaluation, where we train a model on one dataset

[2] For datasets where there is no pre-defined training/test split, we evaluate using 10-fold cross validation. Refer to Kim (2014) for more details on the datasets.

[3] https://www.cs.cornell.edu/people/pabo/movie-review-data/

[4] http://www.cs.uic.edu/~liub/FBS/sentiment-analysis.html

[5] http://nlp.stanford.edu/sentiment/

[6] This was to avoid creating new n-grams which would occur when symbols are deleted from the input. Masking tokens instead results in partially masked n-grams as input to the convolutional filters.

Table 1: Accuracy (%) with increasing word-level dropout across the four datasets. For each dataset, we apply four levels of noise $\alpha = \{0, 0.1, 0.2, 0.3\}$; the best result for each combination of α and dataset is indicated in **bold**. The Baseline model is a simple CNN model without regularization. The last model combines dropout and our method with fixed parameters β and λ as indicated.

and apply it to another. For this, we use the pairing of MR and CR, where the first dataset is based on movie reviews and the second on product reviews, but both use the same label set. Note that there is a significant domain shift between these corpora, due to the very nature of the items reviewed.

3.2 Word Vectors and Hyper-parameters

To set the hyper-parameters of the CNN, we follow the guidelines of Zhang and Wallace (2015), setting word embeddings to $m = 300$ dimensions and initialising based on word2vec pre-training (Mikolov et al., 2013). Words not in the pre-trained vector table were initialized randomly by the uniform distribution $U([-0.25, 0.25)^m)$. The window sizes of filters (t) are set to $3, 4, 5$, with 128 filters for each size, resulting in a hidden layer dimensionality of $384 = 128 \times 3$. We use the Adam optimizer (Kingma and Ba, 2015) for training.

4 Results and Discussions

The results for word-level dropout noise are presented in Table 1. In general, increasing the word-level dropout noise leads to a drop in accuracy for all four datasets, however the relative dropoff in accuracy for Robust Regularization is less than for Word Dropout, and in 15 out of 16 cases (four noise levels across the four datasets), our method achieves the best result. Note that this includes the case of $\alpha = 0$, where the test data is left in its original form, which shows that Robust Regularization is also an effective means of preventing overfitting in the model.

For each dataset, we also evaluated based on the combination of Word Dropout and Robust Regularization using the fixed parameters $\beta = 0.5$ and $\lambda = 10^{-2}$, which are overall the best individual settings. The combined approach performs better than either individual method for the highest noise levels tested across all datasets. This indicates that Robust

Train/Test		MR/CR	CR/MR

Table 2: Accuracy under cross-domain evaluation; the best result for each dataset is indicated in **bold**.

Regularization acts in a complementary way to Word Dropout.

Table 2 presents the results of the cross-domain experiment, whereby we train a model on MR and test on CR, and vice versa, to measure the robustness of the different regularization methods in a more real-world setting. Once again, we see that our regularization method is superior to word-level dropout and the baseline CNN, and the techniques combined do very well, consistent with our findings for synthetic noise.

4.1 Running Time

Our method requires second-order derivatives, and thus is a little slower at training time. Figure 1 is a plot of the training and test accuracy at varying points during training over SST.

We can see that the runtime till convergence is only slightly slower for Robust Regularization than standard training, at roughly 30 minutes on a two-core CPU (one fold) with standard training vs. 35–40 minutes with Robust Regularization. The convergence time for Robust Regularization is comparable to that for Word Dropout.

5 Conclusions

In this paper, we present a robust regularization method which explicitly minimises a neural model's sensitivity to small changes in its hidden representation. Based on evaluation over four sentiment analysis datasets using convolutional neural networks, we found our method to be both superior and complementary to conventional word-level dropout under varying levels of noise, and in a cross-domain evaluation.

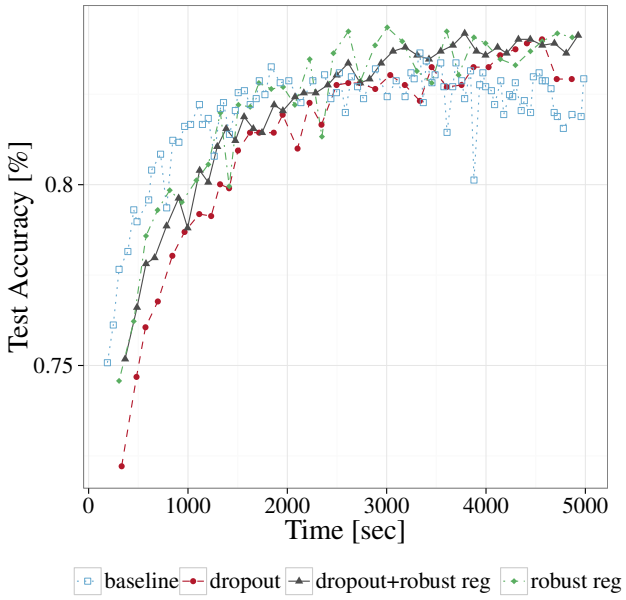

Figure 1: Time–accuracy evaluation over the different combinations of Word Dropout (dropout) and Robust Regularization (robust reg) over SST, without injecting noise.

For future work, we plan to apply our regularization method to other models and tasks to determine how generally applicable our method is. Also, we will explore methods for more realistic linguistic noise, such as lexical, syntactic and semantic noise, to develop models that are robust to the kinds of data often encountered at test time.

Acknowledgments

We are grateful to the anonymous reviewers for their helpful feedback and suggestions. This work was supported by the Australian Research Council (grant numbers FT130101105 and FT120100658). Also, we would like to thank the developers of Tensorflow (Abadi et al., 2015), which was used for the experiments in this paper.

Modified Dirichlet Distribution: Allowing Negative Parameters to Induce Stronger Sparsity*

Kewei Tu

tukw@shanghaitech.edu.cn

Abstract

The Dirichlet distribution (Dir) is one of the most widely used prior distributions in statistical approaches to natural language processing. The parameters of Dir are required to be positive, which significantly limits its strength as a sparsity prior. In this paper, we propose a simple modification to the Dirichlet distribution that allows the parameters to be negative. Our modified Dirichlet distribution (mDir) not only induces much stronger sparsity, but also simultaneously performs smoothing. mDir is still conjugate to the multinomial distribution, which simplifies posterior inference. We introduce two simple and efficient algorithms for finding the mode of mDir. Our experiments on learning Gaussian mixtures and unsupervised dependency parsing demonstrate the advantage of mDir over Dir.

1 Dirichlet Distribution

The Dirichlet distribution (Dir) is defined over probability vectors $\boldsymbol{x} = \langle x_1, \ldots, x_n \rangle$ with positive parameter vector $\boldsymbol{\alpha} = \langle \alpha_1, \ldots, \alpha_n \rangle$:

$$\mathrm{Dir}(\boldsymbol{x}; \boldsymbol{\alpha}) = \frac{1}{\mathrm{B}(\boldsymbol{\alpha})} \prod_{i=1}^{n} x_i^{\alpha_i - 1}$$

where the normalization factor $\mathrm{B}(\boldsymbol{\alpha})$ is the multivariate beta function. When the elements in $\boldsymbol{\alpha}$ are larger than one, Dir can be used as a smoothness prior that prefers more uniform probability vectors, with larger $\boldsymbol{\alpha}$ values inducing more smoothness. When the elements in $\boldsymbol{\alpha}$ are less than one, Dir can be seen as a sparsity prior that prefers sparse probability vectors, with smaller $\boldsymbol{\alpha}$ values inducing stronger sparsity. To better understand its sparsity preference, we take the logarithm of Dir:

$$\log \mathrm{Dir}(\boldsymbol{x}; \boldsymbol{\alpha}) = \sum_{i=1}^{n} (\alpha_i - 1) \log x_i + \text{constant}$$

Since $\alpha_i - 1$ is negative, the closer x_i is to zero, the higher the log probability becomes. The coefficient $\alpha_i - 1$ controls the strength of the sparsity preference. However, α_i is required to be positive in Dir because otherwise the normalization factor becomes divergent. Consequently, the strength of the sparsity preference is upper bounded. This becomes problematic when a strong prior is needed, for instance, when the training dataset is large relative to the model size (e.g., in unsupervised learning of an unlexicalized probabilistic grammar) and thus the likelihood may dominate the posterior without a strong prior.

2 Modified Dirichlet Distribution

We make a simple modification to the Dirichlet distribution that allows the parameters in $\boldsymbol{\alpha}$ to become negative. To handle the divergent normalization factor, we require that each x_i must be lower bounded by a small positive constant ϵ. Our modified Dirichlet distribution (mDir) is defined as follows.

$$\mathrm{mDir}(\boldsymbol{x}; \boldsymbol{\alpha}, \epsilon) = \begin{cases} 0 & \text{if } \exists i, x_i < \epsilon \\ \frac{1}{Z(\boldsymbol{\alpha}, \epsilon)} \prod_{i=1}^{n} x_i^{\alpha_i - 1} & \text{otherwise} \end{cases}$$

where we require $0 < \epsilon \leq \frac{1}{n}$ and do *not* require α_i to be positive. With fixed values of $\boldsymbol{\alpha}$ and ϵ, the

*This work was supported by the National Natural Science Foundation of China (61503248).

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1986–1991,
Austin, Texas, November 1-5, 2016.

unnormalized probability density is always bounded and hence the normalization factor $Z(\boldsymbol{\alpha}, \epsilon)$ is finite.

It is easy to show that mDir is still conjugate to the multinomial distribution. Similar to Dir, mDir can be used as a smoothness/sparsity prior depending on the values of $\boldsymbol{\alpha}$. Because $\boldsymbol{\alpha}$ is no longer required to be positive, we can achieve very strong sparsity preference by using a highly negative vector of $\boldsymbol{\alpha}$. Note that here we no longer achieve sparsity in its strict sense; instead, by sparsity we mean most elements in $\boldsymbol{x}$ reach their lower bound ϵ. Parameter ϵ can thus be seen as a smoothing factor that prevents any element in $\boldsymbol{x}$ to become too small. Therefore, with proper parameters, mDir is able to simultaneously achieve sparsity and smoothness. This can be useful in many applications where one wants to learn a sparse multinomial distribution in an iterative way without premature pruning of components.

2.1 Finding the Mode

If $\forall i, \alpha_i - 1 \leq 0$, then the mode of mDir can be shown to be:

$$x_i = \begin{cases} 1 - (n-1)\epsilon & \text{if } i = \arg\max_i \alpha_i \\ \epsilon & \text{otherwise} \end{cases}$$

Otherwise, we can find the mode with Algorithm 1. The algorithm first lets $x_i = \epsilon$ if $\alpha_i \leq 1$ and otherwise lets x_i be proportional to $\alpha_i - 1$. It then looks for variables in $\boldsymbol{x}$ that are less than ϵ, increases them to ϵ, and renormalizes the rest of the variables. The renormalization may decrease some additional variables below ϵ, so the procedure is repeated until all the variables are larger than or equal to ϵ.

Theorem 1. *If $\exists i, \alpha_i > 1$, then Algorithm 1 correctly finds a mode of* $\mathrm{mDir}(\boldsymbol{x}; \boldsymbol{\alpha}, \epsilon)$.

Proof. First, we can show that for any i such that $\alpha_i \leq 1$, we must have $x_i = \epsilon$ at the mode. This is because if $x_i > \epsilon$, then we can increase the probability density by first decreasing x_i to ϵ (hence increasing $x_i^{\alpha_i - 1}$), and then increasing some other variable x_j with $\alpha_j > 1$ to satisfy the normalization condition (hence also increasing $x_j^{\alpha_j - 1}$). This is consistent with the output of the algorithm.

Once we fix the value to ϵ for any variable x_i s.t. $\alpha_i \leq 1$, the log probability density function becomes strictly concave on the simplex specified by the linear constraints $\sum_i x_i = 1$ and $x_i \geq \epsilon$.

Algorithm 1 Mode-finding of $\mathrm{mDir}(\boldsymbol{x}; \boldsymbol{\alpha}, \epsilon)$

```
S ← {i|α_i ≤ 1}
T ← ∅
repeat
    T ← T ⋃ S
    for i ∈ T do
        x_i ← ε
    end for
    z ← Σ_{i∉T} (α_i − 1)
    for i ∉ T do
        x_i ← ((α_i − 1)/z) × (1 − ε|T|)
    end for
    S ← {i|x_i < ε}
until S = ∅
return ⟨x_1, ..., x_n⟩
```

The strict concavity can be proved by showing that the log probability density function is twice differentiable and the Hessian is negative definite at any point of the simplex.

With a concave function and linear constraints, the KKT conditions are sufficient for optimality. We need to show that the output of the algorithm satisfies the following KKT conditions:

- Stationarity: $\forall i, \frac{\alpha_i - 1}{x_i} = -\mu_i + \lambda$
- Primal feasibility: $\forall i, x_i \geq \epsilon$ and $\sum_i x_i = 1$
- Dual feasibility: $\forall i, \mu_i \geq 0$
- Complementary slackness: $\forall i, \mu_i(x_i - \epsilon) = 0$

Let $x_i^{(k)}$ and $T^{(k)}$ be the values of x_i and T after k iterations of the algorithm. Suppose the algorithm terminates after K iterations. So the output of the algorithm is $\langle x_1^{(K)}, \ldots, x_n^{(K)} \rangle$, which we will prove satisfies the KKT conditions.

For any i s.t. $x_i^{(K)} > \epsilon$, we set $\mu_i = 0$ and $\lambda = \frac{\alpha_i - 1}{x_i^{(K)}}$ to satisfy all the conditions involving $x_i^{(K)}$.

For any j s.t. $x_j^{(K)} = \epsilon$, suppose $x_j^{(k)} < \epsilon$, i.e., x_j falls below ϵ in iteration k and is set to ϵ afterwards. Pick some i s.t. $i \notin T^{(K)}$. After iteration k and $k+1$ respectively, we have:

$$\frac{x_i^{(k)}}{\alpha_i - 1} = \frac{1 - \epsilon \|T^{(k)}\| - \sum_{j' \in T^{(k+1)} \setminus T^{(k)}} x_{j'}^{(k)}}{\sum_{j' \notin T^{(k+1)}} \alpha_{j'} - 1}$$

$$\frac{x_i^{(k+1)}}{\alpha_i - 1} = \frac{1 - \epsilon \|T^{(k+1)}\|}{\sum_{j' \notin T^{(k+1)}} \alpha_{j'} - 1}$$

Algorithm 2 Fast mode-finding of mDir($\boldsymbol{x}; \boldsymbol{\alpha}, \epsilon$)

$\langle \alpha_{k_1}, \ldots, \alpha_{k_n} \rangle \leftarrow \langle \alpha_1, \ldots, \alpha_n \rangle$ in ascending order
$s_n \leftarrow \alpha_{k_n} - 1$
for $i = n-1, \ldots, 1$ **do**
    $s_i = s_{i+1} + \alpha_{k_i} - 1$ ▷ So $s_i = \sum_{j \geq i} (\alpha_{k_j} - 1)$
end for
$t \leftarrow 0$
for $i = 1, \ldots, n$ **do**
    $x_{k_i} \leftarrow \frac{\alpha_{k_i} - 1}{s_i} \times (1 - \epsilon\, t)$
    if $x_{k_i} < \epsilon$ **then**
        $x_{k_i} \leftarrow \epsilon\,, \quad t \leftarrow t + 1$
    end if
end for
return $\langle x_1, \ldots, x_n \rangle$

Because for any $j' \in T^{(k+1)} \backslash T^{(k)}$ we have $x_{j'}^{(k)} < \epsilon$, from the two equations above we can deduce that $x_i^{(k)} > x_i^{(k+1)}$, i.e., x_i monotonically decreases over iterations. Therefore,

$$(\alpha_j - 1) \times \frac{x_i^{(K)}}{\alpha_i - 1} < (\alpha_j - 1) \times \frac{x_i^{(k)}}{\alpha_i - 1} = x_j^{(k)} < \epsilon$$

So we get

$$\frac{\alpha_j - 1}{\epsilon} < \frac{\alpha_i - 1}{x_i^{(K)}} = \lambda$$

So we set $\mu_j = \lambda - \frac{\alpha_j - 1}{\epsilon}$ and all the conditions involving $x_j^{(K)}$ are also satisfied. The proof is now complete. □

The worst-case time complexity of Algorithm 1 is $O(n^2)$, but in practice when ϵ is small, the algorithm almost always terminates after only one iteration, leading to linear running time. We also provide a different mode-finding algorithm with better worst-case time complexity $\Theta(n \log n)$ (Algorithm 2). It differs from Algorithm 1 in that the elements of $\boldsymbol{\alpha}$ are first sorted, so we can finish computing $\boldsymbol{x}$ in one pass. It can be more efficient than Algorithm 1 when both ϵ and n are larger. Its correctness can be proved in a similar way to that of Algorithm 1.

2.2 Related Distribution

The closest previous work to mDir is the pseudo-Dirichlet distribution (Larsson and Ugander, 2011). It also allows negative parameters to achieve stronger sparsity. However, the pseudo-Dirichlet distribution is no longer conjugate to the multinomial distribution. Consequently, its maximum a posteriori inference becomes complicated and has no time-complexity guarantee.

3 Learning Mixtures of Gaussians

We first evaluate mDir in learning mixtures of Gaussians from synthetic data. The ground-truth model contains two bivariate Gaussian components with equal mixing probabilities (Figure 5(a)). From the ground-truth we sampled two training datasets of 20 and 200 data points. We then tried to fit a Gaussian mixture model with five components.

Three approaches were tested: maximum likelihood estimation using expectation-maximization (denoted by EM), which has no sparsity preference; mean-field variational Bayesian inference with a Dir prior over the mixing probabilities (denoted by VB-Dir), which is the most frequently used inference approach for Dir with $\alpha < 1$; maximum a posteriori estimation using expectation-maximization with a mDir prior over the mixing probabilities (denoted by EM-mDir). The Dir and mDir priors that we used are both symmetric, i.e., all the elements in vector $\boldsymbol{\alpha}$ have the same value, denoted by α. For mDir, we set $\epsilon = 10^{-5}$. We ran each approach under each parameter setting for 300 times with different random initialization and then reported the average results. During learning, we pruned a Gaussian component whenever its covariance matrix becomes numerically singular (which means the component is estimated from only one or two data samples).

Figure 1–4 show the average test set log likelihood and the effective numbers of mixture components of the models learned with different values of parameter α from 20 and 200 samples respectively. For VB-Dir, we show the results with the α value as low as 10^{-5}. Further decreasing α did not improve the results. It can be seen that both VB-Dir and EM-mDir can achieve better test set likelihood and lower effective numbers of components than EM with proper α values. EM-mDir outperforms VB-Dir even with positive α values, and its performance is further boosted when α becomes negative. The improvement of EM-mDir when α becomes negative is smaller in the 20-sample case than in the 200-sample case. This is because when the train-

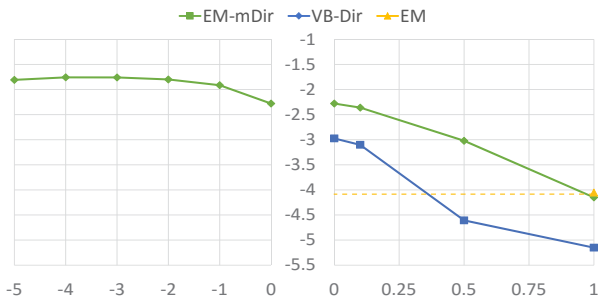

Figure 1: Test set log likelihood vs. the value of α (20 training samples)

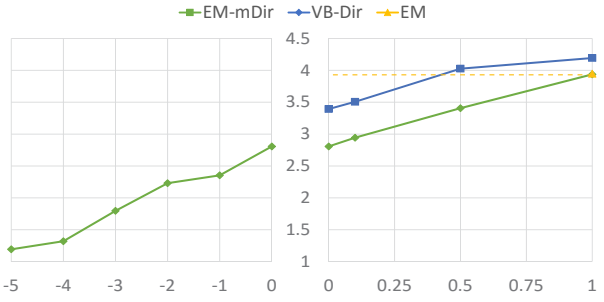

Figure 2: Effective number of components vs. the value of α (20 training samples)

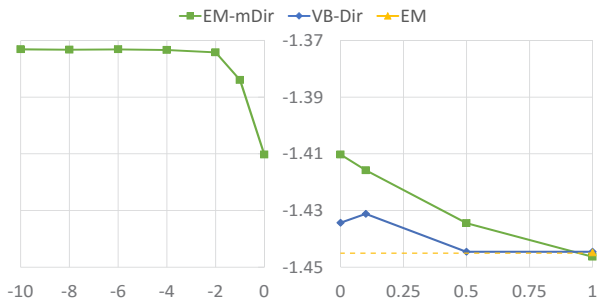

Figure 3: Test set log likelihood vs. the value of α (200 training samples)

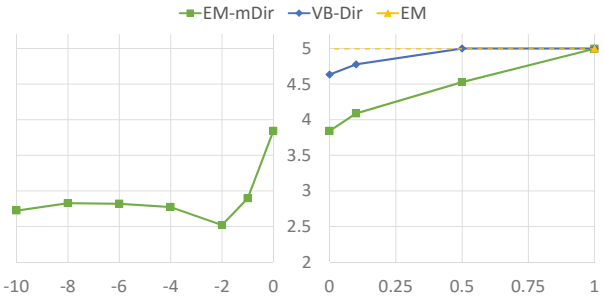

Figure 4: Effective number of components vs. the value of α (200 training samples)

ing dataset is small, a small positive α value may already be sufficient in inducing enough sparsity.

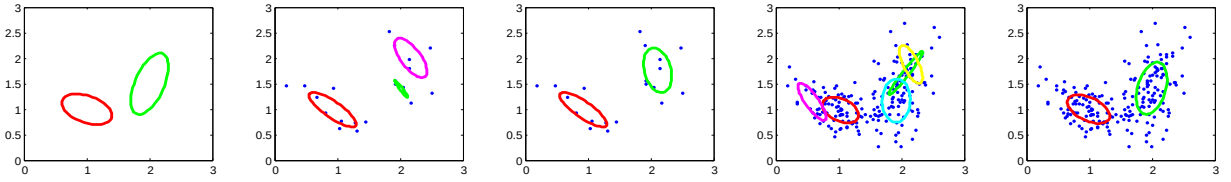
Figure 5(b)–(e) show the typical models learned by VB-Dir and EM-mDir. When the training dataset is small, both Dir and mDir are effective sparsity priors that help prune unnecessary mixture components, though mDir can be more effective with a negative α value. When the training dataset is large, however, the Dir prior is overwhelmed by the likelihood in posterior inference and cannot effectively prune mixture components. On the other hand, with a highly negative α value, mDir is still effective as a sparsity prior.

4 Unsupervised Dependency Parsing

Unsupervised dependency parsing aims to learn a dependency grammar from unannotated text. Previous work has shown that sparsity regularization improves the performance of unsupervised dependency parsing (Johnson et al., 2007; Gillenwater et al., 2010). In our experiments, we tried to learn a dependency model with valence (DMV) (Klein and Manning, 2004) from the Wall Street Journal corpus, with section 2-21 for training and section 23 for testing. Following previous work, we used sentences of length ≤ 10 with punctuation stripped off. Since DMV is an unlexicalized model, the number of dependency rules is small relative to the training corpus size. This suggests that a strong prior can be helpful in counterbalancing the influence of the training data.

We tested six approaches. With a mDir prior, we tried EM, hard EM, and softmax-EM with $\sigma = 0.5$ (Tu and Honavar, 2012) (denoted by EM-mDir, HEM-mDir, SEM-mDir). With a Dir prior, we tried variational inference, hard variational inference, and softmax variational inference with $\sigma = 0.5$ (Tu and Honavar, 2012) (denoted by VB-Dir, HVB-Dir, SVB-Dir). Again, we used symmetric Dir and mDir priors. For mDir, we set $\epsilon = 10^{-4}$ by default.

Figure 6 shows the directed accuracy of parsing the test corpus using the learned dependency models. It can be seen that with positive α values, Dir and mDir have very similar accuracy under the standard, hard and softmax versions of inference respectively. With negative α values, the accuracy of EM-mDir decreases; but for HEM-mDir and SEM-mDir, the accuracy is significantly improved with moder-



(a) Ground-truth (b) VB-Dir, $\alpha = 10^{-5}$ (c) EM-mDir, $\alpha = -2$ (d) VB-Dir, $\alpha = 10^{-5}$ (e) EM-mDir, $\alpha = -30$

Figure 5: The ground-truth model and four typical models learned by VB-Dir and EM-mDir. (b),(c): 20 training samples. (d),(e): 200 training samples.

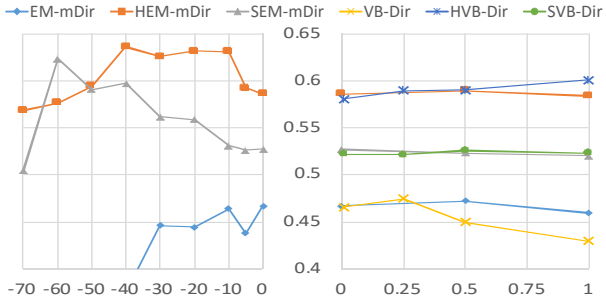


Figure 6: Parsing accuracy vs. the value of α

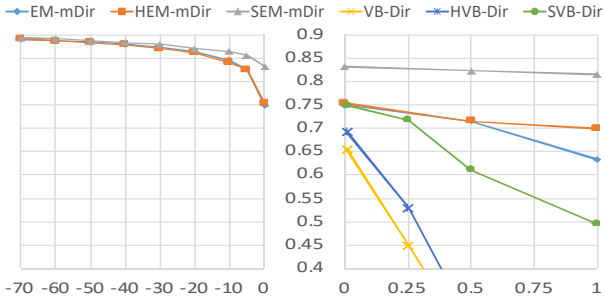

Figure 7: Sparsity of the learned grammars vs. the value of α

ately negative α values. HEM-mDir consistently produces accuracy around 0.63 with a large range of α values (from -10 to -40), which is on a par with the best published results in learning the original DMV model (Cohen and Smith, 2009; Gillenwater et al., 2010; Berg-Kirkpatrick et al., 2010), even though these previous approaches employed more sophisticated features and advanced regularization techniques than ours.

Figure 7 shows the degree of sparsity of the learned dependency grammars. We computed the percentage of dependency rules with probabilities below 10^{-3} to measure the degree of sparsity. It can be seen that even with positive α values, mDir leads to significantly more sparse grammars than Dir does. With negative values of α, mDir can induce even more sparsity.

Figure 8 plots the parsing accuracy with different values of parameter ϵ in mDir (α is set to -20). The best accuracy is achieved when ϵ is neither too large nor too small. This is because if ϵ is too large, the probabilities of dependency rules become too uniform to be discriminative. On the other hand, if ϵ is too small, then the probabilities of many dependency rules may become too small in the early stages of learning and never be able to recover. Similar observation was made by Johnson et al. (2007) when doing maximum a posteriori estimation with a Dir prior (hence with $\epsilon = 0$).

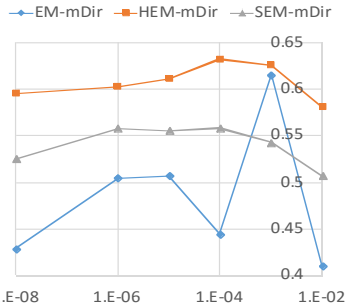

Figure 8: Parsing accuracy vs. the value of ϵ

5 Conclusion

We modify the Dirichlet distribution to allow negative values of parameter $\boldsymbol{\alpha}$ so that it induces stronger sparsity when used as a prior of a multinomial distribution. A second parameter ϵ is introduced which prevents divergence of the normalization factor and also acts as a smoothing factor. Our modified Dirichlet distribution (mDir) is still conjugate to the multinomial distribution. We propose two efficient algorithms for finding the mode of mDir. Our experiments on learning Gaussian mixtures and unsupervised dependency parsing show the advantage of mDir over the Dirichlet distribution.

Abstract

We introduce a recurrent neural network language model (RNN-LM) with long short-term memory (LSTM) units that utilizes both character-level and word-level inputs. Our model has a gate that adaptively finds the optimal mixture of the character-level and word-level inputs. The gate creates the final vector representation of a word by combining two distinct representations of the word. The character-level inputs are converted into vector representations of words using a bidirectional LSTM. The word-level inputs are projected into another high-dimensional space by a word lookup table. The final vector representations of words are used in the LSTM language model which predicts the next word given all the preceding words. Our model with the gating mechanism effectively utilizes the character-level inputs for rare and out-of-vocabulary words and outperforms word-level language models on several English corpora.

1 Introduction

Recurrent neural networks (RNNs) achieve state-of-the-art performance on fundamental tasks of natural language processing (NLP) such as language modeling (RNN-LM) (Józefowicz et al., 2016; Zoph et al., 2016). RNN-LMs are usually based on the word-level information or subword-level information such as characters (Mikolov et al., 2012), and predictions are made at either word level or subword level respectively.

In word-level LMs, the probability distribution over the vocabulary conditioned on preceding words is computed at the output layer using a softmax function. [1] Word-level LMs require a predefined vocabulary size since the computational complexity of a softmax function grows with respect to the vocabulary size. This closed vocabulary approach tends to ignore rare words and typos, as the words do not appear in the vocabulary are replaced with an out-of-vocabulary (OOV) token. The words appearing in vocabulary are indexed and associated with high-dimensional vectors. This process is done through a word lookup table.

Although this approach brings a high degree of freedom in learning expressions of words, information about morphemes such as prefix, root, and suffix is lost when the word is converted into an index. Also, word-level language models require some heuristics to differentiate between the OOV words, otherwise it assigns the exactly same vector to all the OOV words. These are the major limitations of word-level LMs.

In order to alleviate these issues, we introduce an RNN-LM that utilizes both character-level and word-level inputs. In particular, our model has a gate that adaptively choose between two distinct ways to represent each word: a word vector derived from the character-level information and a word vector stored in the word lookup table. This gate is trained to make this decision based on the input word.

According to the experiments, our model with the gate outperforms other models on the Penn Treebank (PTB), BBC, and IMDB Movie Review datasets. Also, the trained gating values show that the gating mechanism effectively utilizes the character-level

[1] softmax function is defined as $f(x_i) = \frac{\exp x_i}{\sum_k \exp x_k}$.

Austin, Texas, November 1-5, 2016.

information when it encounters rare words.

Related Work Character-level language models that make word-level prediction have recently been proposed. Ling et al. (2015a) introduce the compositional character-to-word (C2W) model that takes as input character-level representation of a word and generates vector representation of the word using a bidirectional LSTM (Graves and Schmidhuber, 2005). Kim et al. (2015) propose a convolutional neural network (CNN) based character-level language model and achieve the state-of-the-art perplexity on the PTB dataset with a significantly fewer parameters.

Moreover, word–character hybrid models have been studied on different NLP tasks. Kang et al. (2011) apply a word–character hybrid language model on Chinese using a neural network language model (Bengio et al., 2003). Santos and Zadrozny (2014) produce high performance part-of-speech taggers using a deep neural network that learns character-level representation of words and associates them with usual word representations. Bojanowski et al. (2015) investigate RNN models that predict characters based on the character and word level inputs. Luong and Manning (2016) present word–character hybrid neural machine translation systems that consult the character-level information for rare words.

2 Model Description

The model architecture of the proposed word–character hybrid language model is shown in Fig. 1.

Word Embedding At each time step t, both the word lookup table and a bidirectional LSTM take the same word w_t as an input. The word-level input is projected into a high-dimensional space by a word lookup table $\mathbf{E} \in \mathbb{R}^{|V| \times d}$, where $|V|$ is the vocabulary size and d is the dimension of a word vector:

$$\mathbf{x}^{\text{word}}_{w_t} = \mathbf{E}^\top \mathbf{w}_{w_t}, \tag{1}$$

where $\mathbf{w}_{w_t} \in \mathbb{R}^{|V|}$ is a one-hot vector whose i-th element is 1, and other elements are 0. The character–level input is converted into a word vector by using a bidirectional LSTM. The last hidden states of forward and reverse recurrent networks are linearly

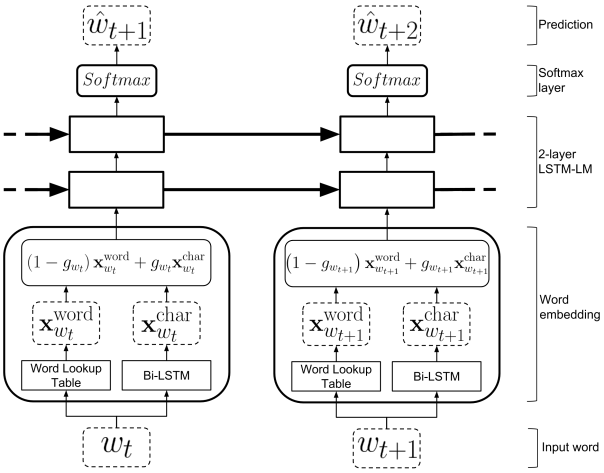

Figure 1: The model architecture of the gated word-character recurrent language model. w_t is an input word at t. $\mathbf{x}^{\text{word}}_{w_t}$ is a word vector stored in the word lookup table. $\mathbf{x}^{\text{char}}_{w_t}$ is a word vector derived from the character-level input. g_{w_t} is a gating value of a word w_t. $\hat{w}_{t+1}$ is a prediction made at t.

combined:

$$\mathbf{x}^{\text{char}}_{w_t} = \mathbf{W}^f \mathbf{h}^f_{w_t} + \mathbf{W}^r \mathbf{h}^r_{w_t} + \mathbf{b}, \tag{2}$$

where $\mathbf{h}^f_{w_t}, \mathbf{h}^r_{w_t} \in \mathbb{R}^d$ are the last states of the forward and the reverse LSTM respectively. $\mathbf{W}^f, \mathbf{W}^r \in \mathbb{R}^{d \times d}$ and $\mathbf{b} \in \mathbb{R}^d$ are trainable parameters, and $\mathbf{x}^{\text{char}}_{w_t} \in \mathbb{R}^d$ is the vector representation of the word w_t using a character input. The generated vectors $\mathbf{x}^{\text{word}}_{w_t}$ and $\mathbf{x}^{\text{char}}_{w_t}$ are mixed by a gate g_{w_t} as

$$\begin{aligned} g_{w_t} &= \sigma\left(\mathbf{v}_g^\top \mathbf{x}^{\text{word}}_{w_t} + b_g\right) \\ \mathbf{x}_{w_t} &= (1 - g_{w_t})\,\mathbf{x}^{\text{word}}_{w_t} + g_{w_t}\mathbf{x}^{\text{char}}_{w_t}, \end{aligned} \tag{3}$$

where $\mathbf{v}_g \in \mathbb{R}^d$ is a weight vector, $b_g \in \mathbb{R}$ is a bias scalar, $\sigma(\cdot)$ is a sigmoid function. This gate value is independent of a time step. Even if a word appears in different contexts, the same gate value is applied. Hashimoto and Tsuruoka (2016) apply a very similar approach to compositional and non-compositional phrase embeddings and achieve state-of-the-art results on compositionality detection and verb disambiguation tasks.

Language Modeling The output vector $\mathbf{x}_{w_t}$ is used as an input to a LSTM language model. Since the word embedding part is independent from the language modeling part, our model retains the flexibility to change the architecture of the language modeling part. We use the architecture similar to the non-regularized LSTM model by Zaremba et al. (2014).

Table 1: Validation and test perplexities on Penn Treebank (PTB), BBC, IMDB Movie Reviews datasets.

One step of LSTM computation corresponds to

$$\begin{aligned}
\mathbf{f}_t &= \sigma\left(\mathbf{W}_f \mathbf{x}_{w_t} + \mathbf{U}_f \mathbf{h}_{t-1} + \mathbf{b}_f\right) \\
\mathbf{i}_t &= \sigma\left(\mathbf{W}_i \mathbf{x}_{w_t} + \mathbf{U}_i \mathbf{h}_{t-1} + \mathbf{b}_i\right) \\
\tilde{\mathbf{c}}_t &= \tanh\left(\mathbf{W}_{\tilde{c}} \mathbf{x}_{w_t} + \mathbf{U}_{\tilde{c}} \mathbf{h}_{t-1} + \mathbf{b}_{\tilde{c}}\right) \\
\mathbf{o}_t &= \sigma\left(\mathbf{W}_o \mathbf{x}_{w_t} + \mathbf{U}_o \mathbf{h}_{t-1} + \mathbf{b}_o\right) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh\left(\mathbf{c}_t\right),
\end{aligned} \tag{4}$$

where $\mathbf{W}_s, \mathbf{U}_s \in \mathbb{R}^{d \times d}$ and $\mathbf{b}_s \in \mathbb{R}^d$ for $s \in \{f, i, \tilde{c}, o\}$ are parameters of LSTM cells. $\sigma(\cdot)$ is an element-wise sigmoid function, $\tanh(\cdot)$ is an element-wise hyperbolic tangent function, and $\odot$ is an element-wise multiplication.

The hidden state $\mathbf{h}_t$ is affine-transformed followed by a softmax function:

$$\Pr\left(w_{t+1} = k | w_{<t+1}\right) = \frac{\exp\left(\mathbf{v}_k^\top \mathbf{h}_t + b_k\right)}{\sum_{k'} \exp\left(\mathbf{v}_{k'}^\top \mathbf{h}_t + b_{k'}\right)}, \tag{5}$$

where $\mathbf{v}_k$ is the k-th column of a parameter matrix $\mathbf{V} \in \mathbb{R}^{d \times |V|}$ and b_k is the k-th element of a bias vector $\mathbf{b} \in \mathbb{R}^d$. In the training phase, we minimizes the negative log-likelihood with stochastic gradient descent.

3 Experimental Settings

We test five different model architectures on the three English corpora. Each model has a unique word embedding method, but all models share the same LSTM language modeling architecture, that has 2 LSTM layers with 200 hidden units, $d = 200$. Except for the character only model, weights in the language modeling part are initialized with uniform random variables between -0.1 and 0.1. Weights of a bidirectional LSTM in the word embedding part are initialized with Xavier initialization (Glorot and Bengio, 2010). All biases are initialized to zero.

Stochastic gradient decent (SGD) with mini-batch size of 32 is used to train the models. In the first k epochs, the learning rate is 1. After the k-th epoch, the learning rate is divided by l each epoch. k manages learning rate decay schedule, and l controls speed of decay. k and l are tuned for each model based on the validation dataset.

As the standard metric for language modeling, perplexity (PPL) is used to evaluate the model performance. Perplexity over the test set is computed as $\text{PPL} = \exp\left(-\frac{1}{N}\sum_{i=1}^{N} \log p_{(w_i|w_{<i})}\right)$, where N is the number of words in the test set, and $p_{(w_i|w_{<i})}$ is the conditional probability of a word w_i given all the preceding words in a sentence. We use Theano (2016) to implement all the models. The code for the models is available from `https://github.com/nyu-dl/gated_word_char_rlm`.

3.1 Model Variations

Word Only (baseline) This is a traditional word-level language model and is a baseline model for our experiments.

Character Only This is a language model where each input word is represented as a character se-

		Train	Validation	test
PTB	# Sentences	42k	3k	4k
	# Word	888k	70k	79k
BBC	# Sentences	37k	2k	2k
	# Word	890k	49k	53k
IMDB	# Sentences	930k	153k	152k
	# Word	21M	3M	3M

Table 2: The size of each dataset.

quence similar to the C2W model in (Ling et al., 2015a). The bidirectional LSTMs have 200 hidden units, and their weights are initialized with Xavier initialization. In addition, the weights of the forget, input, and output gates are scaled by a factor of 4. The weights in the LSTM language model are also initialized with Xavier initialization. All biases are initialized to zero. A learning rate is fixed at 0.2.

Word & Character This model simply concatenates the vector representations of a word constructed from the character input $\mathbf{x}_{w_t}^{\text{char}}$ and the word input $\mathbf{x}_{w_t}^{\text{word}}$ to get the final representation of a word $\mathbf{x}_{w_t}$, i.e.,

$$\mathbf{x}_{w_t} = \left[\begin{array}{c} \mathbf{x}_{w_t}^{\text{char}}; \mathbf{x}_{w_t}^{\text{word}} \end{array} \right]. \quad (6)$$

Before being concatenated, the dimensions of $\mathbf{x}_{w_t}^{\text{char}}$ and $\mathbf{x}_{w_t}^{\text{word}}$ are reduced by half to keep the size of $\mathbf{x}_{w_t}$ comparably to other models.

Gated Word & Character, Fixed Value This model uses a globally constant gating value to combine vector representations of a word constructed from the character input $\mathbf{x}_{w_t}^{\text{char}}$ and the word input $\mathbf{x}_{w_t}^{\text{word}}$ as

$$\mathbf{x}_{w_t} = (1-g)\,\mathbf{x}_{w_t}^{\text{word}} + g\mathbf{x}_{w_t}^{\text{char}}, \quad (7)$$

where g is some number between 0 and 1. We choose $g = \{0.25, 0.5, 0.75\}$.

Gated Word & Character, Adaptive This model uses adaptive gating values to combine vector representations of a word constructed from the character input $\mathbf{x}_{w_t}^{\text{char}}$ and the word input $\mathbf{x}_{w_t}^{\text{word}}$ as the Eq (3).

3.2 Datasets

Penn Treebank We use the Penn Treebank Corpus (Marcus et al., 1993) preprocessed by Mikolov et al. (2010). We use 10k most frequent words and 51 characters. In the training phase, we use only sentences with less than 50 words.

BBC We use the BBC corpus prepared by Greene & Cunningham (2006). We use 10k most frequent words and 62 characters. In the training phase, we use sentences with less than 50 words.

IMDB Movie Reviews We use the IMDB Move Review Corpus prepared by Maas et al. (2011). We use 30k most frequent words and 74 characters. In the training phase, we use sentences with less than 50 words. In the validation and test phases, we use sentences with less than 500 characters.

3.3 Pre-training

For the word–character hybrid models, we applied a pre-training procedure to encourage the model to use both representations. The entire model is trained only using the word-level input for the first m epochs and only using the character-level input in the next m epochs. In the first m epochs, a learning rate is fixed at 1, and a smaller learning rate 0.1 is used in the next m epochs. After the $2m$-th epoch, both the character-level and the word-level inputs are used. We use $m = 2$ for PTB and BBC, $m = 1$ for IMDB.

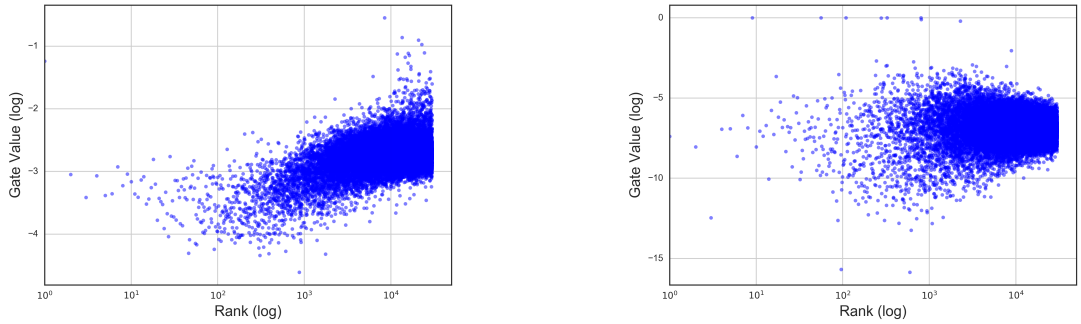
Lample et al. (2016) report that a pre-trained word lookup table improves performance of their word & character hybrid model on named entity recognition (NER). In their method, word embeddings are first trained using skip-n-gram (Ling et al., 2015b), and then the word embeddings are fine-tuned in the main training phase.

4 Results and Discussion

4.1 Perplexity

Table 1 compares the models on each dataset. On the PTB and IMDB Movie Review dataset, the gated word & character model with a fixed gating value, $g_{\text{const}} = 0.25$, and pre-training achieves the lowest perplexity . On the BBC datasets, the gated word & character model without pre-training achieves the lowest perplexity.

Even though the model with fixed gating value performs well, choosing the gating value is not clear and might depend on characteristics of datasets such as size. The model with adaptive gating values does not require tuning it and achieves similar perplexity.



(a) Gated word & character.

(b) Gated word & character with pre-taining.

Figure 2: A log-log plot of frequency ranks and gating values trained in the gated word & character models with/without pre-training.

4.2 Values of Word–Character Gate

The BBC and IMDB datasets retain out-of-vocabulary (OOV) words while the OOV words have been replaced by <unk> in the Penn Treebank dataset. On the BBC and IMDB datasets, our model assigns a significantly high gating value on the unknown word token UNK compared to the other words.

We observe that pre-training results the different distributions of gating values. As can be seen in Fig. 2 (a), the gating value trained in the gated word & character model without pre-training is in general higher for less frequent words, implying that the recurrent language model has learned to exploit the spelling of a word when its word vector could not have been estimated properly. Fig. 2 (b) shows that the gating value trained in the gated word & character model with pre-training is less correlated with the frequency ranks than the one without pre-training. The pre-training step initializes a word lookup table using the training corpus and includes its information into the initial values. We hypothesize that the recurrent language model tends to be word–input–oriented if the informativeness of word inputs and character inputs are not balanced especially in the early stage of training.

Although the recurrent language model with or without pre-training derives different gating values, the results are still similar. We conjecture that the flexibility of modulating between word-level and character-level representations resulted in a better language model in multiple ways.

Overall, the gating values are small. However, this does not mean the model does not utilize the character-level inputs. We observed that the word vectors constructed from the character-level inputs usually have a larger L2 norm than the word vectors constructed from the word-level inputs do. For instance, the mean values of L2 norm of the 1000 most frequent words in the IMDB training set are 52.77 and 6.27 respectively. The small gate values compensate for this difference.

5 Conclusion

We introduced a recurrent neural network language model with LSTM units and a word–character gate. Our model was empirically found to utilize the character-level input especially when the model encounters rare words. The experimental results suggest the gate can be efficiently trained so that the model can find a good balance between the word-level and character-level inputs.

Abstract

We propose a novel unsupervised word alignment method that uses a constraint based on Inversion Transduction Grammar (ITG) parse trees to jointly unify two directional models. Previous agreement methods are not helpful for locating alignments with long distances because they do not use any syntactic structures. In contrast, the proposed method symmetrizes alignments in consideration of their structural coherence by using the ITG constraint softly in the posterior regularization framework (Ganchev et al., 2010). The ITG constraint is also compatible with word alignments that are not covered by ITG parse trees. Hence, the proposed method is robust to ITG parse errors compared to other alignment methods that directly use an ITG model. Compared to the HMM (Vogel et al., 1996), IBM Model 4 (Brown et al., 1993), and the baseline agreement method (Ganchev et al., 2010), the experimental results show that the proposed method significantly improves alignment performance regarding the Japanese-English KFTT and BTEC corpus, and in translation evaluation, the proposed method shows comparable or statistical significantly better performance on the Japanese-English KFTT and IWSLT 2007 corpus.

1 Introduction

Word alignment is an important component of statistical machine translation (SMT) systems such as phrase-based SMT (Koehn et al., 2003) and hierarchical phrase-based SMT (Chiang, 2007). In addition, word alignment is utilized for multi-lingual tasks other than SMT, such as bilingual lexicon extraction (Liu et al., 2013). The most conventional approaches to word alignment are the IBM models (Brown et al., 1993) and the HMM model (Vogel et al., 1996), which align each source word to a single target word (i.e., directional models). In these models, bidirectional word alignments are traditionally induced by combining the Viterbi alignments in each direction using heuristics (Och and Ney, 2003). Matusov et al. (2004) exploited a symmetrized posterior probability for bidirectional word alignments. In these methods, each directional model is independently trained.

Previous researches have improved bidirectional word alignments by jointly training two directional models to agree with each other (Liang et al., 2006; Graça et al., 2008; Ganchev et al., 2010). Such a constraint on the agreement in a training phase is one of the most effective approaches to word alignment. However, none of the previous agreement constraints have taken into account syntactic structures. Therefore, they have difficulty recovering the alignments with long distances, which frequently occur, especially in grammatically different language pairs.

Some unsupervised word alignment models such as DeNero and Klein (2007) and Kondo et al. (2013), have been based on syntactic structures. In particular, it has been proven that Inversion Transduction Grammar (ITG) (Wu, 1997), which captures structural coherence between parallel sentences, helps in word alignment (Zhang and Gildea, 2004; Zhang and Gildea, 2005). However, ITG has not been introduced into an agreement constraint so far.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1998–2004,
Austin, Texas, November 1-5, 2016.

We propose an alignment method that uses an ITG constraint to encourage agreement between two directional models in consideration of their structural coherence. Our ITG constraint is based on the Viterbi alignment decided by a bracketing ITG parse tree, and used as a soft constraint in the posterior regularization framework (Ganchev et al., 2010). In addition, our ITG constraint works also on word alignments that are not covered by ITG parse trees, as a standard symmetric constraint. Hence, the proposed method is robust to ITG parse errors compared to an alignment method that uses an ITG directly in model training (e.g., Zhang and Gildea (2004, 2005)).

Word alignment evaluations show that the proposed method achieves significant gains in F-measure and alignment error rate (AER) on the KFTT (Neubig, 2011) and the BTEC Japanese-English (Ja-En) corpus (Takezawa et al., 2002). Machine translation evaluations show that our constraint significantly outperforms or is comparable to the baseline symmetric constraint (Ganchev et al., 2010) in BLEU on the KFTT Ja-En and IWSLT 2007 Ja-En corpus (Fordyce, 2007).

2 ITG Constraint in the Posterior Regularization Framework

2.1 Overview

The proposed method introduces an ITG constraint into the posterior regularization framework (Ganchev et al., 2010) in model training. The proposed model is trained as follows, where agreement constraints are imposed in the E-step of the EM algorithm[1]:

E-step:

1. Calculate a source-to-target posterior probability $\overrightarrow{p_\theta}(\boldsymbol{z}|\boldsymbol{x})$ and a target-to-source posterior probability $\overleftarrow{p_\theta}(\boldsymbol{z}|\boldsymbol{x})$ for each bilingual sentence $\boldsymbol{x} = \{\boldsymbol{f}, \boldsymbol{e}\}$ under the current model parameters $\boldsymbol{\theta}$, where $\boldsymbol{z}$ denotes an alignment in a sentence pair $\boldsymbol{x}$. In particular, $z_{i,j}$=1, if f_i is aligned to e_j (otherwise $z_{i,j}$=0).
2. Repeat the following steps for all sentence pairs in the training data.
(a) Find the Viterbi alignment $\boldsymbol{z}^*$ through ITG parsing (see Section 2.2). Here, $z^*_{i,j}$=1, if f_i is aligned to e_j (otherwise $z^*_{i,j}$=0).
(b) Symmetrize $\overrightarrow{p_\theta}(\boldsymbol{z}|\boldsymbol{x})$ and $\overleftarrow{p_\theta}(\boldsymbol{z}|\boldsymbol{x})$ under the constraint of $\boldsymbol{z}^*$ (see Section 2.3 and 2.4).

M-step:

1. Estimate all parameters $\boldsymbol{\theta}$ based on the symmetrized posterior probabilities $\overrightarrow{q_\lambda}(\boldsymbol{z}|\boldsymbol{x})$ and $\overleftarrow{q_\lambda}(\boldsymbol{z}|\boldsymbol{x})$ (see Section 2.3 and 2.4).

2.2 ITG Parsing

In this section, we present our ITG parsing method, which uses bracketing ITG (Wu, 1997). The rules of the bracketing ITG are as follows: $A \rightarrow \langle Y/Z \rangle$, $A \rightarrow [Y/Z]$, $A \rightarrow f_i/e_j$, $A \rightarrow f_i/\epsilon$, and $A \rightarrow \epsilon/e_j$, where A, Y, and Z are non-terminal symbols, f_i and e_j are terminal strings, ϵ is a null symbol, $\langle\rangle$ denotes the inversion of two phrase positions, and [] denotes the reversion of two phrase positions.

In general, a bracketing ITG has $O(|\boldsymbol{f}|^3|\boldsymbol{e}|^3)$ time complexity for parsing a sentence pair $\{\boldsymbol{f}, \boldsymbol{e}\}$, where $|\boldsymbol{f}|$ and $|\boldsymbol{e}|$ are the lengths of $\boldsymbol{f}$ and $\boldsymbol{e}$. For efficient ITG parsing, we use the two-step parsing approach (Xiao et al., 2012), which has been proposed to induce Synchronous Context Free Grammar (SCFG) using n-best pruning[2] with time complexity $O(|\boldsymbol{f}|^3)$. Because ITG is a kind of SCFG, this method can be adopted for our ITG parsing. Our two-step parsing first parses a bilingual sentence in the bottom up manner, and then derives the Viterbi alignment $\boldsymbol{z}^*$ in the top down manner.

To parse a bilingual sentence $\boldsymbol{x} = \{\boldsymbol{f}, \boldsymbol{e}\}$, we define the probability for each ITG rule. The probability of a rule $A \rightarrow f_i/e_j$ is defined as:

$$P(A \rightarrow f_i/e_j) = \frac{\overrightarrow{p}_\theta(z_{i,j}=1|\boldsymbol{x}) + \overleftarrow{p}_\theta(z_{i,j}=1|\boldsymbol{x})}{2}.$$

We provide a constant value p_{null}[3] both to $P(A \rightarrow \epsilon/e_j)$ and $P(A \rightarrow f_i/\epsilon)$. To reduce computational cost, the probabilities of phrasal rules $P(A \rightarrow \langle Y/Z \rangle)$ and $P(A \rightarrow [Y/Z])$ are not trained, which are set to 0.5 following Saers et al. (2012). In addition to the probability of each ITG rule, we must provide a probability to an one-to-many alignment because the two step parsing approach must pre-compute probabilities for all one-to-many alignments in the first step. An one-to-many alignment

[1] Step 1 in the E and M steps can be performed in the same way as in Ganchev et al. (2010).

[2] We set n to 30 in our experiments.

[3] We set p_{null} to 10^{-5}.

can be decomposed to a rule $A \rightarrow f_i/e_j$ and some $A \rightarrow \epsilon/e_j$ rules under the ITG form. We select a set of rules with the highest probability for an one-to-many alignment using Viterbi algorithm, which has a complexity of $O(|\boldsymbol{e}|)$.

2.3 Previous Agreement Constraint

This section provides an overview of the previous agreement constraint proposed by Ganchev et al. (2010), which is our baseline. In the posterior regularization framework, source-to-target and target-to-source posterior probabilities $\overrightarrow{p}_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x})$ and $\overleftarrow{p}_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x})$ are replaced with $\overrightarrow{q}_{\boldsymbol{\lambda}}(\boldsymbol{z}|\boldsymbol{x})$ and $\overleftarrow{q}_{\boldsymbol{\lambda}}(\boldsymbol{z}|\boldsymbol{x})$, defined as follows:

$$\overrightarrow{q}_{\boldsymbol{\lambda}}(\boldsymbol{z}|\boldsymbol{x}) = \overrightarrow{p}_{\theta}(\boldsymbol{z}|\boldsymbol{x}) \cdot exp^{(-\boldsymbol{\lambda}\cdot\boldsymbol{\phi}^{\text{agree}}(\boldsymbol{x},\boldsymbol{z}))}/Z_{\overrightarrow{q}},$$
$$\overleftarrow{q}_{\boldsymbol{\lambda}}(\boldsymbol{z}|\boldsymbol{x}) = \overleftarrow{p}_{\theta}(\boldsymbol{z}|\boldsymbol{x}) \cdot exp^{(-\boldsymbol{\lambda}\cdot\boldsymbol{\phi}^{\text{agree}}(\boldsymbol{x},\boldsymbol{z}))}/Z_{\overleftarrow{q}},$$

where $Z_{\overrightarrow{q}}$ is a normalization term for $\sum_{\boldsymbol{z}} \overrightarrow{q}_{\boldsymbol{\lambda}}(\boldsymbol{z}|\boldsymbol{x}) = 1$ ($Z_{\overleftarrow{q}}$ is analogous) and $\boldsymbol{\lambda}$ is a vector of weight parameters that controls the balance between two directional posterior probabilities. Here, $\boldsymbol{\phi}^{\text{agree}}$ is a feature of agreement constraint, which assigns each alignment direction to a sign (i.e., +1 or -1). In particular, $\boldsymbol{\phi}^{\text{agree}}$ is defined as follows:

$$\phi^{\text{agree}}_{i,j}(\boldsymbol{x},\boldsymbol{z}) = \begin{cases} +1 & (\boldsymbol{z} \in \overleftarrow{\boldsymbol{Z}}) \wedge (z_{i,j}{=}1), \\ -1 & (\boldsymbol{z} \in \overrightarrow{\boldsymbol{Z}}) \wedge (z_{i,j}{=}1), \\ 0 & otherwise, \end{cases}$$

where $\overrightarrow{\boldsymbol{Z}}$ and $\overleftarrow{\boldsymbol{Z}}$ are sets of possible alignments generated by source-to-target and target-to-source alignment models, respectively. So that $\overrightarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ and $\overleftarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ become equal probabilities for each i,j (i.e., $\overrightarrow{q}_{\boldsymbol{\lambda}}(\boldsymbol{z}|\boldsymbol{x})$ and $\overleftarrow{q}_{\boldsymbol{\lambda}}(\boldsymbol{z}|\boldsymbol{x})$ are symmetrical), the agreement constraint is defined as follows:

$$\forall i, \forall j, \overrightarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x}) - \overleftarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x}) = 0. \quad (1)$$

To satisfy the constraint (1), each $\lambda_{i,j}$ is updated by a stochastic gradient descent in the E-step of EM algorithm.

2.4 Proposed ITG Constraint

This section presents the proposed ITG constraint based on the Viterbi alignment $\boldsymbol{z}^*$, which has previously been identified by the bracketing ITG parsing. The ITG constraint uses a feature $\boldsymbol{\phi}^{\text{ITG}}$ instead of $\boldsymbol{\phi}^{\text{agree}}$:

$$\phi^{\text{ITG}}_{i,j}(\boldsymbol{x},\boldsymbol{z}) = \begin{cases} 0 & \overleftarrow{Y}(i,j) \wedge (z^*_{i,j}{=}1) \wedge (\delta_{i,j}(\boldsymbol{x},\boldsymbol{z}){<}0), \\ +1 & \overleftarrow{Y}(i,j) \wedge (z^*_{i,j}{=}1) \wedge (\delta_{i,j}(\boldsymbol{x},\boldsymbol{z}){>}0), \\ -1 & \overrightarrow{Y}(i,j) \wedge (z^*_{i,j}{=}1) \wedge (\delta_{i,j}(\boldsymbol{x},\boldsymbol{z}){<}0), \\ 0 & \overrightarrow{Y}(i,j) \wedge (z^*_{i,j}{=}1) \wedge (\delta_{i,j}(\boldsymbol{x},\boldsymbol{z}){>}0), \\ +1 & \overleftarrow{Y}(i,j) \wedge (z^*_{i,j}{\neq}1), \\ -1 & \overrightarrow{Y}(i,j) \wedge (z^*_{i,j}{\neq}1), \\ 0 & otherwise, \end{cases}$$

where $\overleftarrow{Y}(i,j) = (\boldsymbol{z} \in \overleftarrow{\boldsymbol{Z}}) \wedge (z_{i,j}{=}1)$, $\overrightarrow{Y}(i,j) = (\boldsymbol{z} \in \overrightarrow{\boldsymbol{Z}}) \wedge (z_{i,j}{=}1)$, and $\delta_{i,j}(\boldsymbol{x},\boldsymbol{z}) = \overrightarrow{p}_{\theta}(z_{i,j}{=}1|\boldsymbol{x}) - \overleftarrow{p}_{\theta}(z_{i,j}{=}1|\boldsymbol{x})$. Similarly to $\boldsymbol{\phi}^{\text{agree}}$, $\boldsymbol{\phi}^{\text{ITG}}$ is imposed on $\overrightarrow{q}_{\boldsymbol{\lambda}_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ and $\overleftarrow{q}_{\boldsymbol{\lambda}_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ under the constraint (1). If $z^*_{i,j} \neq 1$, our feature $\phi^{\text{ITG}}_{i,j}$ operates similarly to $\phi^{\text{agree}}_{i,j}$ according to the last three rules. If $z^*_{i,j}{=}1$, $\boldsymbol{\phi}^{\text{ITG}}$ adjusts probabilities of alignments $\overrightarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ and $\overleftarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ by increasing the lower probability without decreasing the higher probability according to the first four rules. For example, when $z^*_{i,j} = 1$ and $\overrightarrow{q}_{\lambda_{i,j}}(z_{i,j}=1|\boldsymbol{x})$ is larger than $\overleftarrow{q}_{\lambda_{i,j}}(z_{i,j}=1|\boldsymbol{x})$, $\overleftarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ is increased until $\overleftarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ equals $\overrightarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ according to the second and fourth rules. When $z^*_{i,j}{=}1$ and $\overleftarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ is larger than $\overrightarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$, $\overrightarrow{q}_{\lambda_{i,j}}(z_{i,j}{=}1|\boldsymbol{x})$ is increased until $\overleftarrow{q}_{\lambda_{i,j}}(z_{i,j}=1|\boldsymbol{x})$ equals $\overrightarrow{q}_{\lambda_{i,j}}(z_{i,j}=1|\boldsymbol{x})$ according to the first and third rules. As a result, probabilities of word alignments in $\boldsymbol{z}^*$ tend to be higher than those of the other alignments.

3 Evaluation

We compared our proposed ITG constraint (*itg*) with the baseline agreement constraint (Ganchev et al., 2010) (*sym*) on word alignment and machine translation tasks. In word alignment evaluations, we used the French-English (Fr-En) Hansard Corpus (Mihalcea and Pedersen, 2003), Ja-En KFTT[4] (Neubig,

[4]We used the cleaned dataset distributed on the KFTT official web site (http://www.phontron.com/kftt/index.html).

2011), and Ja-En BTEC Corpus (Takezawa et al., 2002). We used the first 10K sentence pairs in the training data for the IWSLT 2007 translation task, which were manually annotated with word alignment (Chooi-Ling et al., 2010), as the BTEC Corpus. In translation evaluations, we used the KFTT and Ja-En IWSLT 2007 translation tasks[5].

Table 1 shows each corpus size. In each training data set, all words were lowercased and sentences with over 80 words on either side were removed.

3.1 Word Alignment Evaluation

We measured the performance of word alignment with AER and F-measure (Och and Ney, 2003). We used only sure alignments for calculating F-measure (Fraser and Marcu, 2007)[6]. We introduced *itg* and *sym* into the HMM and IBM Model 4. Training is bootstrapped from IBM Model 1, followed by HMM and IBM Model 4. All models were trained with five consecutive iterations. In the many-to-many alignment extraction, we used the filtering method (Matusov et al., 2004), where a threshold is optimized on the corresponding AER of the baseline model (i.e., HMM+*sym* or IBM Model 4+*sym*)[7].

Table 2 shows the results of word alignment evaluations[8], where *none* denotes that the model has no constraint. In KFTT and BTEC Corpus, *itg* achieved significant improvement against *sym* and *none* on IBM Model 4 ($p \leq 0.05$)[9]. However, in the Hansard Corpus, *itg* shows no improvement against *sym*. This indicates that capturing structural coherence by *itg* yields a significant benefit to word alignment in a linguistically different language pair such as Ja-En. For example, some function words appear more than once in both a source and target sentence, and they are not symmetrically aligned with each other, especially in regards to the Ja-En language pair. Although the baseline methods tend to be unable to align such long-distance word pairs, the proposed method can correctly catch them because *itg* can determine the relation of long-distance words. We discuss more details about the effectiveness of the ITG constraint in Section 4.1.

3.2 Translation Evaluation

We measured translation performance with BLEU (Papineni et al., 2002). All language models are 5-gram and trained using SRILM (Stolcke and others, 2002) on target side sentences in the training data. When extracting phrases, we apply the method proposed by Matusov et al. (2004), where many-to-many alignments are generated based on the averages of the posterior probabilities from two directional models[10].

We used the Moses phrase-based SMT systems (Koehn et al., 2007) for decoding. We set the distortion-limit parameter to infinite[11], and other pa-

[5]BTEC Corpus is a subset of IWSLT 2007. To uniform tokenization, we retokenized all Japanese sentences both in IWSLT 2007 and BTEC Corpus using ChaSen (Asahara and Matsumoto, 2000).

[6]Since there exists no distinction for sure-possible alignments in the KFTT and BTEC data sets, we treat all alignments of them as sure alignments.

[7]We tried values from 0.1 to 1.0 at an interval of 0.1.

[8]The values in bold indicate the best score.

[9]The statistical significance test was performed by the paired bootstrap resampling (Koehn, 2004).

[10]The posterior thresholds were decided in the same way as the word alignment evaluation.

[11]This setting is generally used for Ja-En translation tasks (Murakami et al., 2007).

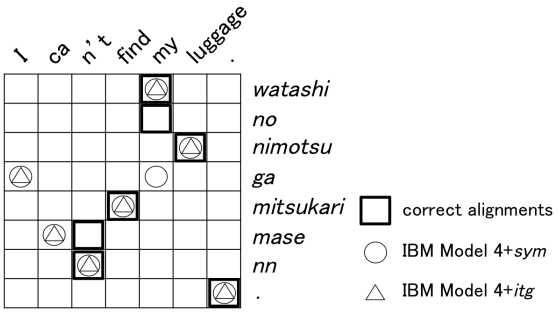

Figure 1: Word alignment examples on the BTEC corpus.

rameters as default settings. Parameter tuning was conducted by 100-best batch MIRA (Cherry and Foster, 2012) with 25 iterations.

Table 3 shows the average BLEU of five different tunings[12]. In both KFTT and IWSLT 2007, *itg* achieved significant improvement against both *none* and *sym* on HMM model. On IBM Model4, *itg* significantly outperforms *none* and is comparable to *sym* in KFTT, while *itg* significantly outperforms *sym* and is comparable to *none* in IWSLT 2007.

4 Discussion

4.1 Effects of ITG Constraints on Word Alignment and Translation

We discuss the effect of our ITG constraint on word alignment and machine translation. As described in Section 2, the ITG constraint is imposed in the E-step of the EM algorithm, not in decoding steps. Therefore, for the sentences that are not contained in the training corpus, the word alignments are calculated using the emission, transition and fertility tables trained with the constraint. It means that the effects of the constraint are implicitly reflected in the alignment results. On the other hand, the effects of the constraint are directly reflected in the machine translation results because the phrase tables are extracted from the posterior probabilities calculated in training steps. Therefore, our ITG constraint has a potential to achieve a large improvement of machine translation performance relative to an improvement of alignment performance, such as IBM Model 4+*itg* vs. IBM Model 4+*sym* on the BTEC corpus. We would like to improve our model by imposing our ITG constraint on decoding steps in future.

[12]The values in bold represent the best score, and † indicates that the comparisons are not significant over the corresponding model (i.e., HMM+*itg* or IBM Model 4+*itg*) according to the bootstrap resampling test ($p \leq 0.05$). We used multeval (Clark et al., 2011) for significance testing.

4.2 Comparison between Symmetric and ITG Constraint

In KFTT, *itg* is comparable to *sym* on IBM Model 4 in machine translation; however, *itg* achieved significant improvement in terms of word alignment, which follows the previous reports that better word alignment does not always result in better translation (Ganchev et al., 2008; Yang et al., 2013). On the other hand, in BTEC, *itg* outperforms *sym* both on word alignment and machine translation. Figure 1 shows that IBM Model 4+*sym* often generates wrong gappy alignments such as "*ga* (Ja)-I (En)" and "*ga* (Ja)-my (En)". These wrong alignments disturb the phrase extraction, because excessively long phrase pairs are extracted by bridging the gaps in wrong alignments or simply no phrase pairs are extracted from wrong gappy alignments. Consequently, the phrase table generated by IBM Model 4+*sym* tend to be sparse and contain longer phrase pairs than the one generated by IBM Model 4+*itg*.

5 Conclusions

We have proposed a novel alignment method that uses an ITG constraint based on bracketing ITG parse trees as a soft constraint of the posterior regularization framework. Due to the ITG constraint, the proposed method can symmetrize two directional alignments based on their structural coherence. Our evaluations have shown that the proposed ITG constraint significantly improves the baseline word alignment performance on the Ja-En KFTT and BTEC corpus, and significantly improves, or at least keeps, the baseline machine translation performance of KFTT and the Ja-En IWSLT 2007 task. This indicates that the proposed method yields a significant benefit to linguistically different language pairs.

In future work, we plan to incorporate a phrasal ITG (Cherry and Lin, 2007) instead of a bracketing ITG to efficiently handle many-to-many alignments.

Abstract

We adapt the greedy stack LSTM dependency parser of Dyer et al. (2015) to support a training-with-exploration procedure using dynamic oracles (Goldberg and Nivre, 2013) instead of assuming an error-free action history. This form of training, which accounts for model predictions at training time, improves parsing accuracies. We discuss some modifications needed in order to get training with exploration to work well for a probabilistic neural network dependency parser.

1 Introduction

Natural language parsing can be formulated as a series of decisions that read words in sequence and incrementally combine them to form syntactic structures; this formalization is known as transition-based parsing, and is often coupled with a greedy search procedure (Yamada and Matsumoto, 2003; Nivre, 2003; Nivre, 2004; Nivre, 2008). The literature on transition-based parsing is vast, but all works share in common a classification component that takes into account features of the current parser state[1] and predicts the next action to take conditioned on the state. The state is of unbounded size.

Dyer et al. (2015) presented a parser in which the parser's unbounded state is embedded in a fixed-dimensional continuous space using recurrent neural networks. Coupled with a recursive tree composition function, the feature representation is able to capture information from the entirety of the state, without resorting to locality assumptions that were common in most other transition-based parsers. The use of a novel stack LSTM data structure allows the parser to maintain a constant time per-state update, and retain an overall linear parsing time.

The Dyer et al. parser was trained to maximize the likelihood of gold-standard transition sequences, given words. At test time, the parser makes *greedy* decisions according to the learned model. Although this setup obtains very good performance, the training and testing conditions are mismatched in the following way: at training time the historical context of an action is always derived from the gold standard (i.e., perfectly correct past actions), but at test time, it will be a model prediction.

In this work, we adapt the training criterion so as to explore parser states drawn not only from the training data, but also from the model as it is being learned. To do so, we use the method of Goldberg and Nivre (2012; 2013) to dynamically chose an optimal (relative to the final attachment accuracy) action given an imperfect history. By interpolating between algorithm states sampled from the model and those sampled from the training data, more robust predictions at test time can be made. We show that the technique can be used to improve the strong parser of Dyer et al.

2 Parsing Model and Parameter Learning

Our departure point is the parsing model described by Dyer et al. (2015). We do not describe the model in detail, and refer the reader to the original work. At each stage t of the parsing process, the parser state is

[1]The term "state" refers to the collection of previous decisions (sometimes called the history), resulting partial structures, which are typically stored in a stack data structure, and the words remaining to be processed.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2005–2010,
Austin, Texas, November 1-5, 2016.

encoded into a vector $\mathbf{p}_t$, which is used to compute the probability of the parser action at time t as:

$$p(z_t \mid \mathbf{p}_t) = \frac{\exp\left(\mathbf{g}_{z_t}^\top \mathbf{p}_t + q_{z_t}\right)}{\sum_{z' \in \mathcal{A}(S,B)} \exp\left(\mathbf{g}_{z'}^\top \mathbf{p}_t + q_{z'}\right)}, \quad (1)$$

where $\mathbf{g}_z$ is a column vector representing the (output) embedding of the parser action z, and q_z is a bias term for action z. The set $\mathcal{A}(S, B)$ represents the valid transition actions that may be taken in the current state. Since $\mathbf{p}_t$ encodes information about all previous decisions made by the parser, the chain rule gives the probability of any valid sequence of parse transitions $\boldsymbol{z}$ conditional on the input:

$$p(\boldsymbol{z} \mid \boldsymbol{w}) = \prod_{t=1}^{|\boldsymbol{z}|} p(z_t \mid \mathbf{p}_t). \quad (2)$$

The parser is trained to maximize the conditional probability of taking a "correct" action at each parsing state. The definition of what constitutes a "correct" action is the major difference between a static oracle as used by Dyer et al. (2015) and the dynamic oracle explored here.

Regardless of the oracle, our training implementation constructs a computation graph (nodes that represent values, linked by directed edges from each function's inputs to its outputs) for the negative log probability for the oracle transition sequence as a function of the current model parameters and uses forward- and backpropagation to obtain the gradients respect to the model parameters (Lecun et al., 1998, section 4).

2.1 Training with Static Oracles

With a static oracle, the training procedure computes a canonical reference series of transitions for each gold parse tree. It then runs the parser through this canonical sequence of transitions, while keeping track of the state representation $\mathbf{p}_t$ at each step t, as well as the distribution over transitions $p(z_t \mid \mathbf{p}_t)$ which is predicted by the current classifier for the state representation. Once the end of the sentence is reached, the parameters are updated towards maximizing the likelihood of the reference transition sequence (Equation 2), which equates to maximizing the probability of the correct transition, $p(z_{g_t} \mid \mathbf{p_t})$, at each state along the path.

2.2 Training with Dynamic Oracles

In the static oracle case, the parser is trained to predict the best transition to take at each parsing step, assuming all previous transitions were correct. Since the parser is likely to make mistakes at test time and encounter states it has not seen during training, this training criterion is problematic (Daumé III et al., 2009; Ross et al., 2011; Goldberg and Nivre, 2012; Goldberg and Nivre, 2013, *inter alia*). Instead, we would prefer to train the parser to behave optimally even after making a mistake (under the constraint that it cannot backtrack or fix any previous decision). We thus need to include in the training examples states that result from wrong parsing decisions, together with the optimal transitions to take in these states. To this end we reconsider which training examples to show, and what it means to behave optimally on these training examples. The framework of training with exploration using dynamic oracles suggested by Goldberg and Nivre (2012; 2013) provides answers to these questions. While the application of dynamic oracle training is relatively straightforward, some adaptations were needed to accommodate the probabilistic training objective. These adaptations mostly follow Goldberg (2013).

Dynamic Oracles. A *dynamic oracle* is the component that, given a gold parse tree, provides the optimal set of possible actions to take for any valid parser state. In contrast to static oracles that derive a canonical state sequence for each gold parse tree and say nothing about states that deviate from this canonical path, the dynamic oracle is well defined for states that result from parsing mistakes, and they may produce more than a single gold action for a given state. Under the dynamic oracle framework, an action is said to be optimal for a state if the best tree that can be reached after taking the action is no worse (in terms of accuracy with respect to the gold tree) than the best tree that could be reached prior to taking that action.

Goldberg and Nivre (2013) define the arc-decomposition property of transition systems, and show how to derive efficient dynamic oracles for transition systems that are arc-decomposable.[2] Unfortunately, the arc-standard transition system does

[2]Specifically: for every parser configuration $\mathbf{p}$ and group of

not have this property. While it is possible to compute dynamic oracles for the arc-standard system (Goldberg et al., 2014), the computation relies on a dynamic programming algorithm which is polynomial in the length of the stack. As the dynamic oracle has to be queried for each parser state seen during training, the use of this dynamic oracle will make the training runtime several times longer. We chose instead to switch to the arc-hybrid transition system (Kuhlmann et al., 2011), which is very similar to the arc-standard system but is arc-decomposable and hence admits an efficient $O(1)$ dynamic oracle, resulting in only negligible increase to training runtime. We implemented the dynamic oracle to the arc-hybrid system as described by Goldberg (2013).

Training with Exploration. In order to expose the parser to configurations that are likely to result from incorrect parsing decisions, we make use of the probabilistic nature of the classifier. During training, instead of following the gold action, we sample the next transition according to the output distribution the classifier assigns to the current configuration. Another option, taken by Goldberg and Nivre, is to follow the one-best action predicted by the classifier. However, initial experiments showed that the one-best approach did not work well. Because the neural network classifier becomes accurate early on in the training process, the one-best action is likely to be correct, and the parser is then exposed to very few error states in its training process. By sampling from the predicted distribution, we are effectively increasing the chance of straying from the gold path during training, while still focusing on mistakes that receive relatively high parser scores. We believe further formal analysis of this method will reveal connections to reinforcement learning and, perhaps, other methods for learning complex policies.

Taking this idea further, we could increase the number of error-states observed in the training process by changing the sampling distribution so as to bias it toward more low-probability states. We do this by raising each probability to the power of α ($0 < \alpha \leq 1$) and re-normalizing. This transformation keeps the relative ordering of the events, while shifting probability mass towards less frequent events. As we show below, this turns out to be very beneficial for the configurations that make use of external embeddings. Indeed, these configurations achieve high accuracies and sharp class distributions early on in the training process.

The parser is trained to maximize the likelihood of a correct action z_g at each parsing state $\mathbf{p}_t$ according to Equation 1. When using the dynamic oracle, a state $\mathbf{p}_t$ may admit multiple correct actions $\boldsymbol{z_g} = \{z_{g_i}, \ldots, z_{g_k}\}$. Our objective in such cases is the marginal likelihood of all correct actions,[3]

$$p(\boldsymbol{z_g} \mid \mathbf{p}_t) = \sum_{z_{g_i} \in \boldsymbol{z_g}} p(z_{g_i} \mid \mathbf{p}_t). \quad (3)$$

3 Experiments

Following the same settings of Chen and Manning (2014) and Dyer et al (2015) we report results[4] in the English PTB and Chinese CTB-5. Table 1 shows the results of the parser in its different configurations. The table also shows the best result obtained with the static oracle (obtained by rerunning Dyer et al. parser) for the sake of comparison between static and dynamic training strategies.

	English		Chinese	
Method	UAS	LAS	UAS	LAS
Arc-standard (Dyer et al.)	92.40	90.04	85.48	83.94
Arc-hybrid (static)	92.08	89.80	85.66	84.03
Arc-hybrid (dynamic)	92.66	90.43	86.07	84.46
Arc-hybrid (dyn., $\alpha = 0.75$)	92.73	90.60	86.13	84.53
+ pre-training:				
Arc-standard (Dyer et al.)	93.04	90.87	86.85	85.36
Arc-hybrid (static)	92.78	90.67	86.94	85.46
Arc-hybrid (dynamic)	93.15	91.05	87.05	85.63
Arc-hybrid (dyn., $\alpha = 0.75$)	**93.56**	**91.42**	**87.65**	**86.21**

Table 1: Dependency parsing: English (SD) and Chinese.

The score achieved by the dynamic oracle for English is 93.56 UAS. This is remarkable given that the parser uses a completely greedy search procedure. Moreover, the Chinese score establishes the state-of-the-art, using the same settings as Chen and Manning (2014).

arcs A, if each arc in A can be derived from $\mathbf{p}$, then a valid tree structure containing *all* of the arcs in A can also be derived from $\mathbf{p}$. This is a sufficient condition, but whether it is necessary is unknown; hence the question of an efficient, $O(1)$ dynamic oracle for the augmented system is open.

[3] A similar objective was used by Riezler et al (2000), Charniak and Johnson (2005) and Goldberg (2013) in the context of log-linear probabilistic models.

[4] The results on the development sets are similar and only used for optimization and validation.

Table 2: Dependency parsing results. The dynamic oracle uses $\alpha = 0.75$ (selected on English; see Table 1). PP refers to pseudo-projective parsing. Y'15 and A'16 are beam = 1 parsers from Yazdani and Henderson (2015) and Andor et al. (2016), respectively. A'16-beam is the parser with beam larger than 1 by Andor et al. (2016). Bold numbers indicate the best results among the greedy parsers.

The error-exploring dynamic-oracle training always improves over static oracle training controlling for the transition system, but the arc-hybrid system slightly under-performs the arc-standard system when trained with static oracle. Flattening the sampling distribution ($\alpha = 0.75$) is especially beneficial when training with pretrained word embeddings.

In order to be able to compare with similar greedy parsers (Yazdani and Henderson, 2015; Andor et al., 2016)[5] we report the performance of the parser on the multilingual treebanks of the CoNLL 2009 shared task (Hajič et al., 2009). Since some of the treebanks contain nonprojective sentences and arc-hybrid does not allow nonprojective trees, we use the pseudo-projective approach (Nivre and Nilsson, 2005). We used predicted part-of-speech tags provided by the CoNLL 2009 shared task organizers. We also include results with pretrained word embeddings for English, Chinese, German, and Spanish following the same training setup as Dyer et al. (2015); for English and Chinese we used the same pretrained word embeddings as in Table 1, for German we used the monolingual training data from the WMT 2015 dataset and for Spanish we used the Spanish Gigaword version 3. See Table 2.

4 Related Work

Training greedy parsers on non-gold outcomes, facilitated by dynamic oracles, has been explored by several researchers in different ways (Goldberg and Nivre, 2012; Goldberg and Nivre, 2013; Goldberg et al., 2014; Honnibal et al., 2013; Honnibal and Johnson, 2014; Gómez-Rodríguez et al., 2014; Björkelund and Nivre, 2015; Tokgöz and Eryiğit, 2015; Gómez-Rodríguez and Fernández-González, 2015; Vaswani and Sagae, 2016). More generally, training greedy search systems by paying attention to the expected classifier behavior during test time has been explored under the imitation learning and learning-to-search frameworks (Abbeel and Ng, 2004; Daumé III and Marcu, 2005; Vlachos, 2012; He et al., 2012; Daumé III et al., 2009; Ross et al., 2011; Chang et al., 2015). Directly modeling the probability of making a mistake has also been explored for parsing (Yazdani and Henderson, 2015). Generally, the use of RNNs to conditionally predict actions in sequence given a history is spurring increased interest in training regimens that make the learned model more robust to test-time prediction errors. Solutions based on curriculum learning (Bengio et al., 2015), expected loss training (Shen et al., 2015), and reinforcement learning have been proposed (Ranzato et al., 2016). Finally, abandoning greedy search in favor of approximate global search offers an alternative solution to the problems with greedy search (Andor et al., 2016), and has been analyzed as well (Kulesza and Pereira, 2007; Finley and Joachims, 2008), including for parsing (Martins et al., 2009).

5 Conclusions

Dyer et al. (2015) presented stack LSTMs and used them to implement a transition-based dependency parser. The parser uses a greedy learning strategy which potentially provides very high parsing speed while still achieving state-of-the-art results. We have demonstrated that improvement by training the greedy parser on non-gold outcomes; dynamic

[5]We report the performance of these parsers in the most comparable setup, that is, with beam size 1 or greedy search.

oracles improve the stack LSTM parser, achieving 93.56 UAS for English, maintaining greedy search.

Capturing Argument Relationships for Chinese Semantic Role Labeling

Abstract

In this paper, we capture the argument relationships for Chinese semantic role labeling task, and improve the task's performance with the help of argument relationships. We split the relationship between two candidate arguments into two categories: (1) Compatible arguments: if one candidate argument belongs to a given predicate, then the other is more likely to belong to the same predicate; (2) Incompatible arguments: if one candidate argument belongs to a given predicate, then the other is less likely to belong to the same predicate. However, previous works did not explicitly model argument relationships. We use a simple maximum entropy classifier to capture the two categories of argument relationships and test its performance on the Chinese Proposition Bank (CPB). The experiments show that argument relationships is effective in Chinese semantic role labeling task.

1 Introduction

Semantic Role Labeling (SRL) is defined as the task to recognize arguments for a given predicate and assign semantic role labels to them. Because of its ability to encode semantic information, there has been an increasing interest in SRL on many languages (Gildea and Jurafsky, 2002; Sun and Jurafsky, 2004). Figure 1 shows an example in Chinese Proposition Bank (CPB) (Xue and Palmer, 2003), which is a Chinese corpus annotated with semantic role labels.

Previous works of Chinese SRL include feature-based approaches and neural network based approaches. Feature-based approaches often extract a large number of handcrafted features from the sentence, and feed these features to statistical classifiers such as CRF, MaxEnt and SVM (Sun and Jurafsky, 2004; Xue, 2008; Ding and Chang, 2008; Ding and Chang, 2009; Sun, 2010). Neural network based approaches usually take Chinese SRL as sequence labeling task and use bidirectional recurrent neural network (RNN) with long-short-term memory (LSTM) to solve the problem (Wang et al., 2015).

However, both of the above two kinds of approaches identify each candidate argument separately without considering the relationship between arguments. We define two categories of argument relationships here: (1) **Compatible arguments**: if one candidate argument belongs to a given predicate, then the other is more likely to belong to the same predicate; (2) **Incompatible arguments**: if one candidate argument belongs to a given predicate, then the other is less likely to belong to the same predicate. For example, in Figure 1, the word "外商"(foreign businessman) and "企业"(entrepreneur) tend to be compatible arguments when the predicate word is "投资"(invest). On the other hand, "企业"(entrepreneur) and " 规定"(rule) are not likely to belong to the same predicate "投资"(invest).

In this paper, we propose to use a quadratic optimization method to explicitly model the relationship between candidate arguments to improve the performance of Chinese SRL. We train a maximum entropy classifier, and then use the classifier to predict argument relationships between any two candidate arguments in a sentence. Experiments show that argument relationships can greatly improve the performance of Chinese SRL.

Figure 1: A sentence with semantic roles labeled from CPB. "rel" represents the predicate, English translation: "Six rules to protect foreign businessman's legal profits when investing entrepreneurs"

2 Related Work

Semantic Role Labeling (SRL) task was first proposed by Gildea and Jurafsky (2002). Previous approaches on Chinese SRL can be classified into two categories: (1) feature-based approaches (2) neural network based approaches.

Among feature-based approaches, Sun and Jurafsky (2004) did the preliminary work on Chinese SRL without any large semantically annotated corpus and produced promising results. Xue and Palmer (2003) proposed Chinese Proposition Bank (CPB), which leads to more complete and systematic research on Chinese SRL (Xue and Palmer, 2005; Xue, 2008; Ding and Chang, 2009). Sun et al. (2009) extended the work of Chen et al. (2006), performed Chinese SRL with shallow parsing, which took partial parses as inputs. Yang and Zong (2014) proposed multi-predicate SRL, which showed improvements both on English and Chinese Proposition Bank.

Neural network based approaches are free of handcrafted features, Collobert and Weston (2008) proposed a convolutional neural network for SRL. Their approach achieved competitive performance on English SRL without requiring task specific feature. Wang et al. (2015) proposed a bidirectional LSTM-RNN for Chinese SRL.

However, most of the aforementioned approaches did not take the compatible arguments and incompatible arguments into account. Inspired by Sha et al. (2016), our approach model the two argument relationships explicitly to achieve a better performance on Chinese SRL.

3 Capturing the Relationship Between Arguments

We found that there are two typical relationships between candidate arguments: (1) Compatible arguments: if one candidate argument belongs to one event, then the other is more likely to belong to the same event; (2) incompatible arguments: if one candidate argument belongs to one event, then the other is less likely to belong to the same event.

We trained a maximum entropy classifier to predict the relationship between two candidate arguments. We choose the following features:

1. PREDICATE: the predicate in the current sentence
2. ARGUMENT DISTANCE: the distance between the two candidate arguments in the sentence
3. Whether the two candidate arguments occur on the same side of the predicate
4. PARENT DEPENDENCY DISTANCE: the distance between the two candidate arguments' parents in the dependency parse tree
5. PARENT POS: if the two candidate arguments share the same parent, take the common parent's POS tag as a feature
6. Whether the two candidate arguments occur on the same side of the common parent if the two candidate arguments share the same parent

All the words in one sentence except for the predicate are candidate arguments. The word pairs in the ground truth Chinese SRL annotation (training data) are extracted as training data. The training examples are generated as follows: For an candidate argument pair, if both of them are labeled as semantic roles, we take it as positive example. For each positive example, we randomly exchange one of the arguments with an irrelevant argument[1] to get a negative example.

[1] an irrelevant argument is in the same sentence with the predicate, but it is not labeled as semantic role

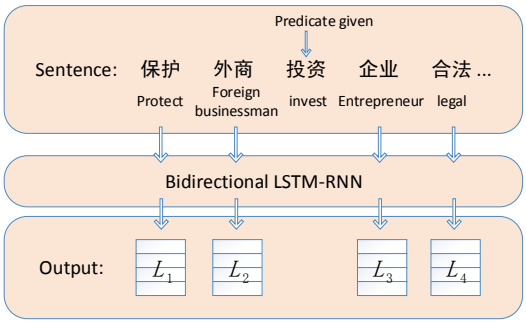

Figure 2: The bidirectional LSTM-RNN architecture.

The chinese sentences should be segmented to chinese words first. For a sentence with $n+1$ words, we denote $C \in \mathbb{R}^{n \times n}$ as the argument relationship matrix. In the testing procedure, the maximum entropy classifier is used to predict the relationship between argument i and argument j as C_{ij}.

When the output of the maximum entropy classifier is around 0.5, it is not easy to figure out whether it is the first relationship or the second, we call this kind of information "uncertain information"(unclear relationship). For a better performance, we **strengthen** the certain information and weaken the uncertain information. We transform the result of maximum entropy classifier as follows:

$$C(i,j) = \begin{cases} 1 & 0.8 < MaxEnt(i,j) \leq 1.0 \\ 0 & 0.2 \leq MaxEnt(i,j) \leq 0.8 \\ -1 & 0.0 \leq MaxEnt(i,j) < 0.2 \end{cases} \quad (1)$$

We set two thresholds, if the output of the maximum entropy classifier is larger than 0.8, we set $C_{i,j} = 1$ (compatible arguments), if the output is lower than 0.2, we set $C_{i,j} = -1$ (incompatible arguments), otherwise, we set $C_{i,j} = 0$ (unclear relationship). The threshold 0.8 and 0.2 are tuned by development set.

4 Quadratic Optimization Method (QOM)

4.1 Post-processing Module of Bidirectional LSTM-RNN

Our quadratic optimization method is a post-processing module of bidirectional LSTM-RNN(Wang et al., 2015). The simplified architecture of bidirectional LSTM-RNN is shown as Figure 2.

Each dimension of the output vector $L_i \in \mathbb{R}^{n_L}, i = 1 \cdots n$ corresponds to the score of a certain semantic role label. n_L represents the number of semantic role labels. Then we normalize L_i over semantic roles as Eq 2 shows.

$$\widetilde{L_i} = Normalize(L_i) \quad (2)$$

Each dimension of $\widetilde{L_i}$ represents the probability of a certain semantic role label.

Let $P_{Arg} \in \mathbb{R}^n$ be a probability vector, each dimension of which represents the probability that the current word has a semantic role as is shown in Eq 3. $P_{Role} \in \mathbb{R}^n$ is another probability vector, each dimension represents the probability of the most likely semantic role the current word may be labeled as is shown in Eq 4.

$$P_{Arg}(i) = \sum_j \widetilde{L_i}(j)[label(j) \neq \text{'0'}] \quad (3)$$

$$P_{Role}(i) = \max_j \widetilde{L_i}(j) \quad (4)$$

where $[\cdot]$ equals to 1 if the inner statement is true and 0 otherwise. $label(j) \neq$ '0' means the j-th word is not labeled with semantic role.

4.2 Quadratic Optimization

We use a n-dim vector X to represent the identification result of candidate arguments. Each entry of X is 0 or 1, 0 represents "noArg", 1 represents "arg". X can be assigned by maximizing $E(X)$ as defined by Eq 5.

$$\begin{aligned} X &= \operatorname*{argmax}_X E(X) \\ E(X) &= \lambda_1 X^T C X + \lambda_2 X^T P_{arg} \\ &\quad + (1 - \lambda_1 - \lambda_2) X^T P_{role} \end{aligned} \quad (5)$$

Here, $X^T C X$ means to add up all the relationship value if the two arguments are identified. Hence, the more the identified arguments are related, the larger the value $X^T C X$ is. $X^T P_{arg}$ is the sum of all chosen arguments probability. $X^T P_{role}$ is the sum of all the classified roles' probability.

Eq 5 means that, while we should select the semantic role with a larger probability, the argument relationship evaluation should also as large as possible.

We use Beam Search method (Algorithm 1) to search for the optimal assignment X. The hyper-parameters λ_1 and λ_2 can be chosen according to development set.

Input: Argument relationship matrix: C
the argument probabilities required by P^{arg}_{sum}
the role probabilities required by P^{role}_{sum}
Data: K: Beam size
n: Number of candidate arguments
Output: The best assignment X
Set beam $\mathcal{B} \leftarrow [\epsilon]$;
for $i \leftarrow 1 \cdots n$ **do**
  buf$\leftarrow \{z' \circ l | z' \in \mathcal{B}, l \in \{0, 1\}\}$;
  $\mathcal{B} \leftarrow [\epsilon]$;
  while $j \leftarrow 1 \cdots K$ **do**
    $x_{best} = \text{argmax}_{x \in \text{buf}} E(x)$;
    $\mathcal{B} \leftarrow \mathcal{B} \cup \{x_{best}\}$;
    buf$\leftarrow$buf$-\{x_{best}\}$;
  end
end
Sort $\mathcal{B}$ descendingly according to $E(X)$;
return $\mathcal{B}[0]$;

Algorithm 1: Beam Search decoding algorithm for SRL. $\circ$ means to concatenate an element to the end of a vector.

5 Experiment

We conduct experiments to compare our model with previous landmark methods on the benchmark dataset CPB for Chinese SRL. We use Wang et al. (2015)'s model as baseline. The result reveals that our quadratic optimization method can further improve the result of bidirectional LSTM-RNN.

5.1 Experiment Settings

We conduct experiments on the standard benchmark dataset CPB 1.0[2]. We follow the same data setting as previous work (Xue, 2008; Sun et al., 2009), which divided the dataset into three parts: 648 files (from `chtb_081.fid` to `chtb_899.fid`) are used as the training set. The development set includes 40 files, from `chtb_041.fid` to `chtb_080.fid`. The test set includes 72 files, which are `chtb_001.fid` to `chtb_040.fid`, and `chtb_900.fid` to `chtb_931.fid`.

Method	$F_1(\%)$
Xue (2008)	71.90
Collobert and Weston (2008)	74.05
Sun et al. (2009)	74.12
Yang and Zong (2014)	75.31
Wang et al. (2015)	77.21
QOM - stengthen	76.24
QOM - feature 4,5,6	77.52
QOM	77.69

Table 1: Results comparison on CPB dataset.

The training dataset of the argument relationship matrix contains 1.6M cases (736K positive and 864K negative) which are randomly generated according to the ground truth in the training documents. We use Stanford Parser[3] for dependency parsing.

We tuned the coefficients λ_1 and λ_2 of Eq 5 on the development set, and finally we set $\lambda_1 = 0.10$ and $\lambda_2 = 0.45$.

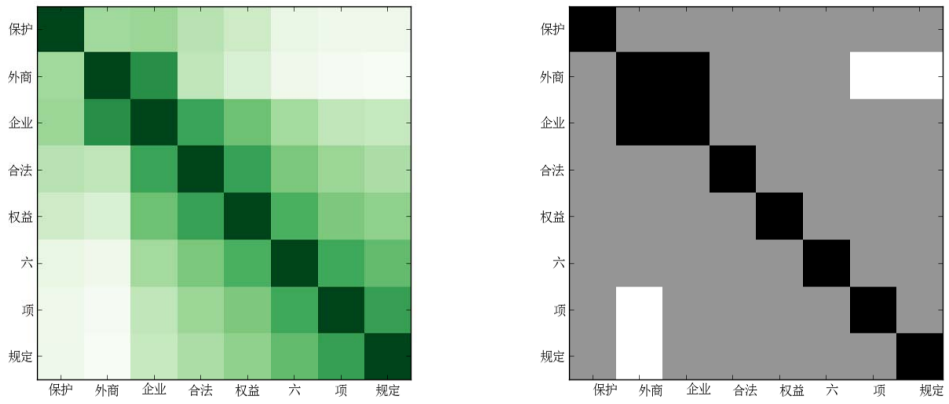
5.2 Chinese SRL Performance

Table 1 shows our SRL performance compared to previous landmark results. We can see that with quadratic optimization method as the post-processing module, our approach (QOM) outperforms Wang et al. (2015) by a large margin (Wilcoxon Signed Rank Test, $p < 0.05$). We also did some ablation test, in Table 1, "QOM - stengthen" is the result when we do not strengthen the argument relationship matrix. We can see that the uncertain information is very harmful to the performance, which worsen the accuracy for about 1%. "QOM - feature 4,5,6" is the performance when we do not use the dependency features when capturing the argument relationships since Wang et al. (2015) didn't use any dependency feature. We can see that event without dependency feature, our method still can outperform Wang et al. (2015)'s result.

Figure 3 visualizes the candidate argument relationship matrix. From this graph, we captured the compatible arguments ("外 商$_{\text{foreign businessman}}$" and "企 业$_{\text{entrepreneur}}$"), incompatible arguments ("项$_{\text{item}}$" and "外 商$_{\text{foreign businessman}}$"), ("规 定$_{\text{rule}}$"

[2]https://catalog.ldc.upenn.edu/LDC2005T23

[3]http://nlp.stanford.edu/software/lex-parser.shtml



Chinese	保护	外商	企业	合法	权益	六	项	规定
English translation	protect	foreign businessman	entrepreneur	legal	profit	six	item	rule

Figure 3: The Visualization of argument relationship Matrix, Left is the origin matrix. Right is the strengthened matrix. In the origin matrix, we can directly see the argument relationship we captured (the darker green means stronger relationship, lighter green means weaker relationship). After strengthening, on the right, the words with strong relationship are classified as compatible arguments (the black squares), weak relationship are classified as incompatible arguments (the white squares). Others (the grey squares) are unclear relationship.

and "外商$_{\text{foreign businessman}}$"). Therefore, "外商$_{\text{foreign businessman}}$" and "企业$_{\text{entrepreneur}}$" should be the roles of "投资$_{\text{invest}}$" simultaneously , ("项$_{\text{item}}$", "外商$_{\text{foreign businessman}}$") and ("规定$_{\text{rule}}$", "外商$_{\text{foreign businessman}}$") should not be the roles of "投资$_{\text{invest}}$" simultaneously.

6 Conclusion

In this paper, we propose to use a quadratic optimization method based on two kinds of argument relationships to improve the performance of Chinese SRL. We first train a maximum entropy classifier to capture the compatible arguments and incompatible arguments. Then we use quadratic optimization to improve the result of bidirectional LSTM-RNN(Wang et al., 2015). The experiment has proved the effectiveness of our approach. This method can also be used in other probabilistic methods.

BrainBench:
A Brain-Image Test Suite for Distributional Semantic Models

Abstract

The brain is the locus of our language ability, and so brain images can be used to ground linguistic theories. Here we introduce BrainBench, a lightweight system for testing distributional models of word semantics. We compare the performance of several models, and show that the performance on brain-image tasks differs from the performance on behavioral tasks. We release our benchmark test as part of a web service.

1 Introduction

There is active debate over how we should test semantic models. In fact, in 2016 there was an entire workshop dedicated to the testing of semantic representations (RepEval, 2016). Several before us have argued for the usage of brain data to test semantic models (Anderson et al., 2013; Murphy et al., 2012; Anderson et al., 2015), as a brain image represents a snapshot of one person's own semantic representation. Still, testing semantic models against brain imaging data is rarely done by those not intimately involved in psycholinguistics or neurolinguistics. This may be due to a lack of familiarity with neuroimaging methods and publicly available datasets.

We present the first iteration of BrainBench, a new system that makes it easy to test semantic models using brain imaging data (Available at `http://www.langlearnlab.cs.uvic.ca/brainbench/`). Our system has methodology that is similar to popular tests based on behavioral data (see Section 2.2), and has the additional benefit of being fast enough to offer as a web service.

*Corresponding Author

2 The Tasks

Here we outline the set of tasks we used to evaluate several popular Distributional Semantic (DS) models.

2.1 Brain Image Data

For BrainBench we use two brain image datasets collected while participants viewed 60 concrete nouns with line drawings (Mitchell et al., 2008; Sudre et al., 2012). One dataset was collected using fMRI (Functional Magnetic Resonance Imaging) and one with MEG (Magnetoencephalography). Each dataset has 9 participants, but the participants sets are disjoint, thus there are 18 unique participants in all. Though the stimuli is shared across the two experiments, as we will see, MEG and fMRI are very different recording modalities and thus the data are not redundant.

fMRI measures the change in blood oxygen levels in the brain, which varies according to the amount of work being done by a particular brain area. An fMRI image is a 3D volume of the brain where each point in the volume (called a voxel) represents brain activity at a particular place in the brain. In the fMRI dataset used here, each voxel represents a 3mm x 3mm x 5mm area of the brain. Each of the 60 words was presented 6 times in random order, for a total of 360 brain images. The number of voxels depends on the size and shape of a person's brain, but there are around 20,000 voxels per participant in this dataset.

MEG measures the magnetic field caused by

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2017–2021,
Austin, Texas, November 1-5, 2016.

many neurons firing in the same direction at the same time. This signal is very weak, and so must be measured in a magnetically shielded room. The MEG machine is essentially a large helmet with 306 sensors that measure aspects of the magnetic fields at different locations in the brain. A MEG brain image is the time signals recorded from each of these sensors. Here, the sampling rate is 200 Hz. For each word, the MEG recording is 800ms long resulting in 306×160 data points. Each of the words was presented 20 times (in random order) for a total of 1200 brain images. For simplicity we will use the term "brain image feature" to refer to both fMRI voxels and MEG sensor/time points.

A non-trivial portion of our participants' brain activity may be driven by the low-level visual properties of the word/line-drawing stimulus, rather than by semantics. As there is a possibility of confounding visual properties with semantic properties, we have attempted to remove the activity attributable to visual properties from the brain images. In total we have 11 visual features which include things like the length of the word, the number of white pixels, and features of the line drawing (Sudre et al., 2012). To remove the visual stimulus' contribution to the signal, we train a regression model that predicts the signal in each brain image feature as a function of the 11 visual features. We then subtract the predicted value from the observed value of the brain image feature. This process is known as "partialling out" an effect. Thus, the signal that remains in the brain image will not be correlated with the visual stimuli, and should only be related to the semantics of the word itself (or noise).

Brain images are quite noisy, so we used the methodology from Mitchell et al. (2008) to select the most stable brain image features for each of the 18 participants. The stability metric assigns a high score to features that show strong self-correlation over presentations of the same word. We noticed that tuning the number of features to keep made little or no difference in the absolute ordering of the different DS models. Thus, we use the optimal number of features averaged over all 6 DS models described in Section 3: the top 13% of MEG sensor/time points, and 3% of fMRI voxels. Finally, we average all brain images corresponding to repetitions of the same word.

2.2 Behavioral Tasks

We include, for comparison, four popular word vector evaluation benchmarks.

MEN This dataset contains 3,000 word pairs, such that each word appears frequently in two separate corpora. Human participants were presented with two word pairs and asked to choose the word pair that was more related, resulting in a ranking of relatedness amongst word pairs (Bruni and Baroni, 2013).

SimLex-999 A word pairing task meant to specifically target similarity rather than the more broad "relatedness" (Hill et al., 2015).

WS-353-[SIM|REL] A set of 353 word pairs with relatedness ratings (Finkelstein et al., 2002). This dataset was subsequently split into sets where the pairs denote similarity and relatedness, named WS-353-SIM and WS-353-REL, respectively (Agirre et al., 2009).

3 Distributional Models

We test six semantic models against both the fMRI and behavioral datasets. The six models are:

Skip-gram: A neural network trained to predict the words before and after the current word, given the current word. We selected a model with 300 dimensions trained on the Google news corpus (Mikolov et al., 2013).

Glove: A regression-based model that combines global context information (term-document cooccurrence) with local information (small windows of word-word cooccurrence) (Pennington et al., 2014). This 300-dimensional model was trained on the Wikipedia and Gigaword 5 corpora combined.

RNN: A recurrent neural network with 640-dimensional hidden vectors. These models are trained to predict the next word in a sequence and have the ability to encode (theoretically) infinitely distant contextual information (Mikolov et al., 2011). The model was trained on broadcast news transcriptions.

Global: A neural network model that incorporates global and local information, like that of the Glove

model (Huang et al., 2012). This model is our smallest, with dimension 50, and was trained on Wikipedia.

Cross-lingual: A tool that projects distributional representations from multiple language into a shared representational space (Faruqui and Dyer, 2014). Here we use the German-English model (512 dimensions), trained on the WMT-2011 corpus.

Non-distributional: This model is based solely on hand-crafted linguistic resources (Faruqui and Dyer, 2015). Several resources like WordNet (Fellbaum, 1998) and FrameNet (Baker et al., 1998) are combined to make very sparse word vector representations. Due to their sparsity, these vectors are of very high dimension ($171,839$). This is a particularly interesting model because it is not built from a corpus (unlike every other model in this list).

Note that we are not aiming to compare the goodness of any of these distributional models, as they are trained on different corpora with different algorithms. Instead, we wish to compare the patterns of performance on behavioral benchmarks to that of a brain-image based task.

4 Methodology

Each of the behavioral tasks included here assigns a similarity score to word pairs. For each DS model we calculate the correlation between the vectors for every pair of words in the behavioral datasets. We then calculate the correlation between the DS vector correlations and the behavioral scores.

We follow a very similar methodology for the brain image datasets. Let us represent each DS model with a matrix $X \in \mathbb{R}^{w \times p}$ where w is the number of words for which we have brain images (here $w = 60$), and p is the number of dimensions in a particular DS model. From X we calculate the correlation between each pair of word vectors, resulting in a matrix $C_{DS} \in \mathbb{R}^{w \times w}$.

Let us represent each participant's brain images with a matrix $Y \in \mathbb{R}^{w \times v}$ where v is the number of selected brain image features. From this matrix we calculate the correlation between each pair of brain images, resulting in a matrix $C_{BI} \in \mathbb{R}^{w \times w}$ (BI for brain image). This final representation is similar to the behavioral tasks above, but now we have a similarity measure for *every* pair of words in our dataset.

Here is where the evaluation for brain imaging tasks differs from the behavioral tasks. Instead of measuring the correlation between C_{BI} and C_{DS}, as is done in Representational Similarity Analysis (RSA) (Kriegeskorte et al., 2008), we use the testing methodology from Mitchell et al. (2008), which we will refer to as the 2 vs. 2 test. The 2 vs. 2 test was developed to help detect statistically significant predictions on brain imaging data, and, compared to RSA, can better differentiate the performance of a model from chance. We perform a 2 vs. 2 test for all pairs of C_{DS} and C_{BI} (that is, for every pair of DS model and fMRI/MEG participant).

For each 2 vs. 2 test we select the same two words (rows) w_1, w_2 from C_{DS} and C_{BI}. We omit the columns which correspond to the correlation to w_1 and w_2, as they contain a perfect signal for the 2 vs. 2 test. We now have four vectors, $C_{DS}(w_1)$, $C_{DS}(w_2)$, $C_{BI}(w_1)$ and $C_{BI}(w_2)$, all of length $w - 2$. We compute the correlation (corr) between vectors derived from C_{DS} and C_{BI} to see if:

$$\text{corr}(C_{DS}(w_1), C_{BI}(w_1)) + \text{corr}(C_{DS}(w_2), C_{BI}(w_2))$$

(the correlation of correctly matched rows: w_1 to w_1 and w_2 to w_2) is greater than:

$$\text{corr}(C_{DS}(w_1), C_{BI}(w_2)) + \text{corr}(C_{DS}(w_2), C_{BI}(w_1))$$

(the correlation of incorrectly matched rows). If the correctly matched rows are more similar than incorrectly matched rows, then the 2 vs. 2 test is considered correct. We perform the 2 vs. 2 test for all possible pairs of words, for 1770 tests in total. The 2 vs. 2 accuracy is the percentage of 2 vs. 2 tests correct. Chance is 50%.

Our process of computing 2 vs. 2 accuracy over rows of a correlation matrix is different than the original methodology for these datasets (Mitchell et al., 2008; Sudre et al., 2012). Previous work trained regression models that took brain images as input and predicted the dimensions of a DS model as output. Training these regression models for all 1770 pairs of words takes hours to complete, whereas the test we suggest here is much faster, and the correlation matrices C_{BI} can be computed ahead of time. This makes the tests fast enough to offer as a web service. We hope our web offering will remove barriers to the wider adoption of brain-based tests from within the computational linguistics community.

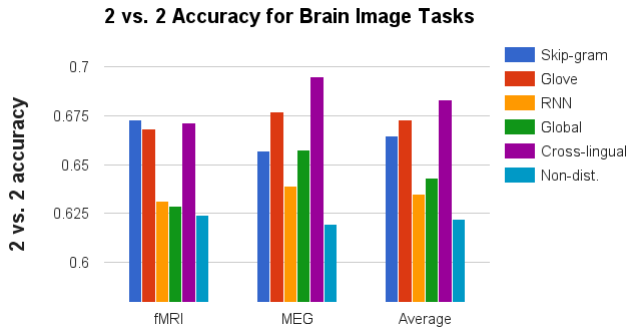

Figure 1: Performance of Distributional Semantic models on the brain-image datasets.

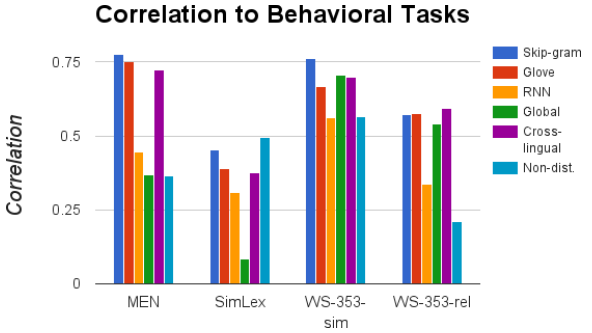

Figure 2: Performance of Distributional Semantic models on several benchmark behavioral tasks.

5 Results

Figure 1 shows the results for each of the DS models against the fMRI and MEG datasets. On average, the Skip-gram, Glove and Cross-lingual models perform quite well, whereas the multi-layer NNs (RNN, Global) perform less well. The one DS model to be built from hand-crafted resources (Non-distributional) performs poorly on both brain image tests.

As previously mentioned, we are not claiming to show that any one of the DS models is better than any other. Indeed, that would be comparing apples to oranges, as each DS model is trained with a different algorithm on a different corpus. Instead, notice that the *pattern* of performance for the fMRI task is remarkably similar to the pattern on the MEN behavioral task. This is interesting given that our dataset contains only 60 words and the MEN dataset contains > 700. On the MEG data, the Cross-lingual model performs best, and its performance pattern is unlike any of the behavioral tasks in Figure 2. The averaged BrainBench results are most similar to the results for WS-353-REL. However, averaging the results together may be misleading, as the fMRI and MEG result patterns are different.

6 Discussion

There are some caveats about the analyses herein. Firstly, the brain-based tests include only 60 concrete nouns, so they will necessarily favor distributional models with good noun representations, regardless of the representations of other parts of speech. We are currently working with various research groups to expand the number of brain-image datasets included in this benchmark to have a more diverse test base. The behavioral benchmarks were not reduced to include only the 60 words for which we have brain data, because this would have rendered the benchmarks essentially useless, as very rarely are a pair of the 60 words from the brain image data scored as a pair in the behavioral benchmarks.

7 Conclusion

We have presented our new system, BrainBench, which is a fast and lightweight alternative to previous methods for comparing DS models to brain images. Our proposed methodology is more similar to well-known behavioral tasks, as BrainBench also uses the similarity of words as a proxy for meaning. We hope that this contribution will bring brain imaging tests "to the masses" and encourage discussion around the testing of DS models against brain imaging data.

Abstract

We compare the effectiveness of four different syntactic CCG parsers for a semantic slot-filling task to explore how much syntactic supervision is required for downstream semantic analysis. This extrinsic, task-based evaluation also provides a unique window into the semantics captured (or missed) by unsupervised grammar induction systems.

1 Introduction

The past several years have seen significant progress in unsupervised grammar induction (Carroll and Charniak, 1992; Yuret, 1998; Klein and Manning, 2004; Spitkovsky et al., 2010; Garrette et al., 2015; Bisk and Hockenmaier, 2015). But how useful are unsupervised syntactic parsers for downstream NLP tasks? What phenomena are they able to capture, and where would additional annotation be required? Instead of standard intrinsic evaluations – attachment scores that depend strongly on the particular annotation styles of the gold treebank – we examine the utility of unsupervised and weakly supervised parsers for semantics. We perform an extrinsic evaluation of unsupervised and weakly supervised CCG parsers on a grounded semantic parsing task that will shed light on the extent to which these systems recover semantic information. We focus on English to perform a direct comparison with supervised parsers (although unsupervised or weakly supervised approaches are likely to be most beneficial for domains or languages where supervised parsers are not available).

[*]Equal contribution

Specifically, we evaluate different parsing scenarios with varying amounts of supervision. These are designed to shed light on the question of how well syntactic knowledge correlates with performance on a semantic evaluation. We evaluate the following scenarios (all of which assume POS-tagged input): 1) no supervision; 2) a lexicon containing words mapped to CCG categories; 3) a lexicon containing POS tags mapped to CCG categories; 4) sentences annotated with CCG derivations (i.e., fully supervised). Our evaluation reveals which constructions are problematic for unsupervised parsers (and annotation efforts should focus on). Our results indicate that unsupervised syntax is useful for semantics, while a simple semi-supervised parser outperforms a fully unsupervised approach, and could hence be a viable option for low resource languages.

2 CCG Intrinsic Evaluations

CCG (Steedman, 2000) is a lexicalized formalism in which words are assigned syntactic types, also known as *supertags*, encoding subcategorization information. Consider the sentence *Google acquired Nest in 2014*, and its CCG derivations shown in Figure 1. In (a) and (b), the supertag of *acquired*, $(\mathsf{S}\backslash\mathsf{NP})/\mathsf{NP}$, indicates that it has two arguments, and the prepositional phrase *in 2014* is an adjunct, whereas in (c) the supertag $((\mathsf{S}\backslash\mathsf{NP})/\mathsf{PP})/\mathsf{NP}$ indicates *acquired* has three arguments including the prepositional phrase. In (a) and (b), depending on the supertag of *in*, the derivation differs. When trained on labeled treebanks, (a) is preferred. However note that all these derivations could lead to the same semantics (e.g., to the logical form in Equation 1). Without syntactic su-

Figure 1: Example of multiple valid derivations that can be grounded to the same Freebase logical form (Eq. 1) even though they differ dramatically in performance under parsing metrics (5, 4, or 3 "correct" supertags).

pervision, there may not be any reason for the parser to prefer one analysis over the other. One procedure to evaluate unsupervised induction methods has been to compare the assigned supertags to treebanked supertags, but this evaluation does not consider that multiple derivations could lead to the same semantics. This problem is also not solved by evaluating syntactic dependencies. Moreover, while many dependency standards agree on the head direction of simple constituents (e.g., noun phrases) they disagree on the most semantically useful ones (e.g., coordination and relative clauses).[1]

3 Our Proposed Evaluation

The above syntax-based evaluation metrics conceal the real performance differences and their effect on downstream tasks. Here we propose an extrinsic evaluation where we evaluate our ability to convert sentences to Freebase logical forms starting via CCG derivations. Our motivation is that most sentences can only have a single realization in Freebase, and any derivation that could lead to this realization is potentially a correct derivation. For example, the Freebase logical form for the example sentence in Figure 1 is shown below, and none of its derivations are penalized if they could result in this logical form.

$$\begin{aligned} &\lambda e.\,\text{business.acquisition}(e) \\ &\wedge\,\text{acquiring\_company}(e, \textsc{Google}) \\ &\wedge\,\text{company\_acquired}(e, \textsc{Nest}) \\ &\wedge\,\text{date}(e, 2014) \end{aligned} \tag{1}$$

Since grammar induction systems are traditionally trained on declarative sentences, we would ideally require declarative sentences paired with Freebase logical forms. But such datasets do not exist in the Freebase semantic parsing literature (Cai and Yates, 2013; Berant et al., 2013). To alleviate this problem, and yet perform Freebase semantic parsing, we propose an entity slot-filling task.

Entity Slot-Filling Task. Given a declarative sentence containing mentions of Freebase entities, we randomly remove one of the mentions to create a blank slot. The task is to fill this slot by translating the declarative sentence into a Freebase query. Consider the following sentence where the entity *Nest* has been removed:

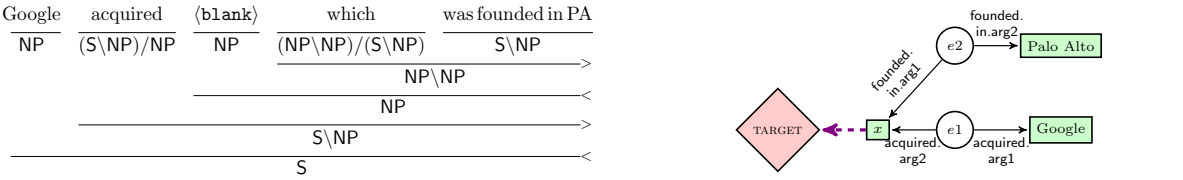
Google acquired _____ which was founded in Palo Alto

To correctly fill in the blank, one has to query Freebase for the entities acquired by *Google* (constraint 1) and founded in *Palo Alto* (constraint 2). If either of those constraints are not applied, there will be many entities as answers. For each question, we execute a single Freebase query containing all the constraints and retrieve a list of answer entities. From this list, we pick the first entity as our predicted answer, and consider the prediction as correct if the gold answer is the same as the predicted answer.

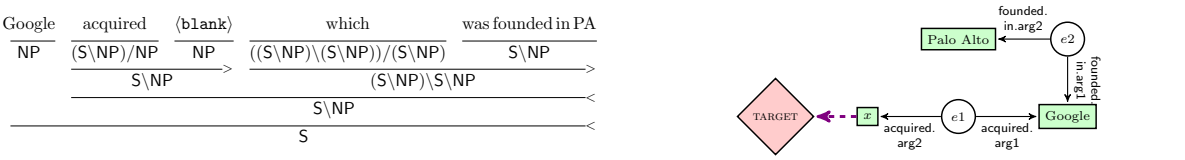
4 Sentences to Freebase Logical Forms

CCG provides a clean interface between syntax and semantics, i.e. each argument of a words syntactic category corresponds to an argument of the lambda expression that defines its semantic interpretation (e.g., the lambda expression corresponding to the category $(\mathsf{S}\backslash\mathsf{NP})/\mathsf{NP}$ of the verb *acquired* is $\lambda f.\lambda g.\lambda e.\exists x.\exists y.\text{acquired}(e) \wedge f(x) \wedge g(y) \wedge arg_1(e,y) \wedge arg_2(e,x)$), and the logical form for the complete sentence can be constructed by composing word level lambda expressions following the syntactic derivation (Bos et al., 2004). In Figure 2 we show two syntactic derivations for the same sentence, and the corresponding logical forms and equivalent graph representations derived by GRAPHPARSER (Reddy et al., 2014). The graph representations are possible because GRAPHPARSER assumes access to coindexations of input CCG categories. We provide

[1] Please see Bisk and Hockenmaier (2013) for more details.



$\lambda e_1.\exists x e_2.\ \text{TARGET}(x) \wedge \text{acquired}(e_1) \wedge arg_1(e_1, \text{Google}) \wedge arg_2(e_1, x) \wedge \text{founded}(e_2) \wedge \mathbf{arg_2}(\mathbf{e_2}, x) \wedge \text{in}(e_2, \text{PaloAlto})$



$\lambda e_1.\exists x e_2.\ \text{TARGET}(x) \wedge \text{acquired}(e_1) \wedge arg_1(e_1, \text{Google}) \wedge arg_2(e_1, x) \wedge\ \text{founded}(e_2) \wedge \mathbf{arg_2}(\mathbf{e_2}, \text{Google}) \wedge \text{in}(e_2, \text{PaloAlto})$

Figure 2: The lexical categories for *which* determine the relative clause attachment and therefore the resulting ungrounded logical form. The top derivation correctly executes a query to retrieve companies founded in Palo Alto and acquired by Google. The bottom incorrectly asserts that Google was founded in Palo Alto.

co-indexation for all induced categories, including multiple co-indexations when an induced category is ambiguous. For example, $(S\backslash N)/(S\backslash N)$ refers to either $(S_x\backslash N_y)/(S_x\backslash N_y)$ indicating an auxiliary verb or $(S_x\backslash N_y)/(S_z\backslash N_y)$ indicating a control verb. Initially, the predicates in the expression/graph will be based entirely on the surface form of the words in the sentence. This is the "*ungrounded*" semantic representation.

Our next step is to convert these ungrounded graphs to Freebase graphs.[2] Like Reddy et al. (2014), we treat this problem as a graph matching problem. Using GRAPHPARSER we retrieve all the Freebase graphs that are isomorphic to the ungrounded graph, and select only the graphs that could correctly predict the blank slot, as candidate graphs. Using these candidate graphs, we train a structured perceptron that learns to rank grounded graphs for a given ungrounded graph.[3] We use ungrounded predicate and Freebase predicate alignments as our features.

5 Experiments

5.1 Training and Evaluation Datasets

Our dataset SPADES (**S**emantic **PA**rsing of **DE**clarative **S**entences) is constructed from the declarative sentences collected by Reddy et al. (2014) from CLUEWEB09 (Gabrilovich et al., 2013) based on the following constraints: 1) There exists at least one isomorphic Freebase graph to the ungrounded representation of the input sentence; 2) There are no variable nodes in the ungrounded graph (e.g., *Google acquired a company* is discarded whereas *Google acquired the company Nest* is selected). We split this data into training (85%), development (5%) and testing (10%) sentences (Table 1). We introduce empty slots into these sentences by randomly removing an entity. SPADES can be downloaded at `http://github.com/sivareddyg/graph-parser`.

	Sentences	Tokens	Types	Entities
Train	79,247	685,922	69,095	37,606
Dev	4,763	41,102	9,306	4,358
Test	9,309	80,437	15,180	7,431

Table 1: SPADES Corpus Statistics

There has been other recent interest in similar datasets for sentence completion (Zweig et al., 2012) and machine reading (Hermann et al., 2015), but unlike other corpora our data is tied directly to Freebase and requires the execution of a semantic parse to correctly predict the missing entity. This is made more explicit by the fact that one third of the entities in our test set are never seen during training, so without a general approach to query creation and execution there is a limit on a system's performance.

5.2 Our Models

We use different CCG parsers varying in the amounts of supervision. For the UNSUPERVISED scenario, we use Bisk and Hockenmaier (2015)'s parser which

[2] Note that there is one-to-one correspondence between Freebase graphs and Freebase logical forms.

[3] Please see Section 4.3 of Reddy et al. (2016) for details.

		CCGbank (Syntax)		Slot Filling (Semantics)			
		LF1	UF1	2	3	4	Overall
	Sentences			∼6K	∼3K	∼600	∼10K
	Bag-of-Words	–	–	50.8	36.8	**20.9**	45.2
Syntax	UNSUPERVISED	37.1	64.2	41.6	30.4	**24.5**	37.3
Syntax	SEMI-SUPERVISED-POS	53.0	68.5	45.9	33.7	**29.1**	41.4
Syntax	SEMI-SUPERVISED-WORD	53.5	68.9	46.8	38.2	**28.3**	43.2
Syntax	SUPERVISED	84.2	91.0	49.3	42.0	**30.9**	46.1

Table 2: Syntactic and semantic evaluation of the parsing models. Left: Simplified labeled F1 and undirected unlabeled F1 on CCGbank, Section 23. Right: Slot filling performance (by number of entities per sentence).

exploits a small set of universal rules to automatically induce and weight a large set of lexical categories. For the semi-supervised, we explore two options – SEMI-SUPERVISED-WORD and SEMI-SUPERVISED-POS. We use Bisk et al. in both settings but we constrain its lexicon manually rather than inducing it from scratch. In the former, we restrict the top 200 words in English to occur only with the CCG categories that comprise 95% of the occurrences of a word's use in Section 22 of WSJ/CCGbank. In the latter, we restrict the POS tags instead of words. For the SUPERVISED scenario, we use EasyCCG (Lewis and Steedman, 2014) trained on CCGbank.

Finally, in order to further demonstrate the amount of useful information being learned by our parsers, we present a competitive Bag-of-Words baseline, which is a perceptron classifier that performs "semantic parsing" by predicting either a Freebase or a null relation between the empty slot and every other entity in the sentence, using the words in the sentence as features. This naive approach is competitive on simple sentences with only two entities, rivaling even the fully supervised parser, but falters as complexity increases.

5.3 Results and Discussion

Our primary focus is a comparison of intrinsic syntactic evaluation with our extrinsic semantic evaluation. To highlight the differences we present Section 23 parsing performance for our four models (Table 2). Dependency performance is evaluated on both the simplified labeled F1 of Bisk and Hockenmaier (2015) and Undirected Unlabeled F1.

Despite the supervised parser performing almost twice as well as the semi-supervised parsers on CCGbank LF1 (53 vs 84), in our semantic evaluation we see a comparatively small gain in performance (43 vs 46). It is interesting that such weakly supervised models are able to achieve over 90% of the performance of a fully supervised parser. To explore this further, we break down the semantics performance of all our models by the number of entities in a sentence. Each sentence has two, three, or four entities, one of which will be dropped for prediction. The more entities there are in a sentence, the more likely the models are to misanalyze a relation leading to their making the wrong prediction. These results are presented on the right side of Table 2. There are still notable discrepancies in performance, which we analyze more closely in the next section.

Another interesting result is the drop in performance by the Bag-of-Words Model. As the number of entities in the sentence increase, the model weakens, performing worse than the unsupervised parser on sentences with four entities. It becomes non-trivial for it to isolate which entities and relations should be used for prediction. This seems to indicate that the unsupervised grammar is capturing more useful syntactic/semantic information than what is available from the words alone. Ensemble systems that incorporate syntax and a Bag-of-Words baseline may yield even better performance.

5.4 The Benefits of Annotation

The performance of SEMI-SUPERVISED-POS and SEMI-SUPERVISED-WORD suggests that when resources are scarce, it is beneficial to create a even a small lexicon of CCG categories. We analyze this further in Figure 3. Here we show how performance changes as a function of the number of labeled lexical types. Our values range from 0 to 1000 lexical types. We see syntactic improvements of 16pts and seman-

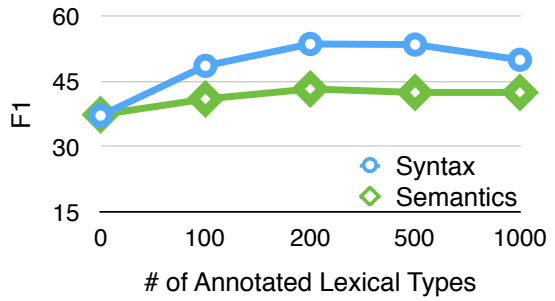


Figure 3: When our word based lexicon grows past 200 lexical types the semantic performance plateaus and the syntax begins to degrade. This is presumably due to the use of rare categories coupled with domain differences.

	Error	Example
Prevalent	Incorrect conjunction	*Stockholm, Sweden*
	Appositive	*, a chemist ,*
	Introductory clauses	*In Frankfurt, ...*
	Reduced relatives	*... , established in 1909, ...*
B&H 15	Verb chains	*is also headquartered*
	Possessive	*Anderson 's Foundation*
	PP Attachment	*of the foundation in Vancouver*

Table 3: Causes of semantic grounding errors with examples not previously isolated via intrinsic evaluation.

tic gains of 6pts with 200 words, before performance degrades. It is possible that increasing annotation may only benefit fully supervised models. Finally, when computing the most frequent lexical types we excluded commas. We found a 3pt performance drop when restricting commas to the category , (they are commonly conj in our data). Additional in-domain knowledge might further improve performance.

5.5 Common Errors

Bisk and Hockenmaier (2015) performed an in-depth analysis of the types of categories learned and correctly used by their models (the same models as this paper). Their analysis was based on syntactic evaluation against CCGbank. In particular, they found the most egregious "semantic" errors to be the misuse of verb chains, possessives and PP attachment (bottom of Table 3). Since we now have access to a purely semantic evaluation, we can therefore ask whether these errors exist here, and how common they are. We do this analysis in two steps. First, we manually analyzed parses for which the unsupervised model failed to predict the correct semantics, but where the supervised parser succeeded. The top of Table 3 presents several of the most common reasons for failure. These mistakes were more mundane (e.g. incorrect use of a conjunction) than failures to use complex CCG categories or analyze attachments.

Second, we can compare grammatical decisions made by the semi-supervised and unsupervised parsers against EasyCCG on sentences they successfully grounded. Bisk and Hockenmaier (2015) found that their unsupervised parser made mistakes on many very simple categories. We found the same result. When evaluating our parsers against the treebank we found the unsupervised model only correctly predicted transitive verbs 20% of the time and adverbs 39% of the time. In contrast, on our data, we produced the correct transitive category (according to EasyCCG) 65% of the time, and the correct adverb 68% of the time. These correct parsing decisions also lead to improved performance across many other categories (e.g. prepositions). This is likely due to our corpus containing simpler constructions. In contrast, auxiliary verbs, relative clauses, and commas still proved difficult or harder than in the treebank. This implies that future work should tailor the annotation effort to their specific domain rather than relying on guidance solely from the treebank.

6 Conclusion

Our goal in this paper was to present the first semantic evaluation of induced grammars in order to better understand their utility and strengths. We showed that induced grammars are learning more semantically useful structure than a Bag-of-Words model. Furthermore, we showed how minimal syntactic supervision can provide substantial gains in semantic evaluation. Our ongoing work explores creating a syntax-semantics loop where each benefits the other with no human (annotation) in the loop.

Vector-space models for PPDB paraphrase ranking in context

Marianna Apidianaki
LIMSI, CNRS, Université Paris-Saclay
91403 Orsay, France
marianna.apidianaki@limsi.fr

Abstract

The PPDB is an automatically built database which contains millions of paraphrases in different languages. Paraphrases in this resource are associated with features that serve to their ranking and reflect paraphrase quality. This context-unaware ranking captures the semantic similarity of paraphrases but cannot serve to estimate their adequacy in specific contexts. We propose to use vector-space semantic models for selecting PPDB paraphrases that preserve the meaning of specific text fragments. This is the first work that addresses the substitutability of PPDB paraphrases in context. We show that vector-space models of meaning can be successfully applied to this task and increase the benefit brought by the use of the PPDB resource in applications.

1 Introduction

Paraphrases are alternative ways to convey the same information and can improve natural language processing by making systems more robust to language variability and unseen words. The paraphrase database (PPDB) (Ganitkevitch et al., 2013) contains millions of automatically acquired paraphrases in 21 languages associated with features that serve to their ranking. In PPDB's most recent release (2.0), such features include natural logic entailment relations, distributional and word embedding similarities, formality and complexity scores, and scores assigned by a supervised ranking model (Pavlick et al., 2015b). These features serve to identify good quality paraphrases but do not say much about their substitutability in context.

To judge the adequacy of paraphrases for specific instances of words or phrases, the surrounding context needs to be considered. This can be done using vector-space models of semantics which calculate the meaning of word occurrences in context based on distributional representations (Mitchell and Lapata, 2008; Erk and Padó, 2008; Dinu and Lapata, 2010; Thater et al., 2011). These models capture the influence of the context on the meaning of a target word through vector composition. More precisely, they represent the contextualised meaning of a target word w in context c by a vector obtained by combining the vectors of w and c using some operation such as component-wise multiplication or addition (Thater et al., 2011). We use this kind of representations to rank the PPDB paraphrases in context and retain the ones that preserve the semantics of specific text fragments. We evaluate the vector-based ranking models on data hand-annotated with lexical variants and compare the obtained ranking to confidence estimates available in the PPDB, highlighting the importance of context filtering for paraphrase selection.

2 Context-based paraphrase ranking

2.1 Paraphrase substitutability

The PPDB[1] provides millions of lexical, phrasal and syntactic paraphrases in 21 languages – acquired by applying bi- and multi-lingual pivoting on parallel corpora (Bannard and Callison-Burch, 2005) – and is largely exploited in applications (Denkowski and Lavie, 2010; Sultan et al., 2014; Faruqui et al.,

[1] http://paraphrase.org/#/download

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2028–2034,
Austin, Texas, November 1-5, 2016.

2015). PPDB paraphrases come into packages of different sizes (going from S to XXXL): smaller packages contain high-precision paraphrases while larger ones aim for high coverage. Until now, pivot paraphrases have been used as equivalence sets (i.e. all paraphrases available for a word are viewed as semantically equivalent) and their substitutability in context has not yet been addressed.

Substitutability might be restrained by several factors which make choosing the appropriate paraphrase for a word or phrase in different contexts a non-trivial task. In case of polysemous words, paraphrases describe different meanings and can lead to erroneous semantic mappings if substituted in texts (Apidianaki et al., 2014; Cocos and Callison-Burch, 2016). Even when paraphrases capture the same general sense, they are hardly ever equivalent synonyms and generally display subtle differences in meaning, connotation or usage (Edmonds and Hirst, 2002). Stylistic variation might also be present within paraphrase sets and substituting paraphrases that differ in terms of complexity and formality can result in a change in style (Pavlick and Nenkova, 2015). To increase paraphrase applicability in context, Pavlick et al. (2015a) propose to extract domain-specific pivot paraphrases by biasing the parallel training data used by the pivot method towards a specific domain. This customised model greatly improves paraphrase quality for the target domain but does not allow to rank and filter the paraphrases already in the PPDB according to specific contexts. To our knowledge, this is the first work that addresses the question of in-context substitutability of PPDB paraphrases. We show how existing substitutability models can be applied to this task in order to increase the usefulness of this large-scale resource in applications.

2.2 Vector-space models of paraphrase adequacy

Vector-based models of meaning determine a gradual concept of semantic similarity which does not rely on a fixed set of dictionary senses. They are used for word sense discrimination and induction (Schütze, 1998; Turney and Pantel, 2010) and can capture the contextualised meaning of words and phrases (Mitchell and Lapata, 2008; Erk and Padó, 2008; Thater et al., 2011). Vector composition methods build representations that go beyond individual words to obtain word meanings in context. Some models use explicit sense representations while others modify the basic meaning vector of a target word with information from the vectors of the words in its context. In the framework proposed by Dinu and Lapata (2010), for example, word meaning is represented as a probability distribution over a set of latent senses reflecting the out-of-context likelihood of each sense, and the contextualised meaning of a word is modeled as a change in the original sense distribution.[2] Reisinger and Mooney (2010) propose a multi-prototype vector-space model of meaning which produces multiple "sense-specific" vectors for each word, determined by clustering the contexts in which the word appears (Schütze, 1998). The cluster centroids serve as prototype vectors describing a word's senses and the meaning of a specific occurrence is determined by choosing the vector that minimizes the distance to the vector representing the current context. On the contrary, Thater et al. (2011) use no explicit sense representation. Their models allow the computation of vector representations for individual uses of words, characterising the specific meaning of a target word in its sentential context. When used for paraphrase ranking, these models derive a contextualised vector for a target word by reweighting the components of its basic meaning vector on the basis of the context of occurrence.[3] Paraphrase candidates for a target word are then ranked according to the cosine similarity of their basic vector representation to the contextualised vector of the target.[4]

3 Experimental Set-up

Data In our experiments, we use the CoInCo corpus (Kremer et al., 2014), a subset of the "Manually Annotated Sub-Corpus" MASC (Ide et al., 2010) which comprises more than 15K word in-

[2]The latent senses are induced using non-negative matrix factorization (NMF) (Lee and Seung, 2001) and latent Dirichlet allocation (LDA) (Blei et al., 2003).

[3]Depending on the model, the vector combination function might be addition or multiplication of vector elements.

[4]Thater et al.'s (2011) models delivered best results in paraphrase ranking on the CoInCo corpus (Kremer et al., 2014) and the SemEval-2007 Lexical Substitution dataset (McCarthy and Navigli, 2007).

	$\|P\| > 1$			$\|P\| \geq 1$
PPDB	# Instances	# Lemmas	Avg $\|P\|$	# Instances
S	2146	560	2.67	5573
M	3716	855	2.92	7771
L	6228	1394	3.57	10100
XL	13344	2822	10.33	14060
XXL	14507	3308	185.09	14593

Table 1: Number of CoInCo instances and distinct lemmas covered by each PPDB package.

stances manually annotated with single and multi-word substitutes. The manual annotations serve to evaluate the performance of the vector-space models on the task of ranking PPDB paraphrases. For each annotated English target word (noun, verb, adjective or adverb) in CoInCo, we collect the lexical paraphrases ($P = \{p_1, p_2, ..., p_n\}$) available for the word in each PPDB package (from S to XXL).[5] We do not filter by syntactic label as annotations often include substitutes of different grammatical categories. Table 1 shows the number of CoInCo tokens with paraphrases in each PPDB package and the average size of the retained paraphrase sets. The larger the size of the resource, the greater the coverage of target words in CoInCo. The last column of the table gives the total number of instances covered, including the ones with only one paraphrase. In the ranking experiments, we focus on lemmas having more than one paraphrase in the PPDB.[6]

Methodology We follow the methodology proposed in Kremer et al. (2014) to explore the extent to which vector-based models can select appropriate paraphrases for words in context. Given a target word w in a sentential context and a set of paraphrases P extracted for w from a PPDB package, the task is to rank the elements in P according to their adequacy as paraphrases of w in the given context.

We carry out experiments with three versions of the Thater et al. (2011) ranking model: (a) a *syntactically structured* model (Syn.Vec) that uses vectors recording co-occurrences based on dependency triples, explicitly recording syntactic role information within the vectors; (b) a *syntactically filtered model* (Filter.Vec) using dependency-based co-occurrence information without explicitly representing the syntactic role in the vector representations, as in Padó and Lapata (2007); (c) a bag of words model (Bow.Vec) using a window of $\pm$ 5 words. Co-occurrence counts were extracted from the English Gigaword corpus[7] analysed with Stanford dependencies (de Marneffe et al., 2006). The syntactic model vectors are based on dependency triples that occur at least 5 times in the corpus and have a PMI score of at least 2. The same thresholds apply to the bag of words model where the frequency threshold defines the minimum number of times that two words have been observed in the same context window. The task of the vector-space models for each target word instance is to rank the contents of the corresponding paraphrase set (which contains all the substitution candidates available for the target in the PPDB) so that the actual substitutes are ranked higher than the rest. For example, *newspaper, manuscript* and *document* are good paraphrase candidates for *paper* but we would expect *newspaper* to be ranked higher than the other two in this sentence: "*the paper's local administrator*".

A contextualised vector is derived from the basic meaning vector of a target word w by reinforcing its dimensions that are licensed by the context of the specific instance under consideration. In the Bow.Vec model, the context is made up of 5 words before and after the target while in the syntactic models, it corresponds to the target's direct syntactic dependents. The contextualised vector for w is obtained through vector addition and contains information about the context words. Paraphrase candidates are ranked according to the cosine similarity between the contextualised vector of the target word and the basic meaning vectors of the candidates. Following Kremer et al. (2014), we compare the resulting ranked list to the CoInCo gold standard annotation (the paraphrase set of the target instance) using Generalised Average Precision (GAP) (Kishida, 2005) and annotation frequency as weights. GAP scores range between 0 and 1: a score of 1 indicates a perfect ranking in which all correct substitutes precede all incorrect ones, and

[5] Since the XXL package covers almost all annotated instances in CoInCo (14,507 out of 15,629) and there are 185.09 paraphrases in average for each instance, we exclude the XXXL package from these experiments.

[6] We retain paraphrases of the lemmatised forms of the target words but these unsupervised ranking models can be easily applied to the whole PPDB resource and in different languages.

correct high-weight substitutes precede low-weight ones. For calculating the GAP score, we assign a very low score (0.001) to paraphrases that are not present in CoInCo for a target word (i.e. not proposed by the annotators).

4 Results

The average GAP scores obtained by the three vector-space models (Bow.Vec, Syn.Vec and Filter.Vec) are shown in Table 2. The upper part of the table reports scores obtained for words with more than one paraphrase in the PPDB ($|P| > 1$) while the lower part gives the scores for all words.

We compare the GAP scores to five different rankings reflecting paraphrase quality in the PPDB (Pavlick et al., 2015b). We retain the following scores: 1. **AGigaSim** captures the distributional similarity of a phrase e_1 and its paraphrase e_2 computed according to contexts observed in the Annotated Gigaword corpus (Napoles et al., 2011); 2. **GoogleNgramSim** reflects the distributional similarity of e_1 and e_2 computed according to contexts observed in the Google Ngram corpus (Brants and Franz, 2006); 3. **ParProb**: the paraphrase probability of e_2 given the original phrase e_1 (Bannard and Callison-Burch, 2005); 4. **Ppdb1**: the heuristic scoring used for ranking in the original release of the PPDB (Ganitkevitch et al., 2013); 5. **Ppdb2**: the improved ranking of English paraphrases available in PPDB 2.0. The results are also compared to the output of a baseline where the paraphrases are randomly ranked. The reported baseline figures are PPDB package-specific since a different paraphrase set is retained from each package, and correspond to averages over 5 runs. The quality of the ranking produced by the baseline clearly decreases as the size of the PPDB resource increases due to the higher number of retained paraphrases which makes ranking harder.

The results in the upper part of the table show that the vector-space models provide a better ranking than the PPDB estimates and largely outperform the random baseline. The three models perform similarly on this ranking task according to average GAP with the syntactically-informed models getting slightly higher scores. Differences between Syn.Vec and Filter.Vec, as well as between Bow.Vec and the syntactic models, are highly significant in the XL and XXL packages (p-value < 0.001) as computed with approximate randomisation (Padó, 2006). In the L package, the difference between Syn.Vec and Filter.Vec is significant ($p < 0.05$) and the one between Bow.Vec and Filter.Vec is highly significant. Finally, in the M package, only the difference between Bow.Vec and Filter.Vec is significant ($p < 0.05$), while Syn.Vec and Filter.Vec seem to deal similarly well with the contents of this package.

Two PPDB ranking methods, AGiga and Ppdb2, obtain good results. AgigaSim reflects the distributional similarity of the paraphrases in the Annotated Gigaword corpus (Napoles et al., 2011). As noted by Kremer et al. (2014), the whole-document annotation in CoInCo faces the natural skewed distribution towards predominant senses which favors non-contextualised baseline models. The good performance of Ppdb2 is due to the use of a supervised scoring model trained on human judgments of paraphrase quality. The human judgments were

used to fit a regression to the features available in PPDB 1.0 plus numerous new features including cosine word embedding similarity, lexical overlap features, WordNet features and distributional similarity features.[8] The small difference observed between the Ppdb2 and the syntactic models score in the XXL package is highly significant. For the moment, Ppdb2 scores are available in the PPDB only for English. Since the vector-space methodology is unsupervised and language independent, it could be easily applied to paraphrase ranking in other languages. The performance of the models remains high with the XL package which contains paraphrase sets of reasonable size (about 10 paraphrases per word) and ensures a high coverage, and lowers in XXL which contains 185 paraphrases in average per word (cf. Table 1). To use this package more efficiently, one could initially reduce the number of erroneous paraphrases on the basis of the Ppdb2 score which provides a good ranking of the XXL package contents before applying the vector-based models.

The increase in GAP score observed when words with one paraphrase are considered shows that these paraphrases are often correct. Here too, the contextual models provide a better ranking than the out-of-context scores and outperform the random baseline. As in the previous case, the Ppdb2 score is slightly higher in the XXL package.

5 Conclusion

We have shown that vector-based models of semantics can be successfully applied to in-context ranking of PPDB paraphrases. Allowing for better context-informed substitutions, they can be used to filter PPDB paraphrases on the fly and select variants preserving the correct semantics of words and phrases in texts. This processing would be beneficial to numerous applications that need paraphrase support (e.g. summarisation, query reformulation and language learning), providing a practical means for exploiting the extensive multilingual knowledge available in the PPDB resource.

This study opens up many avenues for future work. Although tested on English, the proposed methodology can be applied to all languages in the PPDB even to the ones that do not dispose of a dependency parser (as shown by the high performance of the Bow.Vec models).

An ideal testbed for evaluation in a real application and on multiple languages is offered by MT evaluation. The METEOR-NEXT metric (Denkowski and Lavie, 2010) provides a straightforward framework for testing as it already exploits PPDB paraphrases for capturing sense correspondences between text fragments. In its current version, the metric views paraphrases as equivalent classes which can lead to erroneous sense mappings due to semantic distinctions present in the paraphrase sets. We have recently showed that the context-based filtering of semantic variants improves METEOR's correlation with human judgments of translation quality (Marie and Apidianaki, 2015). We believe that a context-based paraphrase ranking mechanism will enhance correct substitutions and further improve the metric. Last but not least, the paraphrase vectors can be used for mapping the contents of the PPDB resource to other multilingual resources for which vector representations are available (Camacho-Collados et al., 2015a; Camacho-Collados et al., 2015b). The interest of mapping paraphrases in the vector space to concepts found in existing semantic resources is twofold: it would permit to analyse the semantics of the paraphrases by putting them into correspondence with explicit concept representations and would serve to enrich other semantic resources (e.g. BabelNet synsets) with semantically similar paraphrases.

Handling phrasal paraphrases is another natural extension of this work. We consider using a vector space model of semantic composition to calculate the meaning of longer candidate paraphrases (Dinu et al., 2013; Paperno et al., 2014) and select appropriate substitutes for phrases in context.

Acknowledgments

We would like to thank Stefan Thater for sharing the vector-space models, Benjamin Marie for his support with the paraphrase ranking models and the anonymous reviewers for their valuable comments and suggestions.

[8] The features used for computing the paraphrase ranking in PPDB 2.0 are described in detail in Pavlick et al. (2015b).

Interpreting Neural Networks to Improve Politeness Comprehension

Malika Aubakirova

mbansal@cs.unc.edu

Abstract

We present an interpretable neural network approach to predicting and understanding politeness in natural language requests. Our models are based on simple convolutional neural networks directly on raw text, avoiding any manual identification of complex sentiment or syntactic features, while performing better than such feature-based models from previous work. More importantly, we use the challenging task of politeness prediction as a testbed to next present a much-needed understanding of what these successful networks are actually learning. For this, we present several network visualizations based on activation clusters, first derivative saliency, and embedding space transformations, helping us automatically identify several subtle linguistics markers of politeness theories. Further, this analysis reveals multiple novel, high-scoring politeness strategies which, when added back as new features, reduce the accuracy gap between the original featurized system and the neural model, thus providing a clear quantitative interpretation of the success of these neural networks.

1 Introduction

Politeness theories (Brown and Levinson, 1987; Gu, 1990; Bargiela-Chiappini, 2003) include key components such as modality, indirection, deference, and impersonalization. Positive politeness strategies focus on making the hearer feel good through offers, promises, and jokes. Negative politeness examples include favor seeking, orders, and requests. Differentiating among politeness types is a highly nontrivial task, because it depends on factors such as a context, relative power, and culture. Danescu-Niculescu-Mizil et al. (2013) proposed a useful computational framework for predicting politeness in natural language requests by designing various lexical and syntactic features about key politeness theories, e.g., first or second person start vs. plural. However, manually identifying such politeness features is very challenging, because there exist several complex theories and politeness in natural language is often realized via subtle markers and non-literal cues.

Neural networks have been achieving high performance in sentiment analysis tasks, via their ability to automatically learn short and long range spatial relations. However, it is hard to interpret and explain what they have learned. In this paper, we first propose to address politeness prediction via simple CNNs working directly on the raw text. This helps us avoid the need for any complex, manually-defined linguistic features, while still performing better than such featurized systems. More importantly, we next present an intuitive interpretation of what these successful neural networks are learning, using the challenging politeness task as a testbed.

To this end, we present several visualization strategies: activation clustering, first derivative saliency, and embedding space transformations, some of which are inspired by similar strategies in computer vision (Erhan et al., 2009; Simonyan et al., 2014; Girshick et al., 2014), and have also been recently adopted in NLP for recurrent neural networks (Li et al., 2016; Kádár et al., 2016). The neuron activation clustering method not only rediscovers and extends several manually defined features from politeness theories, but also uncovers multiple novel strategies, whose importance we measure quantitatively. The first derivative saliency technique allows us to identify the impact of each phrase

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2035–2041,
Austin, Texas, November 1-5, 2016.

on the final politeness prediction score via heatmaps, revealing useful politeness markers and cues. Finally, we also plot lexical embeddings before and after training, showing how specific politeness markers move and cluster based on their polarity. Such visualization strategies should also be useful for understanding similar state-of-the-art neural network models on various other NLP tasks.

Importantly, our activation clusters reveal two novel politeness strategies, namely indefinite pronouns and punctuation. Both strategies display high politeness and top-quartile scores (as defined by Danescu-Niculescu-Mizil et al. (2013)). Also, when added back as new features to the original featurized system, they improve its performance and reduce the accuracy gap between the featurized system and the neural model, thus providing a clear, quantitative interpretation of the success of these neural networks in automatically learning useful features.

2 Related Work

Danescu-Niculescu-Mizil et al. (2013) presented one of the first useful datasets and computational approaches to politeness theories (Brown and Levinson, 1987; Goldsmith, 2007; Kádár and Haugh, 2013; Locher and Watts, 2005), using manually defined lexical and syntactic features. Substantial previous work has employed machine learning models for other sentiment analysis style tasks (Pang et al., 2002; Pang and Lee, 2004; Kennedy and Inkpen, 2006; Go et al., 2009; Ghiassi et al., 2013). Recent work has also applied neural network based models to sentiment analysis tasks (Chen et al., 2011; Socher et al., 2013; Moraes et al., 2013; Dong et al., 2014; dos Santos and Gatti, 2014; Kalchbrenner et al., 2014). However, none of the above methods focused on visualizing and understanding the inner workings of these successful neural networks.

There have been a number of visualization techniques explored for neural networks in computer vision (Krizhevsky et al., 2012; Simonyan et al., 2014; Zeiler and Fergus, 2014; Samek et al., 2016; Mahendran and Vedaldi, 2015). Recently in NLP, Li et al. (2016) successfully adopt computer vision techniques, namely first-order *saliency*, and present representation plotting for sentiment compositionality across RNN variants. Similarly, Kádár et al. (2016) analyze the omission scores and top-k contexts of hidden units of a multimodal RNN. Karpathy et al. (2016) visualize character-level language models. We instead adopt visualization techniques for CNN style models for NLP[1] and apply these to the challenging task of politeness prediction, which often involves identifying subtle and non-literal sociolinguistic cues. We also present a quantitative interpretation of the success of these CNNs on the politeness prediction task, based on closing the performance gap between the featurized and neural models.

3 Approach

3.1 Convolutional Neural Networks

We use one convolutional layer followed by a pooling layer. For a sentence $v_{1:n}$ (where each word v_i is a d-dim vector), a filter m applied on a window of t words, produces a convolution feature $c_i = f(m * v_{i:i+t-1} + b)$, where f is a non-linear function, and b is a bias term. A *feature map* $c \in R^{n-t+1}$ is applied on each possible window of words so that $c = [c_1, ..., c_{n-t+1}]$. This convolutional layer is then followed by a max-over-pooling operation (Collobert et al., 2011) that gives $C = max\{c\}$ of the particular filter. To obtain multiple features, we use multiple filters of varying window sizes. The result is then passed to a fully-connected softmax layer that outputs probabilities over labels.

4 Experimental Setup

4.1 Datasets

We used the two datasets released by Danescu-Niculescu-Mizil et al. (2013): Wikipedia (Wiki) and Stack Exchange (SE), containing community requests with politeness labels. Their 'feature development' was done on the Wiki dataset, and SE was used as the 'feature transfer' domain. We use a simpler train-validation-test split based setup for these datasets instead of the original leave-one-out cross-validation setup, which makes training extremely slow for any neural network or sizable classifier.[2]

[1] The same techniques can also be applied to RNN models.

[2] The result trends and visualizations using cross-validation were similar to our current results, in preliminary experiments. We will release our exact dataset split details.

4.2 Training Details

Our tuned hyperparameters values (on the dev set of Wiki) are a mini-batch size of 32, a learning rate of 0.001 for the Adam (Kingma and Ba, 2015) optimizer, a dropout rate of 0.5, CNN filter windows of 3, 4, and 5 with 75 feature maps each, and ReLU as the non-linear function (Nair and Hinton, 2010). For convolution layers, we use valid padding and strides of all ones. We followed Danescu-Niculescu-Mizil et al. (2013) in using SE only as a transfer domain, i.e., we do not re-tune any hyperparameters or features on this domain and simply use the chosen values from the Wiki setting. The split and other training details are provided in the supplement.

5 Results

Table 1 first presents our reproduced classification accuracy test results (two labels: positive or negative politeness) for the bag-of-words and linguistic features based models of Danescu-Niculescu-Mizil et al. (2013) (for our dataset splits) as well as the performance of our CNN model. As seen, without using any manually defined, theory-inspired linguistic features, the simple CNN model performs better than the feature-based methods.[3]

Next, we also show how the linguistic features baseline improves on adding our novelly discovered features (plus correcting some exising features), revealed via the analysis in Sec. 6. Thus, this reduces the gap in performance between the linguistic features baseline and the CNN, and in turn provides a quantitative reasoning for the success of the CNN model. More details in Sec. 6.

6 Analysis and Visualization

We present the primary interest and contribution of this work: performing an important qualitative and quantitative analysis of what is being learned by our neural networks w.r.t. politeness strategies.[4]

6.1 Activation Clusters

Activation clustering is a non-parametric approach (adopted from Girshick et al. (2014)) of computing each CNN unit's activations on a dataset and then analyzing the top-scoring samples in each cluster. We keep track of which neurons get maximally activated for which Wikipedia requests and analyze the most frequent requests in each neuron's cluster, to understand what each neuron reacts to.

Model	Wiki	SE
Bag-of-Words	80.9%	64.6%
Linguistic Features	82.6%	65.2%
With Discovered Features	83.8%	65.7%
CNN	85.8%	66.4%

Table 1: Accuracy Results on Wikipedia and Stack Exchange.

6.1.1 Rediscovering Existing Strategies

We find that the different activation clusters of our neural network automatically rediscover a number of strategies from politeness theories considered in Danescu-Niculescu-Mizil et al. (2013) (see Table 3 in their paper). We present a few such strategies here with their supporting examples, and the rest (e.g., Gratitude, Greeting, Positive Lexicon, and Counterfactual Modal) are presented in the supplement. The majority politeness label of each category is indicated by (+) and (-).

Deference (+) A way of sharing the burden of a request placed on the addressee. Activation cluster examples: {"*nice work so far on your rewrite...*"; "*hey, good work on the new pages...*"}

Direct Question (-) Questions imposed on the converser in a direct manner with a demand of a factual answer. Activation cluster examples: {"*what's with the radio , and fist in the air?*"; "*what level warning is appropriate?*"}

6.1.2 Extending Existing Strategies

We also found that certain activation clusters depicted interesting extensions of the politeness strategies given in previous work.

Gratitude (+) Our CNN learns a special shade of gratitude, namely it distinguishes a cluster consisting of the bigram *thanks for*. Activation cluster examples: {"*thanks for the good advice.*"; "*thanks for letting me know.*"}

Counterfactual Modal (+) Sentences with *Would you/Could you* get grouped together as expected; but in addition, the cluster contains requests with *Do you mind* as well as gapped 3-grams like *Can you ... please?*, which presumably implies that the combi-

[3]For reference, human performance on the original task setup of Danescu-Niculescu-Mizil et al. (2013) was 86.72% and 80.89% on the Wiki and SE datasets, respectively.

[4]We only use the Wiki train/dev sets for all analysis.

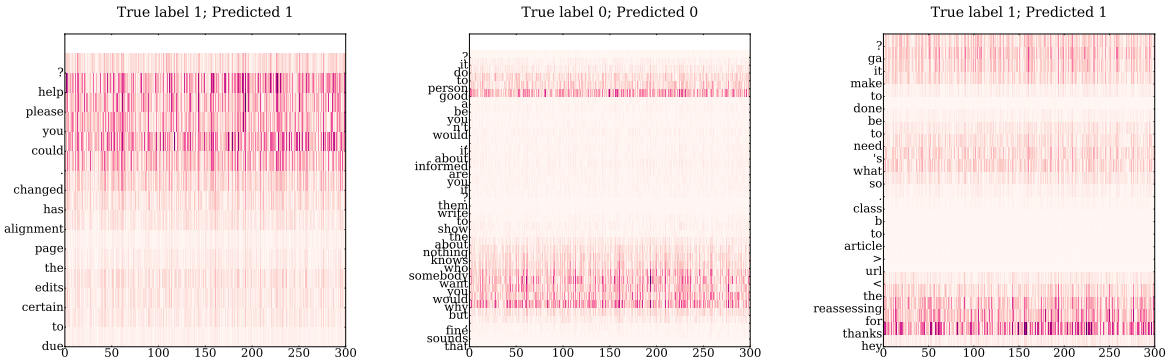

Figure 1: Saliency heatmaps for correctly classified sentences.

nation of a later *please* with future-oriented variants *can/will* in the request gives a similar effect as the conditional-oriented variants *would/could*. Activation cluster examples: {*can this be reported ... grid, please?*"; *do you mind having another look?*"}

6.1.3 Discovering Novel Strategies

In addition to rediscovering and extending politeness strategies mentioned in previous work, our network also automatically discovers some novel activation clusters, potentially corresponding to new politeness strategies.

Indefinite Pronouns (-) Danescu-Niculescu-Mizil et al. (2013) distinguishes requests with first and second person (plural, starting position, etc.). However, we find activations that also react to indefinite pronouns such as *something/somebody*. Activation cluster examples: {"*am i missing something here?*"; "*wait for anyone to discuss it.*"}

Punctuation (-) Though non-characteristic in direct speech, punctuation appears to be an important special marker in online communities, which in some sense captures verbal emotion in text. E.g., one of our neuron clusters gets activated on question marks "???" and one on ellipsis "...". Activation cluster examples: {"*now???*"; "*original article????*"; "*helllo?????*"}[5]

In the next section, via saliency heatmaps, we will further study the impact of indefinite pronouns in the final-decision making of the classifier. Finally, in Sec. 6.4, we will quantitatively show how our newly discovered strategies help directly improve the accuracy performance of the linguistic features baseline and achieve high politeness and top-quartile scores as per Danescu-Niculescu-Mizil et al. (2013).

[5]More examples are given in the supplement.

6.2 First Derivative Saliency

Inspired from neural network visualization in computer vision (Simonyan et al., 2014), the first derivative saliency method indicates how much each input unit contributes to the final decision of the classifier. If E is the input embedding, y is the true label, and $S_y(E)$ is the neural network output, then we consider gradients $\frac{\partial S_y(E)}{\partial e}$. Each image in Fig. 1 is a heatmap of the magnitudes of the derivative in absolute value with respect to each dimension.

The first heatmap gets signals from *please* (Please strategy) and *could you* (Counterfactual Modal strategy), but effectively puts much more mass on *help*. This is presumably due to the nature of Wikipedia requests such that the meaning boils down to asking for some help that reduces the social distance. In the second figure, the highest emphasis is put on *why would you*, conceivably used by Wikipedia administrators as an indicator of questioning. Also, the indefinite pronoun *somebody* makes a relatively high impact on the decision. This relates back to the activation clustering mentioned in the previous section, where indefinite pronouns had their own cluster. In the third heatmap, the neural network does not put much weight on the greeting-based start *hey*, because it instead focuses on the higher polarity[6] gratitude part after the greeting, i.e., on the words *thanks for*. This will be further connected in Sec. 6.3.

6.3 Embedding Space Transformations

We selected key words from Danescu-Niculescu-Mizil et al. (2013) and from our new activation clusters (Sec. 6.1) and plotted (via PCA) their embed-

[6]See Table 3 of Danescu-Niculescu-Mizil et al. (2013) for polarity scores of the various strategies.

	Strategy	Politeness	In top quartile	Examples
21.	Indefinite Pronouns	-0.13	39%	*am i missing something here?*
22.	Punctuation	-0.71	62%	*helllo?????*

Table 2: Extending Table 3 of Danescu-Niculescu-Mizil et al. (2013) with our novelly discovered politeness strategies.

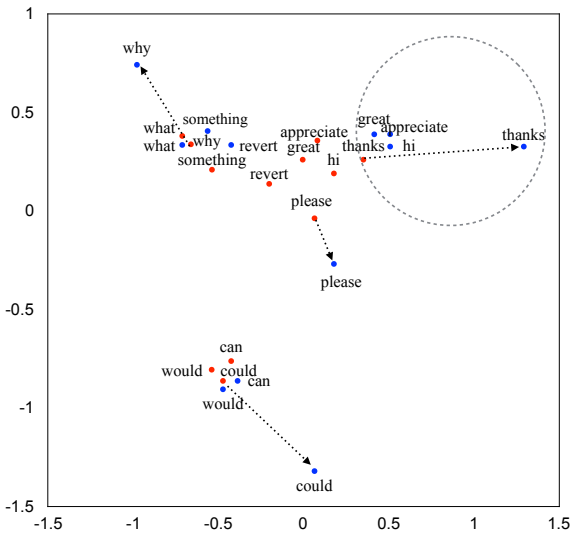

Figure 2: Projection before (red) and after (blue) training.

ding space positions before and after training, to help us gain insights into specific sentiment transformations. Fig. 2 shows that the most positive keys such as *hi*, *appreciate*, and *great* get clustered even more tightly after training. The key *thanks* gets a notably separated position on a positive spectrum, signifying its importance in the NN's decision-making (also depicted via the saliency heatmaps in Sec. 6.2).

The indefinite pronoun *something* is located near direct question politeness strategy keys *why* and *what*. *Please*, as was shown by Danescu-Niculescu-Mizil et al. (2013), is not always a positive word because its sentiment depends on its sentence position, and it moves further away from a positive key group. Counterfactual Modal keys *could* and *would* as well as *can* of indicative modal get far more separated from positive keys. Moreover, after the training, the distance between *could* and *would* increases but it gets preserved between *can* and *would*, which might suggest that *could* has a far stronger sentiment.

6.4 Quantitative Analysis

In this section, we present quantitative measures of the importance and polarity of the novelly discovered politeness strategies in the above sections, as well how they explain some of the improved performance of the neural model.

In Table 3 of Danescu-Niculescu-Mizil et al. (2013), the pronoun politeness strategy with the highest percentage in top quartile is 2nd Person (30%). Our extension Table 2 shows that our novelly discovered Indefinite Pronouns strategy represents a higher percentage (39%), with a politeness score of -0.13. Moreover, our Punctuation strategy also turns out to be a top scoring negative politeness strategy and in the top three among all strategies (after Gratitude and Deference). It has a score of -0.71, whereas the second top negative politeness strategy (Direct Start) has a much lower score of -0.43.

Finally, in terms of accuracies, our newly discovered features of Indefinite Pronouns and Punctuation improved the featurized system of Danescu-Niculescu-Mizil et al. (2013) (see Table 1).[7] This reduction of performance gap w.r.t. the CNN partially explains the success of these neural models in automatically learning useful linguistic features.

7 Conclusion

We presented an interpretable neural network approach to politeness prediction. Our simple CNN model improves over previous work with manually-defined features. More importantly, we then understand the reasons for these improvements via three visualization techniques and discover some novel high-scoring politeness strategies which, in turn, quantitatively explain part of the performance gap between the featurized and neural models.

Acknowledgments

We would like to thank the anonymous reviewers for their helpful comments. This work was supported by an IBM Faculty Award, a Bloomberg Research Grant, and an NVIDIA GPU donation to MB.

[7] Our NN visualizations also led to an interesting feature correction. In the 'With Discovered Features' result in Table 1, we also removed the existing pronoun features (#14-18) based on the observation that those had weaker activation and saliency contributions (and lower top-quartile %) than the new indefinite pronoun feature. This correction and adding the two new features contributed ∼50-50 to the total accuracy improvement.

Does 'well-being' translate on Twitter?

Abstract

We investigate whether psychological well-being translates across English and Spanish Twitter, by building and comparing source language and automatically translated weighted lexica in English and Spanish. We find that the source language models perform substantially better than the machine translated versions. Moreover, manually correcting translation errors does not improve model performance, suggesting that meaningful cultural information is being lost in translation. Further work is needed to clarify when automatic translation of well-being lexica is effective and how it can be improved for cross-cultural analysis.

1 Introduction

Interest in sentiment analysis spans academic and commercial domains, with wide-ranging applications (Pang and Lee, 2008; Liu, 2012). While the majority of tools for sentiment analysis have been developed for English text, ideally sentiment and emotion could be analyzed across many languages. Does one need to build models for each language of interest, or can models be applied cross-culturally? More generally, how do cultures differ in the language they use to express sentiment and feeling?

Sentiment in resource-poor languages has commonly been assessed by first translating text into English and then applying an English sentiment model (Mohammad et al., 2016). This approach is economical and efficient, as building each model of interest in every target language is resource-intensive. Yet it is not clear how much culturally specific information and accuracy are lost in the translation process, and specifically how this varies across languages, cultures, linguistic content, and corpora (e.g., social media vs. news). While extensive work has demonstrated that automatic machine translation (MT) methods are competitive when translating opinion in news and blogs, less research has examined the translation of sentiment on social media, and specifically on Twitter, known for its restriction of individual exchanges to short samples of text (140 characters) and informal language. Moreover, research has not focused on translating subjective well-being specifically.

Beyond sentiment, this paper investigates how expressions of personal well-being translate between English and Spanish on Twitter. We have English and Spanish speakers annotate Tweets in their native language for five components of subjective well-being (positive emotion, engagement, positive relationships, meaning, and accomplishment) (Seligman, 2011). We then compare how well models trained and tested in the same language compare to (a) models developed in one language, and then translated (using Google Translate) to the other language (e.g., how well English models translated to Spanish work on Spanish Tweets) and (b) how well models developed in one language work on Tweets translated from another language (e.g., how well English models work on Tweets translated from Spanish to English).

2 Related Work

There is a vast literature on sentiment analysis which space precludes us from surveying; see (Liu, 2012)

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2042–2047,
Austin, Texas, November 1-5, 2016.

for an excellent overview. A small but rapidly growing camp is developing methods to estimate personality and emotion, asking "how does she feel?" rather than "how much does she like the product?" (Mohammad and Kiritchenko, 2015; Park et al., 2014). In social media, the well-being of individuals as well as communities has been studied, on various platforms such as Facebook and Twitter (Bollen et al., 2011; Schwartz et al., 2013; Eichstaedt et al., 2015; Schwartz et al., 2016).

2.1 Translating sentiment

Past work has, on the whole, regarded state-of-the-art automatic translation for sentiment analysis optimistically. In assessing statistical MT, (Balahur and Turchi, 2012) found that modern SMT systems can produce reliable training data for languages other than English. Comparative evaluations between English and Romanian (Mihalcea et al., 2007) and English and both Spanish and Romanian (Banea et al., 2008) based on the English MPQA sentiment data suggest that, in spite of word ambiguity in either the source or target language, automatic translation is a viable alternative to the construction of models in target languages. Wan (2008) shows that it is useful to improve a system in a target language (Chinese) by applying ensemble methods exploiting sentiment-specific data and lexica from the target language and a source language (English). More recent work has examined how sentiment changes with translation between English and Arabic, also finding that automatic translation of English texts yields competitive results (Abdul-Mageed and Diab, 2014; Mohammad et al., 2016). However, translated texts tend to lose sentiment information such that the translated data is more neutral than the source language (Salameh et al., 2015).

It is less obvious how well expressions of emotion or subjective well-being translate between languages and cultures; the words for liking a phone or TV may be more similar across cultures than the ones for finding life and relationships satisfying, or work meaningful and engaging.

2.2 Well-being

In contrast to classic sentiment analysis, well-being is not restricted to positive and negative emotion. In 2011, the psychologist Martin Seligman proposed PERMA (Seligman, 2011), a five-dimensional model of well-being where 'P' stands for positive emotion, 'E' is engagement, 'R' is positive relationships, 'M' is meaning, and 'A' is a sense of accomplishment. PERMA is of interest to this translation context because while the 'P' dimension maps relatively cleanly onto traditional conceptions of sentiment (i.e., positive and negative emotion), PERMA also includes social and cognitive components which may be expressed with more variation across languages and cultures. In recent work, Schwartz et al. (2016) developed an English PERMA model using Facebook data. In this paper, we adopt a similar method when building our message-level models over Tweets.

Governments around the world are increasingly dedicating resources to the measurement of well-being to complement traditional economic indicators such as gross domestic product. Being able to measure well-being across regions is not only becoming more important for institutions and policymakers, but also for private sector entities that want to assess and promote the well-being of their organizations and customers. This raises the importance of translation, given that resources for the measurement of well-being are disproportionately available in English.

3 Methods

We collected Spanish data using the Twitter API, gathering 15.3 million geolocated Tweets between September and November 2015 using a latitude/longitude bounding box around Spain. This set was reduced to messages containing only Spanish using the Language Identification (LangID) Python package (Lui and Baldwin, 2012). We restricted to messages with an 80% or higher Spanish confidence score as given by LangID. This resulted in 6.1 million Tweets from 290,000 users. We selected 5,100 random messages from this set for annotation. English Tweets were similarly collected using the Twitter API, restricted to the US, and filtered to be (primarily) in English.

3.1 Annotating message-level data

Amazon's Mechanical Turk (MTurk) was used to annotate the 5,000 random English (American)

Tweets[1]. CrowdFlower, an online crowdsourcing platform similar to MTurk, but more widely used in Europe, was used to annotate our 5,100 random Spanish Tweets[1]. As the Tweets exclusively came from Spain, raters were restricted to fluent Spanish speakers who live in Spain.

On both MTurk and CrowdFlower, separate annotation tasks were set up for each of the 10 PERMA components (positive and negative dimensions for the 5 components). Workers were given the definition of the PERMA construct, directions on how to perform the task, and were presented with an example annotation task. During the task workers were asked to indicate "to what extent does this message express" the construct in question on a scale from 1 ("Not at all") to 7 ("Extremely"). Directions were presented in English for the English task, and in Spanish for the Spanish task. The Spanish instructions were translated manually from English by a bilingual English-Spanish speaker and verified by an additional bilingual speaker.

In the English task, two raters assessed each message. If the raters disagreed by more than 3 points, a rating was obtained from a third rater. It proved more difficult to get raters for the Spanish task, even on CrowdFlower. In some cases we were unable to obtain even a single annotation for a given Tweet and PERMA component.

3.2 Developing weighted lexica

Tweets were tokenzied using an emoticon-aware tokenizer, 'happy fun tokenizer'[1]. We then extracted unigrams and bigrams from each corpus, yielding vocabularies of 5,430 and 4,697 'words' in English and Spanish, respectively. The presence/absence of these unigrams and bigrams in each Tweet were used as features in Lasso (L1 penalized regression) (Tibshirani, 1996) models to predict the average annotation score for each of the crowdsourced PERMA labels. Separate models, each consisting of regression weights for each term in the lexicon, were built for each of the ten (five positive and five negative) PERMA components in both English and Spanish[1]. Each model was validated using 10-fold cross validation, with Pearson correlations averaged over the 10 positive/negative PERMA components. Results are presented in Table 1. The models were then transformed into a predictive lexicon using the methods described in (Sap et al., 2014), where the weights in the lexicon were derived from the above Lasso regression model.

Model	*r*
Spanish	0.36
English	0.36

Table 1: Performance as measured by Pearson *r* correlation averaged over the 10 positive/negative PERMA components using 10-fold cross validation.

3.3 Translating the models

We used Google Translate to translate both the original English and Spanish Tweets and the words in the models. We also created versions of the translated models in which we manually corrected apparent translation errors for 25 terms with the largest regression coefficients for each of the 10 PERMA components (the top 250 terms for each model).

3.4 Comparative evaluation

We evaluated how well the different models worked, computing the Pearson correlations between message-level PERMA scores predicted from the different models and the ground-truth annotations. Lexica were built on 80% of the messages and then evaluated on the remaining 20%. Figure 1 shows test accuracies. Comparing the English and Spanish source language and machine translated models, we observe substantially better performance when models were built over the same language they are applied to, i.e., using models built in Spanish to predict on Spanish Tweets. Translating the models (e.g., translating an English model to Spanish and using it on Spanish Tweets) or translating the Tweets (e.g., translating Spanish Tweets to English and using an English model) work substantially less well, with translating the Tweets giving marginally better performance than translating the models. Finally, we translate both the model and Tweets, giving slightly better performance than translating the Tweets alone. Complete PERMA lexica were then built over the entire message sets for public release.

3.5 Error Analysis

To quantify the errors in translation, we took the 25 top-weighted words in each component of the

[1] Available at www.wwbp.org.

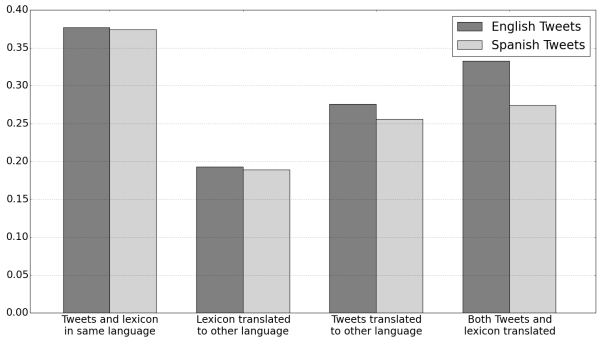

Figure 1: Performance (Pearson *r* correlation) between ground-truth annotations and predicted lexica scores averaged over the 10 PERMA components.

PERMA lexicon (250 terms total) and manually translated them with the help of a native Spanish speaker. The manual translations were then compared against the automatic translations. Out of the top 25 words we calculated the percentage of correct automatic translations (when manual and automatic translations matched) and averaged the percentages across positive and negative PERMA components. The average percentage of correct translations is listed in Table 2 as *correct trans*.

These correctly translated terms were then compared to the terms in the opposite source model (i.e., after translating English PERMA to Spanish, we compared the translations with Spanish PERMA). We calculated the percentage of the top 250 translated words missing in the 250 top words of the source lexicon for each PERMA component and averaged over the 10 components. This value is reported in Table 2 as *missing terms*. For terms that appeared in both the translated and source lexica we compared their respective weights, calculating both percentage of terms in which the weights were of different signs and percentage of terms with substantially different weights. Again, these percentages were averaged over the 10 PERMA components. Percentages are reported in Table 2 as *opp sign* and *weight diff*, respectively. To be considered "substantially different" the two weights must differ by a factor of 2. It is worth noting that at no point were the translated and source weights equal (within a tolerance of 10^{-5}).

We then looked at the errors term by term. Out of the 500 terms considered (top 250 words per source language) only one term weight changed signs between models: "mundo" (world). The weight for this term in the translated English to Spanish model was 0.42 whereas the weight in the Spanish model was -0.18, amounting to a 140% change. Next, for each source model we report terms with the largest and smallest differences in weight. These terms and weights are reported in Table 3. The language abbreviation ("en" or "es") listed under each PERMA component is used to denote the source language we translated from. For example, (en) indicates that we started with English PERMA, translated it into Spanish and then compared to Spanish PERMA.

source lang	correct trans	missing terms	opp sign	weight diff
English	83%	81%	0.5%	6.9%
Spanish	74%	91%	0.0%	4.8%

Table 2: Summary of translation errors. Percentages are averaged over the 10 PERMA components. *Source lang* is the language of the model which was translated, *correct trans* is the percentage of correct automatically translated words, *missing terms* is the percentage of correct automatic translations within the 250 top terms that did not appear in the top 250 words of other source model, *opp sign* is the percentage of terms whose sign switched between models, and *weight diff* is the percentage of terms whose weights between the two models were off by a factor of two.

PERMA	term	weight (en)	weight (es)	% chg
POS_M (en)	mundo* (world)	0.42	-0.18	143
NEG_A (en)	odio** (hate)	0.29	2.19	87
NEG_M (en)	nadie*** (no one)	0.23	0.24	4.2
NEG_R (es)	sad** (triste)	1.70	0.0012	100
NEG_P (es)	hate*** (odio)	1.81	1.75	3.3

Table 3: Examples of specific errors. Error types are denoted by asterisks: * denotes a change in sign, ** denotes the largest change in weight and *** denotes the smallest change in weight per source model. Language listed under each PERMA category is the language of the source model that was translated. The *% chg* column is percentage change relative to the larger weight. For clarity, under each term we include its translation.

4 Discussion

The difference in performance between source and machine translated models can be attributed to a few main problems. First, the translation might be inaccurate (e.g., from our corpus, "te" is not in fact "tea"). We manually corrected translation errors in the prediction models with the help of a native Spanish speaker, but found that translation error accounts for marginal discrepancy between the source language and machine translated models.

A second source of errors are translations which are technically accurate, yet do not translate culturally. For instance, even though "andaluces" translated correctly into "Andalusians," "Andalusia" (an autonomous community in Spain) does not invoke the same cultural meaning in English as it does for Spaniards. A machine would be hard-pressed to translate "Andalusia" into a relevant region within the U.S. that might invoke similar popular sentiment. Although Spanish and American people share some holidays, musicians, and sports heroes, many of these differ (e.g., "Iker Casillas" is not well known in the U.S. and "La selectividad" may be similar to the "SATs," but this is not captured in MT).

A third source of error stems from cultural differences, with certain topics resonating differently cross-culturally. For instance, when comparing the highest weighted positive terms across PERMA, religious language (e.g., "god," "blessed") appears in English but not Spanish, fitting with the popular notion that Americans are more religious than Europeans. Spanish PERMA's positive emotion component contains multiple highly weighted instances of laughter; none have high weights in the English model. Highly weighted English negative emotion terms are marked by general aggression (e.g., "kill," "stupid") whereas the highest weighted Spanish terms include derogatory terms for disliked people (e.g., "douchebag," "fool"). The American positive relationship component is marked by words like "friend" and "friends," while "sister" is weighted more highly in Spanish PERMA.

Note that this is fundamentally a problem of domain adaptation rather than MT, as our error analysis revealed that the majority of top-weighted terms were exclusive to one source model. Different cultures use different words (or at least vastly different word frequencies) when revealing the same kind of well-being. Exploring where the sentiment around a similar concept diverges across languages can provide insight to researchers studying cross-cultural variation.

4.1 Limitations

This work has significant limitations. First, the English and Spanish annotation processes, though kept as similar as possible, were not identical; annotations were gathered on different platforms, and due to our difficulty in recruiting Spanish raters, our total annotations per message varied across tasks. Additionally, the models were built over relatively small corpora of 5,000 English Tweets and 5,100 Spanish Tweets. These Tweets came from different time periods, which may further reduce similarity between the Spanish and English corpora. Finally, our method does not account for the presence of various sub-cultures within the United States and Spain.

5 Conclusion

In this work, we investigated how well expressions of subjective well-being translate across English and Spanish Twitter, finding that the source language models performed substantially better than the machine translated versions. Moreover, manually correcting translation errors in the top 250 terms of the lexica did not improve model performance, suggesting that meaningful cultural information was lost in translation.

Our findings suggest that further work is needed to understand when automatic translation of language-based models will lead to competitive sentiment translation on social media and how such translations can be improved. Cultural differences seem more important than language differences, at least for the tasks we studied here. We expect that language indicators of personality and emotion will similarly translate poorly, but that remains to be studied.

Beyond Canonical Texts: A Computational Analysis of Fanfiction

David Bamman
School of Information
University of California, Berkeley
dbamman@berkeley.edu

Abstract

While much computational work on fiction has focused on works in the literary canon, user-created fanfiction presents a unique opportunity to study an ecosystem of literary production and consumption, embodying qualities both of large-scale literary data (55 billion tokens) and also a social network (with over 2 million users). We present several empirical analyses of this data in order to illustrate the range of affordances it presents to research in NLP, computational social science and the digital humanities. We find that fanfiction deprioritizes main protagonists in comparison to canonical texts, has a statistically significant difference in attention allocated to female characters, and offers a framework for developing models of reader reactions to stories.

1 Introduction

The development of large-scale book collections—such as Project Gutenberg, Google Books, and the HathiTrust—has given rise to serious effort in the analysis and computational modeling of fiction (Mohammad, 2011; Elsner, 2012; Bamman et al., 2014; Jockers, 2015; Chaturvedi et al., 2015; Vala et al., 2015; Iyyer et al., 2016). Of necessity, this work often reasons over historical texts that have been in print for decades, and where the only relationship between the author and the readers is mediated by the text itself. In this work, we present a computational analysis of a genre that defines an alternative relationship, blending aspects of literary production, consumption, and communication in a single, vibrant ecosystem: fanfiction.

Fanfiction is fan-created fiction based on a previously existing, original work of literature. For clarity we will use the term CANON to refer to the original work on which a fanfiction story is based (e.g. Harry Potter) and the term STORY to refer to a single fan-authored story for some canon.

Although stories are based on an original canonical work and feature characters from the canon, fans frequently alter and reinterpret the canon—changing its setting, playing out an alternative ending, adding an original character, exploring a minor character more deeply, or modifying the relationships between characters (Barnes, 2015; Van Steenhuyse, 2011; Thomas, 2011).

In this work, we present an empirical analysis of this genre, and highlight several unique affordances this data presents for contemporary research in NLP, computational social science, and the digital humanities. Our work is the first to apply computational methods to fanfiction; in presenting this analysis, we hope to excite other work in this area.

2 Fanfiction data

Our data, collected between March–April 2016, originates from `fanfiction.net`.[1] In this data, AUTHORS publish stories serially (one chapter at a time); REVIEWERS comment on those chapters.

A summary of data is presented in table 1. The scale of this data is large for text; at 55 billion to-

kens, it is over 50 times larger than the BookCorpus (Zhu et al., 2015) and over 10% the size of Google Books (at 468B tokens).

The dataset is predominantly written in English (88%), but also includes 317,011 stories in Spanish, 148,475 in French, 102,439 in Indonesian, and 73,575 in Portuguese. In total, 44 different languages are represented.

Table 1: Summary of the fanfiction.net corpus

3 Analysis of fanfiction

3.1 Differences between canons and fanfiction

The systematic ways in which fanfiction stories differ from their canonical works can give insight into the characteristics of a story that are desired by fans but may be missing from the mainstream canon. We investigate two questions: 1.) Is there a difference between the characters emphasized in fanfiction compared to the original canon? And 2.) Is gender presented differently in these two sources?

Character differences. In order to explore the differing attention to character, we consider fanfiction from ten canons whose original texts appear in Project Gutenberg; we selected the ten canons from unique authors with the most fanfiction stories associated with them.[2] To extract and compare characters, we run BookNLP (Bamman et al., 2014) on both the canonical work and the top 100 stories (by number of reviews) from each canon, and pair characters across canon/fanfiction with the same name.

To measure how the importance of individual characters varies between canon and fanfiction, we calculate the change in the percent of all character mentions a character has in the canon to the average percent of character mentions that same character has in fanfiction.

Across all canons we find that the most prominent character in the canon had at most a small increase in percent character mentions, while less prominent characters received large increases. The results for two illustrative examples, *Pride and Prejudice* and *Sherlock Holmes*, are shown in Figure 1. The percent of character mentions for the main protagonists (Elizabeth and Holmes) decreases in fanfiction, but the secondary characters of Mr. Darcy and Watson

[2] *Les Miserables* (3996 fanfiction stories), *Sherlock Holmes* (3283), *Pride and Prejudice* (3084), *Peter Pan* (2431), *Alice in Wonderland* (1446), *Anne of Green Gables* (620), *Jane Eyre* (331), *Little Women* (286), *The Scarlet Pimpernel* (255), and the *Secret Garden* (222).

Labels	Terms

Table 2: Top 10 terms in the 10 manually grouped LDA topics.

show a large increase. These findings confirm the results of Xu et al. (2011), who find a greater increase in mentions of Mr. Darcy relative to Elizabeth in a different corpus of *Pride and Prejudice* fanfiction, and supports claims that fanfiction authors may delve deeper into characters that receive less attention in the canon (Jwa, 2012; Thomas, 2011).

Gender differences. Fanfiction has a predominantly female authorship and readership base (Barnes, 2015); these stories often oppose traditional gender norms present in the canon and showcase stronger female characters (Handley, 2012; Scodari and Felder, 2000; Leow, 2011; Busse, 2009).

In order to test whether fanfiction allocates more attention to female characters than canonical stories, we compare the percent of mentions of male and female characters using the same collection of stories from Gutenberg canons as above. 40.1% of character mentions in the canons are to women; in fanfiction, this ratio increases to 42.4%. This effect size is small (2.3% absolute difference), but in a bootstrap hypothesis test of the difference (using 10^6 bootstrapped samples), the difference is highly significant ($p < 0.001$), suggesting that fanfiction does indeed devote more attention to female characters.

3.2 Interaction between users

A unique characteristic of this data is the chapter-by-chapter reader reviews; any user can leave a review for a chapter of a story. Authors are also frequently reviewers of other stories (Thomas, 2011), forming an ecosystem with qualities of a social network.

709,849 authors in this data (52%) are also reviewers; if we define a network node to be a user and edge to be a reviewing relationship (a directed edge exists from $A \rightarrow B$ if A reviews one of B's works), this network contains 9.3M such directed edges, with an average outdegree of 13.2 and indegree of 15.6 (each author on average reviews for 13 other authors, and is reviewed by 16).

To explore the content of these reviews computationally, we sampled one story with more than 500 reviews from 500 different canons and ran Latent Dirichlet Allocation (Blei et al., 2003) with 10 topics on the text of the reviews (excluding names as stopwords). This is an exploratory analysis, but can give insight into the broad functions of reader responses in this domain.

Table 2 presents the results, grouping the topics into three exploratory categories: positive encouragement and pleas for updates, requests to the author about the progression of the story, and emotional reactions to the story. Prior studies that have examined the role of reviews as a form of interaction between the reader and the author have documented the first two categories extensively (Campbell et al., 2016; Magnifico et al., 2015; Lammers and Marsh, 2015; Black, 2006). However, despite a significant portion of the reviews consisting of the reader's emotional responses to the story, the way in which readers use reviews as a means of emotional engagement with the story itself has yet to be examined in such detail.

3.3 Predicting reader responses to character

The presence of reader reviews accompanying each fanfiction chapter presents a unique opportunity to develop a predictive model of how readers respond to text—given the text of a chapter, can we predict

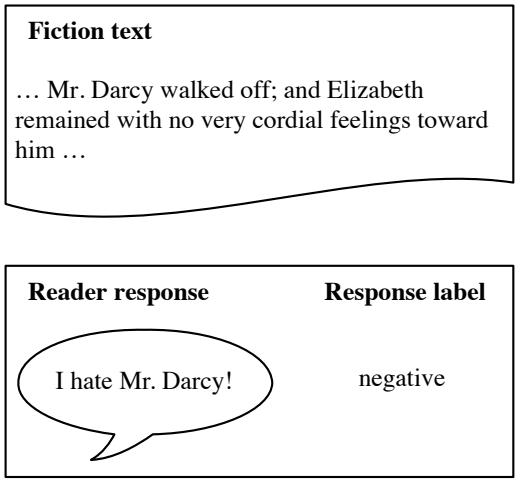

Figure 2: Illustration of data for predicting reader responses. Here we are using features derived only from FICTION TEXT to predict the RESPONSE LABEL.

how readers will react?

To test the feasibility of this task, we focus on reader responses to character. A RESPONSE to a character is operationalized as a sentence from a reader review mentioning that character and no other characters. We create an annotated dataset by randomly sampling a single character with at least 10 reader responses from each of the 500 stories described in §3.2. From this set, we randomly select exactly 10 responses for each character, to yield a total of 5,000 reader responses.

We then present these 5,000 responses to annotators on Amazon Mechanical Turk, and ask them to judge the sentiment *toward the character* expressed in the response as either positive, negative, neutral, or not applicable (in the case of character recognition errors). The overall agreement rate among annotators for this classification task is moderate (Fleiss' κ = 0.438), in part due to the difficulty of assessing the responders' attitudes from short text; while some responses wear their sentiment on their sleeve (*I knew I hated Brandon!*), others require more contextual knowledge to judge (*Ah Link* or *Akira appears!*).

In order to create a higher-precision subset we select responses with only unanimous positive or negative votes from 3 different annotators, yielding a total dataset of 1,069 response labels. We divide the dataset into 80% training/development and 20% for a held-out test (with no overlap in stories between training and test).

We also bootstrap additional semi-supervised data by training a sentiment classifier on the unigrams of the reader responses in the training data (with a 3-class accuracy of 75%; compared to majority baseline of 49.7%), predicting the sentiment label for all responses in the dataset, and selecting examples that a.) have 95% prediction confidence and b.) whose stories do not appear in the training or test data. We sample selected examples to respect the label distribution in the training data, yielding an additional 25,000 data points to supplement learning.

Our core task is to use *only* the text of the story (and not the reader response) to predict the corresponding response sentiment label in order to understand what aspects of the story (and a character's role within it) readers are reacting to. We experiment with several features to represent the characters:

- AGENT, PATIENT, PREDICATIVE, POSSESSIVE relations for each character (as output by BookNLP), both in the specific chapter and in the book overall (under the rationale that readers are responding to the *actions* that characters take).
- Unigrams spoken by the character, both in the chapter and in the book overall.
- Character gender.
- Character's frequency in the book (binary indicators of the decile of their frequency of mention).
- Skip-gram representations trained on 4.1B words of fanfiction text (200-dimensional, grouped into 1000 clusters using k-means clustering); these cluster identities form additional binary features by replacing the lexical indicators for the text features above.

We perform model selection using tenfold cross-validation on the training data alone, training ℓ_2-regularized logistic regression on one partition of the data, tuning the ℓ_2 regularization parameter on another, and assessing performance on a third (note none of the test data described above is seen during this stage).

A majority class (all-positive) baseline on the training data results in an accuracy rate of 75.6%;

only syntactic features yield a significant improvement, achieving an accuracy rate of 80.5%.

Table 3 lists the most informative features for predicting negatively-assessed characters. While these characteristic features have face validity and offer promise for understanding character in more depth, we do not see similar improvements in accuracy on the truly held-out test data (run once before submission); this same feature set achieves an accuracy rate of 70.4% (compared to a majority baseline on the test data of 71.4%). Part of this may be due to the sample size of the test data ($n = 199$); a bootstrap 95% confidence interval (Berg-Kirkpatrick et al., 2012) places the accuracy in the range [0.648, 0.754]. However, this more likely constitutes a negative result that reflects the inherent difficulty of the task; while syntactic features point to a real signal that readers are reacting to when writing their responses, literary character is of course far more complex, and more sophisticated representations of character—and of the readers who react to them—are likely warranted for real predictive performance on this task.

agent	patient	predicative	possessive
hissed	hate	pregnant	phone
sneered	done	human	state

4 Conclusion

In blending aspects of large-scale literary data and social network structure, fanfiction publication constitutes a vibrant ecosystem with ample textual evidence for the production and consumption of literary texts. In this work, we have briefly illustrated three aspects of this data that have the potential to yield interesting insight—the relationship between fanfiction stories and their original source material, the social network structure of authors and their respondents, and the possibility of predicting reader responses from serially published text. Many questions remain; in providing a quantitative description of this dataset, we hope to highlight its potential for analysis, and encourage other work in this domain.

Using Syntactic and Semantic Context to Explore Psychodemographic Differences in Self-reference

Abstract

Psychological analysis of language has repeatedly shown that an individual's rate of mentioning 1st person singular pronouns predicts a wealth of important demographic and psychological factors. However, these analyses are performed out of context — syntactic and semantic — which may change the magnitude or even direction of such relationships. In this paper, we put "pronouns in their context", exploring the relationship between self-reference and age, gender, and depression depending on syntactic position and verbal governor. We find that pronouns are overall more predictive when taking dependency relations and verb semantic categories into account, and, the direction of the relationship can change depending on the semantic class of the verbal governor.

1 Introduction

Approximately 1 in 18 English words on Facebook are first-person singular pronouns.[1] Extensive work in psychological analyses of language has consistently found strong relation between first-person pronoun use and psychological attributes of individuals (Kendall, 1998; Pennebaker and Stone, 2003; Pennebaker, 2011; Twenge et al., 2012; Oishi et al., 2013; Carey et al., 2015). Although such findings have been replicated extensively, little is known about how the syntactic or semantic context of the pronouns may affect their relationship with human traits. Usage in subject or object position may vary, and the type of verb governing the reference may further change its relationship. For instance, while younger individuals are more likely to use 1st-person singular pronouns overall, older individuals may be more likely to use them as the subject of social verbs.

In this study we dive deep into this one type of word which makes up a large portion of our daily lives. We first look at the relationship between first person singular pronouns and age, gender, and depression. We then consider the syntactic position of the pronoun and its occurrence in the subject and direct object position. Next, we explore the self-referenced use of verbs compared to their general use across different semantic categories, followed by an examination of the rate of 1st-person singular pronoun as the subject and the object with different verb categories.

We ultimately show that pronoun relationships with human outcomes can change drastically depending on their syntactic position and the category of their verbal governor. To be more specific, our contributions include: (a) taking the role of context into account in the psychological analysis of personal pronouns, (b) distributional clustering of verbs using Canonical Correlation Analysis (CCA), and (c) exploring the integration of verbal semantic categories in the analysis of pronouns. Utilizing verb categories instead of actual verbs, enables generalization and less sparsity in the semantic comparison of the contexts in which personal pronouns are used.

[1]Within the study dataset, 5.45% of all words from self-identified English speakers were first-person pronouns.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2054–2059,
Austin, Texas, November 1-5, 2016.

2 Background

A wealth of studies have explored pronoun use with regard to age, gender, and personality types. In fact, a whole book, "The Secret Life of Pronouns" has been dedicated summarizing such studies which have built up over several decades of work (Pennebaker, 2011). [2]

We could not come close to a full survey of such work, but rather list some of the most notable and recent results for outcomes related to those of this study. Pennebaker et. al. (2003) and Chung & Pennebaker (2007) found that the use of self-references (i.e. 'I', 'me') decreases over age. Pennebaker et. al. (2003), and Argamon et. al. (2007) showed that females use significantly more first-person singular personal pronouns compared to males. Bucci and Freedman (1981), Weintraub (1981), and Zimmermann et. al. (2013) found that first-person singular pronouns are positively correlated with depressive symptoms. These analyses do not take the role of syntactic and semantic context into consideration which may indicate interesting information about psychological factors.

3 Method

Data Set: Facebook Status Updates. Our dataset consists of the status updates of 74,867 Facebook users who volunteered to share their posts in the "MyPersonality" application (Kosinski et al., 2013), sent between January 2009 and October 2011. The users met the following criteria: (a) have English as a primary language, (b) indicated their gender and age, (c) be less than 65 years old (due to data sparsity beyond this age), and (d) have at least 1,000 words in their status updates (in order to accurately estimate language usage rates). This dataset contains 309 million words within 15.4 million status updates. All users completed a 100-item personality questionnaire (an International Personality Item Pool (IPIP) proxy to the NEO-PI-R (Goldberg, 1999). User-level degree of depression (DDep) was estimated as the average response to seven depression facet items (nested within the larger Neuroticism item pool of the questionnaire) (Schwartz et al., 2014).

Dependency Features. We used dependency annotations in order to determine the syntactic function of personal pronouns i.e. subject (S) and direct object (DO). We obtained dependency parses of our corpus using Stanford Parser (Socher et al., 2013) that provides universal dependencies in (*relation, head, dependent*) triples. In the next step, we extracted the words in in the nominal subject (*"nsubj"*) and direct object (*"dobj"*) positions including *nsubj* 1st-person singular pronoun *"I"*, and *dobj* 1st-person singular pronoun *"me"*. We also extracted the corresponding verbs for each of the nominal subjects, and direct object words.

Verb categorization. In order to integrate the verbal semantic categories in the syntactic analysis of pronouns, we utilize two verb categorization methods (a) linguistically-driven Levin's Verb Classes, and (b) empirically-driven verb clustering based on CCA.

Levin's verb classes (Levin, 1993) includes around 3100 English verbs classified into 47 top level, 193 second and third level classes. This classification is based on Levin's hypothesis that the syntactic behavior of a verb is influenced by its semantic properties, indicating that identifying sets of verbs with comparable behavior at the syntax level will lead to coherent clusters of semantically similar verbs. In this paper we used all of the 193 second and third level Levin's classes (*Lev*). As an alternative way, we also used the 50 top most frequent sub-classes in our social media data (*LevTop*).

To derive empirically driven clusters we use Canonical Correlation Analysis (CCA), a multi-view dimensionality reduction technique. CCA has previously been used in word clustering methods such as multi-view learning of word embeddings (Dhillon et al., 2011), or multilingual word embeddings (Ammar et al., 2016). The advantage of a multi-view technique is that we can leverage both the subject and object context. More precisely, we performed sparse CCA on matrix x that includes 5k by 10k verb-by-nominal-subject (*nsubj*) co-occurrences, and matrix z that includes 5k by 10k verb-by-direct-object (*dobj*) co-occurrences. The output of CCA is a subject by component matrix

[2] To quantify the pervasiveness of pronoun studies in social science, we consider the citation count, via Google Scholar (July, 2016), to works mentioning "pronoun" by one of the top researchers, James W. Pennebaker, which number over 10,000.

Feature Set	Gender (AUC)	Age (MSE)	Dep (MSE)
$P(1p)$	.512	78.9	90.1
$P(1p\|r)$	.589	76.4	90.3
$P(1p\|r,c)$, *Lev*	.660	70.0	89.8
$P(1p\|r,c)$, *Lev* & sent	.695	**68.3**	**89.1**
$P(1p\|r,c)$, *LevTop*	.660	71.5	89.8
$P(1p\|r,c)$, *LevTop* & sent	**.669**	69.0	89.3
$P(1p\|r,c)$, *CCA-D*	.634	73.4	90.3
$P(1p\|r,c)$, *CCA-D* & sent	.649	71.5	89.7
$P(1p\|r,c)$, *CCA-KM*	.632	72.6	90.3
$P(1p\|r,c)$, *CCA-KM* & sent	.645	70.9	89.9

Table 1: Area under the ROC curve (AUC) for gender (higher is better), and Mean Square Error (MSE) for age and depression prediction (lower is better), and the prediction using 1st-per pronoun use overall, in subject and object position, and given verb categories.

bore, worry, scare, bother, annoy, disappoint	-.08

Table 2: Linear regression coefficient of age and 1st person pronoun use in different verb clusters.

(u: *subject-view*), and object by component matrix (v: *object-view*). We then build matrix S by multiplying x by u and matrix O by multiplying z by v to get the verbs by CCA-components from *subject-view*, and verbs by object components from *object-view* respectively. In order to cluster verbs from direct CCA components, we use the average score of *subject-view* and *object-view* components, assigning verbs to those components for which they have a non-zero absolute weight (*CCA-D*). Sparse CCA zeros-out verbs from multiple components so as to assign verbs to components, but we also explore normal CCA and cluster the verbs using k-means ($k = 30$) clustering from the z-scaled values of S and O matrices (*CCA-KM*).

Both Levin's and CCA-based verb classes are derived from syntactic behavior. As a result, they often do not distinguish antonyms. For instance, Levin's "admire" verb class contains both 'love' and 'hate". Building on research showing positive and negative emotions differ across age and gender (Schwartz et al., 2013), we integrate valence information in our verb clustering. We used positive and negative sentiment scores from EmoLex word-emotion association lexicon (Mohammad and Turney, 2013), dividing each of our clusters into *positive*, *negative*, and *neutral* sub-classes.

Analysis. We explore the use of 1st-person singular pronouns across age and gender in different syntactic and semantic contexts. Features are encoded as the mean from maximum likelihood estimation over the probability of mentioning a first person singular pronoun in a given context.

(a) The overall usage first person singular pronoun:

$$P(1p) = P(PN = 1p)$$

(b) The probability of using first person singular pronoun in the *nsubj*, and the *dobj* positions:

$$P(1p|r) = P(PN = 1p \mid rel = r)$$

where $rel \in \{nsubj, dobj\}$.

(c) The probability of using first person singular pronoun in the *nsubj*, and the *dobj* positions of a given verb category:

$$P(1p|r,c) = P(PN = 1p \mid rel = r, vcat = c)$$

where $rel \in \{nsubj, dobj\}$ and $vcat$ is the set of all verb categories being considered.

4 Evaluation

The goal of our work is to expand the knowledge of how the first-person singular pronoun, one of the most common word types in English, is related to who we are – our demographics and psychological states. We work toward this goal in an empirical fashion, by first replicating known general relationships of 1st-person singular pronouns with gender, age, and depression, exploring how their use in different syntactic positions, and, finally, by looking at relationships within specific semantic contexts according to the verb classes described earlier.

Verb Clusters	β
1st person singular pronoun use	.11
1st person singular nominal subject	
love, enjoy, respect, adore, cherish, admire	.29
miss, like, appreciate, trust, support, value	.28
destroy	-.08
kick, shoot, slap, smash, shove, slam	-.07
1st person singular direct object	
make, blow, roll, hack, cast	.22
hold, handle, grasp, clutch, wield, grip	.18
hit, kick, strike, slap, smash, smack, bang, butt	-.10
add, mix, connect, link, combine, blend	-.04

Table 3: Logistic regression coefficient between gender and 1st person singular pronoun use in different verb clusters (positive is female).

Replication. We use standardized linear and logistic regression to correlate gender, age, and depression with $P(1p)$ (first-person singular pronoun use). We control for age in the case of gender, gender in the case of age, and both gender and age in the case of depression by including them as covariates in the regression and reporting the unique coefficient for the variable in question. Logistic regression is used for gender, since it is binary, while linear regression is used for the continuous age and depression variables. Confirming past results, we found significant relationships between first-person pronoun usage and gender ($\beta = .11$, $p < .001$), age ($r = -0.17$, $p < .001$), and depression score ($r = -0.06$, $p < .01$).

Syntactic Context. Taking dependency relationships into account ($P(1p|r)$), we observed shifts in the magnitude of correlations. Specifically, we found significant negative correlations between age and using 1st-person singular pronoun in the subject ($r = -0.12$, $p < .001$), and the object positions ($r = -0.17$, $p < .001$). For gender we found a significant positive correlation between being female and the probability of using 1st-person singular pronoun ($r = 0.11$, $p < .001$), and 1st-person singular pronoun in subject position ($r = 0.16$, $p < .001$). For depression a significant positive correlation between with $P(1p)$ ($r = 0.06$, $p < .05$), and using 1st-person singular pronoun in the subject position ($r = 0.07$, $p < .05$).

Syntactic and Semantic Context. Table 1 reports the area under the ROC curve (AUC) for gender prediction and the Mean Square Error (MSE) for predicting age and depression based on $P(1p)$, $P(1p|r)$, and $P(1p|r, c)$, driven from various categorization approaches. We used AUC since it can capture more differences in performance by evaluating the class probabilities of test instances rather than just finding whether it was right or wrong. We applied 10-fold cross-validation with a linear-SVM in the case of gender, and ridge-regression in the case of depression. The obtained results reveal a consistent pattern: in gender, age, and depression prediction all the features that take context into account outperform $P(1p)$ which is the vastly reported measure of self-reference in the literature. This suggests that there is more information to be gained by utilization syntactic and semantic context. In other words, we can achieve a more meaningful, deeper insight into the relationship of subject and object position of the first person in different contexts, revealing a more complex, and more insightful set of relations.

We achieve the best performance by utilizing verb categories. We first observe that integrating sentiment helps in nearly all verb categorization approaches. Next, we see that while both CCA and Levin verb clusters yield improvement in prediction accuracy, our performance gains using the data-driven CCA-based verb clustering are not as large as that from Levin's linguistically-driven classes.

While we believe our features can improve prediction accuracy, that is not the primary application of social science research. Rather, it is correlating the behavior of referencing the self with psychological conditions, like depression, in order to gain human insights. In the case of correlating behavior with a psychological measure, Pearson coefficients above .1 are considered noteworthy and above .3 are considered approaching a "correlational upperbound" (Meyer et al., 2001).

Tables 2, 3, and 4 show the most predictive features, using the best performing clustering method (i.e. Levin & Sentiment). Note that in the case of age and gender, we see that not only does the magnitude of the relationship change, but it's possible that the direction can completely change.

For example, while males are less likely to

Verb Clusters	r
1st person singular pronoun use	.06
1st person singular nominal subject	
cry, worry, suffer, fear, bother, ache, mourn, anger	.11
scare, annoy, confuse, depress, upset, disappoint	.11
1st person singular direct object	
kill, murder, slay, slaughter, butcher	.09
scare, annoy, confuse, depress, upset, disappoint	.07

Table 4: Linear regression coefficient of depression score and 1st person singular pronoun use in different verb clusters.

use first-person singular pronouns overall, they are much more likely to use them as the subject of aggressive physical contact verbs like “kick", “shoot", “slap", and “smash", suggesting men are more likely to express themselves as agents of aggressive contact. On the other hand, women use first-person singulars in the social sphere, particularly in an affiliative context. They assert themselves as agents of empowering and encouraging others (e.g. “love", “enjoy", “cherish", “admire") and faith in others (e.g. “trust", “value", “support", “respect").

5 Conclusion

We have shown that the well-studied link between the first-person singular pronoun and human psycho-demographics is largely dependent on its syntactic and semantic context. Many theories and conclusions are built on such relationships, but here we show these relationships depend on verbal context; correlations can shrink, grow, and even change directions depending on the verbs governing the pronoun. For example, while the usage of 1st person singular pronoun decreases over age, it increases if it is used as the subject of verbs such as “thank", and “celebrate", or as the object of verbs such as “join". Similarly, while females tend to use 1st person singular pronouns more than males, they use them less often as the subject of “destroy” verbs or as the object of “hit” and “kick” verbs.

By integrating syntactic dependency relationships along with semantic classes of verbs, we can capture more nuanced linguistic relationships with human factors. Beyond pronouns, we ultimately aim to expand the regimen of *open-vocabulary* techniques available for the analysis of psychologically-relevant outcomes.

Abstract

In this paper, we experiment with a resource consisting of metaphorically annotated proverbs on the task of word-level metaphor recognition. We observe that existing feature sets do not perform well on this data. We design a novel set of features to better capture the peculiar nature of proverbs and we demonstrate that these new features are significantly more effective on the metaphorically dense proverb data.

1 Introduction

Recent years have seen a growing attention towards attempts to understand figurative language in text (Steen et al., 2010, Shutova and Teufel, 2010, Turney et al., 2011, Neuman et al., 2013, Klebanov et al., 2015). Recently, Özbal et al. (2016) published a resource consisting of 1,054 proverbs annotated with metaphors at the word and sentence level, making it possible for the first time to test existing models for metaphor detection on such data. More than in other genres, such as news, fiction and essays, in proverbs metaphors can resolve a significant amount of the figurative meaning (Faycel, 2012). The richness of proverbs in terms of metaphors is very fascinating from a linguistic and cultural point of view. Due to this richness, proverbs constitute a challenging benchmark for existing computational models of metaphoricity.

In this paper, we devise novel feature sets especially tailored to cope with the peculiarities of proverbs, which are generally short and figuratively rich. To the best of our knowledge, this is the first attempt to design a word-level metaphor recognizer specifically tailored to such metaphorically rich data. Even though some of the resources that we use (e.g., imageability and concreteness) have been used for this task before, we propose new ways of encoding this information, especially with respect to the density of the feature space and the way that the context of each word is modeled. On the proverb data, the novel features result in compact models that significantly outperform existing features designed for word-level metaphor detection in other genres (Klebanov et al., 2014), such as news and essays. By also testing the new features on these other genres, we show that their generalization power is not limited to proverbs.

2 Background

In this section we provide a brief overview of the efforts of the NLP community to build metaphor datasets and utilize them to develop computational techniques for metaphor processing. Steen et al. (2010) construct the Amsterdam Metaphor Corpus (VUAMC) by annotating a subset of BNC Baby[1]. Linguistic metaphors in VUAMC are annotated by utilizing the Metaphor Annotation Procedure (MIP) proposed by Group (2007). VUAMC contains 200,000 words in sentences sampled from various genres (news, fiction, academic, and conversations) and 13.6% of the words are annotated as metaphoric (Shutova, 2010). Another metaphor annotation study following the MIP procedure is conducted by Shutova and Teufel (2010). A subset of

Austin, Texas, November 1-5, 2016.

the British National Corpus (BNC) (Burnard, 2000) is annotated to reveal word-level verb metaphors and to determine the conceptual mappings of the metaphorical verbs.

Turney et al. (2011) introduce an algorithm to classify word-level metaphors expressed by an adjective or a verb based on their concreteness levels in association with the nouns they collocate. Similarly, Neuman et al. (2013) extend the concreteness model with a selectional preference approach to detect metaphors formed of concrete concepts. They focus on three types of metaphors: i) IS-A, ii) verb-noun, iii) adjective-noun. Rather than restricting the identification task to a particular POS or metaphoric structure, Hovy et al. (2013) aim to recognize any word-level metaphors given an unrestricted text, and they create a corpus containing sentences where one target token for each sentence is annotated as metaphorical or literal. They use SVM and CRF models with dependency tree-kernels to capture the anomalies in semantic patterns. Klebanov et al. (2014) propose a supervised approach to predict the metaphoricity of all content words in a running text. Their model combines unigram, topic model, POS and concreteness features and it is evaluated on VUAMC and a set of essays written for a large-scale assessment of college graduates. Following this study, Klebanov et al. (2015) improve their model by re-weighting the training examples and redesigning the concreteness features.

The experiments in this paper are carried out on PROMETHEUS (Özbal et al., 2016), a dataset consisting of 1,054 English proverbs and their equivalents in Italian. Proverbs are annotated with word-level metaphors, overall metaphoricity, meaning and century of first appearance. For our experiments, we only use the word-level annotations on the English data.

3 Word-level metaphor detection

Similarly to Klebanov et al. (2014), we classify each content word (i.e., adjective, noun, verb or adverb) appearing in a proverb as being used metaphorically or not. Out of 1,054 proverbs in PROMETHEUS, we randomly sample 800 for training, 127 for development and 127 for testing. We carry out the development of new features on the development set; then we compare the performance of different feature sets using 10-fold cross validation on the combination of the development and training data. Finally, we test the most meaningful configurations on the held-out test data. As a baseline, we use a set of features very similar to the one proposed by Klebanov et al. (2014). To obtain results more easily comparable with Klebanov et al. (2014), we use the same classifier, i.e., logistic regression, in the implementation bundled with the *scikit-learn* package (Pedregosa et al., 2011). For all the experiments, we adjust the weight of the examples proportionally to the inverse of the class frequency.

3.1 Baseline features (B)

Unigrams (u_B): Klebanov et al. (2014) use all content word forms as features without stemming or lemmatization. To reduce sparsity, we consider lemmas along with their POS tag.

Part-of-speech (p_B): The coarse-grained part-of-speech (i.e., noun, adjective, verb or adverb) of content words[2].

Concreteness (c_B): We extract the concreteness features from the resource compiled by Brysbaert et al. (2014). Similarly to Klebanov et al. (2014), the mean concreteness ratings, ranging from 1 to 5, are binned in 0.25 increments. We also add a binary feature which encodes the information about whether the lemma is found in the resource.

Topic models (t_B): We use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) using Gibbs sampling for parameter estimation and inference (Griffiths, 2002). We run LDA on the full British National Corpus (Consortium and others, 2001) to estimate 100 topics, using 2000 Gibbs sampling iterations, and keeping the first 1000 words for each topic. As topic model features for a lemma, we use the conditional probability of the topic given the lemma for each of the 100 topics generated by LDA. Besides, we use a binary feature that encodes whether the lemma exists in the LDA model.

3.2 Novel features (N)

We introduce five feature sets that capture other aspects of the data which we consider to be meaningful for the peculiar characteristics of proverbs.

[2]Klebanov et al. (2014) consider the Penn Treebank tagset generated by Stanford POS tagger.

Imageability (i) and Concreteness (c): Imageability and concreteness of the metaphor constituents were found to be highly effective in metaphor identification by several studies in the literature (Turney et al., 2011, Broadwell et al., 2013, Neuman et al., 2013, Tsvetkov et al., 2014). We obtain the imageability and concreteness scores of each lemma from the resource constructed by Tsvetkov et al. (2014), as it accounts for both dimensions. The imageability (concreteness) feature set contains the following four features:

- ***Has score*:** A binary feature that indicates whether the lemma exists in the relevant resource.
- ***Score value*:** The imageability (concreteness) score of the lemma.
- ***Average sentence score*:** The average imageability (concreteness) score of the other lemmas in the sentence.
- ***Score difference*:** The difference between *Average sentence score* and *Score value*.

The last two features take the context of the target lemma into account and encode the intuition that metaphorical lemmas often have higher imageability (concreteness) than the rest of the sentence (Broadwell et al., 2013).

Metaphor counts (m): This feature set consists of three features. The first two features encode the number of times a lemma-POS pair is used as a metaphor and a non-metaphor in the data. The third feature evaluates to the difference between these counts[3].

Standard domains (d_s) and normalized domains (d_n): These features reflect our intuition that there is a strong prior for some domains to be used as a source for metaphors. This notion is backed by the analysis of PROMETHEUS carried out by Özbal et al. (2016). We also expect that words which are clearly out of context with respect to the rest of the sentence are more likely to be used as metaphors. The correlation between word and sentence domains described below aims to model such phenomenon. For each lemma-POS pair, we collect the domain information from WordNet Domains[4] (Magnini et al., 2002, Bentivogli et al., 2004) for the standard domains feature set, which consists of 167 features (1 real valued, 166 binary). It includes a binary indicator set to 1 if the lemma is found in WordNet Domains. A domain vector consisting of 164 binary indicators mark the domains to which the lemma belongs. Then, we compute a sentence domain vector by summing the vectors for all the other lemmas in the sentence, and we encode the Pearson correlation coefficient between the two vectors (lemma and sentence) as a real valued feature. Finally, a binary feature accounts for the cases in which no other lemma in the sentence has associated domain information.

The same process is repeated for the normalized domains. For normalization, we use a reduced set of domains (43 distinct domains) by considering the middle level of the WordNet Domains hierarchy. For instance, VOLLEY or BASKETBALL domains are mapped to the SPORT domain. Normalization already proved to be beneficial in tasks such as word sense disambiguation (Gliozzo et al., 2004). It allows for a good level of abstraction without losing relevant information and it helps to overcome data sparsity. The set of normalized domain features (d_n) consists of 46 features (45 binary, 1 real valued).

Dense signals (s): This set includes three binary features which summarize the concreteness, imageability and metaphor count feature sets. The first (second) feature is set to 1 if the imageability (concreteness) of the lemma is higher than the average

imageability (concreteness) of the rest of the sentence. The third feature is set to 1 if the lemma was observed more frequently as a metaphor than not, as estimated on training data.

3.3 Results

Table 1 shows the results of the 10-fold cross validation on the English proverb data. The value reported in the column labeled C is the optimal inverse of regularization strength, determined via grid-search in the interval $[0.1, 1.0]$ with a step of 0.1. Using only baseline features (B) we measure an average F1 score of 0.738. The performance goes up to 0.833 when the novel features are used in isolation (N) (statistically significant with $p < 0.001$). We believe that the difference in performance is at least in part due to the sparser B features requiring more data to be able to generalize. But most importantly, unlike B, N accounts for the context and the peculiarity of the target word with respect to the rest of the sentence. The combination of the two feature sets ($B \cup N$) very slightly improves over N (0.834), but the difference is not significant. The second block of rows in Table 1 presents a summary of the ablation tests that we conducted to assess the contribution of the different feature groups. Each lowercase letter indicates one of the feature sets introduced in the previous section. All configurations reported, except $N \setminus (d_s \cup d_n)$, significantly outperform B. In two cases, $N \setminus m$ and $N \setminus (d_s \cup d_n)$, there is a significant loss of performance with respect to N. The worst performance is observed when all the domain features are removed (i.e., $N \setminus (d_s \cup d_n)$). These results suggest that the prior knowledge about the domain of a word and the frequency of its metaphorical use are indeed strong predictors of a word metaphoricity in context. The fact that $N \setminus d_n$ and $N \setminus d_s$ do not result in the same loss of performance as $N \setminus (d_s \cup d_n)$ indicates that both d_n and d_s are adequately expressive to model the figuratively rich proverb data. In one case (i.e., $N \setminus s$), the F1 measure is slightly higher than N, even though the difference does not appear to be statistically significant. Our intuition is that each of the three binary indicators is a very good predictor of metaphoricity *per se*, and due to the relatively small size of the data the classifier may tend to over-fit on these features. As another configuration, the last row shows the results obtained by replacing our domain features d_s and d_n with the topic features t from B. With this experiment, we aim to understand the extent to which the two features are interchangeable. The results are significantly worse than N, which is a further confirmation of the suitability of the domain features to model the proverbs dataset.

We then evaluated the best configuration from the cross-fold validation ($N \setminus s$) and the three feature sets B, N and $B \cup N$ on the held-out test data. The results of this experiment reported in Table 2 are similar to the cross-fold evaluation, and in this case the contribution of N features is even more accentuated. Indeed, the absolute F_1 of N and $B \cup N$ is slightly higher on test data, while the f-measure of B decreases slightly. This might be explained by the low-dimensionality of N, which makes it less prone to overfitting the training data. On test data, $N \setminus s$ is not found to outperform N. Interestingly, $N \setminus s$ is the only configuration having higher recall than precision. As shown by the feature ablation experi-

ments, one of the main reasons for the performance difference between N and B is the ability of the former to model domain information. This finding can be further confirmed by inspecting the cases where B misclassifies metaphors that are correctly detected by N. Among these, we can find several examples including words that belong to domains often used as a metaphor source, such as "grist" (domain: "gastronomy") in "All is grist that comes to the mill", or "horse" (domain: "animals") in "You can take a horse to the water , but you can't make him drink".

Finally, Table 3 shows the effect of the different feature sets on VUAMC used by Klebanov et al. (2014). We use the same 12-fold data split as Klebanov et al. (2014), and also in this case we perform a grid-search to optimize the meta-parameter C of the logistic regression classifier. The best value of C identified for each genre and feature set is shown in the column labeled C. On this data, N features alone are significantly outperformed by B ($p < 0.01$). On the other hand, for the genres "academic" and "fiction", combining N and B features improves classification performance over B, and the difference is always statistically significant. Besides, the addition of N always leads to more balanced models, by compensating for the relatively lower precision of B. Due to the lack of a separate test set, as in the original setup by Klebanov et al. (2014), and to the high dimensionality of B's lexicalized features, we cannot rule out over-fitting as an explanation for the relatively good performance of B on this benchmark. It should also be noted that the results reported in (Klebanov et al., 2014) are not the same, due to the mentioned differences in the implementation of the features and possibly other differences in the experimental setup (e.g., data filtering, pre-processing and meta-parameter optimization). In particular, our implementation of the B features performs better than reported by Klebanov et al. (2014) on all four genres, namely: 0.52 vs. 0.51 for "news", 0.51 vs. 0.28 for "academic", 0.39 vs. 0.28 for "conversation" and 0.42 vs. 0.33 for "fiction".

Even though the evidence is not conclusive, these results suggest that the insights derived from the analysis of PROMETHEUS and captured by the feature set N can also be applied to model word-level metaphor detection across very different genres. In particular, we believe that our initial attempt to encode context and domain information for metaphor detection deserves further investigation.

4 Conclusion

We designed a novel set of features inspired by the analysis of PROMETHEUS, and used it to train and test models for word-level metaphor detection. The comparison against a strong set of baseline features demonstrates the effectiveness of the novel features at capturing the metaphoricity of words for proverbs. In addition, the novel features show a positive contribution for metaphor detection on "fiction" and "academic" genres. The experimental results also highlight the peculiarities of PROMETHEUS, which stands out as an especially dense, metaphorically rich resource for the investigation of the linguistic and computational aspects of figurative language.

An Embedding Model for Predicting Roll-Call Votes

Peter E. Kraft Hirsh Jain Alexander M. Rush
School of Engineering and Applied Science, Harvard University
{pkraft, hirshjain}@college.harvard.edu, srush@seas.harvard.edu

Abstract

We develop a novel embedding-based model for predicting legislative roll-call votes from bill text. The model introduces multidimensional *ideal vectors* for legislators as an alternative to single dimensional ideal point models for quantitatively analyzing roll-call data. These vectors are learned to correspond with pre-trained word embeddings which allows us to analyze which features in a bill text are most predictive of political support. Our model is quite simple, while at the same time allowing us to successfully predict legislator votes on specific bills with higher accuracy than past methods.

1 Introduction

Quantitative analysis of political data can contribute to our understanding of governments. One important source of such data is *roll-call votes*, records of how legislators vote on bills. Analysis of roll-call data can reveal interesting information about legislators (such as political leanings and ideological clusters) and can also allow prediction of future votes (Clinton, 2012).

Previous work on analyzing roll-call votes has chiefly involved positioning congresspeople on ideal point models. Ideal point models assume all legislators and bills can be plotted as single points in one-dimensional "political space." The closer a particular bill's position is to a particular congressperson's, the more utility the congressperson is expected to derive from the bill. Initial work on ideal point models focused on using them to test theories about legislative behavior, such as predicting that the relative differences between ideal points of congresspeople of different parties, and thus party polarization, would increase over time (McCarty, 2001). Ideal point models are often created using Bayesian techniques over large amounts of roll-call data (Clinton et al., 2004; Jackman, 2001). However, these models are not used to make predictions. They are trained using the complete vote matrix for the bill, which indicates how each congressperson voted on each bill. Therefore, they cannot say anything about how congresspeople will vote on a new bill, as until some congresspeople have voted on the bill its ideal point is not known.

We target this vote prediction problem: given the text of a bill and a congressperson, can we independently predict how each congressperson will vote on the bill? The first prior attempt at this task was made by Gerrish and Blei (2011) who create an *ideal point topic model* which integrates a topic model similar to LDA for the bill text with an ideal point model for the congresspeople. They use variational inference to approximate the posterior distribution of the topics and ideal points, predicting with a linear model. Gerrish and Blei (2012) further extend this work with an *issue-adjusted model*, a similar model that modifies congressperson ideal points based on topics identified with labeled LDA, but which cannot be used for predictions. Further work in a similar vein includes Wang et al. (2013), who introduced temporal information to a graphical model for predicting Congressional votes, and Kim et al. (2014), who used sparse factor analysis to estimate Senatorial ideal points from bill text and the votes of party leadership.

In this work we revisit this task with a simple bilinear model that learns multidimensional embeddings for both legislators and bills, combining them

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2066–2070,
Austin, Texas, November 1-5, 2016.

to make vote predictions. We represent a bill as the average of its word embeddings. We represent legislators as *ideal vectors*, trained end-to-end for vote prediction. These ideal vectors serve as a useful, easy-to-train, multidimensional representation of legislator ideology that does not rely on elaborate statistical models or any further assumptions about legislator behavior. Finally, we train our model by optimizing a cross-entropy objective instead of the posterior of a topic model. The final model achieves high accuracy at predicting roll-call votes.

2 Model

Our goal is to predict roll-call votes by learning from the texts of bills and from past votes. Our input consists of a congressperson c and the set $\mathcal{B}$ of unique words in a bill. Our output y is whether that the congressperson voted `yea` or `nay` on the bill. We train on the full set of congressional votes on a number of bills. At test time, we supply entirely new bills and predict how each congressperson will vote on each new bill.

We propose a simple bilinear model that uses low-dimensional embeddings to model each word in our dictionary and each congressperson. We represent each bill using its word embeddings in order to capture the multivariate relationships between words and their meanings (Collobert et al., 2011; Mikolov et al., 2013). The model is trained to synthesize information about each congressperson's voting record into a multidimensional ideal vector. At test time, the model combines the embedding representation of a new bill with the trained ideal vector of a congressperson and generates a prediction for how the congressperson will vote on the bill.

Let $\mathbf{e}_w \in \mathbb{R}^{d_{word}}$ be the pretrained embedding for a word w. We initialize to the GloVe embeddings with $d_{word} = 50$ (Pennington et al., 2014), then jointly train them with the model. To represent a bill, we average over the embeddings of the set $\mathcal{B}$ of words in the bill.

To represent a congressperson, we introduce another set of embeddings $\mathbf{v}_c \in \mathbb{R}^{d_{emb}}$ for each congressperson c. The embeddings act as the ideal vector for each legislator. Unlike the word embeddings, we initialize these randomly.

The full model takes in a bill and a congressperson. It applies an affine transformation, represented by a matrix $\mathbf{W} \in \mathbb{R}^{d_{emb} \times d_{word}}$ and bias $\mathbf{b} \in \mathbb{R}^{d_{emb}}$, to map the bill representation into the space of the ideal vectors, and then uses a dot-product to provide a `yea`/`nay` score.

$$p(y = yea|\mathcal{B}, c) = \sigma((\mathbf{W}\left(\sum_{w \in \mathcal{B}} \mathbf{e}_w/|\mathcal{B}|\right) + \mathbf{b}) \cdot \mathbf{v}_c)$$

The full model is simply trained to minimize the negative log-likelihood of the training set, and requires no additional meta-information (such as party affiliation) or additional preprocessing of the bills during training- or test-time.

Congress	# Bills	House	Senate	Pres
106	557	R	R	Clinton
107	505	R	D[2]	Bush
108	607	R	R	Bush
109	579	R	R	Bush
110	854	D	D	Bush
111	965	D	D	Obama

Table 1: Dataset details for 106-111th Congress.

3 Experimental Setup

Data Following past work, our dataset is derived from the Govtrack database.[1] Specifically, our dataset consists of all votes on the full-text (not amendments) of bills or resolutions from the 106th-111th Congress, six of the most recent Congresses for which bill texts are readily available. Details of each these congresses are shown in Table 1.

To create our dataset, we first find a list of all votes on the full text of bills, and create a matrix of how each congressperson voted on each bill, which will be used in training and in testing. In accordance with previous work, we only consider yes-or-no votes and omit abstentions and "present" votes (Gerrish and Blei, 2011). We then simply collect the set of words used in each bill. Overall, our dataset consists of 4067 bills and over a million unique yes-or-no votes.

106	0.524
107	0.546
108	0.595
109	0.628
110	0.728
111	0.737
Avg	0.645

Table 3: Minority class F1 Scores of our model EMB on the 106th-111th Congress.

Model We tested prediction accuracy of the average-of-embeddings model, EMB, by running it for ten epochs at a learning rate of $\eta = 0.1$ and d_{emb} set to 10. Hyperparameters were tuned on a held-out section of the 107th Congress. We ran on each of the 106th to 111th Congresses individually using five-fold cross-validation.

Baselines We compare our results to three different baselines. The first, YEA, is a majority class baseline which assumes all legislators vote `yea`. The second, IDP, is our model with d_{emb} set to 1 to simulate a simple ideal point model. The third, GB, is Gerrish and Blei's reported predictive accuracy of 89 % on average from the 106th to 111th Congresses, which is to the extent of our knowledge the best predictive accuracy on roll-call votes yet achieved in the literature. Gerrish and Blei report on the same data set using cross-validation and like us train and test on each congress individually, but do not split out results into individual congresses.

4 Experiments and Analysis

Predictive Results The main predictive experimental results are shown in Table 2. We see that EMB performs substantially better than YEA on all six Congresses. It has a weighted average of 90.6% on an 84.5% baseline, compared to Gerrish and Blei's 89% on an identical dataset. IDP, however, actually does worse than the baseline, demonstrating that the bulk of our gain in prediction accuracy comes from using ideal vectors instead of ideal points. To further test this hypothesis, we experimented with replacing word embeddings with LDA and obtained an accuracy of 89.5%, in between GB and EMB. This indicates that the word embeddings are also responsible for part, but not all, of the accuracy improvement. We also report minority class F1 scores for EMB in Table 3, finding an overall average F1 score of 0.645.

Ideal Vectors Beyond predictive accuracy, one of the most interesting features of the model is that it produces ideal vectors as its complete representation of congresspeople. These vectors are much easier to compute than standard ideal points, which require relatively complex and computationally intensive statistical models (Jackman, 2001). Additionally unlike ideal point models, which tend to contain many assumptions about legislative behavior, ideal vectors arise naturally from raw data and bill text (Clinton et al., 2004).

In Figure 1, we show the ideal vectors for the 111th Congress. We use PCA to project the vectors down to two dimensions. This graph displays several interesting patterns in agreement with theories of legislative behavior. For example, political scientists theorize that the majority party in a legislature will display more unity in roll-call votes because they decide what gets voted on and only allow a vote on a bill if they can unify behind it and pass it, while that bill may divide the other party (Carrubba et al., 2006; Carrubba et al., 2008). On this graph, in accordance with that prediction, the majority Democrats are more clustered than the minority Republicans. We observe similar trends in the ideal vectors of the other Congresses. Moreover, the model lets us examine the positions of individual congresspeople. In the figure, the 34 Democrats who

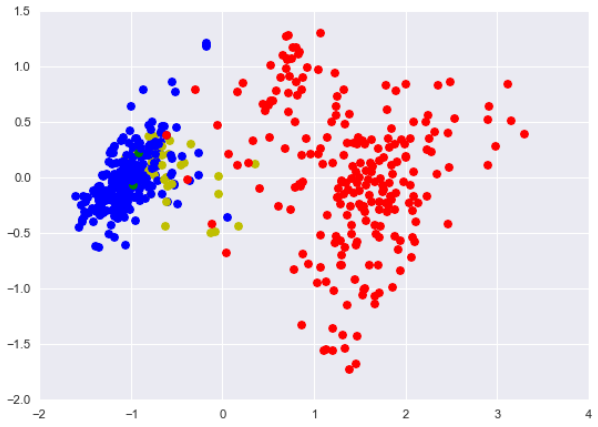

Figure 1: PCA projection of the ideal vectors for 111th Congress, both House and Senate. Republicans shown in red, Democrats who voted for Affordable Care Act (ACA) in blue, Democrats who voted against ACA in yellow, and independents in green.

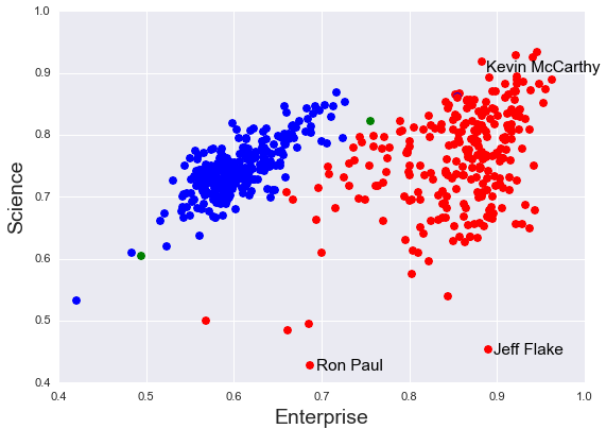

Figure 2: Relative likelihood of congresspeople in the 110th Congress voting for a bill containing only the word "Enterprise" versus only the word "Science." Coordinates are sigmoids of dot products of congressperson vectors with normalized word vectors.

voted against the Affordable Care Act (ACA, better known as Obamacare) are shown in yellow. The ACA was a major Democratic priority and point of difference between the two parties. The Democrats who voted against it tended to be relatively conservative and closer to the Republicans. The model picks up on this distinction.

Furthermore, since our model maps individual words and congresspeople to the same vector space, we can use it to determine how words (and by proxy issues) unite or divide congresspeople and parties. In Figure 2, we show the scaled probabilities that congresspeople will vote for a bill containing only the word "enterprise" versus one containing only the word "science" in the 110th Congress. The word "enterprise," denoting pro-business legislation, neatly divides the parties. Both are for it, but Republicans favor it more. More interestingly, the word "science" creates division *within* the parties, as neither was at the time more for science funding than the other but both contained congresspeople with varying levels of support for it. An ideal point model would likely capture the "enterprise" dimension, but not the "science" one, and would not be able to distinguish between libertarians like Ron Paul (R-TX) who are against both "corporate welfare" and government science funding, conservative budget hawks like Jeff Flake (R-AZ) who favor business but are skeptical of government funding of science, and establishment Republicans like Kevin McCarthy (R-CA) who support both. Indeed, ideal point models are known to perform poorly at describing ideologically idiosyncratic figures like Ron Paul (Gerrish and Blei, 2011). Providing the ability to explore multiple dimensions of difference between legislators will be extremely helpful for political scientists analyzing the dynamics of legislatures.

Lexical Properties Finally, as with topic modeling approaches, we can use our model to analyze the relationships between congresspeople or parties and individual words in bills. For example, Table 4 shows the ten words closest by cosine similarity to each party's average congressperson (stop words omitted) for the 110th Congress. The Democratic list mostly contains words relating to governing and regulating, such as "consumer," "state," and "educational," likely because the Democrats were at the time the majority party with the responsibility for passing large governmental and regulatory bills like budgets. The Republican list is largely concerned with the military, with words like "veterans," "service," and "executive," probably because of the importance at the time of the wars in Iraq and Afghanistan, started by a Republican president.

Democrats	Republicans
economic	veterans
exchange	head
state	opportunities
carrying	provided
government	promote
higher	service
congress	identified
consumer	information
educational	record
special	executive

Table 4: Top ten words by cosine similarity for each party in the 110th Congress with stop words removed.

5 Conclusion

We have developed a novel model for predicting Congressional roll-call votes. This new model provides a new and interesting way of analyzing the behavior of parties and legislatures. It achieves predictive accuracies around 90.6% on average and outperforms any prior model of roll-call voting. We also introduce the idea of ideal vectors as a fast, simple, and multidimensional alternative to ideal point models for analyzing the actions of individual legislators and testing theories about their behavior. Our code and datasets are available online at `https://github.com/kraftp/roll_call_predictor`.

Natural Language Model Re-usability for Scaling to Different Domains

Young-Bum Kim, Alexandre Rochette and **Ruhi Sarikaya**
Microsoft Corporation, Redmond, WA
ybkim,alrochet,ruhi.sarikaya@microsoft.com

Abstract

Natural language understanding is the core of the human computer interactions. However, building new domains and tasks that need a separate set of models is a bottleneck for scaling to a large number of domains and experiences. In this paper, we propose a practical technique that addresses this issue in a web-scale language understanding system: Microsoft's personal digital assistant Cortana. The proposed technique uses a constrained decoding method with a universal slot tagging model sharing the same schema as the collection of slot taggers built for each domain. The proposed approach allows reusing of slots across different domains and tasks while achieving virtually the same performance as those slot taggers trained per domain fashion.

1 Introduction

Recently there has been tremendous investment into the personal digital assistants by big technology companies (Sarikaya, 2015; Sarikaya et al., 2016). Apple's SIRI, Google Now, Microsoft's Cortana and Amazon's Alexa are examples of such systems. Natural language understanding (Gupta et al., 2006; Tur and De Mori, 2011)is at the core of these systems providing natural communication between the user and the agent. These systems support a number of scenarios including creating reminders, setting up alarms, note taking, scheduling meetings, finding and consuming entertainment (i.e. movie, music, games), finding places of interest and getting driving directions to them. The domains supported by these systems are on the order of tens (not in hundreds) and adding new domains and experiences is a scaling problem that has not been solved yet (Tur, 2006; Jeong and Lee, 2009; El-Kahky et al., 2014; Kim et al., 2015d).

The primary reason behind this is that each domain requires potentially a new schema, intents and slots extracted from the natural language query. That, in turn requires collecting and annotating new data, which is the most expensive step in terms of time and money, and building a new set of domain specific models to support the new domains and scenarios. Slot modeling in particular is the most demanding component in terms of the difficulty of annotation and modeling.

In this study, we propose a new approach that reduces the cost of scaling natural language understanding to a large number of domains and experiences without significantly sacrificing the accuracy. The approach consists of a universal slot tagging method and a runtime technique called *constrained decoding* that performs the decoding according a specific schema. The proposed approach, heavily enables reusing existing slot modeling data that are collected and annotated for potentially different domains and applications, for building new domains and applications. The new domains can be expressed in terms of existing semantic schema.

The rest of the paper is organized as follows. In the next section, we talk about universal slot modeling. In section 3, we present the constrained decoding technique. We describe the experimental set up, results and analysis in section 4 followed by the conclusions and future directions in section 5.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2071–2076,
Austin, Texas, November 1-5, 2016.

2 Universal Slot Tagging

The first step is to build a universal slot tagger, a single model that can handle all the domains an agent (e.g. Cortana) can support. In Table 1, we show a subset of the domains that are supported by Cortana for experimentation purposes.

2.1 Universal Slot Tagger Training

To train the universal slot tagger, we consider two simple and intuitive approaches: *Binary* and *All-in-one*.

Suppose we have a combined k slots across domains and also have access to the labeled data, *Binary* approach trains k binary classifier one for each slot type. For each binary slot tagger targeting a specific slot type, the labeled data is programatically mapped to create a new labeled data set, where only the target label is kept while all the other labels are mapped "other" label. *All-in-one* approach simply trains a single model by aggregating queries across all domains.

2.2 Slot Tagging Ambiguity

Universal slot tagging model has an advantage, which can share schema across all domains used for training time. In spite of the advantage, there are ambiguity problems caused by combining all domains (and the underlying data) into a single model. The problems can be grouped into two categories:

- *Imbalanced training data distribution*: The amount of training data varies across domains. Universal slot model may have bias towards predicting the slots in domains with larger training data. For example, slots with less training data (e.g. *app_name* in *MEDIACONTROL* domain could be overwhelmed by slots with large training data (e.g. *place_name* in *PLACES* domain).

- *Domain-specific schema:* In practice, the domains the system handles are not constructed at the same time. They are designed for different application back-ends, requirements and scenarios at different points in time. In other words, the semantic schema for a domain is designed without considering other domains. In *ALARM* domain, the slot indicating time is subdivided into sub-slots such as *start_time* representing starting time, *duration* representing duration for an alarm. In contrast, in *PLACES* domain, there is only a single slot indicating time (*time*).

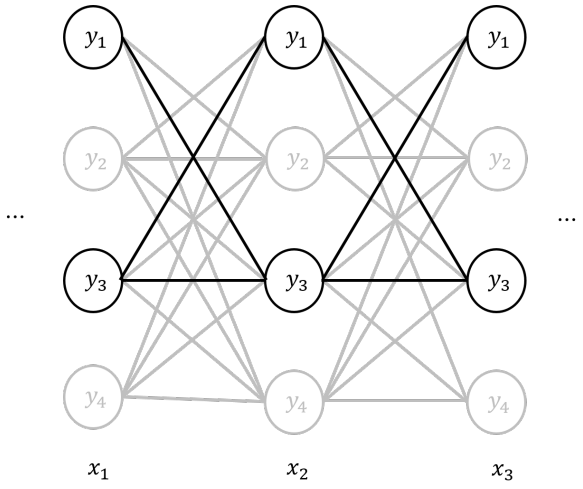

Figure 1: Constrained Lattice: Disabling nodes and transition while decoding the lattice to honor given constraints of domain schema.

3 Constrained Decoding

Slot tagging is considered as a sequence learning problem (Deoras and Sarikaya, 2013; Li et al., 2009; Xu and Sarikaya, 2014; Celikyilmaz et al., 2015; Kim et al., 2015b; Kim et al., 2015c; Kim et al., 2015a). In sequence learning, given a sample query $x_1 \dots x_n$, the decoding problem is to find the most likely slot sequence among all the possible sequences, $y_1 \dots y_n$:

$$f(x_1 \dots x_n) = \arg\max_{y_1 \dots y_n} p(x_1 \dots x_n, y_1 \dots y_n)$$

Here, we assume that output space in training is same as those in test time.

However, in our problem, output (slot) space in test time can be different from those in training time. At test time, we may observe different slot sequences than what is observed in the training time.

This is not an issue for the *Binary* approach, since we can use the output of the selected taggers needed for the new domain. We simply use general decoding approach with each of the selected taggers. Note

that a given query is run as many times as the numbers of slot types covered in a given domain.

For *All-in-One* technique, we consider two possible approaches: *Post-Filter* and *Constrained Decoding*. With *Post-Filter*, we simply provide the best hypothesis generated by the slot tagger that meets the domain schema constraints, by computing the full n-best of slots and filtering out the slot types that do not meet the target domain schema. With *Constrained Decoding*, given a schema $\tilde{y} \subset y$ for the target domain, we first define a constrained lattice *lattice* $\mathcal{Y}(x, \tilde{y}) = \mathcal{Y}(x_1, \tilde{y}) \times \ldots \times \mathcal{Y}(x_n, \tilde{y})$, as shown in Figure 1. Then, we perform the decoding in the constrained lattice:

$$f(x_1 \ldots x_n, \tilde{y}) = \arg\max_{\mathcal{Y}(x,\tilde{y})} p(x_1 \ldots x_n, y_1 \ldots y_n)$$

4 Experiments

In this section, we conducted a series of experiments to evaluate the proposed techniques on datasets obtained from real usage.

4.1 Experimental Setup

To test the effectiveness of the proposed approach, we apply it to a suite of 16 Cortana domains for slot tagging tasks. The data statistics and short descriptions are shown in Table 1. As the table indicates, the domains have different granularity and diverse semantics. Note that we keep domain-specific slots such as alarm_state, but there are enough shared labels across domains. For example, *ALARM* domain, there are 6 shared slots among 8 slots. There are 62 slots appearing more than one domain. Especially, some basic slots such as *time*, *date*,*place_name*,*person_name*,*location* and *product* appear in most domains.

4.2 Slot Taggers

In all our experiments, we trained Conditional Random Fields (CRFs)(Lafferty et al., 2001) and used n-gram features up to n = 3, regular expression, lexicon features, and Brown Clusters (Brown et al., 1992). With these features, we compare the following methods for slot tagging[1]:

- *In-domain*: Train a domain specific model using the domain specific data covering the slots supported in that domain.
- *Binary*: Train a binary classifier for each slot type, combine the slots needed for a given domain schema.
- *Post*: Train a single model with all domain data, take the one-best parse of the tagger and filter-out slots outside the domain schema.
- *Const*: Train a single model with all domain data and then perform constrained decoding using a domain specific schema.

4.3 Results

For the first scenario, we assume that test domain semantic schema is a subset of training domain schema. The results of this scenario are shown in Table 2. We consider *In-domain* as a plausible upper bound on the performance, yielding 94.16% of F1 on average. First, *Binary* has the lowest performance of 75.85%. We believe that when we train a binary classifier for each slot type, the other slots that provide valuable contextual information for the slot sequence are ignored. This leads to degradation in tagging accuracy. *Post* improves F1 scores across domains, resulting into 86.50% F1 on average. Note that this technique does not handle ambiguities and data distribution mismatch due to combining multiple domain specific data with different data sizes. Finally, *Const* lead to consistent gains across all domains, achieving 93.36%, which almost matches the *In-domain* performance. The reason why *Const* performs better than *Binary* is that *Const* constrains the best path search to the target domain schema. It does not consider the schema elements that are outside the target domain schema. By doing so, it addresses the training data distribution issue as well as overlap on various schema elements.

For the second scenario, we consider a new set of test domains not covered in the training set, as shown in Table 3. The amount of training data for the test domains are limited ($< 5K$). These domains lack training data for the *location* and *app_name* slots. When we use universal slot tagger with constrained decoding *Const* yields 94.30%. On average, *Const* increases F1-score by 1.41 percentage points,

[1]For parameter estimation, we used L-BFGS (Liu and Nocedal, 1989) with 100 as the maximum iteration count and 1.0 for the L2 regularization parameter.

corresponding a 20% decrease in relative error. We believe that universal slot tagger learns to tag these slots from data available in *PLACES* and *ENTERTAINMENT* domains.

For the last scenario shown in Table 4, we assume that we do not have training data for the test domains. The *Const* performs reasonably well, yielding 94.48% on average. Interestingly, for the *TRANSIT* domain, we can get almost perfect tagging performance of 99.5%. Note that all tags in *TRANSIT* and *TAXI* domains are fully covered by our universal models, but the *MEDIACONTROL* domain is partially covered.

4.4 Discussion

By using the proposed technique, we maximize the reuse of existing data labeled for different domains and applications. The proposed technique allows mixing and matching of slots across different domains to create new domains. For example, we can tag the slots in the *SHOWTIMES* domain, which involves finding a movie to watch by using *movie_titles, actor_names* from the *ENTERTAINMENT* domain, and the location of the theater by using *location, place_name* slots from the *PLACES* domain. If the new domain needs some new slots that are not covered by the universal tagger, then some examples queries could be annotated and added to the universal slot tagger training data to retrain the models. Instead of maintaining a separate

slot tagger for each domain, one needs to maintain a single slot tagger. The new slots added can be used by future domains and applications.

5 Conclusions

We proposed a solution for scaling domains and experiences potentially to a large number of use cases by reusing existing data labeled for different domains and applications. The universal slot tagging coupled with constrained decoding achieves almost as good a performance as those slot taggers built in a domain specific fashion. This approach enables creation of virtual domains through any combination of slot types covered in the universal slot tagger schema, reducing the need to collect and annotate the same slot types multiple times for different domains. One of the future directions of research is to extend the same idea to the intent modeling, where we can re-use intent data built for different applications and domains for a new domain. Also, we plan to extend the constrained decoding idea to slot tagging with neural networks (Kim et al., 2016), which achieved gains over CRFs.

Abstract

Recurrent Neural Network (RNN) and one of its specific architectures, Long Short-Term Memory (LSTM), have been widely used for sequence labeling. Explicitly modeling output label dependencies on top of RNN/LSTM is a widely-studied and effective extension. We propose another extension to incorporate the global information spanning over the whole input sequence. The proposed method, *encoder-labeler LSTM*, first encodes the whole input sequence into a fixed length vector with the encoder LSTM, and then uses this encoded vector as the initial state of another LSTM for sequence labeling. With this method, we can predict the label sequence while taking the whole input sequence information into consideration. In the experiments of a slot filling task, which is an essential component of natural language understanding, with using the standard ATIS corpus, we achieved the state-of-the-art F_1-score of 95.66%.

1 Introduction

Natural language understanding (NLU) is an essential component of natural human computer interaction and typically consists of identifying the intent of the users (intent classification) and extracting the associated semantic slots (slot filling) (De Mori et al., 2008). We focus on the latter semantic slot filling task in this paper.

Slot filling can be framed as a sequential labeling problem in which the most probable semantic slot labels are estimated for each word of the given word sequence. Slot filling is a traditional task and tremendous efforts have been done, especially since the 1980s when the Defense Advanced Research Program Agency (DARPA) Airline Travel Information System (ATIS) projects started (Price, 1990). Following the success of deep learning (Hinton et al., 2006; Bengio, 2009), Recurrent Neural Network (RNN) (Elman, 1990; Jordan, 1997) and one of its specific architectures, Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), have been widely used since they can capture temporal dependencies (Yao et al., 2013; Yao et al., 2014a; Mesnil et al., 2015). The RNN/LSTM-based slot filling has been extended to be combined with explicit modeling of label dependencies (Yao et al., 2014b; Liu and Lane, 2015).

In this paper, we extend the LSTM-based slot filling to consider sentence-level information. In the field of machine translation, an encoder-decoder LSTM has been gaining attention (Sutskever et al., 2014), where the encoder LSTM encodes the global information spanning over the whole input sentence in its last hidden state. Inspired by this idea, we propose an *encoder-labeler LSTM* that leverages the encoder LSTM for slot filling. First, we encode the input sentence into a fixed length vector by the encoder LSTM. Then, we predict the slot label sequence by the labeler LSTM whose hidden state is initialized with the encoded vector by the encoder LSTM. With this encoder-labeler LSTM, we can predict the label sequence while taking the sentence-level information into consideration.

The main contributions of this paper are twofolds:

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2077–2083,
Austin, Texas, November 1-5, 2016.

1. Proposed an encoder-labeler LSTM to leverage sentence-level information for slot filling.

2. Achieved the state-of-the-art F_1-score of 95.66% in the slot filling task of the standard ATIS corpus.

2 Proposed Method

We first revisit the LSTM for slot filling and enhance this to explicitly model label dependencies. Then we explain the proposed encoder-labeler LSTM.

2.1 LSTM for Slot Filling

Figure 1(a) shows a typical LSTM for slot filling and we call this as *labeler LSTM(W)* where words are fed to the LSTM (Yao et al., 2014a).

Slot filling is a sequential labeling task to map a sequence of T words x_1^T to a sequence of T slot labels y_1^T. Each word x_t is represented with a V dimensional one-hot-vector where V is the vocabulary size and is transferred to d_e dimensional continuous space by the word embedding matrix $E \in \mathbb{R}^{d_e \times V}$ as Ex_t. Instead of simply feeding Ex_t into the LSTM, *Context Window* is a widely used technique to jointly consider k preceding and succeeding words as $Ex_{t-k}^{t+k} \in \mathbb{R}^{d_e(2k+1)}$. The LSTM has the architecture based on Jozefowicz et al. (2015) that does not have peephole connections and yields the hidden state sequence h_1^T. For each time step t, the posterior probabilities for each slot label are calculated by the softmax layer over the hidden state h_t. The word embedding matrix E, LSTM parameters, and softmax layer parameters are estimated to minimize the negative log likelihood over the correct label sequences with Back-Propagation Through Time (BPTT) (Williams and Peng, 1990).

2.2 Explicit Modeling of Label Dependency

A shortcoming of the labeler LSTM(W) is that it does not consider label dependencies. To explicitly model label dependencies, we introduce a new architecture, *labeler LSTM (W+L)*, as shown in Figure 1(b), where the output label of previous time step is fed to the hidden state of current time step, jointly with words, as Mesnil et al. (2015) and Liu and Lane (2015) tried with RNN. For model training, one-hot-vector of ground truth label of previous time step is fed to the hidden state of current time step and for evaluation, left-to-right beam search is used.

2.3 Encoder-labeler LSTM for Slot Filling

We propose two types of the encoder-labeler LSTM that uses the labeler LSTM(W) and the labeler LSTM(W+L). Figure 1(d) shows the *encoder-labeler LSTM(W)*. The encoder LSTM, to the left of the dotted line, reads through the input sentence backward. Its last hidden state contains the encoded information of the input sentence. The labeler LSTM(W), to the right of the dotted line, is the same with the labeler LSTM(W) explained in Section 2.1, *except that its hidden state is initialized with the last hidden state of the encoder LSTM*. The labeler LSTM(W) predicts the slot label conditioned on the encoded information by the encoder LSTM, which means that slot filling is conducted with taking sentence-level information into consideration. Figure 1(e) shows the *encoder-labeler LSTM(W+L)*, which uses the labeler LSTM(W+L) and predicts the slot label considering sentence-level information and label dependencies jointly.

Model training is basically the same as with the baseline labeler LSTM(W), as shown in Section 2.1, except that the error in the labeler LSTM is propagated to the encoder LSTM with BPTT.

This encoder-labeler LSTM is motivated by the encoder-decoder LSTM that has been applied to machine translation (Sutskever et al., 2014), grapheme-to-phoneme conversion (Yao and Zweig, 2015), text summarization (Nallapati et al., 2016) and so on. The difference is that the proposed encoder-labeler LSTM accepts the same input sequence twice while the usual encoder-decoder LSTM accepts the input sequence once in the encoder. Note that the LSTMs for encoding and labeling are different in the encoder-labeler LSTM, but the same word embedding matrix is used both for the encoder and labeler since the same input sequence is fed twice.

2.4 Related Work on Considering Sentence-level Information

Bi-directional RNN/LSTM have been proposed to capture sentence-level information (Mesnil et al., 2015; Zhou and Xu, 2015; Vu et al., 2016). While the bi-directional RNN/LSTM model the preceding and succeeding contexts at a specific word and

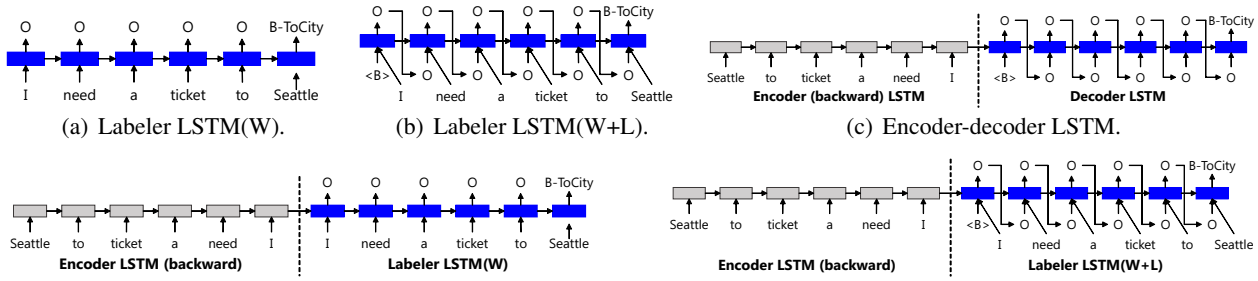

Figure 1: Neural network architectures for slot filling. Input sentence is "I need a ticket to Seattle". "B-ToCity" is slot label for specific meaning and "O"is slot label without specific meaning. "<B>" is beginning symbol for slot sequence.

Sentence	show	flights	from	Boston	to	New	York	today
Slots	O	O	O	B-FromCity	O	B-ToCity	I-ToCity	B-Date

Figure 2: Example of ATIS sentence and annotated slots.

don't explicitly encode the whole sentence, our proposed encoder-labeler LSTM explicitly encodes whole sentence and predicts slots conditioned on the encoded information.

Another method to consider the sentence-level information for slot filling is the attention-based approach (Simonnet et al., 2015). The attention-based approach is novel in aligning two sequences of different length. However, in the slot filling task where the input and output sequences have the same length and the input word and the output label has strong relations, the effect of introducing "soft" attention might become smaller. Instead, we directly fed the input word into the labeler part with using context window method as explained in Section 2.3.

3 Experiments

We report two sets of experiments. First we use the standard ATIS corpus to confirm the improvement by the proposed encoder-labeler LSTM and compare our results with the published results while discussing the related works. Then we use a large-scale data set to confirm the effect of the proposed method in a realistic use-case.

3.1 ATIS Experiment

3.1.1 Experimental Setup

We used the ATIS corpus, which has been widely used as the benchmark for NLU (Price, 1990; Dahl et al., 1994; Wang et al., 2006; Tur et al., 2010). Figure 2 shows an example sentence and its semantic slot labels in In-Out-Begin (IOB) representation. The slot filling task was to predict the slot label sequences from input word sequences.

The performance was measured by the F_1-score: $F_1 = \frac{2 \times Precision \times Recall}{Precision + Recall}$, where precision is the ratio of the correct labels in the system's output and recall is the ratio of the correct labels in the ground truth of the evaluation data (van Rijsbergen, 1979).

The ATIS corpus contains the training data of 4,978 sentences and evaluation data of 893 sentences. The unique number of slot labels is 127 and the vocabulary size is 572. In the following experiments, we randomly selected 80% of the original training data to train the model and used the remaining 20% as the heldout data (Mesnil et al., 2015). We reported the F_1-score on the evaluation data with hyper-parameters that achieved the best F_1-score on the heldout data.

For training, we randomly initialized parameters in accordance with the normalized initialization (Glorot and Bengio, 2010). We used *ADAM* for learning rate control (Kingma and Ba, 2014) and *dropout* for generalization with a dropout rate of 0.5 (Srivastava et al., 2014; Zaremba et al., 2014).

3.1.2 Improvement by Encoder-labeler LSTM

We conducted experiments to compare the labeler LSTM(W) (Section 2.1), the labeler LSTM(W+L) (Section 2.2), and the encoder-labeler LSTM (Section 2.3). As for yet another baseline, we tried the encoder-decoder LSTM as shown in Figure 1(c)[1].

For all architectures, we set the initial learning rate to 0.001 (Kingma and Ba, 2014) and

[1]Length of the output label sequence is equal to that of the input word sequence in a slot filling task. Therefore, ending symbol for slot sequence is not necessary.

the dimension of word embeddings to $d_e = 30$. We changed the number of hidden units in the LSTM, $d_h \in \{100, 200, 300\}$[2], and the size of the context window, $k \in \{0, 1, 2\}$[3]. We used backward encoding for the encoder-decoder LSTM and the encoder-labeler LSTM as suggested in Sutskever et al. (2014). For the encoder-decoder LSTM, labeler LSTM(W+L), and encoder-labeler LSTM(W+L), we used the left-to-right beam search decoder (Sutskever et al., 2014) with beam sizes of 1, 2, 4, and 8 for evaluation where the best F_1-score was reported. During 100 training epochs, we reported the F_1-score on the evaluation data with the epoch when the F_1-score for the heldout data was maximized. Table 1 shows the results.

The proposed encoder-labeler LSTM(W) and encoder-labeler LSTM(W+L) both outperformed the labeler LSTM(W) and labeler LSTM(W+L), which confirms the novelty of considering sentence-level information with the encoder LSTM by our proposed method.

Contrary to expectations, F_1-score by the encoder-labeler LSTM(W+L) was not improved from that by the encoder-labeler LSTM(W). A possible reason for this is the propagation of label prediction errors. We compared the label prediction accuracy for the words after the first label prediction error in the evaluation sentences and confirmed that the accuracy deteriorated from 84.0% to 82.6% by using pthe label dependencies.

For the encoder-labeler LSTM(W) which was better than the encoder-labeler LSTM(W+L), we tried the deep architecture of 2 LSTM layers (*Encoder-labeler deep LSTM(W)*). We also trained the corresponding *labeler deep LSTM(W)*. As in Table 1, we obtained improvement from 94.91% to 95.47% by the proposed encoder-labeler deep LSTM(W), which was statistically significant at the 90% level.

Lastly, F_1-score by the encoder-decoder LSTM was worse than other methods as shown in the first row of Table 1. Since the slot label is closely related with the input word, the encoder-decoder LSTM was not an appropriate approach for the slot filling task.

[2]When using deep architecture later in this section, d_h was tuned for each layer.

[3]In our preliminary experiments with using the labeler LSTM(W), F_1-scores deteriorated with $k \geq 3$.

3.1.3 Comparison with Published Results

Table 2 summarizes the recently published results on the ATIS slot filling task and compares them with the results from the proposed methods.

Recent research has been focusing on RNN and its extensions. Yao et al. (2013) used RNN and outperformed methods that did not use neural networks, such as SVM (Raymond and Riccardi, 2007) and CRF (Deng et al., 2012). Mesnil et al. (2015) tried bi-directional RNN, but reported degradation comparing with their single-directional RNN (94.98%). Yao et al. (2014a) introduced LSTM and deep LSTM and obtained improvement over RNN. Peng and Yao (2015) proposed RNN-EM that used an external memory architecture to improve the memory capability of RNN.

Many studies have been also conducted to explicitly model label dependencies. Xu and Sarikaya (2013) proposed CNN-CRF that explicitly models the dependencies of the output from CNN. Mesnil et al. (2015) used hybrid RNN that combined Elman-type and Jordan-type RNNs. Liu and Lane (2015) used the output label for the previous word to model label dependencies (RNN-SOP).

Vu et al. (2016) recently proposed to use ranking loss function over bi-directional RNNs with achieving 95.47% (R-biRNN) and reported 95.56% by ensemble (5×R-biRNN).

By comparing with these methods, the main difference of our proposed encoder-labeler LSTM is the use of encoder LSTM to leverage sentence-level information [4].

[4]Since Simonnet et al. (2015) did not report the experimental results on ATIS, we could not experimentally compare our result with their attention-based approach. Theoretical comparison is available in Section 2.4.

Table 2: Comparison with published results on ATIS slot filling task. F_1-scores by proposed method are improved from Table 1 due to sophisticated hyper-parameters. [%]

For our encoder-labeler LSTM(W) and encoder-labeler deep LSTM(W), we further conducted hyper-parameter search with a random search strategy (Bergstra and Bengio, 2012). We tuned the dimension of word embeddings, $d_e \in \{30, 50, 75\}$, number of hidden states in each layer, $d_h \in \{100, 150, 200, 250, 300\}$, size of context window, $k \in \{0, 1, 2\}$, and initial learning rate sampled from uniform distribution in range $[0.0001, 0.01]$. To the best of our knowledge, the previously published best F_1-score was 95.56%[5] (Vu et al., 2016). Our encoder-labeler deep LSTM(W) achieved 95.66% F_1-score, outperforming the previously published F_1-score as shown in Table 2.

Note some of the previous results used whole training data for model training while others used randomly selected 80% of data for model training and the remaining 20% for hyper-parameter tuning. Our results are based on the latter setup.

3.2 Large-scale Experiment

We prepared a large-scale data set by merging the MIT Restaurant Corpus and MIT Movie Corpus (Liu et al., 2013a; Liu et al., 2013b; Spoken Laungage Systems Group, 2013) with the ATIS corpus. Since users of the NLU system may provide queries without explicitly specifying their domain, building one NLU model for multiple domains is necessary. The merged data set contains 30,229 training and 6,810 evaluation sentences. The unique number of slot labels is 191 and the vocabulary size is 16,049. With this merged data set, we compared the labeler LSTM(W) and the proposed encoder-labeler LSTM(W) according to the experimental procedure explained in Section 3.1.2. The labeler LSTM(W) achieved the F_1-score of 72.80% and the encoder-labeler LSTM(W) improved it to 74.41%, which confirmed the effect of the proposed method in large and realistic data set [6].

4 Conclusion

We proposed an encoder-labeler LSTM that can conduct slot filling conditioned on the encoded sentence-level information. We applied this method to the standard ATIS corpus and obtained the state-of-the-art F_1-score in a slot filling task. We also tried to explicitly model label dependencies, but it was not beneficial in our experiments, which should be further investigated in our future work.

In this paper, we focused on the slot labeling in this paper. Previous papers reported that jointly training the models for slot filling and intent classification boosted the accuracy of both tasks (Xu and Sarikaya, 2013; Shi et al., 2015; Liu et al., 2015). Leveraging our encoder-labeler LSTM approach in joint training should be worth trying.

Acknowledgments

We are grateful to Dr. Yuta Tsuboi, Dr. Ryuki Tachibana, and Mr. Nobuyasu Itoh of IBM Research - Tokyo for the fruitful discussion and their comments on this and earlier versions of the paper. We thank Dr. Ramesh M. Nallapati and Dr. Cicero Nogueira dos Santos of IBM Watson for their valuable suggestions. We thank the anonymous reviewers for their valuable comments.

[5] There are other published results that achieved better F_1-scores by using other information on top of word features. Vukotic et al. (2015) achieved 96.16% F_1-score by using the named entity (NE) database when estimating word embeddings. Yao et al. (2013) and Yao et al. (2014a) used NE features in addition to word features and obtained improvement with both the RNN and LSTM upto 96.60% F_1-score. Mesnil et al. (2015) also used NE features and reported F_1-score of 96.29% with RNN and 96.46% with Recurrent CRF.

[6] The purpose of this experiment is to confirm the effect of the proposed method. The absolute F_1-scores can not be compared with the numbers in Liu et al. (2013b) since the capitalization policy and the data size of the training data were different.

AMR-to-text generation as a Traveling Salesman Problem

Abstract

The task of AMR-to-text generation is to generate grammatical text that sustains the semantic meaning for a given AMR graph. We attack the task by first partitioning the AMR graph into smaller fragments, and then generating the translation for each fragment, before finally deciding the order by solving an asymmetric generalized traveling salesman problem (AGTSP). A Maximum Entropy classifier is trained to estimate the traveling costs, and a TSP solver is used to find the optimized solution. The final model reports a BLEU score of 22.44 on the SemEval-2016 Task8 dataset.

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a semantic formalism encoding the meaning of a sentence as a rooted, directed graph. Shown in Figure 1, the nodes of an AMR graph (e.g. "boy", "go-01" and "want-01") represent concepts, and the edges (e.g. "ARG0" and "ARG1") represent relations between concepts. AMR jointly encodes a set of different semantic phenomena, which makes it useful in applications like question answering and semantics-based machine translation. AMR has served as an intermediate representation for various text-to-text NLP applications, such as statistical machine translation (SMT) (Jones et al., 2012).

The task of AMR-to-text generation is to generate grammatical text containing the same semantic meaning as a given AMR graph. This task is important yet also challenging since each AMR graph usually has multiple corresponding sentences, and syntactic structure and function words are abstracted away when transforming a sentence into AMR (Banarescu et al., 2013). There has been work dealing with text-to-AMR parsing (Flanigan et al., 2014; Wang et al., 2015; Peng et al., 2015; Vanderwende et al., 2015; Pust et al., 2015; Artzi et al., 2015). On the other hand, relatively little work has been done on AMR-to-text generation. One recent exception is Flanigan et al. (2016), who first generate a spanning tree for the input AMR graph, and then apply a tree transducer to generate the sentence. Here, we directly generate the sentence from an input AMR by treating AMR-to-text generation as a variant of the traveling salesman problem (TSP).

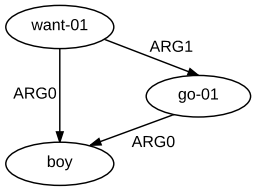

Figure 1: AMR graph for "The boy wants to go".

Given an AMR as input, our method first cuts the graph into several rooted and connected fragments (sub-graphs), and then finds the translation for each fragment, before finally generating the sentence for the whole AMR by ordering the translations. To cut the AMR and translate each fragment, we match the input AMR with rules, each consisting of a rooted, connected AMR fragment and a corresponding translation. These rules serve in a similar way to rules in SMT models. We learn the rules by a modified version of the sampling algorithm of Peng

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2084–2089,
Austin, Texas, November 1-5, 2016.

et al. (2015), and use the rule matching algorithm of Cai and Knight (2013).

For decoding the fragments and synthesizing the output, we define a *cut* to be a subset of matched rules without overlap that covers the AMR, and an *ordered cut* to be a cut with the rules being ordered. To generate a sentence for the whole AMR, we search for an ordered cut, and concatenate translations of all rules in the cut. TSP is used to traverse different cuts and determine the best order. Intuitively, our method is similar to phrase-based SMT, which first cuts the input sentence into phrases, then obtains the translation for each source phrase, before finally generating the target sentence by ordering the translations. Although the computational cost of our method is low, the initial experiment is promising, yielding a BLEU score of 22.44 on a standard benchmark.

2 Method

We reformulate the problem of AMR-to-text generation as an asymmetric generalized traveling salesman problem (AGTSP), a variant of TSP.

2.1 TSP and its variants

Given a *non-directed* graph G_N with n cities, supposing that there is a traveling cost between each pair of cities, TSP tries to find a tour of the minimal total cost visiting each city exactly once. In contrast, the asymmetric traveling salesman problem (ATSP) tries to find a tour of the minimal total cost on a *directed* graph, where the traveling costs between two nodes are different in each direction. Given a directed graph G_D with n nodes, which are clustered into m groups, the asymmetric generalized traveling salesman problem (AGTSP) tries to find a tour of the minimal total cost visiting each *group* exactly once.

2.2 AMR-to-text Generation as AGTSP

Given an input AMR A, each node in the AGTSP graph can be represented as (c, r), where c is a concept in A and $r = (A_{sub}, T_{sub})$ is a rule that consists of an AMR fragment containing c and a translation of the fragment. We put all nodes containing the same concept into one group, thereby translating each concept in the AMR exactly once.

To show a brief example, consider the AMR in Figure 1 and the following rules,

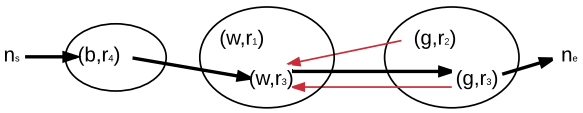

Figure 2: An example AGTSP graph

r_1	(w/want-01) ||| wants
r_2	(g/go-01) ||| to go
r_3	(w/want-01 :ARG1 g/go-01) ||| wants to go
r_4	(b/boy) ||| The boy

We build an AGTSP graph in Figure 2, where each circle represents a group and each tuple (such as (b, r_4)) represents a node in the AGTSP graph. We add two nodes n_s and n_e representing the start and end nodes respectively. Each belongs to a specific group that only contains that node, and a tour always starts with n_s and ends with n_e. Legal moves are shown in black arrows, while illegal moves are shown in red. One legal tour is $n_s \rightarrow (b, r_4) \rightarrow (w, r_3) \rightarrow (g, r_3) \rightarrow n_e$. The order in which nodes within a rule are visited is arbitrary; for a rule with N concepts, the number of visiting orders is $O(N!)$. To reduce the search space, we enforce the breadth first order by setting costs to zero or infinity. In our example, the traveling cost from (w, r_3) to (g, r_3) is 0, while the traveling cost from (g, r_3) to (w, r_3) is infinity. Traveling from (g, r_2) to (w, r_3) also has infinite cost, since there is overlap on the concept "w/want-01" between them.

The traveling cost is calculated by Algorithm 1. We first add n_s and n_e serving the same function as Figure 2. The traveling cost from n_s directly to n_e is infinite, since a tour has to go through other nodes before going to the end. On the other hand, the traveling cost from n_e to n_s is 0 (Lines 3-4), as a tour always goes back to the start after reaching the end. The traveling cost from n_s to $n_i = (c_i, r_i)$ is the model score only if c_i is the first node of the AMR fragment of r_i, otherwise the traveling cost is infinite (Lines 6-9). Similarly, the traveling cost from n_i to n_e is the model score only if c_i is the last node of the fragment of r_i. Otherwise, it is infinite (Lines 10-13). The traveling cost from $n_i = (c_i, r_i)$ to $n_j = (c_j, r_j)$ is 0 if r_i and r_j are the same rule and c_j is the next node of c_i in the AMR fragment of r_i (Lines 16-17).

A tour has to travel through an AMR fragment be-

Algorithm 1: Traveling cost algorithm

fore jumping to another fragment. We choose the breadth-first order of nodes within the same rule, which is guaranteed to exist, as each AMR fragment is rooted and connected. Costs along the breadth-first order within a rule r_i are set to 0, while other costs with a rule are infinite.

If r_i is not equal to r_j, then the traveling cost is the model score if there is no overlap between r_i and r_j's AMR fragment and it moves from r_i's last node to r_j's first node (Lines 18-19), otherwise the traveling cost is infinite (Lines 20-21). All other cases are illegal and we assign infinite traveling cost. We do not allow traveling between overlapping nodes, whose AMR fragments share common concepts. Otherwise the traveling cost is evaluated by a maximum entropy model, which will be discussed in detail in Section 2.4.

2.3 Rule Acquisition

We extract rules from a corpus of (sentence, AMR) pairs using the method of Peng et al. (2015). Given an aligned (sentence, AMR) pair, a *phrase-fragment pair* is a pair $([i, j], f)$, where $[i, j]$ is a span of the sentence and f represents a connected and rooted AMR fragment. A *fragment decomposition forest* consists of all possible phrase-fragment pairs that satisfy the alignment agreement for phrase-based MT (Koehn et al., 2003). The rules that we use for generation are the result of applying an MCMC procedure to learn a set of likely phrase-fragment pairs from the forests containing all possible pairs. One difference from the work of Peng et al. (2015) is that, while they require the string side to be tight (does not include unaligned words on both sides), we expand the tight phrases to incorporate unaligned words on both sides. The intuition is that they do text-to-AMR parsing, which often involves discarding function words, while our task is AMR-to-text generation, and we need to be able to fill in these unaligned words. Since incorporating unaligned words will introduce noise, we rank the translation candidates for each AMR fragment by their counts in the training data, and select the top N candidates.[1]

We also generate *concept rules* which directly use a morphological string of the concept for translation. For example, for concept “w/want-01” in Figure 1, we generate concept rules such as “(w/want-01) ||| want”, “(w/want-01) ||| wants”, “(w/want-01) ||| wanted” and “(w/want-01) ||| wanting”. The algorithm (described in section 2.2) will choose the most suitable one from the rule set. It is similar to most MT systems in creating a translation candidate for each word, besides normal translation rules. It is easy to guarantee that the rule set can fully cover every input AMR graph.

Some concepts (such as “have-rel-role-91”) in an AMR graph do not contribute to the final translation, and we skip them when generating concept rules. Besides that, we use a verbalization list[2] for concept rule generation. For rule “VERBALIZE peacekeeping TO keep-01 :ARG1 peace”, we will create a concept rule “(k/keep-01 :ARG1 (p/peace)) ||| peacekeeping” if the left-hand-side fragment appears in the target graph.

[1] Our code for grammar induction can be downloaded from https://github.com/xiaochang13/AMR-generation

[2] http://amr.isi.edu/download/lists/verbalization-list-v1.06.txt

2.4 Traveling cost

Considering an AGTSP graph whose nodes are clustered into m groups, we define the traveling cost for a tour T in Equation 1:

$$\text{cost}(n_s, n_e) = -\sum_{i=0}^{m} \log p(\text{“yes”}|n_{T_i}, n_{T_{i+1}}) \quad (1)$$

where $n_{T_0} = n_s$, $n_{T_{m+1}} = n_e$ and each n_{T_i} ($i \in [1 \dots m]$) belongs to a group that is different from all others. Here $p(\text{“yes”}|n_j, n_i)$ represents a learned score for a move from n_j to n_i. The choices before n_{T_i} are independent from choosing $n_{T_{i+1}}$ given n_{T_i} because of the Markovian property of the TSP problem. Previous methods (Zaslavskiy et al., 2009) evaluate traveling costs $p(n_{T_{i+1}}|n_{T_i})$ by using a language model. Inevitably some rules may only cover one translation word, making only bigram language models naturally applicable. Zaslavskiy et al. (2009) introduces a method for incorporating a trigram language model. However, as a result, the number of nodes in the AGTSP graph grows exponentially.

To tackle the problem, we treat it as a *local* binary (“yes” or “no”) classification problem whether we should move to n_j from n_i. We train a maximum entropy model, where $p(\text{“yes”}|n_i, n_j)$ is defined as:

$$p(\text{“yes”}|n_i, n_j) = \frac{1}{Z(n_i, n_j)} \exp\Big[\sum_{i=1}^{k} \lambda_i f_i(\text{“yes”}, n_i, n_j)\Big] \quad (2)$$

The model uses 3 real-valued features: a language model score, the word count of the concatenated translation from n_i to n_j, and the length of the shortest path from n_i's root to n_j's root in the input AMR. If either n_i or n_j is the start or end node, we set the path length to 0. Using this model, we can use whatever N-gram we have at each time. Although language models favor shorter translations, word count will balance the effect, which is similar to MT systems. The length of the shortest path is used as a feature because the concepts whose translations are adjacent usually have lower path length than others.

3 Experiments

3.1 Setup

We use the dataset of SemEval-2016 Task8 (Meaning Representation Parsing), which contains 16833 training instances, 1368 dev instances and 1371 test instances. Each instance consists of an AMR graph and a sentence representing the same meaning. Rules are extracted from the training data, and hyperparameters are tuned on the dev set. For tuning and testing, we filter out sentences that have more than 30 words, resulting in 1103 dev instances and 1055 test instances. We train a 4-gram language model (LM) with gigaword (LDC2011T07), and use BLEU (Papineni et al., 2002) as the evaluation metric. To solve the AGTSP, we use Or-tool[3].

System	Dev	Test
PBMT	13.13	16.94
OnlyConceptRule	13.15	14.93
OnlyInducedRule	17.68	18.09
OnlyBigramLM	17.19	17.75
All	21.12	22.44
JAMR-gen	**23.00**	**23.00**

Table 1: Main results.

Our graph-to-string rules are reminiscent of phrase-to-string rules in phrase-based MT (PBMT). We compare our system to a baseline (*PBMT*) that first linearizes the input AMR graph by breadth first traversal, and then adopts the PBMT system from Moses[4] to translate the linearized AMR into a sentence. To traverse the children of an AMR concept, we use the original order in the text file. The MT system is trained with the default setting on the same dataset and LM. We also compare with *JAMR-gen*[5] (Flanigan et al., 2016), which is trained on the same dataset but with a 5-gram LM from gigaword (LDC2011T07).

To evaluate the importance of each module in our system, we develop the following baselines: *OnlyConceptRule* uses only the concept rules, *OnlyInducedRule* uses only the rules induced from the fragment decomposition forest, *OnlyBigramLM* uses both types of rules, but the traveling cost is evaluated by a bigram LM trained with gigaword.

3.2 Results

The results are shown in Table 1. Our method (*All*) significantly outperforms the baseline (*PBMT*)

JAMR-gen: boys want the girl to believe

Table 2: Case study.

on both the dev and test sets. *PBMT* does not outperform *OnlyBigramLM* and *OnlyInducedRule*, demonstrating that our rule induction algorithm is effective. We consider rooted and connected fragments from the AMR graph, and the TSP solver finds better solutions than beam search, as consistent with Zaslavskiy et al. (2009). In addition, *OnlyInducedRule* is significantly better than *OnlyConceptRule*, showing the importance of induced rules on performance. This also confirms the reason that *All* outperforms *PBMT*. This result confirms our expectation that concept rules, which are used for fulfilling the coverage of an input AMR graph in case of OOV, are generally not of high quality. Moreover, *All* outperforms *OnlyBigramLM* showing that our maximum entropy model is stronger than a bigram language model. Finally, *JAMR-gen* outperforms *All*, while *JAMR-gen* uses a higher order language model than *All* (5-gram VS 4-gram).

For rule coverage, around 31% AMR graphs and 84% concepts in the development set are covered by our induced rules extracted from the training set.

3.3 Analysis and Discussions

We further analyze *All* and *JAMR-gen* with an example AMR and show the AMR graph, the reference, and results in Table 2. First of all, both *All* and *JAMR-gen* outputs a reasonable translation containing most of the meaning from the AMR. On the other hand, *All* fails to recognize "boy" as the subject. The reason is that the feature set does not include edge labels, such as "ARG0" and "ARG1". Finally, neither *All* and *JAMR-gen* can handle the situation when a re-entrance node (such as "b/boy" in example graph of Table 2) need to be translated twice. This limitation exists for both works.

4 Related Work

Our work is related to prior work on AMR (Banarescu et al., 2013). There has been a list of work on AMR parsing (Flanigan et al., 2014; Wang et al., 2015; Peng et al., 2015; Vanderwende et al., 2015; Pust et al., 2015; Artzi et al., 2015), which predicts the AMR structures for a given sentence. On the reverse direction, Flanigan et al. (2016) and our work here study sentence generation from a given AMR graph. Different from Flanigan et al. (2016) who map a input AMR graph into a tree before linearization, we apply synchronous rules consisting of AMR graph fragments and text to directly transfer a AMR graph into a sentence. In addition to AMR parsing and generation, there has also been work using AMR as a semantic representation in machine translation (Jones et al., 2012).

Our work also belongs to the task of text generation (Reiter and Dale, 1997). There has been work on generating natural language text from a bag of words (Wan et al., 2009; Zhang and Clark, 2015), surface syntactic trees (Zhang, 2013; Song et al., 2014), deep semantic graphs (Bohnet et al., 2010) and logical forms (White, 2004; White and Rajkumar, 2009). We are among the first to investigate generation from AMR, which is a different type of semantic representation.

5 Conclusion

In conclusion, we showed that a TSP solver with a few real-valued features can be useful for AMR-to-text generation. Our method is based on a set of graph to string rules, yet significantly better than a PBMT-based baseline. This shows that our rule induction algorithm is effective and that the TSP solver finds better solutions than beam search.

Abstract

In this paper, we investigate case restoration for text without case information. Previous such work operates at the word level. We propose an approach using character-level recurrent neural networks (RNN), which performs competitively compared to language modeling and conditional random fields (CRF) approaches. We further provide quantitative and qualitative analysis on how RNN helps improve truecasing.

1 Introduction

Natural language texts (e.g., automatic speech transcripts or social media data) often come in non-standard forms, and normalization would typically improve the performance of downstream natural language processing (NLP) applications. This paper investigates a particular sub-task in text normalization: case restoration or *truecasing*. Truecasing refers to the task of restoring case information (uppercase or lowercase) of characters in a text corpus. Case information is important for certain NLP tasks. For example, Chieu and Ng (2002) used unlabeled mixed case text to improve named entity recognition (NER) on uppercase text.

The task often presents ambiguity: consider the word "apple" in the sentences "he bought an apple" and "he works at apple". While the former refers to a fruit (hence, it should be in lowercase), the latter refers to a company name (hence, it should be capitalized). Moreover, we often need to recover the case information for words that are previously unseen by the system.

In this paper, we propose the use of character-level recurrent neural networks for truecasing. Previous approaches for truecasing are based on word level approaches which assign to each word one of the following labels: all lowercase, all uppercase, initial capital, and mixed case. For mixed case words, an additional effort has to be made to decipher exactly how the case is mixed (e.g., *MacKenzie*). In our approach, we propose a generative, character-based recurrent neural network (RNN) model, allowing us to predict exactly how cases are mixed in such words.

Our main contributions are: (i) we show that character-level approaches are viable compared to word-level approaches, (ii) we show that character-level RNN has a competitive performance compared to character-level CRF, and (iii) we provide our quantitative and qualitative analysis on how RNN helps improve truecasing.

2 Related Work

Word-based truecasing The most widely used approach works at the word level. The simplest approach converts each word to its most frequently seen form in the training data. One popular approach uses HMM-based tagging with an N-gram language model, such as in (Lita et al., 2003; Nebhi et al., 2015). Others used a discriminative tagger, such as MEMM (Chelba and Acero, 2006) or CRF (Wang et al., 2006). Another approach uses statistical machine translation to translate uncased text into a cased one. Interestingly, no previous work operated at the character level. Nebhi et al. (2015) investigated truecasing in tweets, where truecased cor-

pora are less available.

Recurrent neural networks Recent years have shown a resurgence of interest in RNN, particularly variants with long short-term memory (Hochreiter and Schmidhuber, 1997) or gated recurrent units (Cho et al., 2014). RNN has shown an impressive performance in various NLP tasks, such as machine translation (Cho et al., 2014; Luong et al., 2015), language modeling (Mikolov et al., 2010; Kim et al., 2016), and constituency parsing (Vinyals et al., 2015). Nonetheless, understanding the mechanism behind the successful applications of RNN is rarely studied. In this work, we take a closer look at our trained model to interpret its internal mechanism.

3 The Truecasing Systems

In this section, we describe the truecasing systems that we develop for our empirical study.

3.1 Word-Level Approach

A word-level approach truecases one word at a time. The first system is a tagger based on HMM (Stolcke, 2002) that translates an uncased sequence of words to a corresponding cased sequence. An N-gram language model trained on a cased corpus is used for scoring candidate sequences. For decoding, the Viterbi algorithm (Rabiner, 1989) computes the highest scoring sequence.

The second approach is a discriminative classifier based on linear chain CRF (Lafferty et al., 2001). In this approach, truecasing is treated as a sequence labeling task, labelling each word with one of the following labels: all lowercase, all uppercase, initial capital, and mixed case. For our experiments, we used the truecaser in Stanford's NLP pipeline (Manning et al., 2014). Their model includes a rich set of features (Finkel et al., 2005), such as surrounding words, character N-grams, word shape, etc.

Dealing with mixed case Both approaches require a separate treatment for mixed case words. In particular, we need a gazetteer that maps each word to its mixed case form – either manually created or statistically collected from training data. The character-level approach is motivated by this: Instead of treating them as a special case, we train our model to capitalize a word character by character.

3.2 Character-Level Approach

A character-level approach converts each character to either uppercase or lowercase. In this approach, mixed case forms are naturally taken care of, and moreover, such models would generalize better to unseen words. Our third system is a linear chain CRF that makes character-level predictions. Similar to the word-based CRF, it includes surrounding words and character N-grams as features.

Finally, we propose a character-level approach using an RNN language model. RNN is particularly useful for modeling sequential data. At each time step t, it takes an input vector x_t and previous hidden state h_{t-1}, and produces the next hidden state h_t. Different recurrence formulations lead to different RNN models, which we will describe below.

Long short-term memory (LSTM) is an architecture proposed by Hochreiter and Schmidhuber (1997). It augments an RNN with a memory cell vector c_t in order to address learning long range dependencies. The content of the memory cell is updated additively, mitigating the *vanishing gradient problem* in vanilla RNNs (Bengio et al., 1994). Read, write, and reset operations to the memory cell are controlled by input gate i, output gate o, and forget gate f. The hidden state is computed as:

$$
\begin{aligned}
i_t &= \sigma(W_i h_{t-1} + U_i x_t) && (1)\\
o_t &= \sigma(W_o h_{t-1} + U_o x_t) && (2)\\
f_t &= \sigma(W_f h_{t-1} + U_f x_t) && (3)\\
g_t &= \tanh(W_g h_{t-1} + U_g x_t) && (4)\\
c_t &= f_t \odot c_{t-1} + i_t \odot g_t && (5)\\
h_t &= o_t \odot \tanh(c_t) && (6)
\end{aligned}
$$

where σ and tanh are element-wise sigmoid and hyperbolic tangent functions, and W_j and U_j are parameters of the LSTM for $j \in \{i, o, f, g\}$.

Gated recurrent unit (GRU) is a gating mechanism in RNN that was introduced by Cho et al. (2014). They proposed a hidden state computation with reset and update gates, resulting in a simpler LSTM variant:

$$
\begin{aligned}
r_t &= \sigma(W_r h_{t-1} + U_r x_t) && (7)\\
z_t &= \sigma(W_z h_{t-1} + U_z x_t) && (8)\\
\widetilde{h}_t &= \tanh(W_h(r_t \odot h_{t-1}) + U_h x_t) && (9)\\
h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \widetilde{h}_t && (10)
\end{aligned}
$$

Table 2: Truecasing performance in terms of precision (P), recall (R), and F_1. All improvements of the best performing character-based systems (**bold**) over the best performing word-based systems (underlined) are statistically significant using sign test ($p < 0.01$). All improvements of the best performing RNN systems (*italicized*) over CRF-CHAR are statistically significant using sign test ($p < 0.01$).

At each time step, the conditional probability distribution over next characters is computed by linear projection of h_t followed by a softmax:

$$P(x_t = k|x_{1:t-1}) = \frac{\exp(w_k h_t)}{\sum_{j=1}^{|V|} \exp(w_j h_t)} \quad (11)$$

where w_k is the k-th row vector of a weight matrix W. The probability of a sequence of characters $x_{1:T}$ is defined as:

$$P(x_{1:T}) = \prod_{t=1}^{T} P(x_t|x_{1:t-1}) \quad (12)$$

Similar to the N-gram language modeling approach we described previously, we need to maximize Equation 12 in order to decode the most probable cased sequence. Instead of Viterbi decoding, we approximate this using a beam search.

4 Experiments and Results

4.1 Datasets and Tools

Our approach is evaluated on English and German datasets. For English, we use a Wikipedia corpus from (Coster and Kauchak, 2011), WSJ corpus (Paul and Baker, 1992), and the Reuters corpus from the CoNLL-2003 shared task on named entity recognition (Tjong Kim Sang and De Meulder, 2003). For German, we use the ECI Multilingual Text Corpus from the same shared task. Each corpus is tokenized.[1] The input test data is lowercased. Table 1 shows the statistics of each corpus split into training, development, and test sets.

We use SRILM (Stolcke, 2002) for N-gram language model training ($N \in \{3, 5\}$) and HMM decoding. The word-based CRF models are trained using the CRF implementation in Stanford's CoreNLP 3.6.0 (Finkel et al., 2005). We use a recommended configuration for training the truecaser.We use CRFSuite version 0.12 (Okazaki, 2007) to train the character-based CRF model. Our feature set includes character N-grams ($N \in \{1, 2, 3\}$) and word N-grams ($N \in \{1, 2\}$) surrounding the current character. We tune the ℓ_2 regularization parameter λ using a grid search where $\lambda \in \{0.01, 0.1, 1, 10\}$.

DE-ECI	train	2.8M	18M
	dev	51K	329K
	test	52K	327K

Table 1: Statistics of the data.

We use an open-source character RNN implementation.[2] We train a SMALL model with 2 layers and 300 hidden nodes, and a LARGE model with 3 layers and 700 hidden nodes. We also vary the hidden unit type (LSTM/GRU). The network is trained using truncated backpropagation for 50 time steps. We use a mini-batch stochastic gradient descent with batch size 100 and RMSprop update (Tieleman and Hinton, 2012). We use dropout regularization (Srivastava et al., 2014) with 0.25 probability. We choose the model with the smallest validation loss after 30 epochs. For decoding, we set beam size to 10. The experimental settings are reported in more depth in the supplementary materials. Our system and code are publicly available at `http://statnlp.org/research/ta/`.

Figure 1: Cells that are sensitive to lowercased and capitalized words. Text color represents activations ($-1 \leq \tanh(c_t) \leq 1$): positive is blue, negative is red. Darker color corresponds to greater magnitude.

4.2 Results

Table 2 shows the experiment results in terms of precision, recall, and F_1. Most previous work did not evaluate their approaches on the same dataset. We compare our work to (Chelba and Acero, 2006) using the same WSJ sections for training and evaluation on 2M word training data. Chelba and Acero only reported error rate, and all our RNN and CRF approaches outperform their results in terms of error rate.

First, the word-based CRF approach gives up to 8% relative F_1 increase over the LM approach. Other than WSJ, moving to character level further improves CRF by 1.1-3.7%, most notably on the German dataset. Long compound nouns are common in the German language, which generates many out-of-vocabulary words. Thus, we hypothesize that character-based approach improves generalization. Finally, the best F_1 score for each dataset is achieved by the RNN variants: 93.19% on EN-Wiki, 92.43% on EN-WSJ, 93.79% on EN-Reuters, and 98.01% on DE-ECI.

We highlight that different features are used in CRF-WORD and CRF-CHAR. CRF-CHAR only includes simple features, namely character and word N-grams and sentence boundary indicators. In contrast, CRF-WORD contains a richer feature set that is predefined in Stanford's truecaser. For instance, it includes word shape, in addition to neighboring words and character N-grams. It also includes more feature combinations, such as the concatenation of the word shape, current label, and previous label. Nonetheless, CRF-CHAR generally performs better than CRF-WORD. Potentially, CRF-CHAR can be improved further by using larger N-grams. The decision to use simple features is for optimizing the training speed. Consequently, we are able to dedicate more time for tuning the regularization weight.

Training a larger RNN model generally improves performance, but it is not always the case due to possible overfitting. LSTM seems to work better than GRU in this task. The GRU models have 25% less parameters. In terms of training time, it took 12 hours to train the largest RNN model on a single Titan X GPU. For comparison, the longest training time for a single CRF-CHAR model is 16 hours. Training LM and CRF-WORD is much faster: 30 seconds and 5.5 hours, respectively, so there is a speed-accuracy trade-off.

5 Analysis

5.1 Visualizing LSTM Cells

An interesting component of LSTM is its memory cells, which is supposed to store long range dependency information. Many of these memory cells are not human-interpretable, but after introspecting our trained model, we find a few memory cells that are sensitive to case information. In Figure 1, we plot the memory cell activations at each time step (i.e., $\tanh(c_t)$). We can see that these cells activate differently depending on the case information of a word (towards -1 for uppercase and +1 for lowercase).

5.2 Case Category and OOV Performance

Corpus	Lower	Cap.	Upper	Mixed	OOV
EN-Wiki	79.91	18.67	0.91	0.51	2.40
EN-WSJ	84.28	13.06	2.63	0.03	3.11
EN-Reuters	78.36	19.80	1.53	0.31	5.37
DE-ECI	68.62	29.15	1.02	1.21	4.01

Table 3: Percentage distribution of the case categories and OOV words

In this section, we analyze the system performance on each case category. First, we report the percentage distribution of the case categories in each test set in Table 3. For both languages, the most frequent case category is lowercase, followed by capitalization, which generally applies to the first word

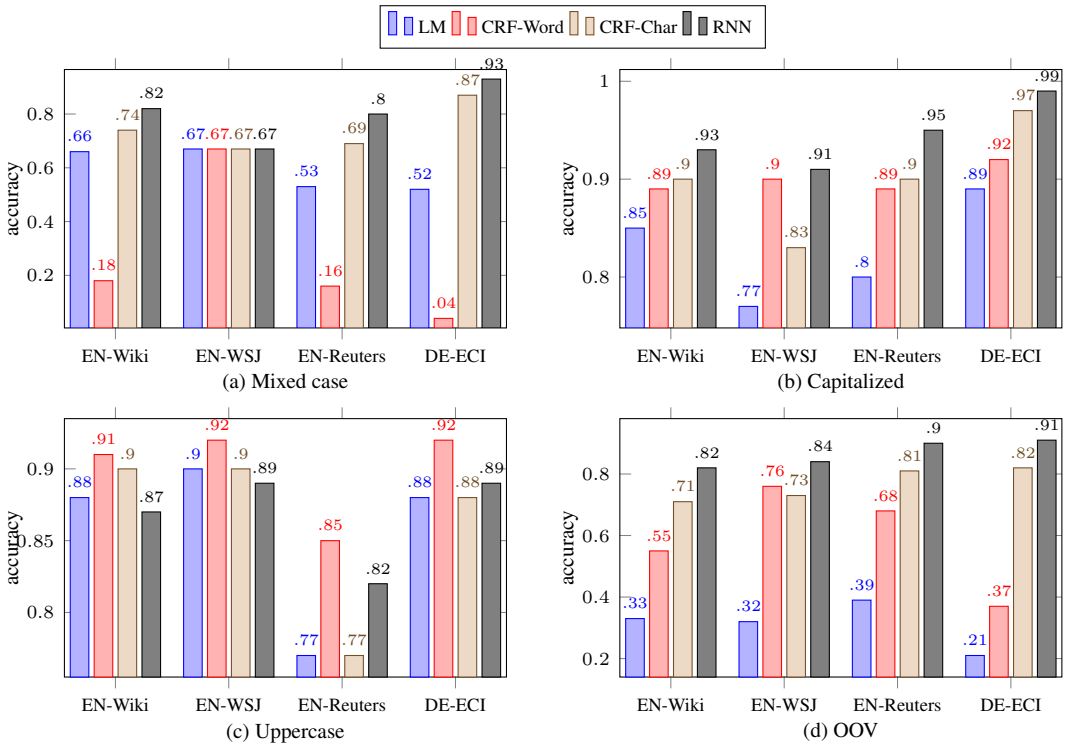

Figure 2: Accuracy on mixed case (a), capitalized (b), uppercase (c), and OOV words (d).

in the sentence and proper nouns. The uppercase form, which is often found in abbreviations, occurs more frequently than mixed case for English, but the other way around for German.

Figure 2 (a) shows system accuracy on mixed case words. We choose the best performing LM and RNN for each dataset. Character-based approaches have a better performance on mixed case words than word-based approaches, and RNN generally performs better than CRF. In CRF-WORD, surface forms are generated after label prediction. This is more rigid compared to LM, where the surface forms are considered during decoding.

In addition, we report system accuracy on capitalized words (first letter uppercase) and uppercase words in Figure 2 (b) and (c), respectively. RNN performs the best on capitalized words. On the other hand, CRF-WORD performs the best on uppercase. We believe this is related to the rare occurrences of uppercase words during training, as shown in Table 3. Although mixed case occurs more rarely in general, there are important clues, such as character prefix. CRF-CHAR and RNN have comparable performance on uppercase. For instance, there are only 2 uppercase words in WSJ that were predicted differently between CRF-CHAR and RNN. All systems perform equally well (∼99% accuracy) on lowercase. Overall, RNN has the best performance.

Last, we present results on out-of-vocabulary (OOV) words with respect to the training set. The statistics of OOV words is given in Table 3. The system performance across datasets is reported in Figure 2 (d). We observe that RNN consistently performs better than the other systems, which shows that it generalizes better to unseen words.

6 Conclusion

In this work, we conduct an empirical investigation of truecasing approaches. We have shown that character-level approaches work well for truecasing, and that RNN performs competitively compared to language modeling and CRF. Future work includes applications in informal texts, such as tweets and short messages (Muis and Lu, 2016).

Abstract

This study measures the effects of Federal Open Market Committee text content on the direction of short- and medium-term interest rate movements. Because the words relevant to short- and medium-term interest rates differ, we apply a supervised approach to learn distinct sets of topics for each dependent variable being examined. We generate predictions with and without controlling for factors relevant to interest rate movements, and our prediction results average across multiple training-test splits. Using data from 1999-2016, we achieve 93% and 64% accuracy in predicting Target and Effective Federal Funds Rate movements and 38%-40% accuracy in predicting longer term Treasury Rate movements. We obtain lower but comparable accuracies after controlling for other macroeconomic and market factors.

1 Introduction

This study uses the verbal content of Federal Open Market Committee (FOMC) public communications to predict the directions of interest rate movements on the days those communications are released. The FOMC, who determines government policies relevant to interest rates, meets roughly eight times a year and releases a statement after each meeting. The FOMC is known to be an important mover of markets, and economic research has found that equity and interest rate markets tend to move when FOMC communications are released (Farka and Fleissig, 2012; Gürkaynak *et al.*, 2005; Mueller, 2015; Rosa, 2011) that the policy actions alone do not explain these responses (and thus the content of the text must be responsible) (Gürkaynak *et al.*, 2005), and that the directions of market movements coincide with a human-coded measure of the sentiment expressed in the texts (Rosa, 2011). Writers in the finance industry and in the popular press have also examined word clouds of FOMC minutes (Cofnas, 2010; Durden, 2011) and have discussed the market implications of the total number of words included in FOMC minutes (Fitz-gerald, 2014; Kennedy, 2014; Wynne, 2013).

A growing body of research applies NLP methods to understand the market effects from the contents of these texts. Researchers have applied Latent Semantic Analysis (LSA) to describe the key topics covered in FOMC minutes, obtaining insights into the FOMC's deliberation process (Hansen *et al.*, 2015; Fligstein *et al.*, 2014; Schonhardt, 2013). Additionally, researchers have used NLP-derived measures of the content of FOMC minutes to predict equity and interest rate volatilities; (Boukus and Rosenberg, 2006) use LSA-defined topics in a regression context, and (Zadeh and Zollman, 2009) apply a dependency-based measure of text content to an expert-classified set of financially relevant words and then use both regression and SVM to predict volatility. Papers have found temporary effects of the sentiments from company-specific news articles and message board postings on stock prices and volatility, company earnings, and trading volumes, using dictionary-based sentiment measures (Davis *et al.*, 2012; Tetlock, 2007; Tetlock *et al.*, 2007; Tetlock, 2011) as well as sentiment measures that are trained on a human-classified subsample (Antweiler

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2096–2102,
Austin, Texas, November 1-5, 2016.

and Frank, 2004, 2006; Das and Chen, 2007).[1] Studies have found temporary effects even when information is "stale" (Tetlock, 2011) and also that short-sales precede negative news (Fox *et al.*, 2009/2010). Researchers also find that the readability of corporate filings is positively associated with earnings and the precision of analysts' forecasts about the company (Li, 2008; Lehavy *et al.*, 2011).

The current study builds upon this literature by examining a somewhat different question than previous researchers do and by applying a different set of techniques that are particularly well-suited for measuring the market effects of texts. Rather than examine the texts' effects on *volatility*, which increases in response to both positive and negative sentiments, we predict the *direction* in which interest rates move, which is the focus of market participants as well as the FOMC texts themselves.[2] The question we ask is also somewhat different than that examined in the literature because we analyze the relatively short FOMC statements that are released immediately following the meetings—and contain the key market-moving content (Gürkaynak *et al.*, 2005; Mueller, 2015)—rather than on the lengthier minutes that have more text to analyze but are only released after the key information from the statements has been available for three weeks.

In addition to making contributions specific to our application, this study highlights methods that are particularly useful for measuring the market effects of text content. FOMC communications are known to provide distinct information about short- versus medium- or long-term policies (Gürkaynak *et al.*, 2005). We consequently use MedLDA (Zhu *et al*, 2009), a supervised topic model, to learn separately the sets of words that are most predictive of movements in short- and medium-term interest rates[3] Through this supervised topic model, we generate topics, based upon context (which words appear together) as well as co-movement with the outcome variables being studied. Hence, the varies depending upon which dependent variable is being considered. Second, we address possible bias from one important set of omitted variables—releases of macroeconomic data, as discussed by (Rosa, 2011)—by estimating specifications in which we control for those factors separately and predict whether interest rates moved more or less than would be expected based upon the latest data on the macroeconomic environment. By examining an immediate market response to the publication of text and controlling for potential confounding factors, this study demonstrates one way in which NLP approaches, in addition to their value in classifying text content, can be applied to estimate statements' causal effects. We control for the effects of macroeconomic data and time-specific factors like day-of-week effects and time trends using only observations from non-FOMC dates, so that we do not lose degrees of freedom in our estimation. Third, unlike Boukus and Rosenberg (2006) and Hendry and Madeley (2010) but similarly to Zadeh and Zollman (2009), we split the sample into training and test sets in order to limit overfitting in our predicted values. Zadeh and Zollman (2009) use data from 1967-2000 as a training set, and then they test their model on data from 2001-2008. Given the importance of context in predicting interest rate movements, we instead restrict our sample to observations from meetings from May 1999 to May 2016[4]. Because autocorrelation in our dependent variables is relatively limited, we treat the observations as independent and, among observations in our sample, average our test performance across multiple training-test splits.

2 Market Effects of Text Content

2.1 Overview of Text Content

FOMC statements contain information about many aspects of the economy, including interest rates, the money supply, inflation, unemployment, and economic growth. These communications are highly repetitive, often containing nearly identical sentences and sentence structures from previous meet-

[1] While not examining market data, (Chua *et al.*, 2009) also examines the problem of classifying sentiment in message board postings.

[2] A related study has applied LDA to measure the impacts on returns and volatility of communications from the Bank of Canada (Hendry and Madeley, 2010).

[3] Other classification methods that we attempted but found to be less effective include regression of rate movements on word count, logit estimation on the frequencies of the most common words, and k-nearest neighbor estimation using a word2vec similarity measure (Mikolov, 2013).

[4] May 1999 was the date of the last major redesign of the FOMC statements

ings. Slight changes in the wordings are known to have major effects on markets (Gürkaynak *et al.*, 2005).

Pre-processing of text: In order to convert the text into a format that can be easily processed, we perform several cleaning operations to the texts. Non-alphabetic characters are removed, and the texts are converted to lower case. Each document is separated into a bag of words, and common words (*e.g.,* mr and federal) and stop words are deleted using the stopwords list from nltk.corpus in Python. Words are stemmed using the Porter stemming algorithm (stem from stemming.porter2 in Python), and one-letter words are dropped.

2.2 MedLDA

LDA (Latent Dirichlet Allocation) (Blei *et al.*, 2003) is an unsupervised model, whereas supervised topic model (sLDA) (Blei and McAuliffe, 2007) introduces a response variable to LDA for each document. Max-Entropy Discrimination LDA (MedLDA) (Zhu *et al*, 2009) is max-margin variant of the supervised topic models. MedLDA can be built for both regression and classification prediction tasks. In this study we employed the model built for classification task. For classification, the response variables y are discrete having values $\{1, 0, -1\}$ denoting the movements of the interest rates. Hence, we consider the multi-class classification version of the MedLDA. It is defined based on a Support Vector Machine (SVM), which integrates the max-margin principle with an underlying LDA model for topics. Formally, the probabiltiies associated with max-entropy discrimination topic models (MedTM) can be generally defined as:

$$min_d \mathcal{L}(q(H)) + KL(q(\Gamma)||p_p(\Gamma)) + U(\xi) \quad (1)$$

where H are hidden variables (e.g., (θ, z) in LDA); are the parameters of the model pertaining to the prediction task (e.g., η in sLDA); Γ are the parameters of the underlying topic model (e.g., the Dirichlet parameter α); and L is a variational upper bound of the negative log likelihood associated with the underlying topic model. U is a convex function over slack variables. For the general MedTM model, we can develop a similar variational EM-algorithm as for the MedLDA.

We apply the MedLDA model on the FOMC documents and considering the interest rates as the response variables (y) to compute topics that are closely related to variations in the interest rates. Eventually these topics are used to classify changes in the rates using the max-margin classifier embedded in the MedLDA model.

2.3 Controlling for Macroeconomic Information

In addition to these text-based data, we supply our classifier with "control" variables describing the latest releases of macroeconomic variables. The macroeconomic data considered in this analysis are three of the most important measures of US economic health: the Consumer Price Index (CPI) used to measure inflation, Unemployment, and real annualized growth in the US Gross Domestic Product (GDP). The values for all three of these statistics are publicly released on a monthly basis. The CPI and Unemployment numbers are measured on a monthly basis and are typically not updated from their initially released values. The CPI data are typically released between 15 and 20 days after the end of the month, and the Unemployment data are typically released 6 to 10 days after the end of the month. GDP is measured on a quarterly basis, and three estimates are provided: "advance," "preliminary" or "second," and "final" or "third," which are released about one, two, and three months after the end of the quarter, respectively. The final GDP numbers are occasionally revised in later releases. Our release date data and some of the macroeconomic statistics were obtained from direct requests to the U.S. Bureau of Economic Analysis (B. of Econ. An. (a), 2015; B. of Econ. An. (b), 2015) and the U.S. Bureau of Labor Stats (B. of Lab. Stat. (a), 2015; B. of Lab. Stat. (d), 2009). Additional data on the GDP and unemployment numbers released were obtained from public sources (Econ. Anal. (c), 1989; Fed. Res. (a), 15).

If macroeconomic information is released on the same day as an FOMC communication, it is possible that this release could influence both the content of the FOMC statement as well as the interest rate movements that day. To avoid that possibility, we implement a modified MedLDA approach using a dependent variable that is "purged" of these potentially confounding influences. In some of our speci-

Table 1: Accuracy of Medlda Classifier after purging out of control for statements between 1999 and May, 2016 [K (topics) = 20]

Outcome variable	MedLDA			Baseline (Random Chance)[5]		
	None	Linear	Interactions	None	Linear	Interactions
Target Fed Funds Rate	0.9321	0.9160	0.8954	0.6849	0.6849	0.6849
Effective Fed Funds Rate	0.6421	0.4479	0.5112	0.4589	0.4658	0.4658
Median Treasury Rate	0.4209	0.3803	0.4012	0.4589	0.4247	0.4247
Average Treasury Rate	0.3803	0.4611	0.3924	0.4726	0.4041	0.4041

fications, we first regress the interest rate movements of interest on these macroeconomic indicators. Our main set of controls includes the latest values for the most recent two values of the unemployment rate, GDP growth rate, and CPI inflation rate and their changes, a daily time trend, and year, month, and day-of-the-week dummies. Some specifications use this set, and others add the full set of two-way interactions across these different variables. For both the main and the interacted set, we regress the change in the rate of interest on the full set of controls for the full set of non-FOMC dates from May 1999 through May 2016. Hence, we estimate the relationship between interest rate movements and the releases of macroeconomic data using dates in which FOMC statements or minutes were not released. Using the coefficients from these regressions, we generate residuals of interest rate movements for the FOMC dates and then create indicators for whether the residual was positive or negative for that interest rate movement on that FOMC date.

3 Empirical Results

We randomly split the data, containing 146 data points (FOMC statements and corresponding movements in the interest rates from May 1999 through May 2016) into a a 80-20% train-test set split to compute the accuracy of the model to predict the movement. For each experiment, we varied the number of topics (K) to see which value of K is giving the best accuracy. In most cases, the best accuracy is given by $K = 20$. The results presented in Table 1 shows the average accuracies of predicting the movements of the interest rates after purging the outcome variables out of control. The presented accuracies are the results of 20 fold validation. When no controls are used, our accuracy is 93% and 64% for the Target and Effective Federal Funds Rates (both better than random chance) and 42% and 38% for the Median and Average Treasury Rates[6] The specifications with control variables have similar but somewhat lower accuracy rates. Hence, our text-mining approach is comparable in effectiveness at measuring whether interest rates moved more or less than expected, after controlling for the economic environment, than it is at predicting the raw directions of movement. MedLDA model is compared against a simple baseline. The baseline is the accuracy, if the interest rate movements are randomly guessed from the prior distribution of each of the interest rates under the different controls. For the Target and Effective rates, the MedLDA model outperforms the baseline with a great margin and for the Median and Average rate, the performance is slightly poorer.

The high target rate prediction accuracy suggests that the MedLDA model can effectively associate the text contents of the meetings with the movements in the rate, even though the numeric values are dropped from the text. Similar arguments can be applied to the effective rate prediction. On the other hand, treasury rates are not directly connected to the text of the FOMC statements, so the factors influencing these rates are not present or mentioned in the text. Thus, to have a better prediction accuracies for these variables information from other sources are necessary which is beyond the scope of this paper. However, the present FOMC meeting might give an indication to future FOMC plans and thus, to the

[5]Our random chance baseline is a classifier that always selects the most likely of the three outcomes (increase, decrease, or no change) based upon their frequencies in the full dataset.

[6]Median Treasury Rate is the median of the -1, 0, and 1 classifications among the movements of the 3m, 1y, 3y, 5y, and 10y Treasury Rates. Average Treasury Rate is the -1/0/1 classification of the average of those rates.

treasury rates. Hence, the prediction accuracies are not much worse than the baseline.

4 Conclusion

This study measures the effects of text-based information released by the FOMC on daily interest rate movements. We used the medLDA model on a set of 146 docs and obtain accuracies of 93% and 64% in predicting the Federal Funds Target Rate and the Effective Rate.

Learning to refine text based recommendations

Youyang Gu and **Tao Lei** and **Regina Barzilay** and **Tommi Jaakkola**

Massachusetts Institute of Technology
{yygu,taolei,regina,tommi}@csail.mit.edu

Abstract

We propose a text-based recommendation engine that utilizes recurrent neural networks to flexibly map textual input into continuous vector representations tailored to the recommendation task. Here, the text objects are documents such as Wikipedia articles or question and answer pairs. As neural models require substantial training time, we introduce a sequential component so as to quickly adjust the learned metric over objects as additional evidence accrues. We evaluate the approach on recommending Wikipedia descriptions of ingredients to their associated product categories. We also exemplify the sequential metric adjustment on retrieving similar Stack Exchange AskUbuntu questions. [1]

1 Introduction

Modern recommender problems involve complex objects, often described in textual form. In order to learn to predict how disparate objects may go together, it is helpful to first map them into a common representation where they are easily compared, regardless of their origin. Neural models are particularly well-suited for this task as continuous vector representations of objects can be tailored in a flexible way to the desired task. While these models have been shown to be effective across NLP tasks (Sutskever et al., 2014; Andreas et al., 2016; Hermann et al., 2015), they take considerable time to learn and are therefore ill-suited to be adjusted rapidly as additional evidence accumulates.

We cast our text-to-text recommendation problem in two phases. In the first phase, flexible neural text-to-vector mappings are learned from currently available data. Such mappings are optimized to function well in a collaborative filtering setting. For example, in the context of recommending food product categories for ingredients based on their Wikipedia pages, the continuous vectors are adjusted so that their inner product directly reflects the degree of association between the objects. Once learned, the mapping can be applied to any previously unseen text to yield the corresponding vector representation, and therefore also used for predicting associations. In the second phase, we no longer adjust text-to-vector mappings but rather parameterize and learn how the vectors are compared. For example, we can optimize the metric separately for each new ingredient based on a few category observations for that ingredient. The goal of this second phase is to specifically boost the accuracy when the neural baseline (unaware of the new evidence) would otherwise not perform well.

Our approach builds on the recent work on recurrent convolutional models to obtain text-to-vector mappings (Lei et al., 2015; Lei et al., 2016). This architecture is particularly well suited for noisy Wikipedia pages as it can learn to omit and highlight different parts of the text, as needed. The additional sequential component is a regularized logistic regression model (for ingredient-product prediction) or a ranking model (for question retrieval). We demonstrate the accuracy of the baseline neural recommender and the gains from the second sequential phase in both of these tasks.

2 Related Work

A great deal of recent effort has gone into developing flexible neural models for text and their use across variety of NLP tasks. This includes building vector representations for sentences and documents (Le and Mikolov, 2014), convolutional neural network models of text (Collobert and Weston, 2008; Zhang and LeCun, 2015), non-consecutive variants of CNNs (Lei et al., 2015), and compositional architectures (Socher et al., 2013), among many others. Our work is most closely related to the use of such models for question retrieval (Lei et al., 2016) but differs, in particular, in terms of our two-phase collaborative filtering formulation and the ingredient mapping task from Wikipedia pages (cf.(Sutskever et al., 2011; Song and Roth, 2015)).

3 Recommender Problems

We explore two recommender problems in this work. In the first problem, we are given a food ingredient, and our goal is to predict which product categories it could appear in. Both ingredients and product categories are provided in terms of natural language descriptions via their associated Wikipedia pages. For example, if given "tomato", we would predict "canned foods" as one likely category for the ingredient. A small number of categories appear as targets for each ingredient.

We also consider the task of predicting questions that are similar to the one provided as a query. The purpose is to facilitate effective question answering by retrieving related past questions (and the associated answers that are available). For this we use Stack Exchange's AskUbuntu question retrieval dataset used in recent work (dos Santos et al., 2015; Lei et al., 2016)

4 Approach

We explain our approach in terms of the first task: predicting product categories from ingredients. Collaborative predictions are made by mapping each ingredient into a vector representation and comparing that representation with an analogous one for product categories. We train these vectors in an end-to-end manner to function well as part of the collaborative task. The vector representations are based on Wikipedia pages that are available for most ingredients and categories in our problem. Rather than derive the vector from the entire article (which can be long), we only use the top summary section. For the AskUbuntu question-answering dataset, we make use of both the title and the question body.

We use a recurrent neural network (RNN) model to map each text description into a vector representation. Our model builds on the recurrent convolutional neural network model of (Lei et al., 2016) used to train the AskUbuntu question representations. We describe below a modified version used for ingredient-product category prediction.

Let $v_\theta(x) \in \mathbb{R}^d$ be the parameterized RNN mapping of text x into a vector representation, where d is the dimension of the hidden representation. Let x_i and z_p be the Wikipedia pages for ingredient $i \in I$ and product category $p \in P$, respectively. We use the same parameters θ to generate the representations for both ingredients and product categories due to their overall similarity. Thus $v_\theta(x_i)$ is the vector representation for ingredient i and $v_\theta(z_p)$ is the vector representation for product category p for an RNN model with parameters θ. We train the RNN model to predict each association $Y_{ip} = 1$ as a binary prediction task, i.e.,

$$P(Y_{ip} = 1|\theta) = \sigma(v_\theta(z_p) \cdot v_\theta(x_i)), \qquad (1)$$

where σ is the sigmoid function $\sigma(t) = (1 + \exp(-t))^{-1}$. The formulation is akin to a binary collaborative filtering task where user/item feature vectors are produced by the RNN. The parameters θ can be learned by back-propagating log-likelihood of the binary 0/1 predictions back to θ.

4.1 Sequential learning

Our RNN model, once trained, will be able to map any new ingredient and product category (their text descriptions) into vectors, and make a binary prediction of whether the two go together. However, training the model takes considerable time and cannot be easily adjusted in the face of new evidence, e.g., a few positive and negative categories for a previously unseen ingredient. Since RNN features are global (affecting the mapping from text to features for all ingredients/products), it is not clear how the adjustments made in light of additional information about

a specific new ingredient will impact predictions for other ingredients. We propose a sequential approach that is instead local, tailored to the new ingredient.

In order to sequentially adjust the model predictions with new evidence, we introduce parameters $w = [w_1, \ldots, w_d], w_j \in \mathbb{R}^+$ that modify the comparison of ingredient and category vectors. Specifically, the association is predicted by

$$P(Y_{ip} = 1|\theta, w) = \sigma\{v_\theta(z_p)^T \text{diag}(w) v_\theta(x_i)\}, \quad (2)$$

where $\text{diag}(w)$ is a diagonal matrix with the entries specified by w. We assume that, at this stage, the RNN parameters θ and therefore the vector representations $v_\theta(z_p)$ and $v_\theta(x_i)$ are nonadjustable. We will only update weights w in response to each new observation, separately for each ingredient. The observations can both be positive ($Y = 1$) and negative ($Y = 0$).

Because we expect a new input may only have a small number of observations, it is important to properly regularize the weights as to avoid overfitting. We append the log-likelihood objective with a regularizer

$$reg(w) = \frac{\lambda}{2} \sum_{j=1}^{d} (w_j - 1)^2 \quad (3)$$

where λ is the overall regularization parameter. Note that for large values of λ, the regularizer keeps the parameters at the default values $w_j = 1$ corresponding to the baseline RNN collaborative predictions, unmodified by the new evidence.

In the context of predicting similar questions, we use a modified binary formulation where the goal is to classify each triplet of questions (x, z_1, z_2) in terms of whether z_1 is closer to the query than z_2. In this ranking model, the probability that z_1 is closer is given by

$$\sigma\Big((v_\theta(z_1) - v_\theta(z_2))^T \text{diag}(w) v_\theta(x)\Big), \quad (4)$$

The parameters w are again trained from observed additional triplet relations in the AskUbuntu dataset. The parameters w are regularized as in the ingredient-product category setup.

The sequential part can therefore be viewed as a content recommendation task which is tailored to the specific query (e.g., ingredient) using features from previously trained RNNs. It assumes additional feedback in order to adjust the feature comparison using the introduced weights w.

5 Experimental Setup and Results

Ingredients: We use the *FoodEssentials LabelAPI*[2] and *Rapid Alert System for Food and Feed (RASFF)*[3] databases to extract 5439 ingredients and the product categories they appear in. On average, each ingredient appears in 16.3 product categories (out of 131 categories). We leverage Mechanical Turk to link each ingredient to the appropriate Wikipedia article. From the 5439 ingredients, there are 1680 unique Wikipedia articles. Each ingredient summary description has a median of 169 tokens.

AskUbuntu: The dataset consists of 167k questions and 16k user-marked similar question pairs taking from a 2014 dump of AskUbuntu website.

5.1 Training, development, and test sets

Ingredients: We take the set of unique Wikipedia articles and randomly split them into training, development, and test sets (60/20/20). We then assign the ingredients to the appropriate data set based on their Wikipedia articles. This is to ensure that the articles of the ingredients used in the development and test sets are not seen in training.

AskUbuntu: We take 8000 human annotated question pairs as our development and test sets. There are 200 query questions in each set. Each query question is paired with 20 candidate questions which are annotated as similar or non-similar. We evaluate by ranking these candidate questions.

5.2 Sequential scenario

Ingredients: Let n be the total number of labeled positive categories for the ingredient. We provide $min(20, n/2)$ positive categories for the sequential model to train. We also include k negative categories, where k is selected using the validation set. We evaluate the performance on the remaining $n - min(20, n/2)$ positive categories as well as on the negative categories not included in training.

[3] http://ec.europa.eu/food/safety/rasff/index_en.htm

Ingredient	*Wikipedia article*	*Prediction 1*	*Prediction 2*	*Prediction 3*
oatmeal	Oatmeal	cereal (0.564)	snack, energy & granola bars (0.196)	breads & buns (0.039)
watermelon juice	Watermelon	fruit & vegetable juice (0.352)	ice cream & frozen yogurt (0.205)	yogurt (0.064)
jasmine rice	Jasmine rice	flavored rice dishes (0.294)	rice (0.237)	herbs & spices (0.062)
shrimp extract	Shrimp (food)	fish & seafood (0.491)	frozen dinners (0.128)	frozen appetizers (0.113)
meatball	Meatball	pizza (0.180)	breakfast sandwiches (0.128)	frozen dinners (0.120)
polysorbate 80	Polysorbate 80	chewing gum & mints (0.531)	candy (0.092)	baking decorations (0.049)
ketchup	Ketchup	ketchup (0.461)	salad dressing & mayonnaise (0.049)	other cooking sauces (0.044)
benzoic acid	Benzoic acid	powdered drinks (0.062)	fruit & vegetable juice (0.051)	candy (0.045)

Table 1: The three most likely food product category predictions generated by the baseline RNN model on eight unseen ingredients. The number in parenthesis represents the probability provided by the model.

AskUbuntu: We use the difference vectors in Equation 4 to compute the loss and sequentially update the feature weights w. Let n be the total number of labeled positive examples (similar questions). We select up to $n/2$ positive and negative examples. From the $n^2/4$ possible pairs, we select the 20 most informative pairs for training.

While we use the loss function commonly used for binary classification during training, we ultimately want to frame our question as a ranking problem. Therefore, after iterating through the initial observations, we compute the mean average precision (MAP) over the remaining (unseen) ingredients/questions and compare it to the MAP of the baseline RNN model on the same unseen examples.

5.3 Hyperparameters

RNN: We use Adam (Kingma and Ba, 2015) as the optimization method with the default setting suggested by the authors. We use a hidden dimension of $d = 50$ for the ingredients and $d = 400$ for the AskUbuntu questions. Additional parameters such as dropout (Hinton et al., 2012), hidden layers, regularization, stopping criteria, batch size, and learning rate is tuned on the development set.

Word Vectors: For the ingredient/product prediction task, we used the GloVe pre-trained vectors (Common Crawl, 42 billion tokens, 300-dimensional) (Pennington et al., 2014). The word vectors for the AskUbuntu vectors are pre-trained using the AskUbuntu and Wikipedia corpora.

Sequential: We utilize the bounded limited-memory BFGS algorithm (L-BFGS-B) (Byrd et al., 1995) to solve for the optimal feature weights with bounds $w_j \in [0.01, 2]$. We tuned the the constraint bounds and the regularization parameter λ on the development set.

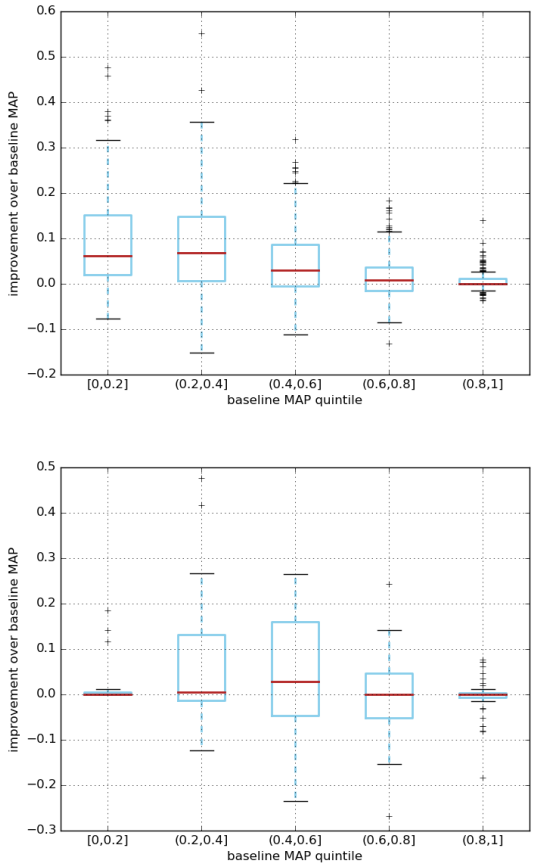

Figure 1: Box plot of the mean absolute mean average precision (MAP) improvement of the sequential model on the ingredients dataset (top) and AskUbuntu questions (bottom). They are divided into five quintiles based on the baseline RNN MAP score. The model shows gains in cases where the baseline RNN model's performance is poor or mediocre. The number of data points in each of the five quintiles of the ingredients dataset are, respectively: 131, 210, 240, 135, 191. For the AskUbuntu dataset, they are: 15, 26, 32, 40, 41.

	Ing / Dev	Ing / Test	AskUbuntu / Dev	AskUbuntu / Test
Mean MAP gain (percent)	0.0525 (30.9%)	0.0492 (26.5%)	0.0246 (8.2%)	0.0224 (7.5%)
Mean # positive observations	8.6	9.1	3.2	2.9

Table 2: We show the mean absolute improvement in the mean average precision (MAP) over the unobserved data points for each ingredient/question. The percent improvement shown is an average percent improvement across the ingredients/questions. They are the average of 100 runs per ingredient and 20 runs per AskUbuntu question.

Model	Validation set	Test set
Random	0.150 / 0.120	0.158 / 0.129
Baseline	0.320 / 0.291	0.331 / 0.300
MLP	0.432 / 0.390	0.459 / 0.416
RNN	**0.476 / 0.422**	**0.478 / 0.426**

Table 3: Results of the RNN model on the ingredient dataset, averaged across 5 runs. The two metrics shown are the mean average precision (MAP) and precision at N (P@N), where N is the total number of positive examples. The random model generates a random ranking of food categories for each ingredient. The baseline model uses the mean occurrence distribution of the food categories for all ingredients to rank the predictions. The multilayer perceptron model (MLP) is a three-layer neural network trained on the hierarchical properties of the input ingredients (extracted from the UMLS Metathesaurus). The RNN model outperforms all other baselines.

5.4 Results

Table 1 and 3 shows our results from using RNN to predict likely food product categories from Wikipedia text descriptions of ingredients.

We show the gains of the sequential update model in Table 2. We are able to generate consistent improvements in the MAP after seeing half of the observations. Box plots of the test set MAP improvements can be seen in Figure 1. For the ingredients prediction task, the sequential model offers the greatest improvements when the baseline RNN has low MAP. In the AskUbuntu questions, on the other hand, the positive effect is greatest when the baseline MAP is around 0.5.

There are three possible reasons for the difference in performance between the two tasks:

- The mean number of positive observations in the AskUbuntu task is 2.9, compared to 9.1 observations in the ingredients task (Table 2). This is a key factor in determining the sequential model's ability to tune for the optimal parameters. Having access to more annotated data would likely result in an increase in performance.

- Owing to the complexity of information encoded, the vectors for the AskUbuntu task are of dimension of 400 as opposed to 50 in the ingredients task. As a result, the sequential model would require more feedback to find near optimal weights w.

- We hypothesize that the sequential model leads to the most increased performance when the baseline model is mediocre. This is especially highlighted in the AskUbuntu task, as extremely poor performance indicate a complete mismatch of questions, while an exceptional performance leaves little room for additional improvement.

6 Conclusion

We demonstrated a text-based neural recommender approach to predict likely food products from a given ingredient as well as other similar questions from a given AskUbuntu question. We then extended this model to an online stream of new data, which improves over the off-line trained version for both of the two tasks tested. This sequential process improves model performance while requiring minimal additional training time and resources.

There's No Comparison: Reference-less Evaluation Metrics in Grammatical Error Correction

Courtney Napoles,[1] **Keisuke Sakaguchi**,[1] and **Joel Tetreault**[2]
[1]Center for Language and Speech Processing, Johns Hopkins University
[2]Grammarly
{napoles,keisuke}@cs.jhu.edu, joel.tetreault@grammarly.com

Abstract

Current methods for automatically evaluating grammatical error correction (GEC) systems rely on gold-standard references. However, these methods suffer from penalizing grammatical edits that are correct but not in the gold standard. We show that reference-less grammaticality metrics correlate very strongly with human judgments and are competitive with the leading reference-based evaluation metrics. By interpolating both methods, we achieve state-of-the-art correlation with human judgments. Finally, we show that GEC metrics are much more reliable when they are calculated at the sentence level instead of the corpus level. We have set up a CodaLab site for benchmarking GEC output using a common dataset and different evaluation metrics.

1 Introduction

Grammatical error correction (GEC) has been evaluated by comparing the changes made by a system to the corrections made in gold-standard annotations. Following the recent shared tasks in this field (e.g., Ng et al. (2014)), several papers have critiqued GEC metrics and proposed new methods. Existing metrics depend on gold-standard corrections and therefore have a notable weakness: systems are penalized for making corrections that do not appear in the references.[1] For example, the following output has low metric scores even though three appropriate corrections were made to the input:

> However , people now can ~~contact~~ **communicate** with ~~anyone~~ **people** all over the world who can use computer**s** at any time , and there is no time delay of messages .

These changes (in red) were not seen in the references and therefore the metrics GLEU and M^2 (described in §2) score this output worse than 75% of 15,000 other generated sentences.

While grammaticality-based, reference-less metrics have been effective in estimating the quality of machine translation (MT) output, the utility of such metrics has not been investigated previously for GEC. We hypothesize that such methods can overcome this weakness in reference-based GEC metrics. This paper has four contributions: 1) We develop three *grammaticality* metrics that are competitive with current reference-based measures and correlate very strongly with human judgments. 2) We achieve state-of-the-art performance when interpolating a leading reference-based metric with a grammaticality metric. 3) We identify an interesting result that the mean of sentence-level scores is substantially better for evaluating systems than the system-level score. 4) We release code for two grammaticality metrics and establish an online platform for evaluating GEC output.

2 Prior work

To our knowledge, this is the first work to evaluate GEC without references. Within MT, this task is called *quality estimation*. MT output is evaluated by its *fluency*, or adherence to accepted conventions of grammaticality and style, and *adequacy*, which is the input's meaning conveyed in the output.

[1]We refer to the gold-standard corrections as *references* because *gold standard* suggests just one accurate correction.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2109–2115,
Austin, Texas, November 1-5, 2016.

Quality estimation targets fluency by estimating the amount of post-editing needed by the output. This has been the topic of recent shared tasks, e.g. Bojar et al. (2015). Specia et al. (2010) evaluated the quality of translations using sentence-level features from the output but not the references, predicting discrete and continuous scores. A strong baseline, *QuEst*, uses support vector regression trained over 17 features extracted from the output (Specia et al., 2013). Most closely related to our work, Parton et al. (2011) applied features from Educational Testing Service's e-rater® (Attali and Burstein, 2006) to evaluate MT output with a ranking SVM, without references, and improved performance by including features derived from MT metrics (BLEU, TERp, and METEOR).

Within the GEC field, recent shared tasks have prompted the development and scrutiny of new metrics for evaluating GEC systems. The Helping Our Own shared tasks evaluated systems using precision, recall, and F-score against annotated gold-standard corrections (Dale and Kilgarriff, 2011; Dale et al., 2012). The subsequent CoNLL Shared Tasks on GEC (Ng et al., 2013; Ng et al., 2014) were scored with the MaxMatch metric (M^2), which captures word- and phrase-level edits by calculating the F-score over an edit lattice (Dahlmeier and Ng, 2012). Felice and Briscoe (2015) identified shortcomings of M^2 and proposed I-measure to address these issues. I-measure computes the accuracy of a token-level alignment between the original, generated, and gold-standard sentences. These precision- and recall-based metrics measure fluency and adequacy by penalizing inappropriate changes, which alter meaning or introduce other errors. Changes consistent with the annotations indicate improved fluency and no change in meaning.

Unlike these metrics, GLEU scores output by penalizing n-grams found in the input and output but not the reference (Napoles et al., 2015). Like BLEU (Papineni et al., 2002), GLEU captures both fluency and adequacy with n-gram overlap. Recent work has shown that GLEU has the strongest correlation with human judgments compared to the GEC metrics described above (Sakaguchi et al., 2016). These GEC metrics are all defined at the corpus level, meaning that the statistics are accumulated over the entire output and then used to calculate a single system score.

3 Explicitly evaluating grammaticality

GLEU, I-measure, and M^2 are calculated based on comparison to reference corrections. These Reference-Based Metrics (*RBMs*) credit corrections seen in the references and penalize systems for ignoring errors and making bad changes (changing a span of text in an ungrammatical way or introducing errors to grammatical text). However, RBMs make two strong assumptions: that the annotations in the references are *correct* and that they are *complete*. We argue that these assumptions are invalid and point to a deficit in current evaluation practices. In GEC, the agreement between raters can be low due to the challenging nature of the task (Bryant and Ng, 2015; Rozovskaya and Roth, 2010; Tetreault and Chodorow, 2008), indicating that annotations may not be correct or complete.

An exhaustive list of all possible corrections would be time-consuming, if not impossible. As a result, RBMs penalize output that has a valid correction that is not present in the references or that addresses an error not corrected in the references. The example in §1 has low GLEU and M^2 scores, even though the output addresses two errors (GLEU=0.43 and $M^2 = 0.00$, in the bottom half and quartile of 15k system outputs, respectively).

To address these concerns, we propose three metrics to evaluate the grammaticality of output without comparing to the input or a gold-standard sentence (Grammaticality-Based Metrics, or *GBMs*). We expect GBMs to score sentences, such as our example in §1, more highly. The first two metrics are scored by counting the errors found by existing grammatical error detection tools. The error count score is simply calculated: $1 - \frac{\#\text{ errors}}{\#\text{ tokens}}$. Two different tools are used to count errors: e-rater®'s grammatical error detection modules (ER) and Language Tool (Miłkowski, 2010) (LT). We choose these because, while e-rater® is a large-scale, robust tool that detects more errors than Language Tool,[2] it is proprietary whereas Language Tool is publicly available and open sourced.

For our third method, we estimate a grammaticality score with a linguistic feature-based model (LFM), which is our implementation of Heilman et

[2]In the data used for this work, e-rater® detects approximately 15 times more errors than Language Tool.

al. (2014).[3] The LFM score is a ridge regression over a variety of linguistic features related to grammaticality, including the number of misspellings, language model scores, OOV counts, and PCFG and link grammar features. It has been shown to effectively assess the grammaticality of learner writing. LFM predicts a score for each sentence while ER and LT, like the RBMs, can be calculated with either sentence- or document-level statistics. To be consistent with LFM, for all metrics in this work we score each sentence individually and report the system score as the mean of the sentence scores. We discuss the effects of modifying metrics from a corpus-level to a sentence-level in §5.

Consistent with our hypothesis, ER and LT score the §1 example in the top quartile of outputs and LFM ranks it in the top half.

3.1 A hybrid metric

The obvious deficit of GBMs is that they do not measure the adequacy of generated sentences, so they could easily be manipulated with grammatical output that is unrelated to the input. An ideal GEC metric would measure both the grammaticality of a generated sentence and its meaning compared to the original sentence, and would not necessarily need references. The available data of scored system outputs are insufficient for developing a new metric due to their limited size, thus we turn to interpolation to develop a sophisticated metric that jointly captures grammaticality and adequacy.

To harness the advantage of RBMs (adequacy) and GBMs (fluency), we build combined metrics, interpolating each RBM with each GBM. For a sentence of system output, the interpolated score (S_{I}) of the GBM score (S_{G}) and RBM score (S_{R}) is computed as follows:

$$S_{\text{I}} = (1 - \lambda)S_{\text{G}} + \lambda S_{\text{R}}$$

All values of S_{G} and S_{R} are in the interval $[0, 1]$, except for I-measure, which falls between $[-1, 1]$, and the distribution varies for each metric.[4] The system score is the average S_{I} of all generated sentences.

[3] Our implementation is slightly modified in that it does not use features from the PET HPSG parser.

[4] Mean scores are GLEU 0.52 ± 0.21, M^2 0.21 ± 0.34, IM 0.10 ± 0.30, ER 0.91 ± 0.10, LFM 0.50 ± 0.16, LT 1.00 ± 0.01.

Metric	Spearman's ρ	Pearson's r
GLEU	**0.852**	**0.838**
ER	**0.852**	0.829
LT	0.808	0.811
I-measure	0.769	0.753
LFM	0.780	0.742
M^2	0.648	0.641

Table 1: Correlation between the human and metric rankings.

4 Experiments

To assess the proposed metrics, we apply the RBMs, GBMs, and interpolated metrics to score the output of 12 systems participating in the CoNLL-2014 Shared Task on GEC (Ng et al., 2014). Recent works have evaluated RBMs by collecting human rankings of these system outputs and comparing them to the metric rankings (Grundkiewicz et al., 2015; Napoles et al., 2015). In this section, we compare each metric's ranking to the human ranking of Grundkiewicz et al. (2015, Table 3c). We use 20 references for scoring with RBMs: 2 original references, 10 references collected by Bryant and Ng (2015), and 8 references collected by Sakaguchi et al. (2016). The motivations for using 20 references are twofold: the best GEC evaluation method uses these 20 references with the GLEU metric (Sakaguchi et al., 2016), and work in machine translation shows that more references are better for evaluation (Finch et al., 2004). Due to the low agreement discussed in §3, having more references can be beneficial for evaluating a system when there are multiple viable ways of correcting a sentence. Unlike previous GEC evaluations, all metrics reported here use the *mean* of the sentence-level scores for each system.

Results are presented in Table 1. The error-count metrics, ER and LT, have stronger correlation than all RBMs except for GLEU, which is the current state of the art. GLEU has the strongest correlation with the human ranking ($\rho = 0.852$, $r = 0.838$), followed closely by ER, which has slightly lower Pearson correlation ($r = 0.829$) but equally as strong rank correlation, which is arguably more important when comparing different systems. I-measure and LFM have similar strength correlations, and M^2 is the lowest performing metric, even though its correlation is still strong ($\rho = 0.648$, $r = 0.641$).

Next we compare the interpolated scores with the human ranking, testing 101 different values of λ

	ranked by Spearman's rank coefficient (ρ)				*ranked by Pearson's correlation coefficient (r)*			
		ER	**LFM**	**LT**		**ER**	**LFM**	**LT**
	no intrpl.	0.852 (0)	0.780 (0)	0.808 (0)	*no intrpl.*	0.829 (0)	0.742 (0)	0.811 (0)
GLEU	0.852 (1)	**0.885** (0.03)	0.874 (0.27)	0.857 (0.04)	0.838 (1)	**0.867** (0.27)	0.845 (0.84)	0.867 (0.09)
I-m.	0.769 (1)	0.874 (0.19)	0.863 (0.37)	0.852 (0.01)	0.753 (1)	0.837 (0.02)	0.791 (0.22)	0.828 (0.01)
M^2	0.648 (1)	0.868 (0.01)	0.852 (0.05)	0.808 (0.00)	0.641 (1)	0.829 (0.00)	0.754 (0.04)	0.811 (0.00)

Table 2: Oracle correlations between interpolated metrics and the human rankings. The λ value for each metric is in parentheses.

GLEU rank	**Intrpl. rank**	**Output sentence**
1	2	*Genectic* testing is a personal decision , with the knowledge that there is a *possiblity* that one could be a carrier or not .
2	3	*Genectic* testing is a personal decision , the *kowledge* that there is a *possiblity* that one could be a carrier or not .
3	1	Genetic testing is a personal decision , with the knowledge that there is a possibility that one could be a carrier or not .

Table 3: An example of system outputs ranked by GLEU and GLEU interpolated with ER. Words in italics are misspelled.

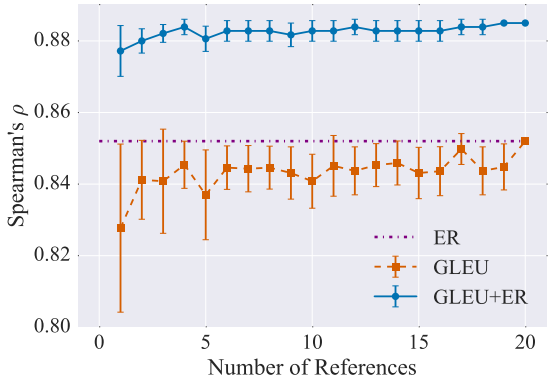

Figure 1: The mean correlation of oracle interpolated GLEU and ER scores across different reference sizes, compared to the uninterpolated metrics. Bars indicate a 95% confidence interval.

[0,1] to find the oracle value. Table 2 shows the correlations between the human judgments and the oracle interpolated metrics. Correlations of interpolated metrics are the upper bound and the correlations of uninterpolated metrics (in the first column and first row) are the lower bound. Interpolating GLEU and IM with GBMs has stronger correlation than any uninterpolated metric (i.e. $\lambda = 0$ or 1), and the oracle interpolation of ER and GLEU manifests the strongest correlation with the human ranking ($\rho = 0.885$, $r = 0.867$).[5] M^2 has the weakest correlation of all uninterpolated metrics and, when combined with GBMs, three of the interpolated metrics have $\lambda = 0$, meaning the interpolated score is equivalent to the GBM and M^2 does not contribute.

Table 3 presents an example of how interpolation can help evaluation. The top two sentences ranked by GLEU have misspellings that were not corrected in the NUCLE references. Interpolating with a GBM rightly ranks the misspelled output below the corrected output.

Since these experiments use a large number of references (20), we determine how different reference sizes affect the interpolated metrics by systematically increasing the number of references from 1 to 20 and randomly choosing n references to use as a gold standard when calculating the RBM scores, repeating 10 times for each value n (Figure 1). The correlation is nearly as strong with 3 and 20 references ($\rho = 0.884$ v. 0.885), and interpolating with just 1 reference is nearly as good (0.878) and improves over any uninterpolated metric.

We acknowledge that using GBMs is in effect using GEC systems to score other GEC systems. Interestingly, we find that even if the GBMs are imperfect, they still boost performance of the RBMs. GBMs have been trained to recognize errors in different contexts and, conversely, can identify correct grammatical constructions in diverse contexts, where the RBMs only recognize corrections made that appear in the gold standards, which are limited. Therefore GBMs can make a nice complement to shortcomings that RBMs may have.

5 Sentence-level evaluation

In the course of our experiments, we noticed that I-measure and GLEU have stronger correlations with the expert human ranking when using the

[5]To verify that these metrics cannot be gamed, we interpolated GBMs with RBMs scored against randomized references, and got scores 15% lower than un-gamed scores, on average.

	Corpus		Sentence	
Metric	ρ	r	ρ	r
GLEU	0.725	0.724	0.852	0.838
I-m.	-0.055*	0.061	0.769	0.753
M^2	0.692	0.617	0.648	0.641

Table 4: Correlation with human ranking when using corpus- and sentence-level metrics. * indicates a significant difference from the corresponding sentence-level correlation ($p < 0.05$).[7]

mean sentence-level score (Table 4).[6] Most notably, I-measure does not correlate at all as a corpus-level metric but has a very strong correlation at the sentence-level (specifically, ρ improves from -0.055 to 0.769). This could be because corpus-level statistics equally distribute counts of correct annotations over all sentences, even those where the output neglects to make any necessary corrections. Sentence-level statistics would not average the correct counts over all sentences in this same way. As a result, a corpus-level statistic may over-estimate the quality of system output. Deeper investigation into this phenomenon is needed to understand why the mean sentence-level scores do better.

6 Summary

We have identified a shortcoming of reference-based metrics: they penalize changes made that do not appear in the references, even if those changes are acceptable. To address this problem, we developed metrics to explicitly measure grammaticality without relying on reference corrections and showed that the error-count metrics are competitive with the best reference-based metric. Furthermore, by interpolating RBMs with GBMs, the system ranking has even stronger correlation with the human ranking. The ER metric, which was derived from counts of errors detected using e-rater®, is nearly as good as the state-of-the-art RBM (GLEU) and the interpolation of these metrics has the strongest reported correlation with the human ranking ($\rho = 0.885$, $r = 0.867$). However, since e-rater® is not widely available to researchers, we also tested a metric using Language Tool, which does nearly as well when interpolated with GLEU ($\rho = 0.857$, $r = 0.867$).

Two important points should be noted: First, due to the small sample size (12 system outputs), none of the rankings significantly differ from one another except for the corpus-level I-measure. Secondly, GLEU and the other RBMs already have strong to very strong correlation with the human judgments, which makes it difficult for any combination of metrics to perform substantially higher. The best uninterpolated and interpolated metrics use an extremely large number of references (20), however Figure 1 shows that interpolating GLEU using just one reference has stronger correlation than any uninterpolated metric. This supports the use of interpolation to improve GEC evaluation in any setting.

This work is the first exploration into applying fluency-based metrics to GEC evaluation. We believe that, for future work, fluency measures could be further improved with other methods, such as using existing GEC systems to *detect* errors, or even using an ensemble of systems to improve coverage (indeed, ensembles have been useful in the GEC task itself (Susanto et al., 2014)). There is also recent work from the MT community, such as the use of confidence bounds (Graham and Liu, 2016) or uncertainty measurement (Beck et al., 2016), which could be adopted by the GEC community.

Finally, in the course of our experiments, we determined that metrics calculated on the sentence-level is more reliable for evaluating GEC output, and we suggest that the GEC community adopt this modification to better assess systems.

To facilitate GEC evaluation, we have set up an online platform[8] for benchmarking system output on the same set of sentences evaluated using different metrics and made the code for calculating LT and LFM available.[9]

Acknowledgments

We would like to thank Matt Post, Martin Chodorow, and the three anonymous reviews for their comments and feedback. We also thank Educational Testing Service for providing e-rater® output. This material is based upon work partially supported by the NSF GRF under Grant No. 1232825.

[6] The correlations in Table 4 differ from what was reported in Grundkiewicz et al. (2015) and Napoles et al. (2015) due to the references and sentence-level computation used in this work.

[7] Significance is found by applying a two-tailed t-test to the Z-scores attained using Fisher's z-transformation.

Cultural Shift or Linguistic Drift? Comparing Two Computational Measures of Semantic Change

William L. Hamilton, Jure Leskovec, Dan Jurafsky
Department of Computer Science, Stanford University, Stanford CA, 94305
wleif,jure,jurafsky@stanford.edu

Abstract

Words shift in meaning for many reasons, including cultural factors like new technologies and regular linguistic processes like subjectification. Understanding the evolution of language and culture requires disentangling these underlying causes. Here we show how two different distributional measures can be used to detect two different types of semantic change. The first measure, which has been used in many previous works, analyzes global shifts in a word's distributional semantics; it is sensitive to changes due to regular processes of linguistic drift, such as the semantic generalization of *promise* ("I promise."→"It promised to be exciting."). The second measure, which we develop here, focuses on local changes to a word's nearest semantic neighbors; it is more sensitive to cultural shifts, such as the change in the meaning of *cell* ("prison cell" → "cell phone"). Comparing measurements made by these two methods allows researchers to determine whether changes are more cultural or linguistic in nature, a distinction that is essential for work in the digital humanities and historical linguistics.

1 Introduction

Distributional methods of embedding words in vector spaces according to their co-occurrence statistics are a promising new tool for diachronic semantics (Gulordava and Baroni, 2011; Jatowt and Duh, 2014; Kulkarni et al., 2014; Xu and Kemp, 2015; Hamilton et al., 2016). Previous work, however, does not consider the underlying causes of semantic change or how to distentangle different types of change.

We show how two computational measures can be used to distinguish between semantic changes caused by cultural shifts (e.g., technological advancements) and those caused by more regular processes of semantic change (e.g., grammaticalization or subjectification). This distinction is essential for research on linguistic and cultural evolution. Detecting cultural shifts in language use is crucial to computational studies of history and other digital humanities projects. By contrast, for advancing historical linguistics, cultural shifts amount to noise and only the more regular shifts matter.

Our work builds on two intuitions: that distributional models can highlight syntagmatic versus paradigmatic relations with neighboring words (Schutze and Pedersen, 1993) and that nouns are more likely to undergo changes due to irregular cultural shifts while verbs more readily participate in regular processes of semantic change (Gentner and France, 1988; Traugott and Dasher, 2001). We use this noun vs. verb mapping as a proxy to compare our two measures' sensitivities to cultural vs. linguistic shifts. Sensitivity to nominal shifts indicates a propensity to capture irregular cultural shifts in language, such as those due to technological advancements (Traugott and Dasher, 2001). Sensitivity to shifts in verbs (and other predicates) indicates a propensity to capture regular processes of linguistic drift (Gentner and France, 1988; Kintsch, 2000; Traugott and Dasher, 2001).

The first measure we analyze is based upon changes to a word's local semantic neighborhood;

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2116–2121,
Austin, Texas, November 1-5, 2016.

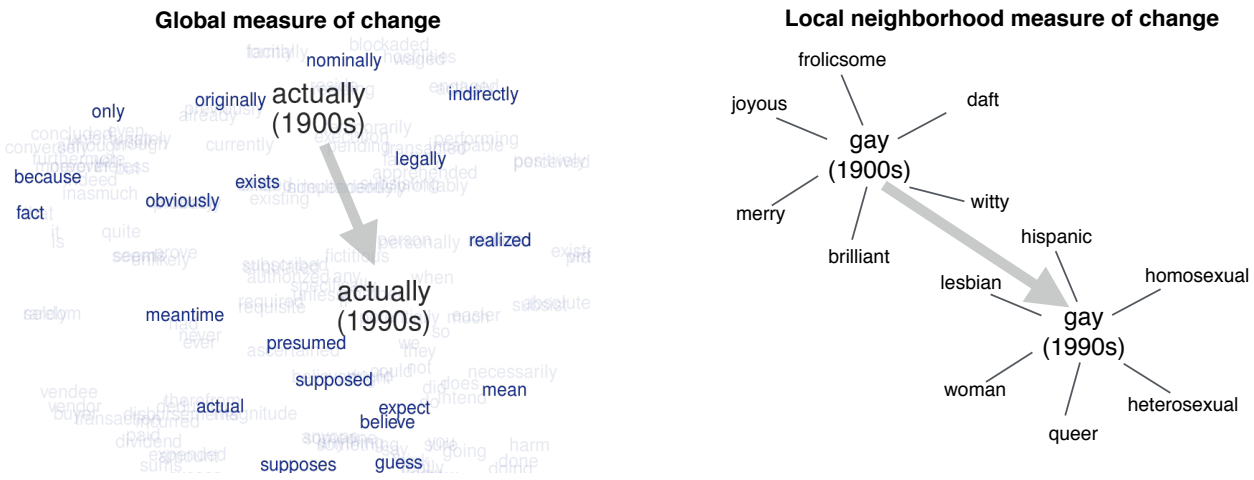

Figure 1: Two different measures of semantic change. With the global measure of change, we measure how far a word has moved in semantic space between two time-periods. This measure is sensitive to subtle shifts in usage and also global effects due to the entire semantic space shifting. For example, this captures how *actually* underwent subjectification during the 20th century, shifting from uses in objective statements about the world ("actually did try") to subjective statements of attitude ("I actually agree"; see Traugott and Dasher, 2001 for details). In contrast, with the local neighborhood measure of change, we measure changes in a word's nearest neighbors, which captures drastic shifts in core meaning, such as *gay*'s shift in meaning over the 20th century.

we show that it is more sensitive to changes in the nominal domain and captures changes due to unpredictable cultural shifts. Our second measure relies on a more traditional global notion of change; we show that it better captures changes, like those in verbs, that are the result of regular linguistic drift.

Our analysis relies on a large-scale statistical study of six historical corpora in multiple languages, along with case-studies that illustrate the fine-grained differences between the two measures.

2 Methods

We use the diachronic word2vec embeddings constructed in our previous work (Hamilton et al., 2016) to measure how word meanings change between consecutive decades.[1] In these representations each word w_i has a vector representation $\mathbf{w}^{(t)}$ (Turney and Pantel, 2010) at each time point, which captures its co-occurrence statistics for that time period. The vectors are constructed using the skip-gram with negative sampling (SGNS) algorithm (Mikolov et al., 2013) and post-processed to align the semantic spaces between years. Measuring the distance between word vectors for consecutive decades allows us to compute the rate at which the different words change in meaning (Gulordava and Baroni, 2011).

We analyzed the decades from 1800 to 1990 using vectors derived from the Google N-gram datasets (Lin et al., 2012) that have large amounts of historical text (English, French, German, and English Fiction). We also used vectors derived from the Corpus of Historical American English (COHA), which is smaller than Google N-grams but was carefully constructed to be genre balanced and contains word lemmas as well as surface forms (Davies, 2010). We examined all decades from 1850 through 2000 using the COHA dataset and used the part-of-speech tags provided with the corpora.

2.1 Measuring semantic change

We examine two different ways to measure semantic change (Figure 1).

Global measure

The first measure analyzes global shifts in a word's vector semantics and is identical to the measure used in most previous works (Gulordava and Baroni, 2011; Jatowt and Duh, 2014; Kim et al., 2014; Hamilton et al., 2016). We simply take a word's vectors for two consecutive decades and measure the cosine distance between them, i.e.

$$d^G(w_i^{(t)}, w_i^{(t+1)}) = \text{cos-dist}(\mathbf{w}_i^{(t)}, \mathbf{w}_i^{(t+1)}). \quad (1)$$

[1] http://nlp.stanford.edu/projects/histwords/. This URL also links to detailed dataset descriptions and the code needed to replicate the experiments in this paper.

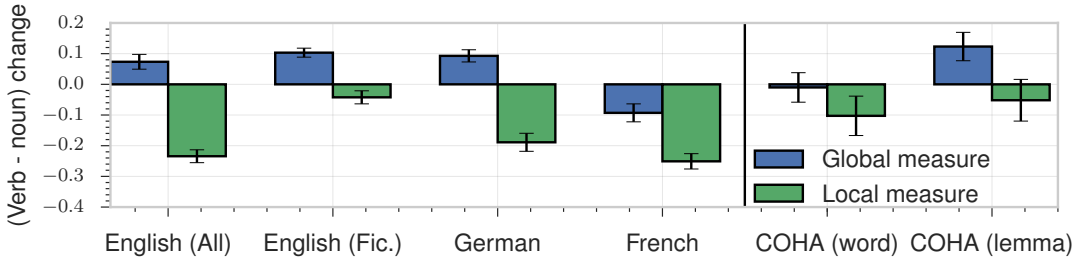

Figure 2: The global measure is more sensitive to semantic changes in verbs while the local neighborhood measure is more sensitive to noun changes. Examining how much nouns change relative to verbs (using coefficients from mixed-model regressions) reveals that the two measures are sensitive to different types of semantic change. Across all languages, the local neighborhood measure always assigns relatively higher rates of change to nouns (i.e., the right/green bars are lower than the left/blue bars for all pairs), though the results vary by language (e.g., French has high noun change-rates overall). 95% confidence intervals are shown.

Local neighborhood measure

The second measure is based on the intuition that only a word's nearest semantic neighbors are relevant. For this measure, we first find word w_i's set of k nearest-neighbors (according to cosine-similarity) within each decade, which we denote by the ordered set $\mathcal{N}_k(w_i^{(t)})$. Next, to measure the change between decades t and $t+1$, we compute a "second-order" similarity vector for $w_i^{(t)}$ from these neighbor sets with entries defined as

$$\mathbf{s}^{(t)}(j) = \text{cos-sim}(\mathbf{w}_i^{(t)}, \mathbf{w}_j^{(t)}) \quad \forall w_j \in \mathcal{N}_k(w_i^{(t)}) \cup \mathcal{N}_k(w_i^{(t+1)}), \quad (2)$$

and we compute an analogous vector for $w_i^{(t+1)}$. The second-order vector, $\mathbf{s}_i^{(t)}$, contains the cosine similarity of $\mathbf{w}_i$ and the vectors of all w_i's nearest semantic neighbors in the the time-periods t and $t+1$. Working with variants of these second-order vectors has been a popular approach in many recent works, though most of these works define these vectors against the full vocabulary and not just a word's nearest neighbors (del Prado Martin and Brendel, 2016; Eger and Mehler, 2016; Rodda et al., 2016).

Finally, we compute the local neighborhood change as

$$d^L(w_i^{(t)}, w_i^{(t+1)}) = \text{cos-dist}(\mathbf{s}_i^{(t)}, \mathbf{s}_i^{(t+1)}). \quad (3)$$

This measures the extent to which w_i's similarity with its nearest neighbors has changed.

The local neighborhood measure defined in (3) captures strong shifts in a word's paradigmatic relations but is less sensitive to global shifts in syntagmatic contexts (Schutze and Pedersen, 1993). We used $k = 25$ in all experiments (though we found the results to be consistent for $k \in [10, 50]$).

Dataset	# Nouns	# Verbs
Google English All	5299	2722
Google English Fic.	4941	3128
German	5443	1844
French	2310	4992
COHA (Word)	4077	1267
COHA (Lemma)	3389	783

Table 1: Number of nouns and verbs tested in each dataset.

2.2 Statistical methodology

To test whether nouns or verbs change more according to our two measures of change, we build on our previous work and used a linear mixed model approach (Hamilton et al., 2016). This approach amounts to a linear regression where the model also includes "random" effects to account for the fact that the measurements for individual words will be correlated across time (McCulloch and Neuhaus, 2001).

We ran two regressions per datatset: one with the global d^G values as the dependent variables (DVs) and one with the local neighborhood d^L values. In both cases we examined the change between all consecutive decades and normalized the DVs to zero-mean and unit variance. We examined nouns/verbs within the top-10000 words by frequency rank and removed all words that occurred <500 times in the smaller COHA dataset. The independent variables are word frequency, the decade of the change (represented categorically), and variable indicating

Word	1850s context	1990s context
actually	"...dinners which you have actually eaten."	"With that, I actually agree."
must	"O, George, we must have faith."	"Which you must have heard ten years ago..."
promise	"I promise to pay you...'	"...the day promised to be lovely."
gay	"Gay bridals and other merry-makings of men."	"...the result of gay rights demonstrations."
virus	"This young man is...infected with the virus."	"...a rapidly spreading computer virus."
cell	"The door of a gloomy cell..."	"They really need their cell phones."

Table 2: Example case-studies of semantic change. The first three words are examples of regular linguistic shifts, while the latter three are examples of words that shifted due to exogenous cultural factors. Contexts are from the COHA data (Davies, 2010).

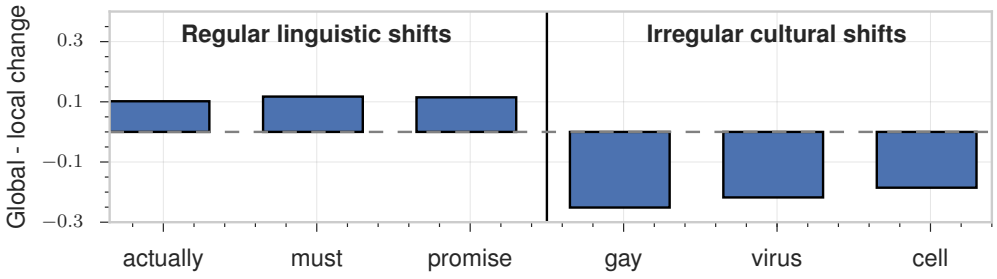

Figure 3: The global measure captures classic examples of linguistic drift while the local measure captures example cultural shifts. Examining the semantic distance between the 1850s and 1990s shows that the global measure is more sensitive to regular shifts (and vice-versa for the local measure). The plot shows the difference between the measurements made by the two methods.

whether a word is a noun or a verb (proper nouns are excluded, as in Hamilton et al., 2016).[2]

3 Results

Our results show that the two seemingly related measures actually result in drastically different notions of semantic change.

3.1 Nouns vs. verbs

The local neighborhood measure assigns far higher rates of semantic change to nouns across all languages and datasets while the opposite is true for the global distance measure, which tends to assign higher rates of change to verbs (Figure 2).

We focused on verbs vs. nouns since they are the two major parts-of-speech and previous research has shown that verbs are more semantically mutable than nouns and thus more likely to undergo linguistic drift (Gentner and France, 1988), while nouns are far more likely to change due to cultural shifts like new technologies (Traugott and Dasher, 2001). However, some well-known regular linguistic shifts include rarer parts of speech like adverbs (included in our case studies below). Thus we also confirmed that the differences shown in Figure 2 also hold when adverbs and adjectives are included along with the verbs. This modified analysis showed analogous significant trends, which fits with previous research arguing that adverbial and adjectival modifiers are also often the target of regular linguistic changes (Traugott and Dasher, 2001).

The results of this large-scale regression analysis show that the local measure is more sensitive to changes in the nominal domain, a domain in which change is known to be driven by cultural factors. In contrast, the global measure is more sensitive to changes in verbs, along with adjectives and adverbs, which are known to be the targets of many regular processes of linguistic change (Traugott and Dasher, 2001; Hopper and Traugott, 2003)

3.2 Case studies

We examined six case-study words grouped into two sets. These case studies show that three examples of well-attested regular linguistic shifts (set A) changed more according to the global measure, while three well-known examples of cultural changes (set B) change more according to the local neighborhood measure. Table 2 lists these words with some representative historical contexts (Davies, 2010).

[2]Frequency was included since it is known to strongly influence the distributional measures (Hamilton et al., 2016).

Set A contains three words that underwent attested regular linguistic shifts detailed in Traugott and Dasher (2001): *actually*, *must*, and *promise*. These three words represent three different types of regular linguistic shifts: *actually* is a case of subjectification (detailed in Figure 1); *must* shifted from a deontic/obligation usage ("you must do X") to a epistemic one ("X must be the case"), exemplifying a regular pattern of change common to many modal verbs; and *promise* represents the class of shifting "performative speech acts" that undergo rich changes due to their pragmatic uses and subjectification (Traugott and Dasher, 2001). The contexts listed in Table 2 exemplify these shifts.

Set B contains three words that were selected because they underwent well-known cultural shifts over the last 150 years: *gay*, *virus*, and *cell*. These words gained new meanings due to uses in community-specific vernacular (*gay*) or technological advances (*virus*, *cell*). The cultural shifts underlying these changes in usage — e.g., the development of the mobile "cell phone" — were unpredictable in the sense that they were not the result of regularities in human linguistic systems.

Figure 3 shows how much the meaning of these word changed from the 1850s to the 1990s according to the two different measures on the English Google data. We see that the words in set A changed more when measurements were made using the global measure, while the opposite holds for set B.

4 Discussion

Our results show that our novel local neighborhood measure of semantic change is more sensitive to changes in nouns, while the global measure is more sensitive to changes in verbs. This mapping aligns with the traditional distinction between irregular cultural shifts in nominals and more regular cases of linguistic drift (Traugott and Dasher, 2001) and is further reinforced by our six case studies.

This finding emphasizes that researchers must develop and use measures of semantic change that are tuned to specific tasks. For example, a cultural change-point detection framework would be more successful using our local neighborhood measure, while an empirical study of grammaticalization would be better off using the traditional global distance approach. Comparing measurements made by these two approaches also allows researchers to assess the extent to which semantic changes are linguistic or cultural in nature.

Abstract

We investigate evaluation metrics for dialogue response generation systems where supervised labels, such as task completion, are not available. Recent works in response generation have adopted metrics from machine translation to compare a model's generated response to a single target response. We show that these metrics correlate very weakly with human judgements in the non-technical Twitter domain, and not at all in the technical Ubuntu domain. We provide quantitative and qualitative results highlighting specific weaknesses in existing metrics, and provide recommendations for future development of better automatic evaluation metrics for dialogue systems.

1 Introduction

An important aspect of dialogue response generation systems, which are trained to produce a reasonable utterance given a conversational context, is how to evaluate the quality of the generated response. Typically, evaluation is done using human-generated supervised signals, such as a task completion test or a user satisfaction score (Walker et al., 1997; Möller et al., 2006; Kamm, 1995), which are relevant when the dialogue is task-focused. We call models optimized for such supervised objectives *supervised dialogue models*, while those that do not are *unsupervised dialogue models*.

This paper focuses on unsupervised dialogue response generation models, such as chatbots. These models are receiving increased attention, particularly using end-to-end training with neural networks (Serban et al., 2016; Sordoni et al., 2015; Vinyals and Le, 2015). This avoids the need to collect supervised labels on a large scale, which can be prohibitively expensive. However, automatically evaluating the quality of these models remains an open question. Automatic evaluation metrics would help accelerate the deployment of unsupervised response generation systems.

Faced with similar challenges, other natural language tasks have successfully developed automatic evaluation metrics. For example, BLEU (Papineni et al., 2002a) and METEOR (Banerjee and Lavie, 2005) are now standard for evaluating machine translation models, and ROUGE (Lin, 2004) is often used for automatic summarization. These metrics have recently been adopted by dialogue researchers (Ritter et al., 2011; Sordoni et al., 2015; Li et al., 2015; Galley et al., 2015b; Wen et al., 2015; Li et al., 2016). However these metrics assume that valid responses have significant word overlap with the ground truth responses. This is a strong assumption for dialogue systems, where there is significant diversity in the space of valid responses to a given context. This is illustrated in Table 1, where two reasonable responses are proposed to the context, but these responses do not share any words in common and do not have the same semantic meaning.

In this paper, we investigate the correlation between the scores from several automatic evaluation metrics and human judgements of dialogue response quality, for a variety of response generation models. We consider both statistical *word-overlap similar-*

Context of Conversation
Speaker A: Hey John, what do you want to do tonight?
Speaker B: Why don't we go see a movie?
Ground-Truth Response
Nah, I hate that stuff, let's do something active.
Model Response
Oh sure! Heard the film about Turing is out!

Table 1: Example showing the intrinsic diversity of valid responses in a dialogue. The (reasonable) model response would receive a BLEU score of 0.

ity metrics such as BLEU, METEOR, and ROUGE, and *word embedding metrics* derived from word embedding models such as Word2Vec (Mikolov et al., 2013). We find that all metrics show either weak or no correlation with human judgements, despite the fact that word overlap metrics have been used extensively in the literature for evaluating dialogue response models (see above, and Lasguido et al. (2014)). In particular, we show that these metrics have only a small positive correlation on the chitchat oriented Twitter dataset, and no correlation at all on the technical Ubuntu Dialogue Corpus. For the word embedding metrics, we show that this is true even though all metrics are able to significantly distinguish between baseline and state-of-the-art models across multiple datasets. We further highlight the shortcomings of these metrics using: a) a statistical analysis of our survey's results; b) a qualitative analysis of examples from our data; and c) an exploration of the sensitivity of the metrics.

Our results indicate that a shift must be made in the research community away from these metrics, and highlight the need for a new metric that correlates more strongly with human judgement.

2 Related Work

We focus on metrics that are *model-independent*, i.e. where the model generating the response does not also evaluate its quality; thus, we do not consider word perplexity, although it has been used to evaluate unsupervised dialogue models (Serban et al., 2015). This is because it is not computed on a per-response basis, and cannot be computed for retrieval models. Further, we only consider metrics that can be used to evaluate proposed responses against ground-truth responses, so we do not consider retrieval-based metrics such as recall, which has been used to evaluate dialogue models (Schatzmann et al., 2005; Lowe et al., 2015). We also do not consider evaluation methods for supervised evaluation methods.[1]

Several recent works on unsupervised dialogue systems adopt the BLEU score for evaluation. Ritter et al. (2011) formulate the unsupervised learning problem as one of translating a context into a candidate response. They use a statistical machine translation (SMT) model to generate responses to various contexts using Twitter data, and show that it outperforms information retrieval baselines according to both BLEU and human evaluations. Sordoni et al. (2015) extend this idea using a recurrent language model to generate responses in a context-sensitive manner. They also evaluate using BLEU, however they produce multiple ground truth responses by retrieving 15 responses from elsewhere in the corpus, using a simple bag-of-words model. Li et al. (2015) evaluate their proposed diversity-promoting objective function for neural network models using BLEU score with only a single ground truth response. A modified version of BLEU, deltaBLEU (Galley et al., 2015b), which takes into account several human-evaluated ground truth responses, is shown to have a weak to moderate correlation to human judgements using Twitter dialogues. However, such human annotation is often infeasible to obtain in practice. Galley et al. (2015b) also show that, even with several ground truth responses available, the standard BLEU metric does not correlate strongly with human judgements.

There has been significant previous work that evaluates how well automatic metrics correlate with human judgements in in both machine translation (Callison-Burch et al., 2010; Callison-Burch et al., 2011; Bojar et al., 2014; Graham et al., 2015) and natural language generation (NLG) (Stent et al., 2005; Cahill, 2009; Reiter and Belz, 2009; Espinosa et al., 2010). There has also been work criticizing the usefulness of BLEU in particular for machine translation (Callison-Burch et al., 2006). While many of the criticisms in these works apply to dialogue generation, we note that generating dialogue responses conditioned on the conversational

[1] Evaluation methods in the supervised setting have been well studied, see (Walker et al., 1997; Möller et al., 2006; Jokinen and McTear, 2009).

context is in fact a more difficult problem. This is because most of the difficulty in automatically evaluating language generation models lies in the large set of correct answers. Dialogue response generation given solely the context intuitively has a higher diversity (or entropy) than translation given text in a source language, or surface realization given some intermediate form (Artstein et al., 2009).

3 Evaluation Metrics

Given a dialogue context and a proposed response, our goal is to automatically evaluate how appropriate the proposed response is to the conversation. We focus on metrics that compare it to the ground truth response of the conversation. In particular, we investigate two approaches: word based similarity metrics and word-embedding based similarity metrics.

3.1 Word Overlap-based Metrics

We first consider metrics that evaluate the amount of *word-overlap* between the proposed response and the ground-truth response. We examine the BLEU and METEOR scores that have been used for machine translation, and the ROUGE score that has been used for automatic summarization. While these metrics have been shown to correlate with human judgements in their target domains (Papineni et al., 2002a; Lin, 2004), they have not been thoroughly investigated for dialogue systems.[2]

We denote the ground truth response as r (thus we assume that there is a single candidate ground truth response), and the proposed response as $\hat{r}$. The j'th token in the ground truth response r is denoted by w_j, with $\hat{w}_j$ denoting the j'th token in the proposed response $\hat{r}$.

BLEU. BLEU (Papineni et al., 2002a) analyzes the co-occurrences of n-grams in the ground truth and the proposed responses. It first computes an n-gram precision for the whole dataset (we assume that there is a single candidate ground truth response per context):

$$P_n(r, \hat{r}) = \frac{\sum_k \min(h(k, r), h(k, \hat{r}_i))}{\sum_k h(k, r_i)}$$

where k indexes all possible n-grams of length n and $h(k, r)$ is the number of n-grams k in r.[3] To avoid the drawbacks of using a precision score, namely that it favours shorter (candidate) sentences, the authors introduce a brevity penalty. BLEU-N, where N is the maximum length of n-grams considered, is defined as:

$$\text{BLEU-N} := b(r, \hat{r}) \exp(\sum_{n=1}^{N} \beta_n \log P_n(r, \hat{r}))$$

β_n is a weighting that is usually uniform, and $b(\cdot)$ is the brevity penalty. The most commonly used version of BLEU uses $N = 4$. Modern versions of BLEU also use sentence-level smoothing, as the geometric mean often results in scores of 0 if there is no 4-gram overlap (Chen and Cherry, 2014). Note that BLEU is usually calculated at the corpus-level, and was originally designed for use with multiple reference sentences.

METEOR. The METEOR metric (Banerjee and Lavie, 2005) was introduced to address several weaknesses in BLEU. It creates an explicit alignment between the candidate and target responses. The alignment is based on exact token matching, followed by WordNet synonyms, stemmed tokens, and then paraphrases. Given a set of alignments, the METEOR score is the harmonic mean of precision and recall between the proposed and ground truth sentence.

ROUGE. ROUGE (Lin, 2004) is a set of evaluation metrics used for automatic summarization. We consider ROUGE-L, which is a F-measure based on the Longest Common Subsequence (LCS) between a candidate and target sentence. The LCS is a set of words which occur in two sentences in the same order; however, unlike n-grams the words do not have to be contiguous, i.e. there can be other words in between the words of the LCS.

[2] To the best of our knowledge, only BLEU has been evaluated in the dialogue system setting quantitatively by Galley et al. (2015a) on the Twitter domain. However, they carried out their experiments in a very different setting with multiple ground truth responses, which are rarely available in practice, and without providing any qualitative analysis of their results.

[3] Note that the min in this equation is calculating the number of co-occurrences of n-gram k between the ground truth response r and the proposed response $\hat{r}$, as it computes the fewest appearances of k in either response.

3.2 Embedding-based Metrics

An alternative to using word-overlap based metrics is to consider the meaning of each word as defined by a *word embedding*, which assigns a vector to each word. Methods such as Word2Vec (Mikolov et al., 2013) calculate these embeddings using distributional semantics; that is, they approximate the meaning of a word by considering how often it co-occurs with other words in the corpus.[4] These embedding-based metrics usually approximate sentence-level embeddings using some heuristic to combine the vectors of the individual words in the sentence. The sentence-level embeddings between the candidate and target response are compared using a measure such as cosine distance.

Greedy Matching. Greedy matching is the one embedding-based metric that does not compute sentence-level embeddings. Instead, given two sequences r and $\hat{r}$, each token $w \in r$ is greedily matched with a token $\hat{w} \in \hat{r}$ based on the cosine similarity of their word embeddings (e_w), and the total score is then averaged across all words:

$$G(r, \hat{r}) = \frac{\sum_{w \in r;} \max_{\hat{w} \in \hat{r}} cos\_sim(e_w, e_{\hat{w}})}{|r|}$$

$$GM(r, \hat{r}) = \frac{G(r, \hat{r}) + G(\hat{r}, r)}{2}$$

This formula is asymmetric, thus we must average the greedy matching scores G in each direction. This was originally introduced for intelligent tutoring systems (Rus and Lintean, 2012). The greedy approach favours responses with key words that are semantically similar to those in the ground truth response.

Embedding Average. The embedding average metric calculates sentence-level embeddings using additive composition, a method for computing the meanings of phrases by averaging the vector representations of their constituent words (Foltz et al., 1998; Landauer and Dumais, 1997; Mitchell and Lapata, 2008). This method has been widely used in other domains, for example in textual similarity tasks (Wieting et al., 2015). The embedding average, $\bar{e}$, is defined as the mean of the word embeddings of each token in a sentence r:

$$\bar{e}_r = \frac{\sum_{w \in r} e_w}{|\sum_{w' \in r} e_{w'}|}.$$

To compare a ground truth response r and retrieved response $\hat{r}$, we compute the cosine similarity between their respective sentence level embeddings: EA $:= \cos(\bar{e}_r, \bar{e}_{\hat{r}})$.

Vector Extrema. Another way to calculate sentence-level embeddings is using vector extrema (Forgues et al., 2014). For each dimension of the word vectors, take the most extreme value amongst *all word vectors in the sentence*, and use that value in the sentence-level embedding:

$$e_{rd} = \begin{cases} \max_{w \in r} e_{wd} & \text{if } e_{wd} > |\min_{w' \in r} e_{w'd}| \\ \min_{w \in r} e_{wd} & \text{otherwise} \end{cases}$$

where d indexes the dimensions of a vector; e_{wd} is the d'th dimensions of e_w (w's embedding). The min in this equation refers to the selection of the largest negative value, if it has a greater magnitude than the largest positive value.

Similarity between response vectors is again computed using cosine distance. Intuitively, this approach prioritizes informative words over common ones; words that appear in similar contexts will be close together in the vector space. Thus, common words are pulled towards the origin because they occur in various contexts, while words carrying important semantic information will lie further away. By taking the extrema along each dimension, we are thus more likely to ignore common words.

4 Dialogue Response Generation Models

In order to determine the correlation between automatic metrics and human judgements of response quality, we obtain response from a diverse range of response generation models in the recent literature, including both *retrieval* and *generative* models.

4.1 Retrieval Models

Ranking or retrieval models for dialogue systems are typically evaluated based on whether they can retrieve the correct response from a corpus of predefined responses, which includes the ground truth

[4] To maintain statistical independence between the task and each performance metric, it is important that the word embeddings used are trained on corpora which do not overlap with the task corpus.

Table 2: Models evaluated using the vector-based evaluation metrics, with 95% confidence intervals.

response to the conversation (Schatzmann et al., 2005). Such systems can be evaluated using recall or precision metrics. However, when deployed in a real setting these models will not have access to the correct response given an unseen conversation. Thus, in the results presented below we *remove* one occurrence of the ground-truth response from the corpus and ask the model to retrieve the most appropriate response from the remaining utterances. Note that this does not mean the correct response will not appear in the corpus at all; in particular, if there exists another context in the dataset with an identical ground-truth response, this will be available for selection by the model.

We then evaluate each model by comparing the retrieved response to the ground truth response of the conversation. This closely imitates real-life deployment of these models, as it tests the ability of the model to generalize to unseen contexts.

TF-IDF. We consider a simple Term Frequency - Inverse Document Frequency (TF-IDF) retrieval model (Lowe et al., 2015). TF-IDF is a statistic that intends to capture how important a given word is to some document, which is calculated as: $\text{tfidf}(w, c, C) = f(w, c) \times \log \frac{N}{|\{c \in C : w \in c\}|}$, where C is the set of all contexts in the corpus, $f(w, c)$ indicates the number of times word w appeared in context c, N is the total number of dialogues, and the denominator represents the number of dialogues in which the word w appears.

In order to apply TF-IDF as a retrieval model for dialogue, we first compute the TF-IDF vectors for each context and response in the corpus. We then return the response with the largest cosine similarity in the corpus, either between the input context and corpus contexts (C-TFIDF), or between the input context and corpus responses (R-TFIDF).

Dual Encoder. Next we consider the recurrent neural network (RNN) based architecture called the Dual Encoder (DE) model (Lowe et al., 2015). The DE model consists of two RNNs which respectively compute the vector representation of an input context and response, $c, r \in \mathbb{R}^n$. The model then calculates the probability that the given response is the ground truth response given the context, by taking a weighted dot product: $p(r \text{ is correct} | c, r, M) = \sigma(c^T M r + b)$ where M is a matrix of learned parameters and b is a bias. The model is trained using negative sampling to minimize the cross-entropy error of all (context, response) pairs. To our knowledge, our application of neural network models to large-scale retrieval in dialogue systems is novel.

4.2 Generative Models

In addition to retrieval models, we also consider generative models. In this context, we refer to a model as generative if it is able to generate entirely new sentences that are unseen in the training set.

LSTM language model. The baseline model is an LSTM language model (Hochreiter and Schmidhuber, 1997) trained to predict the next word in the (context, response) pair. During test time, the model is given a context, encodes it with the LSTM and generates a response using a greedy beam search procedure (Graves, 2013).

HRED. Finally we consider the Hierarchical Recurrent Encoder-Decoder (HRED) (Serban et al., 2015). In the traditional Encoder-Decoder framework, all utterances in the context are concatenated together before encoding. Thus, information from previous utterances is far outweighed by the most recent utterance. The HRED model uses a *hierarchy* of encoders; each utterance in the context passes through an 'utterance-level' encoder, and the

output of these encoders is passed through another 'context-level' encoder, which enables the handling of longer-term dependencies.

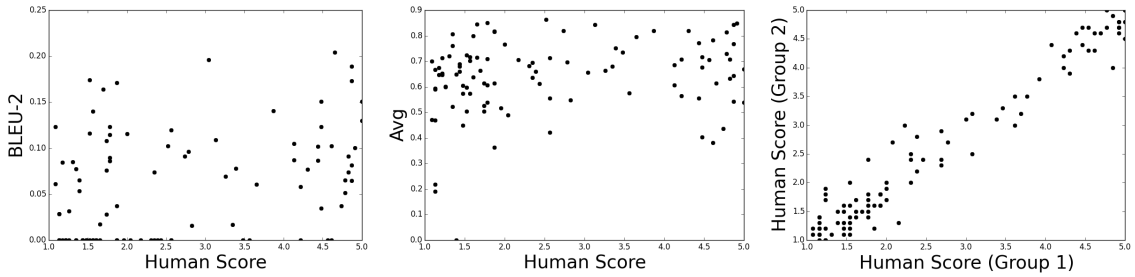
4.3 Conclusions from an Incomplete Analysis

When evaluation metrics are not explicitly correlated to human judgement, it is possible to draw misleading conclusions by examining how the metrics rate different models. To illustrate this point, we compare the performance of selected models according to the embedding metrics on two different domains: the Ubuntu Dialogue Corpus (Lowe et al., 2015), which contains technical vocabulary and where conversations are often oriented towards solving a particular problem, and a non-technical Twitter corpus collected following the procedure of Ritter et al. (2010). We consider these two datasets since they cover contrasting dialogue domains, i.e. technical help vs casual chit-chat, and because they are amongst the largest publicly available corpora, making them good candidates for building data-driven dialogue systems.

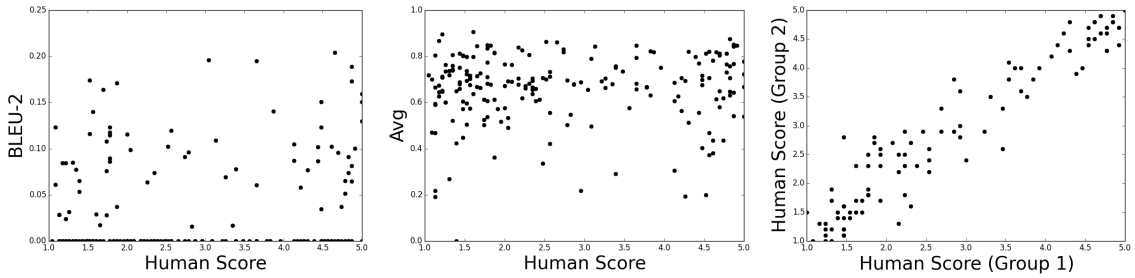
Results on the proposed embedding metrics are shown in Table 2. For the retrieval models, we observe that the DE model significantly outperforms both TFIDF baselines on all metrics across both datasets. Further, the HRED model significantly outperforms the basic LSTM generative model in both domains, and appears to be of similar strength as the DE model. Based on these results, one might be tempted to conclude that there is some information being captured by these metrics, that significantly differentiates models of different quality. However, as we show in the next section, the embedding-based metrics correlate only weakly with human judgements on the Twitter corpus, and not at all on the Ubuntu Dialogue Corpus. This demonstrates that metrics that have not been specifically correlated with human judgements on a new task should not be used to evaluate that task.

5 Human Correlation Analysis

Data Collection. We conducted a human survey to determine the correlation between human judgements on the quality of responses, and the score assigned by each metric. We aimed to follow the procedure for the evaluation of BLEU (Papineni et al.,



(a) Twitter



(b) Ubuntu

Figure 1: Scatter plots showing the correlation between metrics and human judgements on the Twitter corpus (a) and Ubuntu Dialogue Corpus (b). The plots represent BLEU-2 (left), embedding average (center), and correlation between two randomly selected halves of human respondents (right).

2002a). 25 volunteers from the Computer Science department at the author's institution were given a context and one proposed response, and were asked to judge the response quality on a scale of 1 to 5.[5]; a 1 indicates that the response is not appropriate or sensible given the context, and a 5 indicates that the response is very reasonable. Out of the 25 respondents, 23 had Cohen's kappa scores $\kappa > 0.2$ w.r.t. the other respondents, which is a standard measure for inter-rater agreement (Cohen, 1968). The 2 respondents with $\kappa < 0.2$, indicating slight agreement, were excluded from the analysis below. The median κ score was approximately 0.55, roughly indicating moderate to strong annotator agreement.

Each volunteer was given 100 questions per dataset. These questions correspond to 20 unique contexts, with 5 different responses: one utterance randomly drawn from elsewhere in the test set, the response selected from each of the TF-IDF, DE, and HRED models, and a response written by a human annotator. These were chosen as they cover the range of qualities almost uniformly (see Figure 1).

Survey Results. We present correlation results between the human judgements and each metric in Table 3. We compute the Pearson correlation, which estimates linear correlation, and Spearman correlation, which estimates any monotonic correlation.

The first observation is that in both domains the BLEU-4 score, which has previously been used to evaluate unsupervised dialogue systems, shows very weak if any correlation with human judgement. In fact we found that the BLEU-3 and BLEU-4 scores were near-zero for a majority of response pairs; for BLEU-4, only four examples had a score $> 10^{-9}$. Despite this, they still correlate with human judgements on the Twitter Corpus at a rate similar to BLEU-2. This is because of the smoothing constant, which gives a tiny weight to unigrams and bigrams despite the absence of higher-order n-grams. BLEU-3 and BLEU-4 behave as a scaled, noisy version of BLEU-2; thus, if one is to evaluate dialogue

[5]Studies asking humans to evaluate text often rate different aspects separately, such as 'adequacy', 'fluency' and 'informativeness' of the text (Hovy, 1999; Papineni et al., 2002b) Our evaluation focuses on adequacy. We did not consider fluency because 4 out of the 5 proposed responses to each context were generated by a human. We did not consider informativeness because in the domains considered, it is not necessarily important (in Twitter), or else it seems to correlate highly with adequacy (in Ubuntu).

Context of Conversation	**Context of Conversation**
A: dearest! question. how many thousands of people can panaad occupy? B: @user panaad has <number> k seat capacity while rizal has <number> k thats why they choose rizal i think .	A: never felt more sad than i am now B: @user aww why ? A: @user @user its a long story ! sure you wanna know it ? bahaha and thanks for caring btw <heart>
Ground Truth Response	**Ground Truth Response**
A: now i know about the siting capacity . thanks for the info @user great evening.	A: @user i don 't mind to hear it i 've got all day and youre welcome <number>
Proposed Response	**Proposed Response**
A: @user makes sense. thanks!	A: @user i know , i 'm just so happy for you !

Figure 2: Examples where the metrics rated the response poorly and humans rated it highly (left), and the converse (right). Both responses are given near-zero score by BLEU-N for N$>$ 1. While no metric will perform perfectly on all examples, we present these examples to provide intuition on how example-level errors become aggregated into poor correlation to human judgements at the corpus-level.

responses with BLEU, we recommend the choice of $N = 2$ over $N = 3$ or 4. Note that using a test corpus larger than the size reported in this paper may lead to stronger correlations for BLEU-3 and BLEU-4, due to a higher number of non-zero scores.

It is interesting to note that, while some of the embedding metrics and BLEU show small positive correlation in the non-technical Twitter domain, there is no metric that significantly correlates with humans on the Ubuntu Dialogue Corpus. This is likely because the correct Ubuntu responses contain specific technical words that are less likely to be produced by our models. Further, it is possible that responses in the Ubuntu Dialogue Corpus have intrinsically higher variability (or entropy) than Twitter when conditioned on the context, making the evaluation problem significantly more difficult.

Figure 1 illustrates the relationship between metrics and human judgements. We include only the best performing metric using word-overlaps, i.e. the BLEU-2 score (left), and the best performing metric using word embeddings, i.e. the vector average (center). These plots show how weak the correlation is: in both cases, they appear to be random noise. It seems as though the BLEU score obtains a positive correlation because of the large number of responses that are given a score of 0 (bottom left corner of the first plot). This is in stark contrast to the inter-rater agreement, which is plotted between two randomly sampled halves of the raters (right-most plots). We also calculated the BLEU scores after removing stopwords and punctuation from the responses. As shown in Table 4, this weakens the correlation with human judgements for BLEU-2 compared to the values in Table 3, and suggests that BLEU is sensitive to factors that do not change the semantics of the response.

Finally, we examined the effect of response length on the metrics, by considering changes in scores when the ground truth and proposed response had a large difference in word counts. Table 4 shows that BLEU and METEOR are particularly sensitive to this aspect, compared to the Embedding Average metric and human judgement.

Qualitative Analysis. In order to determine specifically why the metrics fail, we examine qualitative samples where there is a disagreement between the metrics and human rating. Although these only show inconsistencies at the example-level, they provide some intuition as to why the metrics don't correlate with human judgements at the corpus-level. We present in Figure 2 two examples where all of the embedding-based metrics and BLEU-1 score the proposed response significantly differently than the humans.

The left of Figure 2 shows an example where the embedding-based metrics score the proposed response lowly, while humans rate it highly. It is clear from the context that the proposed response is reasonable – indeed both responses intend to express gratitude. However, the proposed response has a different wording than the ground truth response, and therefore the metrics are unable to separate the salient words from the rest. This suggests that the embedding-based metrics would ben-

efit from a weighting of word saliency.

The right of the figure shows the reverse scenario: the embedding-based metrics score the proposed response highly, while humans do not. This is most likely due to the frequently occurring 'i' token, and the fact that 'happy' and 'welcome' may be close together in the embedding space. However, from a human perspective there is a significant semantic difference between the responses as they pertain to the context. Metrics that take into account the context may be required in order to differentiate these responses. Note that in both responses in Figure 2, there are no overlapping n-grams greater than unigrams between the ground truth and proposed responses; thus, all of BLEU-2,3,4 would assign a score near 0 to the response.

6 Discussion

We have shown that many metrics commonly used in the literature for evaluating unsupervised dialogue systems do not correlate strongly with human judgement. Here we elaborate on important issues arising from our analysis.

Constrained tasks. Our analysis focuses on relatively unconstrained domains. Other work, which separates the dialogue system into a dialogue planner and a natural language generation component for applications in constrained domains, may find stronger correlations with the BLEU metric. For example, Wen et al. (2015) propose a model to map from dialogue acts to natural language sentences and use BLEU to evaluate the quality of the generated sentences. Since the mapping from dialogue acts to natural language sentences has lower diversity and is more similar to the machine translation task, it seems likely that BLEU will correlate better with human judgements. However, an empirical investigation is still necessary to justify this.

Incorporating multiple responses. Our correlation results assume that only one ground truth response is available given each context. Indeed, this is the common setting in most of the recent literature on training end-to-end conversation models. There has been some work on using a larger set of automatically retrieved plausible responses when evaluating with BLEU (Galley et al., 2015b). However, there is no standard method for doing this in the literature. Future work should examine how retrieving additional responses affects the correlation with word-overlap metrics.

Searching for suitable metrics. While we provide evidence against existing metrics, we do not yet provide good alternatives for unsupervised evaluation. Despite the poor performance of the word embedding-based metrics in this survey, we believe that metrics based on distributed sentence representations hold the most promise for the future. This is because word-overlap metrics will simply require too many ground-truth responses to find a significant match for a reasonable response, due to the high diversity of dialogue responses. As a simple example, the skip-thought vectors of Kiros et al. (2015) could be considered. Since the embedding-based metrics in this paper only consist of basic averages of vectors obtained through distributional semantics, they are insufficiently complex for modeling sentence-level compositionality in dialogue. Instead, these metrics can be interpreted as calculating the *topicality* of a proposed response (i.e. how on-topic the proposed response is, compared to the ground-truth).

All of the metrics considered in this paper directly compare a proposed response to the ground-truth, without considering the context of the conversation. However, metrics that take into account the context could also be considered. Such metrics could come in the form of an *evaluation model* that is learned from data. This model could be either a discriminative model that attempts to distinguish between model and human responses, or a model that uses data collected from the human survey in order to provide human-like scores to proposed responses. Finally, we must consider the hypothesis that learning such models from data is no easier than solving the problem of dialogue response generation. If this hypothesis is true, we must concede and always use human evaluations together with metrics that only roughly approximate human judgements.

Addressee and Response Selection for Multi-Party Conversation

Abstract

To create conversational systems working in actual situations, it is crucial to assume that they interact with multiple agents. In this work, we tackle addressee and response selection for multi-party conversation, in which systems are expected to select *whom* they address as well as *what* they say. The key challenge of this task is to jointly model *who* is talking about *what* in a previous context. For the joint modeling, we propose two modeling frameworks: 1) static modeling and 2) dynamic modeling. To show benchmark results of our frameworks, we created a multi-party conversation corpus. Our experiments on the dataset show that the recurrent neural network based models of our frameworks robustly predict addressees and responses in conversations with a large number of agents.

1 Introduction

Short text conversation (STC) has been gaining popularity: given an input message, predict an appropriate response in a single-round, two-party conversation (Wang et al., 2013; Shang et al., 2015). Modeling STC is simpler than modeling a complete conversation, but instantly helps applications such as chat-bots and automatic short-message replies (Ji et al., 2014).

Beyond two-party conversations, there is also a need for modeling *multi-party conversation*, a form of conversation with several interlocutors conversing with each other (Traum, 2003; Dignum and Vreeswijk, 2003; Uthus and Aha, 2013). For example, in the Ubuntu Internet Relay Chat (IRC), several users cooperate to find a solution for a technical issue contributed by another user. Each agent might have one part of the solution, and these pieces have to be combined through conversation in order to come up with the whole solution.

User	Addressee	Utterance
User 1	-	I have a problem when I install ...
SYSTEM	-	did you set initial params ?
User 2	-	Show the error message, and ...
User 1	*SYSTEM*	how ?
User 1	User 2	ok just a moment !
SYSTEM	[To Whom?]	[What?]
	1. User 1	1. see this URL : http://xxxx
	2. User 2	2. It 's already in os

Figure 1: Addressee and response selection for multi-party conversation. A *SYSTEM* is required to select an appropriate addressee from the interlocutors in the conversational context and an appropriate response from the fixed set of candidates.

A unique issue of such multi-party conversations is *addressing*, a behavior whereby interlocutors indicate to whom they are speaking (Jovanović and Akker, 2004; Akker and Traum, 2009). In face-to-face communication, the basic clue for specifying addressees is turning one's face toward the addressee. In contrast, in voice-only or text-based communication, the explicit declaration of addressee's names is more common.

In this work, we tackle *addressee and response selection* for multi-party conversation: given a context, predict an addressee and response. As Figure 1 shows, a system is required to select an addressee from the agents appearing in the previous context and a response from a fixed set of candidate responses (Section 3).

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2133–2143,
Austin, Texas, November 1-5, 2016.

The key challenge for predicting appropriate addressees and responses is to jointly capture *who* is talking about *what* at each time step in a context. For jointly modeling the speaker-utterance information, we present two modeling frameworks: 1) *static modeling* and 2) *dynamic modeling* (Section 5). While speakers are represented as fixed vectors in the static modeling, they are represented as hidden state vectors that dynamically change with time steps in the dynamic modeling. In practice, our models trained for the task can be applied to retrieval-based conversation systems, which retrieves candidate responses from a large-scale repository with the matching model and returns the highest scoring one with the ranking model (Wang et al., 2013; Ji et al., 2014; Wang et al., 2015). Our trained models work as the ranking model and allow the conversation system to produce addressees as well as responses.

To evaluate the trained models, we provide a corpus and dataset. By exploiting Ubuntu IRC Logs[1], we build a large-scale multi-party conversation corpus, and create a dataset from it (Section 6). Our experiments on the dataset show the models instantiated by the static and dynamic modeling outperform a strong baseline. In particular, the model based on the dynamic modeling robustly predicts appropriate addressees and responses even if the number of interlocutors in a conversation increases.[2]

We make three contributions in this work:

1. We formalize the task of addressee and response selection for multi-party conversation.

2. We present modeling frameworks and the performance benchmarks for the task.

3. We build a large-scale multi-party conversation corpus and dataset for the task.

2 Related Work

This work follows in the footsteps of Ritter et al. (2011), who tackled the response generation problem: given a context, generate an appropriate response. While previous response generation approaches utilize statistical models on top of heuristic rules or templates (Levin et al., 2000; Young et al., 2010; Walker et al., 2003), they apply *statistical machine translation based techniques* without such heuristics, which leads to recent work utilizing the SMT-based techniques with neural networks (Shang et al., 2015; Vinyals and Le, 2015; Sordoni et al., 2015; Serban et al., 2016).

As another popular approach, *retrieval-based techniques* are used to retrieve candidate responses from a repository and return the highest scoring one with the ranking model (Ji et al., 2014; Wang et al., 2015; Hu et al., 2014; Wang et al., 2013; Lu and Li, 2013). Stemming from this approach, the next utterance classification (NUC) task has been proposed, in which a system is required to select an appropriate response from a fixed set of candidates (Lowe et al., 2015; Kadlec et al., 2015). The NUC is regarded as focusing on the ranking problem of retrieval-based system, since it omits the candidate retrieving step. The merit of NUC is that it allows us to easily evaluate the model performance on the basis of accuracy.

Our proposed addressee and response selection task is an extension of the NUC. We generalize the task by integrating the addressee detection, which has been regarded as a problematic issue in multi-party conversation (Traum, 2003; Jovanović and Akker, 2004; Uthus and Aha, 2013). Basically, the addressee detection has been tackled in the spoken/multimodal dialog system research, and the models largely rely on acoustic signal or gaze information (Jovanović et al., 2006; Akker and Traum, 2009; Ravuri and Stolcke, 2014). This current work is different from such previous work in that our models predict addressees with only textual information.

For predicting addressees or responses, how the context is encoded is crucial. In single-round conversation, a system is expected to encode only one utterance as a context (Ritter et al., 2011; Wang et al., 2013). In contrast, in multi-turn conversation, a system is expected to encode multiple utterances (Shang et al., 2015; Lowe et al., 2015). Very recently, individual personalities have been encoded as distributed embeddings used for response generation in two-party conversation (Li et al., 2016). Our work is different from that work in that our proposed personality-independent representation allows us to handle new agents unseen in the training data.

	Type	Notation
Input	Responding Agent	a_{res}
	Context	$\mathcal{C}$
	Candidate Responses	$\mathcal{R}$
Output	Addressee	$a \in \mathcal{A}(\mathcal{C})$
	Response	$\boldsymbol{r} \in \mathcal{R}$

Table 1: Notations for the ARS task.

3 Addressee and Response Selection

We propose and formalize the task of *addressee and response selection* (ARS) for multi-party conversation. The ARS task assumes the situation where a responding agent gives a response to an addressee following a context.[3]

Notation

Table 1 shows the notations for the formalization. We denote vectors with bold lower-case (e.g. $\mathbf{x}_t$, $\mathbf{h}$), matrices with bold upper-case (e.g. $\mathbf{W}$, $\mathbf{H}_a$), scalars with italic lower-case or upper-case (e.g. a_m, Q), and sets with bold italic lower-case or cursive upper-case (e.g. $\boldsymbol{x}$, $\mathcal{C}$) letters.

Formalization

Given an input conversational situation $\boldsymbol{x}$, an addressee a and a response $\boldsymbol{r}$ are predicted:

$$\text{GIVEN} : \boldsymbol{x} = (a_{res},\ \mathcal{C},\ \mathcal{R})$$

$$\text{PREDICT} : a, \boldsymbol{r}$$

where a_{res} is a responding agent, $\mathcal{C}$ is a context and $\mathcal{R}$ is a set of candidate responses. The context $\mathcal{C}$ is a sequence of previous utterances up to the current time step T:

$$\mathcal{C} = (\boldsymbol{u}_{a_1,1}, \cdots, \boldsymbol{u}_{a_T,T})$$

where $\boldsymbol{u}_{a_t,t}$ is an utterance given by an agent a_t at a time step t. Each utterance $\boldsymbol{u}_{a_t,t}$ is a sequence of N_t tokens:

$$\boldsymbol{u}_{a_t,t} = (w_{a_t,t,1}, \cdots, w_{a_t,t,N_t})$$

where $w_{a_t,t,n}$ is a token index in the vocabulary $\mathcal{V}$.

[3] In actual situations, responses can be addressed to multiple agents. In this work, we assume the situation where one specific agent can be the addressee of a response.

To predict an addressee a as a target output, we select an agent from a set of the agents appearing in a context $\mathcal{A}(\mathcal{C})$. Note that a ground-truth addressee is always included in $\mathcal{A}(\mathcal{C})$. To predict an appropriate response $\boldsymbol{r}$, we select a response from a set of candidate responses $\mathcal{R}$, which consists of Q candidates:

$$\mathcal{R} = \{\boldsymbol{r}_1, \cdots, \boldsymbol{r}_Q\}$$

$$\boldsymbol{r}_q = (w_{q,1}, \cdots, w_{q,N_q})$$

where $\boldsymbol{r}_q$ is a candidate response, which consists of N_q tokens, and $w_{q,n}$ is an token index in the vocabulary $\mathcal{V}$.

4 Dual Encoder Models

Our proposed models are extensions of the *dual encoder* (DE) model in (Lowe et al., 2015). The DE model consists of two recurrent neural networks (RNN) that respectively compute the vector representation of an input context and candidate response.

A generic RNN, with input $\mathbf{x}_t \in \mathbb{R}^{d_w}$ and *recurrent* state $\mathbf{h}_t \in \mathbb{R}^{d_h}$, is defined as:

$$\mathbf{h}_t = f(\mathbf{h}_{t-1}, \mathbf{x}_t) = \pi(\mathbf{W}_h \mathbf{h}_{t-1} + \mathbf{W}_x \mathbf{x}_t) \quad (1)$$

where π is a non-linear function, $\mathbf{W}_x \in \mathbb{R}^{d_h \times d_w}$ is a parameter matrix for $\mathbf{x}_t$, $\mathbf{W}_h \in \mathbb{R}^{d_h \times d_h}$ is a parameter matrix for $\mathbf{h}_{t-1}$, and the recurrence is seeded with the $\mathbf{0}$ vector, i.e. $\mathbf{h}_0 = \mathbf{0}$. The recurrent state $\mathbf{h}_t$ acts as a compact *summary* of the inputs seen up to time step t.

In the DE model, each word vector of the context $\mathcal{C}$ and the response $\boldsymbol{r}_q$ is consumed by each RNN, and is then summarized into the context vector $\mathbf{h}_c \in \mathbb{R}^{d_h}$ and the response vector $\mathbf{h}_q \in \mathbb{R}^{d_h}$. Using these vectors, the model calculates the probability that the given candidate response is the ground-truth response given the context as follows:

$$Pr(y(\boldsymbol{r}_q) = 1 | \mathcal{C}, \boldsymbol{r}_q) = \sigma(\mathbf{h}_c^{\mathrm{T}}\ \mathbf{W}\ \mathbf{h}_q) \quad (2)$$

where y is a binary function mapping from $\boldsymbol{r}_q$ to $\{0, 1\}$, in which 1 represents the ground-truth sample and 0 represents the false one, σ is the logistic sigmoid function, and $\mathbf{W} \in \mathbb{R}^{d_h \times d_h}$ is a parameter matrix. As extensions of this model, we propose our multi-party encoder models.

5 Multi-Party Encoder Models

For capturing multi-party conversational streams, we jointly encode *who* is speaking *what* at each time step. Each agent and its utterance are integrated into the hidden states of an RNN.

We present two multi-party modeling frameworks: (i) *static modeling* and (ii) *dynamic modeling*, both of which jointly utilize agent and utterance representation for encoding multiple-party conversation. What distinguishes the models is that while the agent representation in the static modeling framework is fixed, the one in the dynamic modeling framework changes along with each time step t in a conversation.

Modeling Frameworks

As an instance of the static modeling, we propose a static model to capture the *speaking-orders* of agents in conversation. As an instance of the dynamic modeling, we propose a dynamic model using an RNN to track *agent states*. Note that the agent representations are independent of each personality (unique user). The personality-independent representation allows us to handle new agents unseen in the training data.

Formally, similar to Eq. 2, both of the models calculate the probability that the addressee a_p or response $\boldsymbol{r}_q$ is the ground-truth given the input $\mathbf{x}$:

$$Pr(y(a_p) = 1|\mathbf{x}) = \sigma\left([\mathbf{a}_{res}\,;\,\mathbf{h}_c]^{\mathrm{T}}\,\mathbf{W}_a\;\mathbf{a}_p\right) \quad (3)$$

$$Pr(y(\boldsymbol{r}_q) = 1|\mathbf{x}) = \sigma\left([\mathbf{a}_{res}\,;\,\mathbf{h}_c]^{\mathrm{T}}\,\mathbf{W}_r\,\mathbf{h}_q\right) \quad (4)$$

where y is a binary function mapping from a_p or $\boldsymbol{r}_q$ to $\{0, 1\}$, in which 1 represents the ground-truth sample and 0 represents the false one. The function σ is the logistic sigmoid function. $\mathbf{a}_{res} \in \mathbb{R}^{d_a}$ is a responding agent vector, $\mathbf{a}_p \in \mathbb{R}^{d_a}$ is a candidate addressee vector, $\mathbf{h}_c \in \mathbb{R}^{d_h}$ is a context vector, $\mathbf{h}_q \in \mathbb{R}^{d_h}$ is a candidate response vector. These vectors are respectively defined in each model. $\mathbf{W}_a \in \mathbb{R}^{(d_a+d_h)\times d_h}$ is a parameter matrix for the addressee selection probability, and $\mathbf{W}_r \in \mathbb{R}^{(d_a+d_h)\times d_h}$ is a parameter matrix for the response selection probability. These model parameters are learned during training.

On the basis of Eqs. 3 and 4, a resulting addressee and response are selected as follows:

$$\hat{a} = \underset{a_p \in \mathcal{A}(\mathcal{C})}{\operatorname{argmax}}\, Pr(y(a_p) = 1|\mathbf{x}) \quad (5)$$

$$\hat{\boldsymbol{r}} = \underset{\boldsymbol{r}_q \in \mathcal{R}}{\operatorname{argmax}}\, Pr(y(\boldsymbol{r}_q) = 1|\mathbf{x}) \quad (6)$$

where $\hat{a}$ is the highest probability addressee of a set of agents in the context $\mathcal{A}(\mathcal{C})$, and $\hat{\boldsymbol{r}}$ is the highest probability response of a set of candidate responses $\mathcal{R}$.

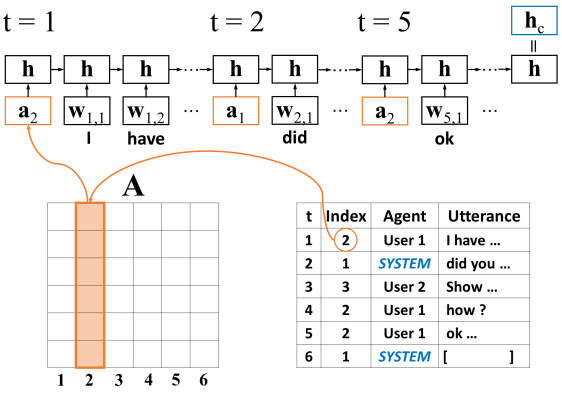

Figure 2: Illustrative example of our static model.

5.1 A Static Model

In the static model, agent matrix $\mathbf{A}$ is defined for the agent vectors in Eqs. 3 and 4. This agent matrix can be defined arbitrarily. We define the agent matrix $\mathbf{A}$ on the basis of *agents' speaking orders*. Intuitively, the agents that spoke in recent time steps are more likely to be an addressee. Our static model captures such property.

The static model is shown in Figure 2. First, agents in the context $\mathcal{A}(\mathcal{C})$ and a responding agent a_{res} are sorted in descending order based on each latest speaking time. Then the order is assigned as an agent index $a_m \in (1, \cdots, |\mathcal{A}(\mathcal{C})|)$ to each agent. In the table shown in Figure 2, the responding agent (represented as `SYSTEM`) has the agent index 1 because he spoke at the most recent time step $t = 6$. Similarly, `User 1` has the index 2 because he spoke at the second most recent time step $t = 5$, and `User 2` has the index 3 because he spoke at the third $t = 3$.

Each speaking-order index a_m is associated with the a_m-th column of the agent matrix $\mathbf{A}$:

$$\mathbf{a}_m = \mathbf{A}[*, a_m]$$

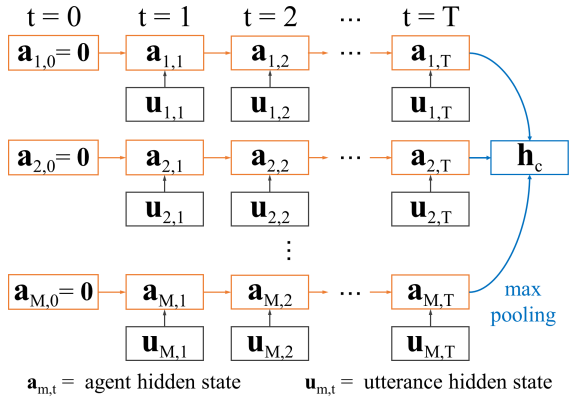

Figure 3: Illustrative example of our dynamic model.

Similarly, a responding agent vector a_{res} and a candidate addressee vector a_p in Eqs. 3 and 4 are respectively extracted from $\mathbf{A}$, i.e. $\mathbf{a}_{res} = \mathbf{A}[*, a_{res}]$ and $\mathbf{a}_p = \mathbf{A}[*, a_p]$.

Consuming the agent vectors, an RNN updates its hidden state. For example, at the time step $t = 1$ in Figure 2, the agent vector $\mathbf{a}_1$ of `User` 1 is extracted from $\mathbf{A}$ on the basis of agent index 2 and then consumed by the RNN. Then, the RNN consumes each word vector $\mathbf{w}$ of `User` 1's utterance. By consuming the agent vector before word vectors, the model can capture which agent speaks the utterance. The last state of the RNN is regarded as $\mathbf{h}_c$. As the transition function f of RNN (Eq. 1), we use the Gated Recurrent Unit (GRU) (Cho et al., 2014; Chung et al., 2014).

For the candidate response vector $\mathbf{h}_q$, each word vector $(\mathbf{w}_{q,1}, \cdots, \mathbf{w}_{q,N_q})$ in the response $\boldsymbol{r}_q$ is summarized with the RNN. Using these vectors $\mathbf{a}_{res}$, $\mathbf{a}_p$, $\mathbf{h}_c$, and $\mathbf{h}_q$, we predict a next addressee and response with the Eqs. 3 and 4.

5.2 A Dynamic Model

In the static model, agent representation $\mathbf{A}$ is a fixed matrix that does not change in a conversational stream. In contrast, in the dynamic model, agent representation $\mathbf{A}_t$ tracks each agent's hidden state which dynamically changes with time steps t.

Figure 3 shows the overview of the dynamic model. Initially, we set a zero matrix as initial agent state $\mathbf{A}_0$, and each column vector of the agent matrix corresponds to an agent hidden state vector. Then, each agent state is updated by consuming the utterance vector at each time step. Note that the states of the agents that are not speaking at the time are updated by zero vectors.

Formally, each column of $\mathbf{A}_t$ corresponds to an agent state vector:

$$\mathbf{a}_{m,t} = \mathbf{A}_t[*, a_m]$$

where an agent state vector $\mathbf{a}_{m,t}$ of an agent a_m at a time step t is the a_m-th column of the agent matrix $\mathbf{A}_t$.

Each vector of the matrix is updated at each time step, as shown in Figure 3. An agent state vector $\mathbf{a}_{m,t} \in \mathbb{R}^{d_a}$ for each agent a_m at each time step t is recurrently computed:

$$\mathbf{a}_{m,t} = g(\mathbf{a}_{m,t-1}, \mathbf{u}_{m,t}), \;\; \mathbf{a}_{m,0} = \mathbf{0}$$

where $\mathbf{u}_{m,t} \in \mathbb{R}^{d_w}$ is a summary vector of an utterance of an agent a_m and computed with an RNN. As the transition function g, we use the GRU. For example, at a time step $t = 2$ in Figure 3, the agent state vector $\mathbf{a}_{1,2}$ is influenced by its utterance vector $\mathbf{u}_{1,2}$ and updated from the previous state $\mathbf{a}_{1,1}$.

The agent matrix updated up to the time step T is denoted as $\mathbf{A}_T$, which is max-pooled and used as a summarized context vector:

$$\mathbf{h}_c = \max_i \; \mathbf{A}_T[i]$$

The agent matrix $\mathbf{A}_T$ is also used for a responding agent vector $\mathbf{a}_{res}$ and a candidate addressee vector $\mathbf{a}_p$, i.e. $\mathbf{a}_{res} = \mathbf{A}_T[*, a_{res}]$ and $\mathbf{a}_p = \mathbf{A}_T[*, a_p]$. $\boldsymbol{r}_q$ is summarized into a response vector $\mathbf{h}_q$ in the same way as the static model.

5.3 Learning

We train the model parameters by minimizing the joint loss function:

$$\mathcal{L}(\boldsymbol{\theta}) = \alpha \, \mathcal{L}_a(\boldsymbol{\theta}) + (1 - \alpha) \, \mathcal{L}_r(\boldsymbol{\theta}) + \frac{\lambda}{2} ||\boldsymbol{\theta}||^2$$

where $\mathcal{L}_a$ is the loss function for the addressee selection, $\mathcal{L}_r$ is the loss function for the response selection, α is the hyper-parameter for the interpolation, and λ is the hyper-parameter for the L2 weight decay.

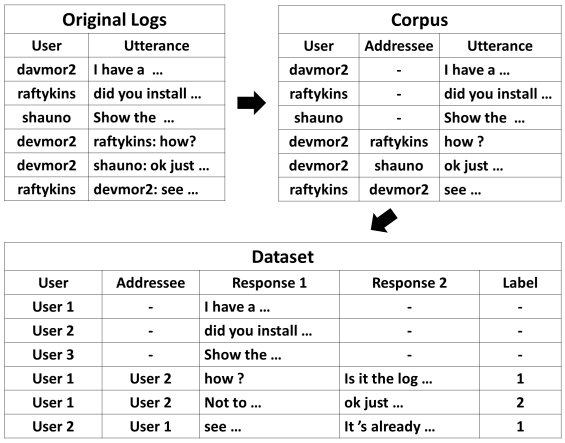

Figure 4: The flow of the corpus and dataset creation. From the original logs, we extract addressee IDs and add them to the corpus. As the dataset, we add candidate responses and the labels.

For addressee and response selection, we use the cross-entropy loss functions:

$$\mathcal{L}_a(\boldsymbol{\theta}) = -\sum_n [\log\ Pr(y(a^+) = 1|\boldsymbol{x}) + \log\left(1 - Pr(y(a^-) = 1|\boldsymbol{x})\right]$$

$$\mathcal{L}_r(\boldsymbol{\theta}) = -\sum_n [\log\ Pr(y(\boldsymbol{r}^+) = 1|\boldsymbol{x}) + \log\left(1 - Pr(y(\boldsymbol{r}^-) = 1|\boldsymbol{x})\right]$$

where $\boldsymbol{x}$ is the input set for the task, i.e. $\boldsymbol{x} = (a_{res}, \mathcal{C}, \mathcal{R})$, a^+ is a ground-truth addressee, a^- is a false addressee, $\boldsymbol{r}^+$ is a ground-truth response, and $\boldsymbol{r}^-$ is a false response. As a false addressee a^-, we pick up and use the addressee with the highest probability from the set of candidate addressees except the ground-truth one ($\mathcal{A}(\mathcal{C}) \setminus a^+$). As a false response, we randomly pick up and use a response from the set of candidate responses except the ground-truth one ($\mathcal{R} \setminus \boldsymbol{r}^+$).

6 Corpus and Dataset

Our goal is to provide a multi-party conversation corpus/dataset that can be used over a wide range of conversation research, such as turn-taking modeling (Raux and Eskenazi, 2009) and disentanglement modeling (Elsner and Charniak, 2010), as well as for the ARS task. Figure 4 shows the flow of the corpus and dataset creation process. We firstly crawl Ubuntu IRC Logs and preprocess the obtained logs.

	Corpus	Dataset		
		Train	Dev	Test
No. of Docs	7355	6,606	367	382
No. of Utters	2.4 M	2.1 M	13.2 k	15.1 k
No. of Words	27.0 M	23.8 M	1.5 M	1.7 M
No. of Samples	-	665.6 k	45.1 k	51.9 k
Avg. W. / U.	11.1	11.1	11.2	11.3
Avg. A. / D.	26.8	26.3	30.68	32.1

Table 2: Statistics of the corpus and dataset. "Docs" is documents, "Utters" is utterances, "W. / U." is the number of words per utterance, "A. / D." is the number of agents per document.

Then, from the logs, we extract and add addressee information to the corpus. In the final step, we set candidate responses and labels as the dataset. Table 2 shows the statistics of the corpus and dataset.

6.1 Ubuntu IRC Logs

The Ubuntu IRC Logs is a collection of logs from Ubuntu-related chat rooms. In each chat room, a number of users chat on and discuss various topics, mainly related to technical support with Ubuntu issues.

The logs are put together into one file per day for each room. Each file corresponds to a document $\mathcal{D}$. In a document, one line corresponds to one log given by a user. Each log consists of three items (`Time`, `UserID`, `Utterance`). Using such information, we create a multi-party conversation corpus.

6.2 The Multi-Party Conversation Corpus

To pick up only the documents written in English, we use a language detection library (Nakatani, 2010). Then, we remove the system logs from each document and leave only user logs. For segmenting the words in each utterance, we use a word tokenizer (`TreebankWordTokenizer`) of the Natural Language Toolkit[4]. Using the preprocessed documents, we create a corpus, whose row consists of the three items (`UserID`, `Addressee`, `Utterance`).

First, the IDs of the users in a document are collected into the user ID list by referring to the `UserID` in each log. Then, as the addressee user ID, we extract the first word of each utterance. In the Ubuntu IRC Logs, users follow the *name mention* convention (Uthus and Aha, 2013), in which they express

[4]http://www.nltk.org/

their addressee by mentioning the addressee's user ID at the beginning of the utterance. By exploiting the name mentions, if the first word of each utterance is identical to a user ID in the user ID list, we extract the addressee ID and then create a table consisting of (UsetID, Addressee, Utterance). In the case that addressee IDs are not explicitly mentioned at the beginning of the utterance, we do not extract anything.

6.3 The ARS Dataset

By exploiting the corpus, we create a dataset for the ARS task. If the line of the corpus includes an addressee ID, we regard it as a sample for the task. As the ground truth addressees and responses, we straightforwardly use the obtained addressee IDs and the preprocessed utterances.

As false responses, we sample utterances elsewhere within a document. This document-within sampling method makes the response selection task more difficult than the random sampling method[5]. One reason for this is that common or similar topics in a document are often discussed and the used words tend to be similar, which makes the word-based features for the task less effective. We partitioned the dataset randomly into a training set (90%), a development set (5%) and a test set (5%).

7 Experiments

We provide performance benchmarks of our learning architectures on the addressee and response selection (ARS) task for multi-party conversation.

7.1 Experimental Setup

Datasets

We use the created dataset for the experiments. The number of candidate responses RES−CAND ($|\mathcal{R}|$) is set to 2 or 10.

Evaluation Metrics

We evaluate performance by accuracies on three aspects: addressee-response pair selection (ADR−RES), addressee selection (ADR), and response selection (RES). In the addressee-response pair selection, we regard the answer as correct if both the addressee and the response are correctly selected. In the addressee/response selection, we regard the answer as correct if the addressee/response is correctly selected.

Optimization

The models are trained by backpropagation through time (Werbos, 1990; Graves and Schmidhuber, 2005). For the backpropagation, we use stochastic gradient descent (SGD) with a mini-batch training method. The mini-batch size is set to 128. The hyper-parameter α for the interpolation between the two loss functions (Section 5.3) is set to 0.5. For the L2 weight decay, the hyper-parameter λ is selected from $\{0.001, 0.0005, 0.0001\}$.

Parameters of the models are randomly initialized over a uniform distribution with support $[-0.01, 0.01]$. To update parameters, we use *Adam* (Kingma and Ba, 2014) with the default setting suggested by the authors. As the word embeddings, we used the 300 dimension vectors pre-trained by *GloVe*[6] (Pennington et al., 2014). To avoid overfitting, the word vectors are fixed across all experiments. The hidden dimensions of parameters are set to $d_w = 300$ and $d_h = 50$ in the both models, and d_a is set to 300 in the static model and 50 in the dynamic model.

To identify the best training epoch and model configuration, we use the *early stopping* method (Yao et al., 2007). In this method, if the best accuracy of ADR−RES on the development set has not been updated for consecutive 5 epochs, training is stopped and the best performing model is picked up. The max epochs is set to 30, which is sufficient for convergence.

Implementation Details

For computational efficiency, we limit the length of a context $\mathcal{C}$ as $\mathcal{C}_{T-N_c+1:T} = (\boldsymbol{u}_{T-N_c+1}, \cdots, \boldsymbol{u}_T)$, where N_c, called *context window*, is the number of utterances prior to a time step t. We set N_c to $\{5, 10, 15\}$. In addition, we truncate the utterances and responses at a maximum of 20 words. For batch processing, we zero-pad them so that the number of words is constant. Out-of-vocabulary words are replaced with <unk>, whose vector is the averaged vector over all word vectors.

[5] Lowe et al. (2015) adopted the random sampling method.

Table 3: Benchmark results: accuracies on addressee-response selection (ADR−RES), addressee selection (ADR), and response selection (RES). N_c is the context window. Bolded are the best per column.

Baseline Model

We set a baseline using the term frequency-inverse document frequency (TF-IDF) retrieval model for the response selection (Lowe et al., 2015). We firstly compute two TF-IDF vectors, one for a context window and one for a candidate response. Then, we compute a cosine similarity for these vectors, and select the highest scoring candidate response as a result. For the addressee selection, we adopt a rule-based method: to determine the agent that gives an utterance most recently except a responding agent, which captures the tendency that agents often respond to the other that spoke immediately before.

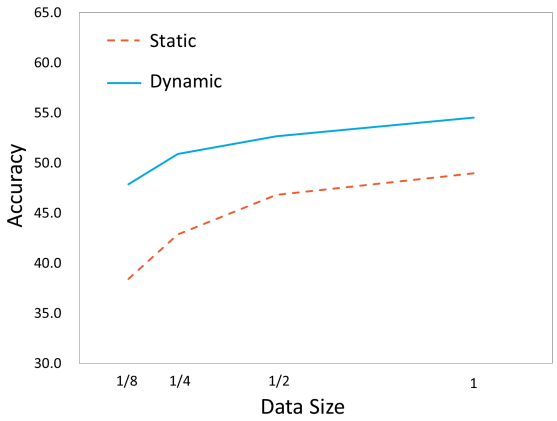

Figure 5: Accuracies in addressee-response selection using different amount of samples for training.

7.2 Results

Overall Performance

Table 3 shows the empirical benchmark results. The dynamic model achieves the best results in all the metrics. The static model outperforms the baseline, but is inferior to the dynamic model.

In addressee selection (ADR), the baseline model achieves around 55% in accuracy. This means that if you select the agents that spoke most recently as an addressee, the half of them are correct. Compared with the baseline, our proposed models achieve better results, which suggests that the models can select the correct addressees that spoke at more previous time steps. In particular, the dynamic model achieves 68% in accuracy, which is 7 point higher than the accuracy of static model.

In response selection (RES), our models outperform the baseline. Compared with the static model, the dynamic model achieves around 0.5 point higher in accuracy.

Effects of the Context Window

In response selection, a performance boost of our proposed models is observed for the context window $\mathcal{N}_c = 10$ over $\mathcal{N}_c = 5$. Comparing the results of the models with the context window $\mathcal{N}_c = 10$ and $\mathcal{N}_c = 15$, the performance is improved but relatively small, which suggests that the performance almost reaches the convergence. In addressee selection, the performance improvements of the static model with the broader context window is limited. In contrast, in the dynamic model, a steady performance boost is observed, yielding an increase of over 5 points between $N_c = 15$ and $N_c = 5$,

Table 4: Performance comparison for different numbers of agents appearing in the context. The numbers are accuracies on the test set with the number of candidate responses CAND−RES $= 2$ and the context window $N_c = 15$.

Effects of the Sample Size

Figure 5 shows the accuracy curves of addressee-response selection (ADR−RES) for different training sample sizes. We use $1/2$, $1/4$, and $1/8$ of the whole training samples for training. The results show that as the amount of the data increases, the performance of our models are improved and gradually approaches the convergence. Remarkably, the performance of the dynamic models using the $1/8$ samples is comparable to that of the static model using the whole samples.

Effects of the Number of Participants

To shed light on the relationship between the model performance and the number of agents in multi-party conversation, we investigate the effect of the number of agents participating in each context. Table 4 compares the performance of the models for different numbers of agents in a context.

In addressee selection, the performance of all models gradually gets worse as the number of agents in the context increases. However, compared with the baseline, our proposed models suppress the performance degradation. In particular, the dynamic model predicts correct addressees most robustly.

In response selection, unexpectedly, the performance of all the models gets better as the number of agents increases. Detailed investigation on the interaction between the number of agents and the response selection complexity is an interesting line of future work.

8 Conclusion

We proposed addressee and response selection for multi-party conversation. Firstly, we provided the formal definition of the task, and then created a corpus and dataset. To present benchmark results, we proposed two modeling frameworks, which jointly model speakers and their utterances in a context. Experimental results showed that our models of the frameworks outperform a baseline.

Our future objective to tackle the task of predicting *whether to respond* to a particular utterance. In this work, we assume that the situations where there is a specific addressee that needs an appropriate response and a system is required to respond. In actual multi-party conversation, however, a system sometimes has to wait and listen to the conversation that other participants are engaging in without needless interruption. Hence, the prediction of *whether to respond* in a multi-party conversation would be an important next challenge.

Abstract

In this paper, we propose a new generative approach for semantic slot filling task in spoken language understanding using a nonparametric Bayesian formalism. Slot filling is typically formulated as a sequential labeling problem, which does not directly deal with the posterior distribution of possible slot values. We present a nonparametric Bayesian model involving the generation of arbitrary natural language phrases, which allows an explicit calculation of the distribution over an infinite set of slot values. We demonstrate that this approach significantly improves slot estimation accuracy compared to the existing sequential labeling algorithm.

1 Introduction

Spoken language understanding (SLU) refers to the challenge of recognizing a speaker's intent from a natural language utterance, which is typically defined as a *slot filling task*. For example, in the utterance "Remind me to call John at 9am tomorrow", the specified information {**"time": *"9am tomorrow"***} and {**"subject": *"to call John"***} should be extracted. The term *slot* refers to a variable such as the **time** or **subject** that is expected to be filled with a value provided through the user's utterance.

The slot filling task is typically formulated as a sequential labeling problem as shown in Figure 1. This labeling scheme naturally represents the recognition of arbitrary phrases that appear in the transcription of an utterance. Formally speaking, when we assume a given set of slots $\{s_1, ..., s_M\}$ and denote the corresponding slot values by $\{v_{s_1}, ..., v_{s_M}\}$ where $v_{s_i} \in V_{s_i}$, the domain of each slot value V_{s_i} is an infinite set of word sequences. In this paper, we use the term *arbitrary slot filling task* to refer to this implicit problem statement, which inherently underlies the sequential labeling formulation.

In contrast, a different line of work has explored the case where V_{s_i} is provided as a finite set of possible values that can be handled by a backend system (Henderson, 2015). We refer to this type of task as a *categorical slot filling task*. In this case, the slot filling task is regarded as a classification problem that explicitly considers a value-based prediction, as shown in Figure 2. From this point of view, we can say that a distribution of slot values is actually concentrated in a small set of typical phrases, even in the arbitrary slot filling task, because users basically know what kind of function is offered by the system.

To reflect this observation, in this paper we explore the value-based formulation approach for arbitrary slot filling tasks. Unlike the sequential labeling formulation, which is basically position-based label prediction, our method directly estimates the posterior distribution over an infinite set of possible values for each slot V_{s_i}. The distribution is represented by using a Dirichlet process (Gershman and Blei, 2012), which is a nonparametric Bayesian formalism that generates a categorical distribution for any space. We demonstrate that this approach improves estimation accuracy in the arbitrary slot filling task compared with conventional sequential labeling approach.

The rest of this paper is organized as follows. In Section 2, we review the existing approaches for categorical and arbitrary slot filling tasks and intro-

duce related work. In Section 3, we present our nonparametric Bayesian formulation, the hierarchical Dirichlet process slot model (HDPSM), which directly models an infinite set of slot values. On the basis of the HDPSM, we develop a generative utterance model that allows us to compute the posterior probability of slot values in Section 4. In Section 5, we introduce a two-stage slot filling algorithm that consists of a candidate generation step and a candidate ranking step using the proposed model. In Section 6, we show the experimental results for multiple datasets in different domains to demonstrate that the proposed algorithm performs better than the baseline sequential labeling method. We conclude in Section 7 with a brief summary.

2 Related Work

The difference between the categorical and arbitrary slot filling approaches has not been explicitly discussed in a comparative manner to date. In this section, we review existing work for both approaches.

For the categorical slot filling approach, various algorithms that directly model the distribution of slot values have been proposed, including generative models (Williams, 2010), maximum entropy linear classifiers (Metallinou et al., 2013), and neural networks (Ren et al., 2014). However, none of these models are applicable for predicting a variable that ranges over an infinite set, and it is not straightforward to extend them suitably. In particular, a discriminative approach is not applicable for arbitrary slot filling tasks because it requires a fixed finite set of slot values to take statistics.

The arbitrary slot filling approach is a natural application of shallow semantic parsing (Gildea, 2002), which is naturally formulated as a sequential labeling problem. Various sequential labeling algorithms have been applied to this task, including support vector machines, conditional random fields (CRF) (Lafferty et al., 2001; Hahn et al., 2011), and deep neural networks (Mesnil et al., 2015; Xu and Sarikaya, 2013). Vukotic et al. (2015) reported that the CRF is still the most accurate, rapid, and stable method among them. Because the focus of this paper is arbitrary slot filling tasks, we use CRFs as our baseline method.

In this paper, we apply nonparametric Bayesian models (Gershman and Blei, 2012) to represent the distribution over arbitrary phrases for each slot. The effectiveness of this phrase modeling approach has been examined in various applications including morphological analysis (Goldwater et al., 2011) and infinite vocabulary topic models (Zhai and Boyd-graber, 2013). Our method can be regarded as an application of this idea, although it is not straightforward to integrate it with the utterance generation process, as we explain later.

Consequently, our proposed method is categorized as a generative approach. There are many advantages inherent in generative approaches that have been examined, including unsupervised SLU (Chen et al., 2015), automatic feature extraction (Tur et al., 2013), and integration with syntactic modeling (Lorenzo et al., 2013). Another convenient property of generative models is that prior knowledge can be integrated in an intuitive way (Raymond et al., 2006). This often leads to better performance with less training data compared with discriminative models trained completely from scratch (Komatani et al., 2010).

3 Hierarchical Dirichlet Process Slot Model

In this section, we present a nonparametric Bayesian formulation that directly models the distribution over an infinite set of possible values for each slot. Let $S = \{s_1, ..., s_{M_S}\}$ be a given set of slots and M_S be the number of slots. We define each slot s_i as a random variable ranging over an infinite set of

letter sequences V, which is represented as follows:

$$V = \{b_1, ..., b_L | b_\iota \in C, L \geq 0\}$$

where C is a set of characters including the blank character and any other character that potentially appears in the transcription of an utterance. Consequently, we regard the set of slots S as also being a random variable that ranges over V^{M_S}. The objective of this section is to develop the formulation of the probabilistic distribution $p(S)$.

3.1 Dirichlet Process

We apply the Dirichlet process (DP) to model both the distribution for an individual slot $p_i(s_i)$ and the joint distribution $p(S)$. In this subsection, we review the definition and key properties of DP with general notation for the target distribution G over the domain $\mathcal{X}$. In the DP for the prior of $p_i(s_i)$ that is described in Section 3.2, the domain $\mathcal{X}$ corresponds to a set of slot values V, e.g., "fen ditton", "new chesterton", and None. In the DP for $p(S)$ presented in Section 3.3, $\mathcal{X}$ indicates a set of tuples of slot values V^{M_S}, e.g., ("restaurant", "new chesterton", "fast food") and ("restaurant", "fen ditton", None).

The DP is a probabilistic distribution over the distribution G. DP is parameterized by α^0 and G^0, where $\alpha^0 > 0$ is a concentration parameter and G^0 is a base distribution over $\mathcal{X}$. If G is drawn from $DP(\alpha^0, G^0)$ (i.e., $G \sim DP(\alpha^0, G^0)$), then the following Dirichlet distributed property holds for any partition of $\mathcal{X}$ denoted by $\{A_1, ..., A_L\}$:

$$(G(A_1), ..., G(A_L)) \sim Dir(\alpha(A_1), ..., \alpha(A_L))$$

where $\alpha(A) = \alpha^0 G^0(A)$, which is known as the base measure of DP.

Ferguson (1973) proved an important property of a posterior distribution of repeated i.i.d. samples $\mathbf{x}_{1:N} = \{x_1, ..., x_N\}$ drawn from $G \sim DP(\alpha^0, G^0)$. Consider a countably infinite set of *atoms* $\boldsymbol{\phi} = \{\phi_1, \phi_2, ...\}$ that are independently drawn from G^0. Let $c_i \in \mathbb{N}$ be the *assignment* of an atom for sample x_i, which is generated by a sequential draw with the following conditional probability:

$$p(c_{N+1} = k | \mathbf{c}_{1:N}) = \begin{cases} \frac{n_k}{N+\alpha^0} & k \leq K \\ \frac{\alpha^0}{N+\alpha^0} & k = K+1 \end{cases}$$

where n_k is the number of times that the kth atom appears in $\mathbf{c}_{1:N}$ and K is the number of different atoms in $\mathbf{c}_{1:N}$. Given the assignment $\mathbf{c}_{1:N}$, the predictive distribution of $x_{N+1} \in \mathcal{X}$ is represented in the following form:

$$P(x_{N+1} = \theta | \mathbf{c}_{1:N}, \boldsymbol{\phi}_{1:K}, \alpha^0, G^0) = \sum_{k=1}^{K} \frac{n_k}{N+\alpha^0} \delta(\phi_k, \theta) + \frac{\alpha^0}{N+\alpha^0} G^0(\theta)$$

The base distribution possibly generates an identical value for different atoms, such as (ϕ_1 = "fen ditton", ϕ_2 = "new chesterton", ϕ_3 = "fen ditton"). The assignment c_i is an auxiliary variable to indicate which of these atoms is assigned to the ith data point x_i; when x_i = "fen ditton", c_i can be 1 or 3. The posterior distribution above depends on the frequency of atom n_k, not on the frequency of θ itself. The atoms $\boldsymbol{\phi}$ and the assignment $\mathbf{c}$ are latent variables that should be determined at runtime.

3.2 Individual Slot Model

First we formulate the distribution for an individual slot as $p_i(s_i) \sim DP(\alpha_i^0, G_i^0)$ where G_i^0 is a base distribution over the set of phrases V. [1] We define G_i^0 as a generative model that consists of two-step generation: generation of the phrase length $0 \leq L_i \leq L^{max}$ using a categorical distribution and generation of a letter sequence $s_i^{1:L}$ using an n-gram model, as follows:

$$L_i \sim Categorical(\boldsymbol{\lambda}_i)$$
$$s_i^\iota \sim p(s_i^\iota | s_i^{\iota-n+1:\iota-1}, \boldsymbol{\eta}_i)$$

where $\boldsymbol{\lambda}_i$ and $\boldsymbol{\eta}_i$ are parameters for the categorical distribution and the n-gram model for slot s_i, respectively. This explicit modeling of the length helps avoid the bias toward shorter phrases and leads to a better distribution, as reported by Zhai and Boydgraber (2013). We define G_i^0 as a joint distribution of these models:

$$G_i^0(s_i^{1:L_i}) = p(L_i | \boldsymbol{\lambda}_i) \prod_{\iota=1}^{L_i} p(s_i^\iota | s_i^{\iota-n+1:\iota-1}, \boldsymbol{\eta}_i) \quad (1)$$

G_i^0 potentially generates an empty phrase of $L_i = 0$ to express the case that the slot value v_{s_i} is not

[1] Note that the subscript i for s, p, α^0 and G^0 indicates the slot type such as "type", "area" and "food" in Figure 2.

provided by an utterance. Therefore, the distribution $p_i(s_i)$ can naturally represent the probability of $None$, which is shown in Figure 2.

We consider prior distributions of the parameters $\boldsymbol{\lambda}_i$ and $\boldsymbol{\eta}_i$ to treat the n-gram characteristics of each slot in a fully Bayesian manner. $p(\boldsymbol{\lambda})$ is given as a L^{max}-dimensional symmetric Dirichlet distribution with parameter a. We also define the $|C|$-dimensional symmetric Dirichlet distributions with parameter b for each n-gram context, since given the context $p(s_i^\iota | s_i^{\iota-n+1:\iota-1}, \boldsymbol{\eta}_i)$ is just a categorical distribution that ranges over C. Consider we observe N phrases $\mathbf{s}_i$ for slot i. Let $n_{i\iota}^L$ be the number of phrases that have length ι and n_{ih}^γ be the number of times that letter $s^\iota = h$ appears after context $s^{\iota-n+1:\iota-1} = \gamma$. The predictive probability of a phrase is represented as follows:

$$G_i^0(s_i^{1:L_i}|\mathbf{s}_i) = \frac{n_{i\iota}^L + b}{N + bC} \prod_{\iota=1}^{L_i} \frac{n_{is_i^\iota}^\gamma + a}{\sum_c n_{ic}^\gamma + a \sum_{l=1}^{L^{max}} n_{il}^L}$$

3.3 Generative Model for a Set of Slot Values

A naive definition of the joint distribution $p(S)$ is a product of all slot probabilities $\prod_{i=1}^{M_S} p_i(s_i)$ for making an independence assumption. However, the slot values are generally correlated with each other (Chen et al., 2015). To obtain more accurate distribution, we formulate $p(S)$ using another DP that recognizes a frequent combination of slot values, as $p(S) \sim DP(\alpha^1, G^2)$ where G^2 is a base distribution over V^{M_S}. We apply the naive independence assumption to G^2 as follows:

$$G^2(S) = \prod_{i=1}^{M_S} p_i(s_i)$$

The whole generation process of S involves two-layered DPs that share atoms among them. In this sense, this generative model is regarded as a hierarchical Dirichlet process (Teh et al., 2005).

Let $G_i^1(s_i) = p_i(s_i)$ and $G^3(S) = p(S)$ for consistent notations. In summary, we define the hierarchical Dirichlet process slot model (HDPSM) as a generative model that has the following generation process.

$$\begin{aligned} G_i^1 &\sim DP(\alpha_i^0, G_i^0) \\ G^3 &\sim DP(\alpha^1, G^2) \\ S &\sim G^3 \end{aligned}$$

3.4 Inference of HDPSM

In a slot filling task, observations of $\mathbf{S}_{1:T} = \{S_1, ..., S_T\}$ are available as training data. The inference of HDPSM refers to the estimation of $\boldsymbol{\lambda}$, $\boldsymbol{\eta}$ and the atom assignments for each DP.

We formulate the HDPSM in a form of the Chinese restaurant franchise process, which is one of the explicit representations of hierarchical DPs obtained by marginalizing out the base distributions. Teh et al. (2005) presents a Gibbs sampler for this representation, which involves a repetitive resampling of atoms and assignment. In our method, we prefer to adopt a single pass inference, which samples the assignment for each observation only once. Our preliminary experiments showed that the quality of inference is not affected because S is observed unlike the settings in Teh et al. (2005).

We denote the atoms and the atom assignment in the first level DP $DP(\alpha^1, G^2)$ by $\boldsymbol{\phi}^1$ and $\mathbf{c}_{1:N}^1$, respectively. The posterior probability of atom assignment for a new observation S_{N+1} is represented as follows:

$$\begin{aligned} &p(c_{N+1}^1 = k | \mathbf{c}_{1:N}^1, \boldsymbol{\phi}^1, S_{N+1}) \\ &\quad \propto \begin{cases} n_k^1 \delta(\phi_k^1, S_{N+1}) & k \leq K \\ \alpha^1 G^2(S_{N+1}) & k = K+1 \end{cases} \end{aligned}$$

where n_k^1 is the number of times that the kth atom appears in $\mathbf{c}_{1:N}^1$ and K is the number of different atoms in $\mathbf{c}_{1:N}^1$.

$\boldsymbol{\phi}_i^0$ and $\mathbf{c}_{i1:K}^0$ denote the atoms and the assignment in the second level DPs $DP(\alpha_i^0, G_i^0)$. The second level DPs assign atoms to each first level atom ϕ_k^1, i.e. the second level atom ϕ_{it}^0 is generated only when a new atom is assigned for S_{N+1} at the first level. The posterior probability of atom assignment at the second level is:

$$\begin{aligned} &p(c_{iK+1}^0 = t | \mathbf{c}_{i1:K}^0, \boldsymbol{\phi}_i^0, s_{N+1i}) \\ &\quad \propto \begin{cases} n_{it}^0 \delta(\phi_{it}^0, S_{N+1}) & t \leq T_i \\ \alpha_i^0 G^0(S_{N+1}) & t = T_i + 1 \end{cases} \end{aligned}$$

where n_{it}^0 is the number of times that the tth atom appears in $\mathbf{c}_{i1:K}^0$ and T_i is the number of different atoms in $\mathbf{c}_{i1:K}^0$.

The single pass inference procedure is presented in Algorithm 1. Given the atoms $\boldsymbol{\phi}$ and the assignments $\mathbf{c}$, the predictive distribution of $S_{N+1} =$

$\{s_{N+11}, ..., s_{N+1M_S}\}$ is calculated as follows:

$$P(S_{N+1}|\mathbf{c}, \boldsymbol{\phi}) = \sum_{k=1}^{K} \frac{n^1_k}{N + \alpha^1} \delta(\phi^1_k, S_{N+1}) + \frac{\alpha^1}{N + \alpha^1} \prod_{i=1}^{M_S} P(s_{N+1i}|\mathbf{c}^0_i, \boldsymbol{\phi}^0_i) \quad (2)$$

$$P(s_{N+1i}|\mathbf{c}^0_i, \boldsymbol{\phi}^0_i) = \sum_{t=1}^{T_i} \frac{n^0_{it}}{K + \alpha^0_i} \delta(\phi^0_{it}, s_{N+1i}) + \frac{\alpha^0_i}{K + \alpha^0_i} G^0_i(s_{N+1i}|\boldsymbol{\phi}^0_i)$$

4 Generative Model for an Utterance

We present a generative utterance model to derive a slot estimation algorithm given utterance u. Figure 3 presents the basic concept of our generative model. In the proposed model, we formulate the distribution of slot values as well as the distribution of non-slot parts. In Figure 3, the phrases "hi we're in um" and "and we need a" should be removed to identify the slot information. We call these non-slot phrases as *functional fillers* because they more or less have a function to convey information. Identifying the set of non-slot phrases is equivalent to identifying the set of slot phrases. Therefore, we define a generative model of functional fillers in the same way as the slot values.

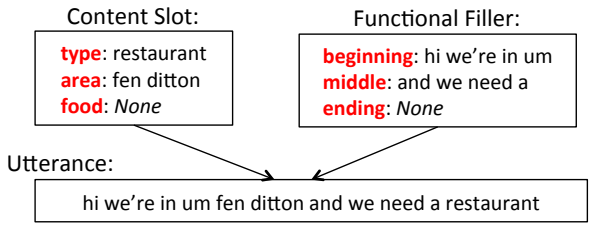

Figure 3: The proposed generative utterance model. We attempt to find the best combination of the slot parts and the non-slot parts (i.e., functional filler parts) by using this model.

4.1 Functional Filler

We assume an utterance u is a concatenation of slot values S and functional fillers F. A functional filler is represented as a phrase that ranges over V. To derive the utterance model, we first formulate a generative model for functional fillers.

In our observation, the distribution of the functional filler depends on its position in an utterance. For example, utterances often begin with typical phrases such as "Hello I'm looking for ..." or "Hi please find ...", which can hardly ever appear at other positions. To reflect this observation, we introduce a *filler slot* to separately model the functional fillers based on a position feature. Specifically, we define three filler slots: *beginning filler* f_1, which precedes any slot value, *ending filler* f_3, which appears at the end of an utterance, and *middle filler* f_2, which is inserted between slot values. We use the term *content slot* to refer to S when we intend to explicitly distinguish it from a filler slot.

Let $F = \{f_1, f_2, f_3\}$ be a set of filler slots and $M_F = 3$ be the number of filler slots. Each slot f_i is a random variable ranging over V and F is a random variable over V^{M_F}. These notations for filler slots indicate compatibility to a content slot, which suggests that we can formulate F using HDPSMs, as follows:

$$H^1_i \sim DP(\beta^0_i, H^0_i)$$
$$H^3 \sim DP(\beta^1, H^2)$$
$$F \sim H^3$$

where H^0_i is an n-gram-based distribution over V that is defined in an identical way to (1) and $H^2(F) = \prod_{i=1}^{M_F} H^1_i(F)$.

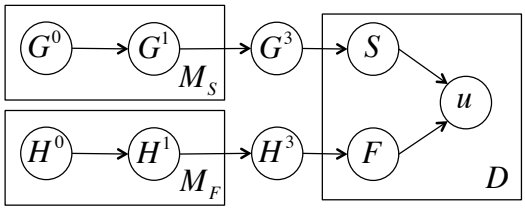

Figure 4: Graphical model of the utterance model.

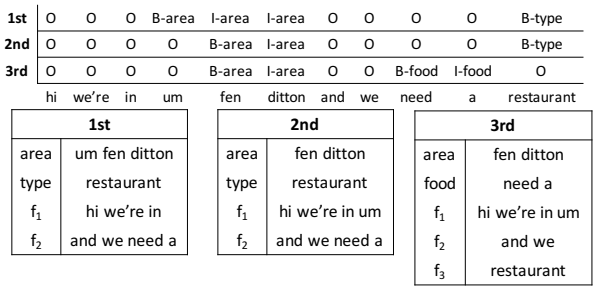

Figure 5: Candidate generation using sequential labeling algorithm. The figure shows the case of $N = 3$.

4.2 Utterance Model

Figure 4 presents the graphical model of our utterance model. We assume that an utterance u is built with phrases provided by S and F. Therefore, the conditional distribution $p(u|S, F)$ basically involves a distribution over the permutation of these slot values with two constraints: f_1 is placed first and f_3 has to be placed last. In our formulation, we simply adopt a uniform distribution over all possible permutations.

For training the utterance model, we assume that a set of annotated utterances is available. Each training instance consists of utterance u and annotated slot values S. Given u and S, we assume that the functional fillers F can be uniquely identified. For the example in Figure 3, we can identify the subsequence in u that corresponds to each content slot value of "restaurant" and "fen ditton". This matching result leads to the identification of filler slot values. Consequently, a triple (u, S, F) is regarded as an observation. Because the HDPSMs of the content slot and of the filler slot are conditionally independent given S and F, we can separately apply Algorithm 1 to train each HDPSM.

For slot filling, we examine the posterior probability of content slot values S given u, which can be reformed as follows:

$$P(S|u) \propto \sum_F P(u|S, F)P(S)P(F)$$

In this equation, we can remove the summation of F because filler slot values F are uniquely identified regarding u and S in our assumption. Additionally, we approximately regard $P(u|S, F)$ as a constant if u can be built with S and F. By using these assumptions, the posterior probability is reduced to the following formula:

$$P(S|u) \propto P(S)P(F) \quad (3)$$

where F in this formula is fillers identified given u and S. Consequently, the proposed method attempts to find the most likely combination of the slot values and the non-slot phrases, since all words in an utterance have to belong to either of them. By using trained HDPSM (i.e., the posterior given all training data), $P(S)$ and $P(F)$ can be computed by (2).

5 Candidate Generation

For estimating slot values given u, we adopt a candidate generation approach (Williams, 2014) that leverages another slot filling algorithm to enumerate likely candidates. [2] Specifically, we assume a candidate generation function $g(u)$ that generates N candidates $\{S_1, ..., S_N\}$ regarding u. Our slot filling algorithm computes the posterior probability by (3) for each candidate slot S_j and takes the candidate that has the highest posterior probability. In this estimation process, our utterance model works as a secondary filter that covers the error of the primary analysis.

Figure 5 provides an example of candidate generation by using a sequential labeling algorithm with IOB tags. The subsequences to which the O tag is assigned can be regarded as functional fillers. The values for each filler slot are identified depending on the position of the subsequence, as the figure shows.

6 Experiments

We evaluate the performance of the proposed generative model with an experiment using the algorithm

[2] The direct inference of the generative utterance model is a topic for near future work. The MCMC method will circumvent the difficulty of searching the entire candidate space.

Table 1: Datasets in the experiment. Max. diversity refers to the maximum number of value types that are taken by a slot.

described in Section 5. We adopt a conditional random field (CRF) as a candidate generation algorithm that generates N-best estimation as candidates. For the CRF, we apply commonly used features including unigram and bigram of the surface form and part of speech of the word. We used CRF++[3] as the CRF implementation.

6.1 Dataset

The performance of our method is evaluated using two datasets from different languages, as summarized in Table 1. The first dataset is provided by the third Dialog State Tracking Challenge (Henderson, 2015), hereafter referred to as the DSTC corpus. The DSTC corpus consists of dialogs in the tourist information domain. In our experiment, we use the user's first utterance in each dialog, which typically describes the user's query to the system. Utterances without any slot information are excluded. We manually modified the annotated slot values into "as-is form" to allow a sequential labeling method to extract the ground-truth values. This identification process can be done in a semi-automatic manner that involves no expert knowledge. We apply the part of speech tagger in NLTK[4] for the CRF application.

The second dataset is a weather corpus consisting of user utterances in an in-house corpus of human-machine dialogues in the weather domain. It contains 1,442 questions spoken in Japanese. In this corpus, the number of value types for each slot is higher than DSTC, which indicates a more challenging task. We applied the Japanese morphological analyzer MeCab (Kudo et al., 2004) to segment the Japanese text into words before applying CRF.

For both datasets, we examine the effect of the amount of available annotated utterances by varying the number of training data in $25, 50, 75, 100, 200, 400, 800, all$.

#train	CRF best	HDP $N = 5$	HDP $N = 300$
25	0.560	0.706*	0.684*
50	0.709	0.791*	0.765*
75	0.748	0.824*	0.817*
100	0.791	0.845*	0.837*
200	0.839	0.901*	0.876*
400	0.904	0.938*	0.936*
800	0.926	0.953*	0.947*
1296	0.938	0.960*	0.951

Table 2: Slot estimation accuracy for the DSTC corpus. The asterisk (*) indicates that the accuracy is statistically significant compared against CRF best ($p < 0.005$).

#train	CRF best	HDP $N = 5$	HDP $N = 300$
25	0.327	0.452*	0.480*
50	0.379	0.488*	0.499*
75	0.397	0.504*	0.522*
100	0.418	0.501*	0.512*
200	0.493	0.526*	0.531*
400	0.512	0.551*	0.549*
800	0.533	0.555*	0.554*
1297	0.546	0.560*	0.554

Table 3: Slot estimation accuracy for the Japanese weather corpus. An asterisk (*) indicates statistical significance against CRF best ($p < 0.01$).

6.2 Evaluation Metrics

The methods are compared in terms of slot estimation accuracy. Let n_c be the number of utterances for which the estimated slot S and the ground-truth slot $\hat{S}$ are perfectly matched, and let n_e be the number of the utterances including an estimation error. The slot estimation accuracy is simply calculated as $\frac{n_c}{n_c+n_e}$. All evaluation scores are calculated as the average of 10-fold cross validation. We also conduct a binomial test to examine the statistical significance of the improvement in the proposed algorithm compared to the CRF baseline.

6.3 Results

Tables 2 and 3 present the slot estimation accuracy for the DSTC corpus and the Japanese weather corpus, respectively. The baseline (CRF best) is a method that takes only one best output of CRF for slot estimation. HDP with $N = 5$ and $N = 300$ is the proposed method, where N is the number of candidates generated by the CRF candidate genera-

utterance	estimation by CRF best	estimation by HDP $N = 5$
im looking for a restaurant that serves fast food	type:restaurant (*)	type:restaurant,food:fast food
i want a moderate restaurant in the new chesterton area	area:new chesterton, type:restaurant, food:moderate (*)	area:new chesterton, type:restaurant, pricerange:moderate
im looking for a cheap chine chinese takeaway restaurant	pricerange:cheap,type:restaurant, food:chinese takeaway	pricerange:cheap,type:restaurant, food:chine chinese takeaway (*)

Table 4: Examples of estimated slot values for the condition of #train is 800. An asterisk (*) indicates misrecognition.

tor. The asterisks (*) beside the HDP accuracy indicate the statistical significance against CRF best, which is tested using the binomial test.

Results show that our proposed method performs significantly better than CRF. Especially when the amount of training data is limited, the proposed method outperforms the baseline. This property is attractive for practical speech recognition systems that offer many different functions. Accurate recognition at an early stage of development allows a practitioner to launch a service that results in quickly collecting hundreds of speech examples.

Since we use the CRF as a candidate generator, we expect that the CRF N-best can rank the correct answer higher in the candidate list. In fact, the top five candidates cover almost all of the correct answers. Therefore, the result in the comparison of $N = 5$ and $N = 300$ suggests the stability of the proposed method against the mostly noisy 295 candidates. Because the proposed algorithm makes no use of the original ranking order, $N = 300$ is a harder condition in which to identify the correct answer. Nevertheless, the result shows that the drop in the performance is limited; the accuracy is still significantly better than the baseline. This result suggests that the proposed method is less dependent on the performance of the candidate generator.

Table 4 presents some examples of the slot values estimated by CRF best and HDP with $N = 5$ for the condition where the number of training utterances is 800. The first two are samples where CRF best failed to predict the correct values. These errors are attributed to infrequent sequential patterns caused by the less trained expressions "that serves fast food" and "moderate restaurant" because CRF is a position-based classifier. The value-based formulation allows the model to learn that the phrase "fast food" is more likely to be a food name than to be a functional filler and to reject the candidate.

The third example in Table 4 shows an error using HDP, which extracted "chine chinese takeaway" which includes a reparandum of disfluency (Georgila et al., 2010). This error can be attributed to the fact that this kind of disfluency resembles the true slot value, which leads to a higher probability of "chine" in the food slot model compared to in the functional filler model. Regarding this type of error, preliminary application of a disfluency detection method (Zayats et al., 2016) is promising for improving accuracy.

The execution time for training the proposed HDP utterance model with 1297 training data in the Japanese weather corpus was about 0.3 seconds. This is a good performance since the CRF training takes about 5.5 seconds. Moreover, the training of the proposed HDP model is scalable and works in an online manner because it is a single pass algorithm. When we have a very large number of training examples, the bottleneck is the CRF training, which requires scanning the whole dataset repeatedly.

7 Conclusion

In this paper, we proposed an arbitrary slot filling method that directly deals with the posterior probability of slot values by using nonparametric Bayesian models. We presented a two-stage method that involves an N-best candidate generation step, which is typically done using a CRF. Experimental results show that our method significantly improves recognition accuracy. This empirical evidence suggests that the value-based formulation is a promising approach for arbitrary slot filling tasks, which is worth exploring further in future work.

Abstract

Recently a variety of LSTM-based conditional language models (LM) have been applied across a range of language generation tasks. In this work we study various model architectures and different ways to represent and aggregate the source information in an end-to-end neural dialogue system framework. A method called snapshot learning is also proposed to facilitate learning from supervised sequential signals by applying a *companion* cross-entropy objective function to the conditioning vector. The experimental and analytical results demonstrate firstly that competition occurs between the conditioning vector and the LM, and the differing architectures provide different trade-offs between the two. Secondly, the discriminative power and transparency of the conditioning vector is key to providing both model interpretability and better performance. Thirdly, snapshot learning leads to consistent performance improvements independent of which architecture is used.

1 Introduction

Recurrent Neural Network (RNN)-based conditional language models (LM) have been shown to be very effective in tackling a number of real world problems, such as machine translation (MT) (Cho et al., 2014) and image caption generation (Karpathy and Fei-Fei, 2015). Recently, RNNs were applied to task of generating sentences from an explicit semantic representation (Wen et al., 2015a). Attention-based methods (Mei et al., 2016) and Long Short-term Memory (LSTM)-like (Hochreiter and Schmidhuber, 1997) gating mechanisms (Wen et al., 2015b) have both been studied to improve generation quality. Although it is now clear that LSTM-based conditional LMs can generate plausible natural language, less effort has been put in comparing the different model architectures. Furthermore, conditional generation models are typically tested on relatively straightforward tasks conditioned on a single source (e.g. a sentence or an image) and where the goal is to optimise a single metric (e.g. BLEU). In this work, we study the use of conditional LSTMs in the generation component of neural network (NN)-based dialogue systems which depend on multiple conditioning sources and optimising multiple metrics.

Neural conversational agents (Vinyals and Le, 2015; Shang et al., 2015) are direct extensions of the sequence-to-sequence model (Sutskever et al., 2014) in which a conversation is cast as a source to target transduction problem. However, these models are still far from real world applications because they lack any capability for supporting domain specific tasks, for example, being able to interact with databases (Sukhbaatar et al., 2015; Yin et al., 2016) and aggregate useful information into their responses. Recent work by Wen et al. (2016a), however, proposed an end-to-end trainable neural dialogue system that can assist users to complete specific tasks. Their system used both distributed and symbolic representations to capture user intents, and these collectively condition a NN language generator to generate system responses. Due to the diversity of the conditioning information sources, the best way to represent and combine them is non-trivial.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2153–2162,
Austin, Texas, November 1-5, 2016.

In Wen et al. (2016a), the objective function for learning the dialogue policy and language generator depends solely on the likelihood of the output sentences. However, this sequential supervision signal may not be informative enough to learn a good conditioning vector representation resulting in a generation process which is dominated by the LM. This can often lead to inappropriate system outputs.

In this paper, we therefore also investigate the use of snapshot learning which attempts to mitigate this problem by heuristically applying *companion* supervision signals to a subset of the conditioning vector. This idea is similar to deeply supervised nets (Lee et al., 2015) in which the final cost from the output layer is optimised together with the companion signals generated from each intermediary layer. We have found that snapshot learning offers several benefits: (1) it consistently improves performance; (2) it learns discriminative and robust feature representations and alleviates the vanishing gradient problem; (3) it appears to learn transparent and interpretable subspaces of the conditioning vector.

2 Related Work

Machine learning approaches to task-oriented dialogue system design have cast the problem as a partially observable Markov Decision Process (POMDP) (Young et al., 2013) with the aim of using reinforcement learning (RL) to train dialogue policies online through interactions with real users (Gašić et al., 2013). In order to make RL tractable, the state and action space must be carefully designed (Young et al., 2010) and the understanding (Henderson et al., 2014; Mrkšić et al., 2015) and generation (Wen et al., 2015b; Wen et al., 2016b) modules were assumed available or trained standalone on supervised corpora. Due to the underlying hand-coded semantic representation (Traum, 1999), the conversation is far from natural and the comprehension capability is limited. This motivates the use of neural networks to model dialogues from end to end as a conditional generation problem.

Interest in generating natural language using NNs can be attributed to the success of RNN LMs for large vocabulary speech recognition (Mikolov et al., 2010; Mikolov et al., 2011). Sutskever et al. (2011) showed that plausible sentences can be obtained by sampling characters one by one from the output layer of an RNN. By conditioning an LSTM on a sequence of characters, Graves (2013) showed that machines can synthesise handwriting indistinguishable from that of a human. Later on, this idea has been tried in several research fields, for example, generating image captions by conditioning an RNN on a convolutional neural network (CNN) output (Karpathy and Fei-Fei, 2015; Xu et al., 2015); translating a source to a target language by conditioning a decoder LSTM on top of an encoder LSTM (Cho et al., 2014; Bahdanau et al., 2015); or generating natural language by conditioning on a symbolic semantic representation (Wen et al., 2015b; Mei et al., 2016). Among all these methods, attention-based mechanisms (Bahdanau et al., 2015; Hermann et al., 2015; Ling et al., 2016) have been shown to be very effective improving performance using a dynamic source aggregation strategy.

To model dialogue as conditional generation, a sequence-to-sequence learning (Sutskever et al., 2014) framework has been adopted. Vinyals and Le (2015) trained the same model on several conversation datasets and showed that the model can generate plausible conversations. However, Serban et al. (2015b) discovered that the majority of the generated responses are generic due to the maximum likelihood criterion, which was latter addressed by Li et al. (2016a) using a maximum mutual information decoding strategy. Furthermore, the lack of a consistent system persona was also studied in Li et al. (2016b). Despite its demonstrated potential, a major barrier for this line of research is data collection. Many works (Lowe et al., 2015; Serban et al., 2015a; Dodge et al., 2016) have investigated conversation datasets for developing chat bot or QA-like general purpose conversation agents. However, collecting data to develop goal oriented dialogue systems that can help users to complete a task in a specific domain remains difficult. In a recent work by Wen et al. (2016a), this problem was addressed by designing an online, parallel version of Wizard-of-Oz data collection (Kelley, 1984) which allows large scale and cheap in-domain conversation data to be collected using Amazon Mechanical Turk. An NN-based dialogue model was also proposed to learn from the collected dataset and was shown to be able to assist human subjects to complete specific tasks.

Snapshot learning can be viewed as a special form of weak supervision (also known as distant- or self supervision) (Craven and Kumlien, 1999; Snow et al., 2004), in which supervision signals are heuristically labelled by matching unlabelled corpora with entities or attributes in a structured database. It has been widely applied to relation extraction (Mintz et al., 2009) and information extraction (Hoffmann et al., 2011) in which facts from a knowledge base (e.g. Freebase) were used as objectives to train classifiers. Recently, self supervision was also used in memory networks (Hill et al., 2016) to improve the discriminative power of memory attention. Conceptually, snapshot learning is related to curriculum learning (Bengio et al., 2009). Instead of learning easier examples before difficult ones, snapshot learning creates an easier target for each example. In practice, snapshot learning is similar to deeply supervised nets (Lee et al., 2015) in which *companion* objectives are generated from intermediary layers and optimised altogether with the output objective.

3 Neural Dialogue System

The testbed for this work is a neural network-based task-oriented dialogue system proposed by Wen et al. (2016a). The model casts dialogue as a source to target sequence transduction problem (modelled by a sequence-to-sequence architecture (Sutskever et al., 2014)) augmented with the dialogue history (modelled by a belief tracker (Henderson et al., 2014)) and the current database search outcome (modelled by a database operator). The model consists of both encoder and decoder modules. The details of each module are given below.

3.1 Encoder Module

At each turn t, the goal of the encoder is to produce a distributed representation of the system action $\mathbf{m}_t$, which is then used to condition a decoder to generate the next system response in skeletal form[1]. It consists of four submodules: intent network, belief tracker, database operator, and policy network.

Intent Network The intent network takes a sequence of tokens[1] and converts it into a sentence embedding representing the user intent using an LSTM network. The hidden layer of the LSTM at the last encoding step $\mathbf{z}_t$ is taken as the representation. As mentioned in Wen et al. (2016a), this representation can be viewed as a distributed version of the speech act (Traum, 1999) used in traditional systems.

Belief Trackers In addition to the intent network, the neural dialogue system uses a set of slot-based belief trackers (Henderson et al., 2014; Mrkšić et al., 2015) to track user requests. By taking each user input as new evidence, the task of a belief tracker is to maintain a multinomial distribution p over values $v \in V_s$ for each informable slot[2] s, and a binary distribution for each requestable slot[2]. These probability distributions $\mathbf{p}_t^s$ are called belief states of the system. The belief states $\mathbf{p}_t^s$, together with the intent vector $\mathbf{z}_t$, can be viewed as the system's comprehension of the user requests up to turn t.

Database Operator Based on the belief states $\mathbf{p}_t^s$, a DB query is formed by taking the union of the maximum values of each informable slot. A vector $\mathbf{x}_t$ representing different degrees of matching in the DB (no match, 1 match, ... or more than 5 matches) is produced by counting the number of matched entities and expressing it as a 6-bin 1-hot encoding. If $\mathbf{x}_t$ is not zero, an associated entity pointer is maintained which identifies one of the matching DB entities selected at random. The entity pointer is updated if the current entity no longer matches the search criteria; otherwise it stays the same.

Policy Network Based on the vectors $\mathbf{z}_t$, $\mathbf{p}_t^s$, and $\mathbf{x}_t$ from the above three modules, the policy network combines them into a single action vector $\mathbf{m}_t$ by a three-way matrix transformation,

$$\mathbf{m}_t = \tanh(\mathbf{W}_{zm}\mathbf{z}_t + \mathbf{W}_{xm}\mathbf{x}_t + \textstyle\sum_{s\in\mathbb{G}} \mathbf{W}_{pm}^s \mathbf{p}_t^s) \quad (1)$$

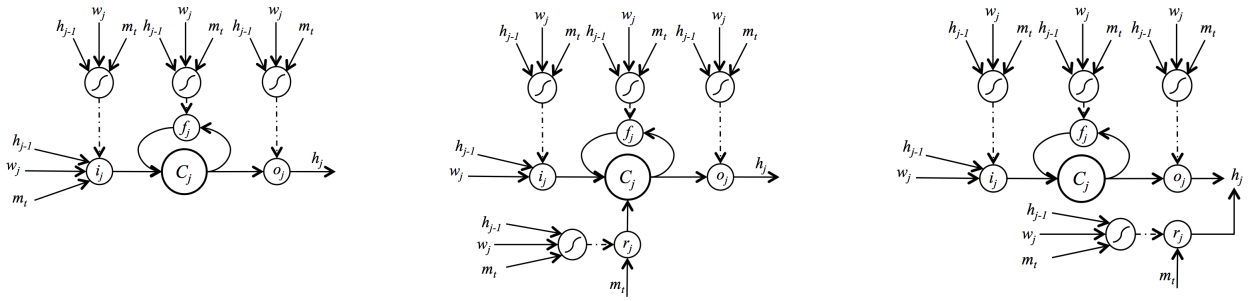
where matrices $\mathbf{W}_{zm}$, $\mathbf{W}_{pm}^s$, and $\mathbf{W}_{xm}$ are parameters and $\mathbb{G}$ is the domain ontology.

3.2 Decoder Module

Conditioned on the system action vector $\mathbf{m}_t$ provided by the encoder module, the decoder module uses a conditional LSTM LM to generate the required system output token by token in skeletal form[1]. The final system response can then be formed

[1]Delexicalisation: slots and values are replaced by generic tokens (e.g. keywords like *Chinese food* are replaced by *[v.food] [s.food]* to allow weight sharing.

[2]Informable slots are slots that users can use to constrain the search, such as food type or price range; Requestable slots are slots that users can ask a value for, such as phone number. This information is specified in the domain ontology.



(a) Language model type LSTM (b) Memory type LSTM (c) Hybrid type LSTM

Figure 1: Three different conditional generation architectures.

by substituting the actual values of the database entries into the skeletal sentence structure.

3.2.1 Conditional Generation Network

In this paper we study and analyse three different variants of LSTM-based conditional generation architectures:

Language Model Type The most straightforward way to condition the LSTM network on additional source information is to concatenate the conditioning vector $\mathbf{m}_t$ together with the input word embedding $\mathbf{w}_j$ and previous hidden layer $\mathbf{h}_{j-1}$,

$$\begin{pmatrix} \mathbf{i}_j \\ \mathbf{f}_j \\ \mathbf{o}_j \\ \hat{\mathbf{c}}_j \end{pmatrix} = \begin{pmatrix} \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \\ \tanh \end{pmatrix} \mathbf{W}_{4n,3n} \begin{pmatrix} \mathbf{m}_t \\ \mathbf{w}_j \\ \mathbf{h}_{j-1} \end{pmatrix}$$

$$\mathbf{c}_j = \mathbf{f}_j \odot \mathbf{c}_{j-1} + \mathbf{i}_j \odot \hat{\mathbf{c}}_j$$

$$\mathbf{h}_j = \mathbf{o}_j \odot \tanh(\mathbf{c}_j)$$

where index j is the generation step, n is the hidden layer size, $\mathbf{i}_j, \mathbf{f}_j, \mathbf{o}_j \in [0,1]^n$ are input, forget, and output gates respectively, $\hat{\mathbf{c}}_j$ and $\mathbf{c}_j$ are proposed cell value and true cell value at step j, and $\mathbf{W}_{4n,3n}$ are the model parameters. The model is shown in Figure 1a. Since it does not differ significantly from the original LSTM, we call it the *language model type* (lm) conditional generation network.

Memory Type The *memory type* (mem) conditional generation network was introduced by Wen et al. (2015b), shown in Figure 1b, in which the conditioning vector $\mathbf{m}_t$ is governed by a standalone reading gate $\mathbf{r}_j$. This reading gate decides how much information should be read from the conditioning vector and directly writes it into the memory cell $\mathbf{c}_j$,

$$\begin{pmatrix} \mathbf{i}_j \\ \mathbf{f}_j \\ \mathbf{o}_j \\ \mathbf{r}_j \end{pmatrix} = \begin{pmatrix} \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \end{pmatrix} \mathbf{W}_{4n,3n} \begin{pmatrix} \mathbf{m}_t \\ \mathbf{w}_j \\ \mathbf{h}_{j-1} \end{pmatrix}$$

$$\hat{\mathbf{c}}_j = \tanh\left(\mathbf{W}_c(\mathbf{w}_j \oplus \mathbf{h}_{j-1})\right)$$

$$\mathbf{c}_j = \mathbf{f}_j \odot \mathbf{c}_{j-1} + \mathbf{i}_j \odot \hat{\mathbf{c}}_j + \mathbf{r}_j \odot \mathbf{m}_t$$

$$\mathbf{h}_j = \mathbf{o}_j \odot \tanh(\mathbf{c}_j)$$

where $\mathbf{W}_c$ is another weight matrix to learn. The idea behind this is that the model isolates the conditioning vector from the LM so that the model has more flexibility to learn to trade off between the two.

Hybrid Type Continuing with the same idea as the *memory type* network, a complete separation of conditioning vector and LM (except for the gate controlling the signals) is provided by the *hybrid type* network shown in Figure 1c,

$$\begin{pmatrix} \mathbf{i}_j \\ \mathbf{f}_j \\ \mathbf{o}_j \\ \mathbf{r}_j \end{pmatrix} = \begin{pmatrix} \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \end{pmatrix} \mathbf{W}_{4n,3n} \begin{pmatrix} \mathbf{m}_t \\ \mathbf{w}_j \\ \mathbf{h}_{j-1} \end{pmatrix}$$

$$\hat{\mathbf{c}}_j = \tanh\left(\mathbf{W}_c(\mathbf{w}_j \oplus \mathbf{h}_{j-1})\right)$$

$$\mathbf{c}_j = \mathbf{f}_j \odot \mathbf{c}_{j-1} + \mathbf{i}_j \odot \hat{\mathbf{c}}_j$$

$$\mathbf{h}_j = \mathbf{o}_j \odot \tanh(\mathbf{c}_j) + \mathbf{r}_j \odot \mathbf{m}_t$$

This model was motivated by the fact that long-term dependency is not needed for the conditioning vector because we apply this information at every step j anyway. The decoupling of the conditioning vector and the LM is attractive because it leads to better interpretability of the results and provides the potential to learn a better conditioning vector and LM.

3.2.2 Attention and Belief Representation

Attention An attention-based mechanism provides an effective approach for aggregating multiple information sources for prediction tasks. Like Wen et al.

(2016a), we explore the use of an attention mechanism to combine the tracker belief states in which the policy network in Equation 1 is modified as

$$\mathbf{m}_t^j = \tanh(\mathbf{W}_{zm}\mathbf{z}_t + \mathbf{W}_{xm}\mathbf{x}_t + \sum_{s\in\mathbb{G}} \alpha_s^j \mathbf{W}_{pm}^s \mathbf{p}_t^s)$$

where the attention weights α_s^j are calculated by,

$$\alpha_s^j = \text{softmax}\big(\mathbf{r}^\intercal \tanh\left(\mathbf{W}_r \cdot (\mathbf{v}_t \oplus \mathbf{p}_t^s \oplus \mathbf{w}_j^t \oplus \mathbf{h}_{j-1}^t)\right)\big)$$

where $\mathbf{v}_t = \mathbf{z}_t + \mathbf{x}_t$ and matrix $\mathbf{W}_r$ and vector $\mathbf{r}$ are parameters to learn.

Belief Representation The effect of different belief state representations on the end performance are also studied. For user informable slots, the *full* belief state $\mathbf{p}_t^s$ is the original state containing all categorical values; the *summary* belief state contains only three components: the summed value of all categorical probabilities, the probability that the user said they "don't care" about this slot and the probability that the slot has not been mentioned. For user requestable slots, on the other hand, the full belief state is the same as the summary belief state because the slot values are binary rather than categorical.

3.3 Snapshot Learning

Learning conditional generation models from sequential supervision signals can be difficult, because it requires the model to learn both long-term word dependencies and potentially distant source encoding functions. To mitigate this difficulty, we introduce a novel method called *snapshot learning* to create a vector of binary labels $\mathbf{\Upsilon}_t^j \in [0,1]^d$, $d < dim(\mathbf{m}_t^j)$ as the *snapshot* of the remaining part of the output sentence $T_{t,j:|T_t|}$ from generation step j. Each element of the snapshot vector is an indicator function of a certain event that will happen in the future, which can be obtained either from the system response or dialogue context at training time. A *companion* cross entropy error is then computed to force a subset of the conditioning vector $\hat{\mathbf{m}}_t^j \subset \mathbf{m}_t^j$ to be close to the snapshot vector,

$$L_{ss}(\cdot) = -\sum_t \sum_j \mathbb{E}[H(\Upsilon_t^j, \hat{m}_t^j)] \quad (2)$$

where $H(\cdot)$ is the cross entropy function, Υ_t^j and $\hat{m}_t^j$ are elements of vectors $\mathbf{\Upsilon}_t^j$ and $\hat{\mathbf{m}}_t^j$, respectively. In order to make the $\tanh$ activations of $\hat{\mathbf{m}}_t^j$ compatible with the 0-1 snapshot labels, we squeeze each value of $\hat{\mathbf{m}}_t^j$ by adding 1 and dividing by 2 before computing the cost.

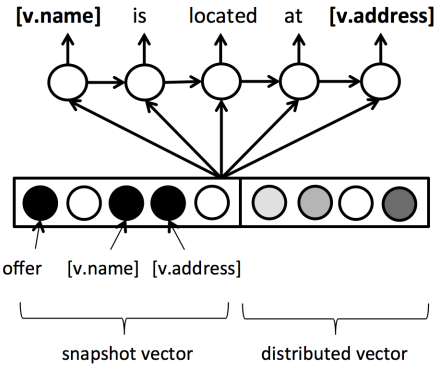


Figure 2: The idea of snapshot learning. The snapshot vector was trained with additional supervisions on a set of indicator functions heuristically labelled using the system response.

The indicator functions we use in this work have two forms: (1) whether a particular slot value (e.g., *[v.food]*[1]) is going to occur, and (2) whether the system has offered a venue[3], as shown in Figure 2. The *offer* label in the snapshot is produced by checking the delexicalised name token (*[v.name]*) in the entire dialogue. If it has occurred, every label in subsequent turns is labelled with 1. Otherwise it is labelled with 0. To create snapshot targets for a particular slot value, the output sentence is matched with the corresponding delexicalised token turn by turn, per generation step. At each generation step, the target is labelled with 0 if that delexicalised token has been generated; otherwise it is set to 1. However, for the models without attention, the targets per turn are set to the same because the condition vector will not be able to learn the dynamically changing behaviour without attention.

4 Experiments

Dataset The dataset used in this work was collected in the Wizard-of-Oz online data collection described by Wen et al. (2016a), in which the task of the system is to assist users to find a restaurant in Cambridge, UK area. There are three informable slots (*food*, *pricerange*, *area*) that users can use to constrain the search and six requestable slots (*address*, *phone*, *postcode* plus the three informable

[3]Details of the specific application used in this study are given in Section 4 below.

Table 1: Performance comparison of different model architectures, belief state representations, and snapshot learning. The numbers to the left and right of the **/** sign are learning without and with snapshot, respectively. The model with the best performance on a particular metric (column) is shown in bold face. The *lm* models in *Conditional architecture* and *Attention-based model* are the same models as in Wen et al. (2016a). Statistical significance was computed using two-tailed Wilcoxon Signed-Rank Test (* p $<$0.05) to compare models w/ and w/o snapshot learning.

slots) that the user can ask a value for once a restaurant has been offered. There are 676 dialogues in the dataset (including both finished and unfinished dialogues) and approximately 2750 turns in total. The database contains 99 unique restaurants.

Training The training procedure was divided into two stages. Firstly, the belief tracker parameters θ_b were pre-trained using cross entropy errors between tracker labels and predictions. Having fixed the tracker parameters, the remaining parts of the model $\theta_{\setminus b}$ are trained using the cross entropy errors from the generation network LM,

$$L(\theta_{\setminus b}) = -\sum_t \sum_j H(\mathbf{y}_j^t, \mathbf{p}_j^t) + \lambda L_{ss}(\cdot) \qquad (3)$$

where $\mathbf{y}_j^t$ and $\mathbf{p}_j^t$ are output token targets and predictions respectively, at turn t of output step j, $L_{ss}(\cdot)$ is the snapshot cost from Equation 2, and λ is the tradeoff parameter in which we set to 1 for all models trained with snapshot learning. We treated each dialogue as a batch and used stochastic gradient descent with a small $l2$ regularisation term to train the model. The collected corpus was partitioned into a training, validation, and testing sets in the ratio 3:1:1. Early stopping was implemented based on the validation set considering only LM log-likelihoods. Gradient clipping was set to 1. The hidden layer sizes were set to 50, and the weights were randomly initialised between -0.3 and 0.3 including word embeddings. The vocabulary size is around 500 for both input and output, in which rare words and words that can be delexicalised have been removed.

Decoding In order to compare models trained with different recipes rather than decoding strategies, we decode all the trained models with the average log probability of tokens in the sentence. We applied beam search with a beamwidth equal to 10, the search stops when an end-of-sentence token is generated. In order to consider language variability, we ran decoding until 5 candidates were obtained and performed evaluation on them.

Metrics We compared models trained with different recipes by performing a corpus-based evaluation in which the model is used to predict each system response in the held-out test set. Three evaluation metrics were used: BLEU score (on top-1 and top-5 candidates) (Papineni et al., 2002), slot matching rate and objective task success rate (Su et al., 2015). The dialogue is marked as successful if both: (1) the offered entity matches the task that was specified to the user, and (2) the system answered all the associated information requests (e.g. *what is the address?*) from the user. The slot matching rate is the percentage of delexicalised tokens (e.g. *[s.food]* and *[v.area]*[1]) appear in the candidate also appear in the

(b) *Hybrid* LSTM w/ snapshot learning

Figure 3: Learned attention heat maps over trackers. The first three columns in each figure are informable slot trackers and the rest are requestable slot trackers. The generation model is the *hybrid* type LSTM.

reference. We computed the BLEU scores on the skeletal sentence forms before substituting with the actual entity values. All the results were averaged over 10 random initialised networks.

Results Table 1 shows the evaluation results. The numbers to the left and right of each table cell are the same model trained w/o and w/ snapshot learning. The first observation is that snapshot learning consistently improves on most metrics regardless of the model architecture. This is especially true for BLEU scores. We think this may be attributed to the more discriminative conditioning vector learned through the snapshot method, which makes the learning of the conditional LM easier.

In the first block *belief state representation*, we compare the effect of two different belief representations. As can be seen, using a succinct representation is better (*summary*>*full*) because the identity of each categorical value in the belief state does not help when the generation decisions are done in skeletal form. In fact, the full belief state representation may encourage the model to learn incorrect co-adaptation among features when the data is scarce.

In the *conditional architecture* block, we compare the three different conditional generation architectures as described in section 3.2.1. This result shows that the language model type (*lm*) and memory type (*mem*) networks perform better in terms of BLEU score and slot matching rate, while the hybrid type (*hybrid*) networks achieve higher task success. This is probably due to the degree of separation between the LM and conditioning vector: a coupling approach (*lm, mem*) sacrifices the conditioning vector but learns a better LM and higher BLEU; while a complete separation (*hybrid*) learns a better conditioning vector and offers a higher task success.

Model	$\mathbf{i}_j$	$\mathbf{f}_j$	$\mathbf{r}_j/\mathbf{o}_j$
hybrid, full	0.567	0.502	0.405
hybrid, summary	0.539	0.540	0.428
+ att.	0.540	0.559	0.459

Table 2: Average activation of gates on test set.

Lastly, in the *attention-based model* block we train the three architectures with the attention mechanism and compare them again. Firstly, the characteristics of the three models we observed above also hold for attention-based models. Secondly, we found that the attention mechanism improves all the three architectures on task success rate but not BLEU scores. This is probably due to the limitations of using n-gram based metrics like BLEU to evaluate the generation quality (Stent et al., 2005).

5 Model Analysis

Gate Activations We first studied the average activation of each individual gate in the models by averaging them when running generation on the test set. We analysed the *hybrid* models because their reading gate to output gate activation ratio ($\mathbf{r}_j/\mathbf{o}_j$) shows clear tradeoff between the LM and the conditioning vector components. As can be seen in Ta-

Figure 4: Three example responses generated from the hybrid model trained with snapshot and attention. Each line represents a neuron that detects a particular snapshot event.

ble 2, we found that the average forget gate activations ($\mathbf{f}_j$) and the ratio of the reading gate to the output gate activation ($\mathbf{r}_j/\mathbf{o}_j$) have strong correlations to performance: a better performance (*row 3>row 2>row 1*) seems to come from models that can learn a longer word dependency (higher forget gate $\mathbf{f}_t$ activations) and a better conditioning vector (therefore higher reading to output gate ratio $\mathbf{r}_j/\mathbf{o}_j$).

Learned Attention We have visualised the learned attention heat map of models trained with and without snapshot learning in Figure 3. The attention is on both the informable slot trackers (first three columns) and the requestable slot trackers (the other columns). We found that the model trained with snapshot learning (Figure 3b) seems to produce a more accurate and discriminative attention heat map comparing to the one trained without it (Figure 3a). This may contribute to the better performance achieved by the snapshot learning approach.

Snapshot Neurons As mentioned earlier, snapshot learning forces a subspace of the conditioning vector $\hat{\mathbf{m}}_t^j$ to become discriminative and interpretable. Three example generated sentences together with the snapshot neuron activations are shown in Figure 4. As can be seen, when generating words one by one, the neuron activations were changing to detect different events they were assigned by the snapshot training signals: e.g. in Figure 4b the *light blue* and *orange* neurons switched their domination role when the token *[v.address]* was generated; the *offered* neuron is in a high activation state in Figure 4b because the system was offering a venue, while in Figure 4a it is not activated because the system was still helping the user to find a venue.

6 Conclusion and Future Work

This paper has investigated different conditional generation architectures and a novel method called snapshot learning to improve response generation in a neural dialogue system framework. The results showed three major findings. Firstly, although the *hybrid type* model did not rank highest on all metrics, it is nevertheless preferred because it achieved the highest task success and also it provided more interpretable results. Secondly, snapshot learning provided gains on virtually all metrics regardless of the architecture used. The analysis suggested that the benefit of snapshot learning mainly comes from the more discriminative and robust subspace representation learned from the heuristically labelled companion signals, which in turn facilitates optimisation of the final target objective. Lastly, the results suggested that by making a complex system more interpretable at different levels not only helps our understanding but also leads to the highest success rates.

However, there is still much work left to do. This work focused on conditional generation architectures and snapshot learning in the scenario of generating dialogue responses. It would be very helpful if the same comparison could be conducted in other application domains such as machine translation or image caption generation so that a wider view of the effectiveness of these approaches can be assessed. Furthermore, removing slot-value delexicalisation and learning confirmation behaviour in noisy speech conditions are also main research problems from the system development prospective.

Relations such as Hypernymy: Identifying and Exploiting Hearst Patterns in Distributional Vectors for Lexical Entailment

Abstract

We consider the task of predicting *lexical entailment* using distributional vectors. We perform a novel qualitative analysis of one existing model which was previously shown to only measure the prototypicality of word pairs. We find that the model strongly learns to identify hypernyms using *Hearst patterns*, which are well known to be predictive of lexical relations. We present a novel model which exploits this behavior as a method of feature extraction in an iterative procedure similar to Principal Component Analysis. Our model combines the extracted features with the strengths of other proposed models in the literature, and matches or outperforms prior work on multiple data sets.

1 Introduction

As the field of Natural Language Processing has developed, more ambitious semantic tasks are starting to be addressed, such as Question Answering (QA) and Recognizing Textual Entailment (RTE). These systems often depend on the use of lexical resources like WordNet in order to infer entailments for individual words, but these resources are expensive to develop, and always have limited coverage.

To address these issues, many works have considered on how lexical entailments can be derived automatically using distributional semantics. Some focus mostly on the use of unsupervised techniques, and study measures which emphasize particular word relations (Baroni and Lenci, 2011). Many are based on the Distributional Inclusion Hypothesis, which states that the contexts in which a hypernym appears are a superset of its hyponyms' contexts (Zhitomirsky-Geffet and Dagan, 2005; Kotlerman et al., 2010). More recently, a great deal of work has pushed toward using supervised methods (Baroni et al., 2012; Roller et al., 2014; Weeds et al., 2014; Levy et al., 2015; Kruszewski et al., 2015), varying by their experimental setup or proposed model.

Yet the literature disagrees about which models are strongest (Weeds et al., 2014; Roller et al., 2014), or even if they work at all (Levy et al., 2015). Indeed, Levy et al. (2015) showed that two existing lexical entailment models fail to account for similarity between the antecedent and consequent, and conclude that such models are only learning to predict *prototypicality*: that is, they predict that *cat* entails *animal* because *animal* is usually entailed, and therefore will also predict that *sofa* entails *animal*. Yet it remains unclear why such models make for such strong baselines (Weeds et al., 2014; Kruszewski et al., 2015; Levy et al., 2015).

We present a novel qualitative analysis of one prototypicality classifier, giving new insight into why prototypicality classifiers perform strongly in the literature. We find the model overwhelmingly learns to identify hypernyms using Hearst patterns available in the distributional space, like "animals such as cats" and "animals including cats." These patterns have long been used to identify lexical relations (Hearst, 1992; Snow et al., 2004).

We propose a novel model which exploits this behavior as a method of feature extraction, which we call *H-feature detectors*. Using an iterative procedure similar to Principal Component Analysis, our

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2163–2172,
Austin, Texas, November 1-5, 2016.

model is able to extract and learn using multiple H-feature detectors. Our model also integrates overall word similarity and Distributional Inclusion, bringing together strengths of several models in the literature. Our model matches or outperforms prior work on multiple data sets. The code, data sets, and model predictions are made available for future research.[1]

2 Background

Research on lexical entailment using distributional semantics has now spanned more than a decade, and has been approached using both unsupervised (Weeds et al., 2004; Kotlerman et al., 2010; Lenci and Benotto, 2012; Santus, 2013) and supervised techniques (Baroni et al., 2012; Fu et al., 2014; Roller et al., 2014; Weeds et al., 2014; Kruszewski et al., 2015; Levy et al., 2015; Turney and Mohammad, 2015; Santus et al., 2016). Most of the work in unsupervised methods is based on the Distributional Inclusion Hypothesis (Weeds et al., 2004; Zhitomirsky-Geffet and Dagan, 2005), which states that the contexts in which a hypernym appear should be a superset over its hyponyms' contexts.

This work focuses primarily on the supervised works in the literature. Formally, we consider methods which treat lexical entailment as a supervised classification problem, which take as input the distributional vectors for a pair of words, $(H,\ w)$, and predict on whether the antecedent w entails the consequent H.[2]

One of the earliest supervised approaches was Concat (Baroni et al., 2012). In this work, the *concatenation* of the pair $\langle H,\ w\rangle$ was used as input to an off-the-shelf SVM classifier. At the time, it was very successful, but later works noted that it had major problems with *lexical memorization* (Roller et al., 2014; Weeds et al., 2014; Levy et al., 2015). That is, when the training and test sets were carefully constructed to ensure they were completely disjoint, it performed extremely poorly. Nonetheless, Concat is continually used as a strong baseline in more recent work (Kruszewski et al., 2015).

In response to these issues of lexical memorization, alternative models were proposed. Of particular note are the *Diff* (Fu et al., 2014; Weeds et al., 2014) and *Asym* classifiers (Roller et al., 2014). The Diff model takes the vector difference $H - w$ as input, while the Asym model uses both the vector difference and the squared vector difference as input. Weeds et al. (2014) found that Concat moderately outperformed Diff, while Roller et al. (2014) found that Asym outperformed Concat. Both Diff and Asym can also be seen as a form of supervised Distributional Inclusion Hypothesis, with the vector difference being analogous to the set-inclusion measures of some unsupervised techniques (Roller et al., 2014). All of these works focused exclusively on *hypernymy detection*, rather than the more general task of lexical entailment.

Recently, other works have begun to analyze Concat and Diff for their ability to go beyond just hypernymy detection. Vylomova et al. (2016) take an extensive look at Diff's ability to model a wide variety of lexical relations and conclude it is generally robust, and Kruszewski et al. (2015) have success with a neural network model based on the Distributional Inclusion Hypothesis.

On the other hand, Levy et al. (2015) analyze both Concat and Diff in their ability to detect general lexical entailment on five data sets: two consisting of only hypernymy, and three covering a wide variety of other entailing word relations. They find that both Concat and Diff fail, and analytically show that they are learning to predict the *prototypicality* of the consequent H, rather than the relationship between the antecedent and the consequent, and consider this a form of lexical memorization. They propose a new model, Ksim, which addresses their concerns, but lacks any notion of Distributional Inclusion. In particular, they argue for directly including the cosine similarity of w and H as a term in a custom SVM kernel, in order to determine whether w and H are related all. Ultimately, Levy et al. (2015) conclude that distributional vectors may simply be the wrong tool for the job.

3 Data and Resources

Prior work on lexical entailment relied on a variety of data sets, each constructed in a different manner.

[1] `http://github.com/stephenroller/emnlp2016`

[2] We use the notation w and H for *word* and *hypernym*. These variables refer to either the lexical items, or their distributional vectors, depending on context.

We focus on four different data sets, each of which has been used for evaluation in prior work. Two data sets contain only hypernymy relations, and two consider general lexical entailment.

Our first data set is **LEDS**, the Lexical Entailment Data Set, originally created by Baroni et al. (2012). The data set contains 1385 hyponym-hypernym pairs extracted directly from WordNet, forming a set of positive examples. Negative examples were generated by randomly shuffling the original set of 1385 pairs. As such, LEDS only contains examples of hypernymy and random relations.

Another major data set has been **BLESS**, the Baroni and Lenci (2011) Evaluation of Semantic Spaces. The data set contains annotations of word relations for 200 unambiguous, concrete nouns from 17 broad categories. Each noun is annotated with its co-hyponyms, meronyms, hypernym and some random words. In this work, we treat hypernymy as positive, and other relations as negative.

These two data sets form our hypernymy data sets, but we cannot overstate their important differences: LEDS is balanced, while BLESS contains mostly negative examples; negatives in BLESS include both random pairs *and* pairs exhibiting other strong semantic relations, while LEDS only contains random pairs. Furthermore, all of the negative examples in LEDS are the same lexical items as the positive items, which has strong implications on the prototypicality argument of Levy et al. (2015).

The next data set we consider is **Medical** (Levy et al., 2014). This data set contains high quality annotations of subject-verb-object entailments extracted from medical texts, and transformed into noun-noun entailments by argument alignments. The data contains 12,600 annotations, but only 945 positive examples encompassing various relations like hypernymy, meronomy, synonymy and contextonymy.[3] This makes it one of the most difficult data sets: it is both domain specific and highly unbalanced.

The final data set we consider is **TM14**, a variation on the SemEval 2012 Shared Task of identifying the degree to which word pairs exhibit various relations. These relationships include a small amount of hypernymy, but also many more uncommon relations (agent-object, cause-effect, time-activity, etc). Relationships were binarized into (non-)entailing pairs by Turney and Mohammad (2015). The data set covers 2188 pairs, 1084 of which are entailing.

These two entailment data sets also contain important differences, especially in contrast to the hypernymy data sets. Neither contains any random negative pairs, meaning general semantic similarity measures should be less useful; And both exhibit a variety of non-hypernymy relations, which are less strictly defined and more difficult to model.

3.1 Distributional Vectors

In all experiments, we use a standard, count-based, syntactic distributional vector space. We use a corpus composed of the concatenation of Gigaword, Wikipedia, BNC and ukWaC. We preprocess the corpus using Stanford CoreNLP 3.5.2 (Chen and Manning, 2014) for tokenization, lemmatization, POS-tagging and universal dependency parses. We compute a syntactic distributional space for the 250k most frequent lemmas by counting their dependency neighbors across the corpus. We use only the top 1M most frequent dependency attachments as contexts. We use CoreNLP's "collapsed dependencies", in which prepositional dependencies are collapsed e.g. "go to the store" emits the tuples (go, prep:to+store) and (store, prep:to^{-1}+go). After collecting counts, vectors are transformed using PPMI, SVD reduced to 300 dimensions, and normalized to unit length. The use of collapsed dependencies is very important, as we will see in Section 4, but other parameters are reasonably robust.

4 Motivating Analysis

As discussed in Section 2, the Concat classifier is a classifier trained on the concatenation of the word vectors, $\langle H,\ w\rangle$. As additional background, we first review the findings of Levy et al. (2015), who showed that Concat trained using a linear classifier is only able to capture notions of *prototypicality*; that is, Concat guesses that (*animal*, *sofa*) is a positive example because *animal* looks like a hypernym.

Formally, a linear classifier like Logistic Regression or Linear SVM learns a decision hyperplane represented by a vector $\hat{p}$. Data points are compared to this plane with the inner product: those above

[3] A term for entailments that occur in some contexts, but do not cleanly fit in other categories; e.g. *hospital* entails *doctor*.

the plane (positive inner product) are classified as entailing, and those below as non-entailing. Crucially, since the input features are the concatenation of the pair vectors $\langle H,\ w\rangle$, the hyperplane $\hat{p}$ vector can be *decomposed* into separate H and w components. Namely, if we rewrite the decision plane $\hat{p} = \langle \hat{H}, \hat{w}\rangle$, we find that each pair $\langle H,\ w\rangle$ is classified using:

$$\begin{aligned}&\hat{p}^\top \langle H,\ w\rangle \\ &= \langle \hat{H}, \hat{w}\rangle^\top \langle H,\ w\rangle \\ &= \hat{H}^\top H + \hat{w}^\top w.\end{aligned} \tag{1}$$

This analysis shows that, when the hyperplane $\hat{p}$ is evaluated on a novel pair, it lacks any form of direct interaction between H and w like the inner product $H^\top w$. Without any interaction terms, the Concat classifier has no way of estimating the relationship *between* the two words, and instead only makes predictions based on two independent terms, $\hat{H}$ and $\hat{w}$, the *prototypicality vectors*. Furthermore, the Diff classifier can be analyzed in the same fashion and therefore has the same fatal property.

We agree with this prototypicality interpretation, although we believe it is incomplete: while it places a fundamental ceiling on the performance of these classifiers, it does not explain *why* others have found them to persist as strong baselines (Weeds et al., 2014; Roller et al., 2014; Kruszewski et al., 2015; Vylomova et al., 2016). To approach this question, we consider a baseline Concat classifier trained using a linear model. This classifier should most strongly exhibit the prototypicality behavior according to Equation 1, making it the best choice for analysis. We first consider the most pessimistic hypothesis: is it only learning to memorize which words are hypernyms at all?

We train the baseline Concat classifier using Logistic Regression on each of the four data sets, and extract the vocabulary words which are most similar to the $\hat{H}$ half of the learned hyperplane $\hat{p}$. If the classifier is only learning to memorize the training data, we would expect items from the data to dominate this list of closest vocabulary terms. Table 1 gives the five most similar words to the learned hyperplane, with bold words appearing directly in the data set.

Interestingly, we notice there are very few bold words at all in the list. In LEDS, we actually see some hypernyms of data set items that do not even appear in the data set, and the Medical and TM14 words do not even appear related to the content of the data sets. Similar results were also found for Diff and Asym, and both when using Linear SVM and Logistic Regression. These lists cannot explain the success of the prototypicality classifiers in prior work. Instead, we propose an alternative interpretation of the hyperplane: that of a feature detector for hypernyms, or an *H-feature detector*.

Table 1: Most similar words to the prototype $\hat{H}$ learned by the Concat model. Bold items appear in the data set.

4.1 H-Feature Detectors

Recall that distributional vectors are derived from a matrix M containing counts of how often words co-occur with the different syntactic contexts. This co-occurrence matrix is factorized using Singular Value Decomposition, producing both W, the ubiquitous word-embedding matrix, and C, the context-embedding matrix (Levy and Goldberg, 2014):

$$M \approx WC^\top$$

Since the word and context embeddings implicitly live in the same vector space (Melamud et al., 2015), we can also compare Concat's hyperplane with the context matrix C. Under this interpretation, the Concat model does not learn what words are hypernyms, but rather what *contexts* or *features* are indicative of hypernymy. Table 2 shows the syntactic contexts with the highest cosine similarity to the $\hat{H}$ prototype for each of the different data sets.

This view of Concat as an H-feature detector produces a radically different perspective on the classifier's hyperplane. Nearly all of the features learned take the form of Hearst patterns (Hearst, 1992; Snow et al., 2004). The most recognizable and common pattern learned is the "such as" pattern, as in "animals such as cats". These patterns have been well known to be indicative of hypernymy for over two decades. Other interesting pat-

Table 2: Most similar contexts to the prototype $\hat{H}$ learned by the Concat model.

terns are the "including" pattern ("animals including cats") and "many" pattern ("many animals"). Although we list only the six most similar context items for the data sets, we find similar contexts continue to dominate the list for the next 30-50 items. Taken together, it is remarkable that the model identified these patterns using only distributional vectors and only the positive/negative example pairs. However, the reader should note these are not true Hearst patterns: Hearst patterns explicitly relate a hypernym and hyponym using an exact pattern match of a *single* co-occurrence. On the other hand, these *H-features* are *aggregate indicators* of hypernymy across a large corpus.

These learned features are much more interpretable than those found in the analysis of prior work like Roller et al. (2014) and Levy et al. (2015). Roller et al. (2014) found no signals of H-features in their analysis of one classifier, but their model was focused on *bag-of-words* distributional vectors, which perform significantly worse on the task. Levy et al. (2015) also performed an analysis of lexical entailment classifiers, and found weak signals like "such" and "of" appearing as prominent contexts in their classifier, giving an early hint of H-feature detectors, but not to such an overwhelming degree as we see in this work. Critically, their analysis focused on a classifier trained on high-dimensional, *sparse* vectors, rather than focusing on *context embeddings* as we do. By using these sparse vectors, their model was unable to generalize across similar contexts. Additionally, their model did not make use of *collapsed dependencies*, making features like "such" much weaker signals of entailment and therefore less dominant during analysis.

Among these remarkable lists, the LEDS and TM14 data sets stand out for having much fewer "such as" patterns compared to BLESS and Medical. The reason for this is explained by the construction of the data sets: since LEDS contains the same words used as both positive and negative examples, the classifier has a hard time picking out clear signal. The TM14 data set, however, does not contain any such negative examples.

We hypothesize the TM14 data set contains too many diverse and mutually exclusive forms of lexical entailment, like instrument-goal (e.g. "honey" $\rightarrow$ "sweetness"). To test this, we retrained the model with only hypernymy as positive examples, and all other relations as negative. We find that "such as" type patterns become top features, but also some interesting data specific features, like "retailer of [clothes]". Examining the data shows it contains many consumer goods, like "beverage" or "clothes", which explains these features.

5 Proposed Model

As we saw in the previous section, Concat only acts as a sort of H-feature detector for whether H is a prototypical hypernym, but does not actually infer the relationship between H and w. Nonetheless, this is powerful behavior which should still be used in combination with the insights of other models like Ksim and Asym. To this end, we propose a novel model which exploits Concat's H-feature detector behavior, extends its modeling power, and adds two other types of evidence proposed in the literature: overall similarity, and distributional inclusion.

Our model works through an iterative procedure similar to Principal Component Analysis (PCA). Each iteration repeatedly trains a Concat classifier under the assumption that it acts as an H-feature detector, and then explicitly discards this information from the distributional vectors. By training a new H-feature detector on these modified distributional vectors, we can find *additional* features indicative of entailment which were missed by the first classifier. The entire procedure is iteratively repeated similar

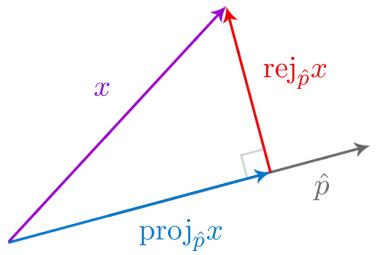

Figure 1: A vector $\hat{p}$ is used to break x into two orthogonal components, its projection and the rejection over $\hat{p}$.

to how in Principal Component Analysis, the second principal component is computed after the first principal component has been removed from the data.

The main insight is that after training some H-feature detector using Concat, we can *remove* this prototype from the distributional vectors through the use of *vector projection*. Formally, the vector projection of x onto a vector $\hat{p}$, $\text{proj}_{\hat{p}}(x)$ finds the *component* of x which is in the direction of $\hat{p}$,

$$\text{proj}_{\hat{p}}(x) = \left(\frac{x^\top \hat{p}}{\|\hat{p}\|}\right)\hat{p}.$$

Figure 1 gives a geometric illustration of the vector projection. If x forms the hypotenuse of a right triangle, $\text{proj}_{\hat{p}}(x)$ forms a leg of the triangle. This also gives rise to the *vector rejection*, which is the vector forming the third leg of the triangle. The vector rejection is orthogonal to the projection, and intuitively, is the original vector after the projection has been removed:

$$\text{rej}_{\hat{p}}(x) = x - \text{proj}_{\hat{p}}(x).$$

Using the vector rejection, we take a learned H-feature detector $\hat{p}$, and discard these features from each of the word vectors. That is, for every data point $\langle H, w\rangle$, we replace it by its vector rejection and rescale it to unit magnitude:

$$H_{i+1} = \text{rej}_{\hat{p}}(H)/\|\text{rej}_{\hat{p}}(H)\|$$
$$w_{i+1} = \text{rej}_{\hat{p}}(w)/\|\text{rej}_{\hat{p}}(w)\|$$

A new classifier trained on the $\langle H_{i+1}, w_{i+1}\rangle$ data *must* now learn a different decision plane than $\hat{p}$, as $\hat{p}$ is no longer present in any data points. This repetition of the procedure is roughly analogous to learning the second principal component of the data; we wish to classify the pairs without using any information learned from the previous iteration.

This second classifier *must* perform strictly worse than the original, otherwise the first classifier would have learned this second hyperplane. Nonetheless, it will be able to learn *new* H-feature detectors which the original classifier was unable to capture. By repeating this process, we can find several H-feature detectors, $\hat{p}_1, \ldots, \hat{p}_n$. Although the first, $\hat{p}_1$ is the best possible *single* H-feature detector, each additional H-feature detector increases the model's representational power (albeit with diminishing returns).

This procedure alone does not address the main concern of Levy et al. (2015): that these linear classifiers never actually model any connection between H and w. To address this, we explicitly *compare* H and w by extracting additional information about how H and w interact with respect to each of the H-feature detectors. This additional information is then used to train one final classifier which makes the final prediction.

Concretely, in each iteration i of the procedure, we generate a four-valued feature vector F_i, based on the H-feature detector $\hat{p}_i$. Each feature vector contains (1) the similarity of H_i and w_i (before projection); (2) the feature $\hat{p}_i$ applied to H_i; (3) the H-feature detector $\hat{p}_i$ applied to w_i; and (4) the difference of 2 and 3.

$$F_i(\langle H_i, w_i\rangle, \hat{p}_i) = \langle H_i^\top w_i, H_i^\top \hat{p}_i, w_i^\top \hat{p}_i, (H_i - w_i)^\top \hat{p}_i\rangle$$

These four "meta"-features capture all the benefits of the H-feature detector (slots 2 and 3), while still addressing Concat's issues with similarity arguments (slot 1) *and* distributional inclusion (slot 4). The final feature's relation to the DIH comes from the observation of Roller et al. (2014) that the vector difference intuitively captures whether the hypernym *includes* the hyponym.

The union of all the feature vectors $F_1, \ldots, F_n$ from repeated iteration form a $4n$-dimensional feature vector which we use as input to one final classifier which makes the ultimate decision. This classifier is trained on the same training data as each of the individual H-feature detectors, so our iterative procedure acts *only* as a method of feature extraction.

For our final classifier, we use an SVM with an RBF-kernel, though decision trees and other nonlinear classifiers also perform reasonably well. The nonlinear final classifier can be understood as doing a form of logical reasoning about the four slots: "animal" is a hypernym of "cat" because (1) they are similar words where (2) animal looks like a hypernym, but (3) cat does not, and (4) some "animal" contexts are not good "cat" contexts.

6 Experimental Setup and Evaluation

In our experiments, we use a variation of 20-fold cross validation which accounts for lexical overlap. To simplify explanation, we first explain how we generate splits for training/testing, and then afterwards introduce validation methodology.

We first pool all the words from the antecedent (LHS) side of the data into a set, and split these lexical items into 20 distinct cross-validation folds. For each fold F_i, we then use all pairs (w, H) where $w \in F_i$ as the test set pairs. That is, if "car" is in the test set fold, then "car $\rightarrow$ vehicle" and "car $\nrightarrow$ truck" will appear as test set pairs. The training set will then be *every pair* which does not contain *any* overlap with the test set; e.g. the training set will be all pairs which do not contain "car", "truck" or "vehicle" as either the antecedent or consequent. This ensures that both (1) there is zero lexical overlap between training and testing and (2) every pair is used as an item in a test fold exactly once. One quirk of this setup is that all test sets are approximately the same size, but training sizes vary dramatically.

This setup differs from those of previous works like Kruszewski et al. (2015) and Levy et al. (2015), who both use single, fixed train/test/val sets without lexical overlap. We find our setup has several advantages over fixed sets. First, we find there can be considerable variance if the train/test set is regenerated with a different random seed, indicating that multiple trials are necessary. Second, fixed setups consistently discard roughly half the data as ineligible for either training or test, as lexical items appear in many pairs. Our CV-like setup allows us to evaluate performance over every item in the data set exactly once, making a much more efficient and representative use of the original data set.

Our performance metric is F1 score. This is more representative than accuracy, as most of the data sets are heavily unbalanced. We report the mean F1 scores across all cross validation folds.

6.1 Hyperparameter Optimization

In order to handle hyperparameter selection, we actually generate the test set using fold i, and use fold $i-1$ as a validation set (removing pairs which would overlap with test), and the remaining 18 folds as training (removing pairs which would overlap with test *or* validation). We select hyperparameters using grid search. For all models, we optimize over the regularization parameter $C \in \{10^{-4}, 10^{-3}, \ldots, 10^{4}\}$, and for our proposed model, the number of iterations $n \in \{1, \ldots, 6\}$. All other hyperparameters are left as defaults provided by Scikit-Learn (Pedregosa et al., 2011), except for using balanced class weights. Without balanced class weights, several of the baseline models learn degenerate functions (e.g. always guess non-entailing).

7 Results

We compare our proposed model to several existing and alternative baselines from the literature. Namely, we include a baseline Cosine classifier, which only learns a threshold which maximizes F1 score on the training set; three linear models of prior work, Concat, Diff and Asym; and the RBF and Ksim models found to be successful in Kruszewski et al. (2015) and Levy et al. (2015). We also include two additional novel baselines, Concat+Diff and Concat+Asym, which add a notion of Distributional Inclusion into the Concat baseline, but are still linear models. We cannot include baselines like

Model	LEDS	BLESS	Medical	TM14
No Similarity	.099	.061	.034	.003
No Detectors	-.008	.136	.018	.028
No Inclusion	.010	.031	.014	.001

Table 4: Absolute decrease in mean F1 on the development sets with the different feature types ablated. Higher numbers indicate greater feature importance.

Ksim+Asym, because Ksim is based on a custom SVM kernel which is not amenable to combinations.

Table 3 the results across all four data sets for all of the listed models. Our proposed model improves significantly[4] over Concat in the LEDS, BLESS and Medical data sets, indicating the benefits of combining these aspects of similarity and distributional inclusion with the H-feature detectors of Concat. The Concat+Asym classifier also improves over the Concat baseline, further emphasizing these benefits. Our model performs approximately the same as Ksim on the LEDS and TM14 data sets (no significant difference), while significantly outperforming it on BLESS and Medical data sets.

7.1 Ablation Experiments

In order to evaluate how important each of the various F features are to the model, we also performed an ablation experiment where the classifier is *not* given the similarity (slot 1), prototype H-feature detectors (slots 2 and 3) or the inclusion features (slot 4). To evaluate the importance of these features, we fix the regularization parameter at $C = 1$, and train all ablated classifiers on each training fold with number of iterations $n = 1, \ldots, 6$. Table 4 shows the decrease (absolute difference) in performance between the full and ablated models on the development sets, so higher numbers indicate greater feature importance.

We find the similarity feature is extremely important in the LEDS, BLESS and Medical data sets, therefore reinforcing the findings of Levy et al. (2015). The similarity feature is especially important in the LEDS and BLESS data sets, where negative examples include many random pairs. The detector features are moderately important for the Medical and TM14 data sets, and critically important on BLESS, where we found the strongest evidence of Hearst patterns in the H-feature detectors. Surprisingly, the detector features are moderately *detrimental* on the LEDS data set, though this can also be understood in the data set's construction: since the negative examples are randomly shuffled positive examples, the *same* detector signal will appear in both positive and negative examples. Finally, we find the model performs somewhat robustly without the inclusion feature, but still is moderately impactful on three of the four data sets, lending further evidence to the Distributional Inclusion Hypothesis. In general, we find all three components are valuable sources of information for identifying hypernymy and lexical entailment.

[4]Bootstrap test, $p < .01$.

7.2 Analysis by Number of Iterations

In order to evaluate how the iterative feature extraction affects model performance, we fix the regularization parameter at $C = 1$, and train our model fixing the number of iterations to $n = \{1, \ldots, 6\}$. We then measure the mean F1 score across the development folds and compare to a baseline which uses only one iteration. Figure 2 shows these results across all four data sets, with the 0 line set at performance of the $n = 1$ baseline. Models above 0 benefit from the additional iterations, while models below do not.

In the figure, we see that the iterative procedure moderately improves performance LEDS, while greatly improving the scores of BLESS and TM14, but on the medical data set, additional iterations actually hurt performance. The differing curves indicate that the optimal number of iterations is very data set specific, and provides differing amounts of improvement, and therefore should be tuned carefully. The LEDS and BLESS curves indicate a sort of "sweet spot" behavior, where further iterations degrade performance.

To gain some additional insight into what is captured by the various iterations of the feature extraction procedure, we repeat the procedure from Section 4: we train our model on the entire BLESS data set using a fixed four iterations and regularization parameter. For each iteration, we compare its learned H-feature detector to the context embeddings, and report the most similar contexts for each iteration in Table 5.

The first iteration is identical to the one in Ta-

Figure 2: Performance of model on development folds by number of iterations. Plots show the improvement (absolute difference) in mean F1 over the model fixed at one iteration.

Table 5: Most similar contexts to the H-feature detector for each iteration of the PCA-like procedure. This model was trained on all data of BLESS. The first and second iterations contain clear Hearst patterns, while the third and fourth contain some data-specific and non-obvious signals.

ble 2, as expected. The second iteration includes many H-features not picked up by the first iteration, mostly those of the form "X including Y". The third iteration picks up some data set specific signal, like "free-swimming [animal]" and "value of [computer]", and so on. By the fourth iteration, the features no longer exhibit any obvious Hearst patterns, perhaps exceeding the sweet spot we observed in Figure 2. Nonetheless, we see how multiple iterations of the procedure allows our model to capture many more useful features than a single Concat classifier on its own.

8 Conclusion

We considered the task of detecting lexical entailment using distributional vectors of word meaning. Motivated by the fact that the Concat classifier acts as a strong baseline in the literature, we proposed a novel interpretation of the model's hyperplane. We found the Concat classifier overwhelmingly acted as a feature detector which automatically identifies Hearst Patterns in the distributional vectors.

We proposed a novel model that embraces these H-feature detectors fully, and extends their modeling power through an iterative procedure similar to Principal Component Analysis. In each iteration of the procedure, an H-feature detector is learned, and then removed from the data, allowing us to identify several different kinds of Hearst Patterns in the data. Our final model combines these H-feature detectors with measurements of general similarity and Distributional Inclusion, in order to integrate the strengths of different models in prior work. Our model matches or exceeds the performance of prior work, both on hypernymy detection and general lexical entailment.

Acknowledgments

The authors would like to thank I. Beltagy, Vered Shwartz, Subhashini Venugopalan, and the reviewers for their helpful comments and suggestions. Abstract

Verbs play a critical role in the meaning of sentences, but these ubiquitous words have received little attention in recent distributional semantics research. We introduce SimVerb-3500, an evaluation resource that provides human ratings for the similarity of 3,500 verb pairs. SimVerb-3500 covers all normed verb types from the USF free-association database, providing at least three examples for every VerbNet class. This broad coverage facilitates detailed analyses of how syntactic and semantic phenomena together influence human understanding of verb meaning. Further, with significantly larger development and test sets than existing benchmarks, SimVerb-3500 enables more robust evaluation of representation learning architectures and promotes the development of methods tailored to verbs. We hope that SimVerb-3500 will enable a richer understanding of the diversity and complexity of verb semantics and guide the development of systems that can effectively represent and interpret this meaning.

1 Introduction

Verbs are famously both complex and variable. They express the semantics of an event as well the relational information among participants in that event, and they display a rich range of syntactic and semantic behaviour (Jackendoff, 1972; Gruber, 1976; Levin, 1993). Verbs play a key role at almost every level of linguistic analysis. Information related to their predicate argument structure can benefit many NLP tasks (e.g. parsing, semantic role labelling, information extraction) and applications (e.g. machine translation, text mining) as well as research on human language acquisition and processing (Korhonen, 2010). Precise methods for representing and understanding verb semantics will undoubtedly be necessary for machines to interpret the meaning of sentences with similar accuracy to humans.

Numerous algorithms for acquiring word representations from text and/or more structured knowledge bases have been developed in recent years (Mikolov et al., 2013; Pennington et al., 2014; Faruqui et al., 2015). These representations (or *embeddings*) typically contain powerful features that are applicable to many language applications (Collobert and Weston, 2008; Turian et al., 2010). Nevertheless, the predominant approaches to distributed representation learning apply a single learning algorithm and representational form for all words in a vocabulary. This is despite evidence that applying different learning algorithms to word types such as nouns, adjectives and verbs can significantly increase the ultimate usefulness of representations (Schwartz et al., 2015).

One factor behind the lack of more nuanced word representation learning methods is the scarcity of satisfactory ways to evaluate or analyse representations of particular word types. Resources such as MEN (Bruni et al., 2014), Rare Words (Luong et al., 2013) and SimLex-999 (Hill et al., 2015) focus either on words from a single class or small samples of different word types, with automatic approaches already reaching or surpassing the inter-annotator agreement ceiling. Consequently, for word classes such as *verbs*, whose semantics is critical for language understanding, it is practically impossible to achieve statistically robust analyses and comparisons between different

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2173–2182,
Austin, Texas, November 1-5, 2016.

representation learning architectures.

To overcome this barrier to verb semantics research, we introduce *SimVerb-3500* – an extensive intrinsic evaluation resource that is unprecedented in both size and coverage. SimVerb-3500 includes 827 verb types from the University of South Florida Free Association Norms (USF) (Nelson et al., 2004), and at least 3 member verbs from each of the 101 top-level VerbNet classes (Kipper et al., 2008). This coverage enables researchers to better understand the complex diversity of syntactic-semantic verb behaviours, and provides direct links to other established semantic resources such as WordNet (Miller, 1995) and PropBank (Palmer et al., 2005). Moreover, the large standardised development and test sets in SimVerb-3500 allow for principled tuning of hyperparameters, a critical aspect of achieving strong performance with the latest representation learning architectures.

In § 2, we discuss previous evaluation resources targeting verb similarity. We present the new SimVerb-3500 data set along with our design choices and the pair selection process in § 3, while the annotation process is detailed in § 4. In § 5 we report the performance of a diverse range of popular representation learning architectures, together with benchmark performance on existing evaluation sets. In § 6, we show how SimVerb-3500 enables a variety of new linguistic analyses, which were previously impossible due to the lack of coverage and scale in existing resources.

2 Related Work

A natural way to evaluate representation quality is by judging the similarity of representations assigned to similar words. The most popular evaluation sets at present consist of word pairs with similarity ratings produced by human annotators.[1] Nevertheless, we find that all available datasets of this kind are insufficient for judging verb similarity due to their small size or narrow coverage of verbs.

In particular, a number of word pair evaluation sets are prominent in the distributional semantics literature.

Representative examples include RG-65 (Rubenstein and Goodenough, 1965) and WordSim-353 (Finkelstein et al., 2002; Agirre et al., 2009) which are small (65 and 353 word pairs, respectively). Larger evaluation sets such as the Rare Words evaluation set (Luong et al., 2013) (2034 word pairs) and the evaluations sets from Silberer and Lapata (2014) are dominated by noun pairs and the former also focuses on low-frequency phenomena. Therefore, these datasets do not provide a representative sample of verbs (Hill et al., 2015).

Two datasets that do focus on verb pairs to some extent are the data set of Baker et al. (2014) and Simlex-999 (Hill et al., 2015). These datasets, however, still contain a limited number of verb pairs (134 and 222, respectively), making them unrepresentative of the rich variety of verb semantic phenomena.

In this paper we provide a remedy for this problem by presenting a more comprehensive and representative verb pair evaluation resource.

3 The SimVerb-3500 Data Set

In this section, we discuss the design principles behind SimVerb-3500. We first demonstrate that a new evaluation resource for verb similarity is a necessity. We then describe how the final verb pairs were selected with the goal to be representative, that is, to guarantee a wide coverage of two standard semantic resources: USF and VerbNet.

3.1 Design Motivation

Hill et al. (2015) argue that comprehensive high-quality evaluation resources have to satisfy the following three criteria: *(C1) Representative* (the resource covers the full range of concepts occurring in natural language); *(C2) Clearly defined* (it clearly defines the annotated relation, e.g., similarity); (C3) *Consistent and reliable* (untrained native speakers must be able to quantify the target relation consistently relying on simple instructions).

Building on the same annotation guidelines as Simlex-999 that explicitly targets similarity, we ensure that criteria C2 and C3 are satisfied. However, even SimLex, as the most extensive evaluation resource for verb similarity available at present, is still of limited size, spanning only 222 verb pairs and 170

[1] In some existing evaluation sets pairs are scored for relatedness which has some overlap with similarity. SimVerb-3500 focuses on similarity as this is a more focused semantic relation that seems to yield a higher agreement between human annotators. For a broader discussion see (Hill et al., 2015).

distinct verb lemmas in total. Given that 39 out of the 101 top-level VerbNet classes are not represented at all in SimLex, while 20 classes have only one member verb,[2] one may conclude that the criterion C1 is not at all satisfied with current resources.

There is another fundamental limitation of all current verb similarity evaluation resources: automatic approaches have reached or surpassed the inter-annotator agreement ceiling. For instance, while the average pairwise correlation between annotators on SL-222 is Spearman's ρ correlation of 0.717, the best performing automatic system reaches $\rho = 0.727$ (Mrkšić et al., 2016). SimVerb-3500 does not inherit this anomaly (see Tab. 2) and demonstrates that there still exists an evident gap between the human and system performance.

In order to satisfy C1-C3, the new SimVerb-3500 evaluation set contains similarity ratings for 3,500 *verb pairs*, containing 827 verb types in total and 3 member verbs for each top-level VerbNet class. The rating scale goes from 0 (not similar at all) to 10 (synonymous). We employed the SimLex-999 annotation guidelines. In particular, we instructed annotators to give low ratings to antonyms, and to distinguish between similarity and relatedness. Pairs that are related but not similar (e.g., *to snore / to snooze*, *to walk / to crawl*) thus have a fairly low rating. Several example pairs are provided in Tab. 1.

3.2 Choice of Verb Pairs and Coverage

To ensure a wide coverage of a variety of syntactico-semantic phenomena (C1), the choice of verb pairs is steered by two standard semantic resources available online: (1) the USF norms data set[3] (Nelson et al., 2004), and (2) the VerbNet verb lexicon[4] (Kipper et al., 2004; Kipper et al., 2008).

The **USF** norms data set (further USF) is the largest database of free association collected for English. It was generated by presenting human subjects with one of $5,000$ cue concepts and asking them to write the first word coming to mind that is associated with that concept. Each cue concept c was normed in this way by over 10 participants, resulting in a set of associates a for each cue, for a total of over $72,000$ (c, a) pairs. For each such pair, the proportion of participants who produced associate a when presented with cue c can be used as a proxy for the strength of association between the two words.

Pair	Rating
to reply / to respond	9.79
to snooze / to nap	8.80
to cook / to bake	7.80
to participate / to join	5.64
to snore / to snooze	4.15
to walk / to crawl	2.32
to stay / to leave	0.17
to snooze / to happen	0.00

Table 1: Example verb pairs from SimVerb-3500.

The norming process guarantees that two words in a pair have a degree of semantic association which correlates well with semantic relatedness and similarity. Sampling from the USF set ensures that both related but non-similar pairs (e.g., *to run / to sweat*) as well as similar pairs (e.g., *to reply / to respond*) are represented in the final list of pairs. Further, the rich annotations of the output USF data (e.g., concreteness scores, association strength) can be directly combined with the SimVerb-3500 similarity scores to yield additional analyses and insight.

VerbNet (**VN**) is the largest online verb lexicon currently available for English. It is hierarchical, domain-independent, and broad-coverage. VN is organised into verb classes extending the classes from Levin (1993) through further refinement to achieve syntactic and semantic coherence among class members. According to the official VerbNet guidelines,[5] "Verb Classes are numbered according to shared semantics and syntax, and classes which share a top-level number (9-109) have corresponding semantic relationships." For instance, all verbs from the top-level Class 9 are labelled "Verbs of Putting", all verbs from Class 30 are labelled "Verbs of Perception", while Class 39 contains "Verbs of Ingesting".

Among others, three basic types of information are covered in VN: (1) verb subcategorization frames (SCFs), which describe the syntactic realization of the predicate-argument structure (e.g. *The window broke*), (2) selectional preferences (SPs), which capture the semantic preferences verbs have for their

[2]Note that verbs in VerbNet are soft clustered, and one verb type may be associated with more than one class. When computing coverage, we assume that such verbs attribute to counts of all their associated classes.

[3]http://w3.usf.edu/FreeAssociation/

[4]http://verbs.colorado.edu/verb-index/

[5]http://verbs.colorado.edu/verb-index/VerbNet_Guidelines.pdf

arguments (e.g. *a breakable physical object* broke) and (3) lexical-semantic verb classes (VCs) which provide a shared level of abstraction for verbs similar in their (morpho-)syntactic and semantic properties (e.g. *BREAK verbs*, sharing the VN class 45.1, and the top-level VN class 45).[6] The basic overview of the VerbNet structure already suggests that measuring verb similarity is far from trivial as it revolves around a complex interplay between various semantic and syntactic properties.

The wide coverage of VN in SimVerb-3500 assures the wide coverage of distinct verb groups/classes and their related linguistic phenomena. Finally, VerbNet enables further connections of SimVerb-3500 to other important lexical resources such as FrameNet (Baker et al., 1998), WordNet (Miller, 1995), and PropBank (Palmer et al., 2005) through the sets of mappings created by the SemLink project initiative (Loper et al., 2007).[7]

Sampling Procedure We next sketch the complete sampling procedure which resulted in the final set of 3500 distinct verb pairs finally annotated in a crowdsourcing study (§ 4).

(Step 1) We extracted all possible verb pairs from USF based on the associated POS tags available as part of USF annotations. To ensure that semantic association between verbs in a pair is not accidental, we then discarded all such USF pairs that had been associated by 2 or less participants in USF.

(Step 2) We then manually cleaned and simplified the list of pairs by removing all pairs with multi-word verbs (e.g., *quit / give up*), all pairs that contained the non-infinitive form of a verb (e.g., *accomplished / finished*, *hidden / find*), removing all pairs containing at least one auxiliary verb (e.g., *must / to see, must / to be*). The first two steps resulted in 3,072 USF-based verb pairs.

(Step 3) After this stage, we noticed that several top-level VN classes are not part of the extracted set. For instance, 5 VN classes did not have any member verbs included, 22 VN classes had only 1 verb, and 6 VN classes had 2 verbs included in the current set.

We resolved the VerbNet coverage issue by sampling from such 'under-represented' VN classes directly. Note that this step is not related to USF at all. For each such class we sampled additional verb types until the class was represented by 3 or 4 member verbs (chosen randomly).[8] Following that, we sampled at least 2 verb pairs for each previously 'under-represented' VN class by pairing 2 member verbs from each such class. This procedure resulted in 81 additional pairs, now 3,153 in total.

(Step 4) Finally, to complement this set with a sample of entirely unassociated pairs, we followed the SimLex-999 setup. We paired up the verbs from the 3,153 associated pairs at random. From these random parings, we excluded those that coincidentally occurred elsewhere in USF (and therefore had a degree of association). We sampled the remaining 347 pairs from this resulting set of unassociated pairs.

(Output) The final SimVerb-3500 data set contains 3,500 verb pairs in total, covering all associated verb pairs from USF, and (almost) all top-level VerbNet classes. All pairs were manually checked post-hoc by the authors plus 2 additional native English speakers to verify that the final data set does not contain unknown or invalid verb types.

Frequency Statistics The 3,500 pairs consist of 827 distinct verbs. 29 top-level VN classes are represented by 3 member verbs, while the three most represented classes cover 79, 85, and 93 member verbs. 40 verbs are not members of any VN class.

We performed an initial frequency analysis of SimVerb-3500 relying on the BNC counts available online (Kilgarriff, 1997).[9] After ranking all BNC verbs according to their frequency, we divided the list into quartiles: Q1 (most frequent verbs in BNC) - Q4 (least frequent verbs in BNC). Out of the 827 SimVerb-3500 verb types, 677 are contained in Q1, 122 in Q2, 18 in Q3, 4 in Q4 (*to enroll, to hitchhike, to implode, to whelp*), while 6 verbs are not covered in the BNC list. 2,818 verb pairs contain Q1 verbs, while there are 43 verb pairs with both verbs not in Q1. Further empirical analyses are provided in § 6.[10]

[6] https://verbs.colorado.edu/verb-index/vn/break-45.1.php

[7] https://verbs.colorado.edu/semlink/

[8] The following three VN classes are exceptions: (1) Class 56, consisting of words that are dominantly tagged as nouns, but can be used as verbs exceptionally (e.g., *holiday, summer, honeymoon*); (2) Class 91, consisting of 2 verbs (*count, matter*); (3) Class 93, consisting of 2 single word verbs (*adopt, assume*).

[10] Annotations such as VerbNet class membership, relations between WordNet synsets of each verb, and frequency statistics are available as supplementary material.

4 Word Pair Scoring

We employ the Prolific Academic (PA) crowdsourcing platform,[11] an online marketplace very similar to Amazon Mechanical Turk and to CrowdFlower.

4.1 Survey Structure

Following the SimLex-999 annotation guidelines, we had each of the 3500 verb pairs rated by at least 10 annotators. To distribute the workload, we divided the 3500 pairs into 70 tranches, with 79 pairs each. Out of the 79 pairs, 50 are unique to one tranche, while 20 manually chosen pairs are in all tranches to ensure consistency. The remaining 9 are duplicate pairs displayed to the same participant multiple times to detect inconsistent annotations.

Participants see 7-8 pairs per page. Pairs are rated on a scale of 0-6 by moving a slider. The first page shows 7 pairs, 5 unique ones and 2 from the consistency set. The following pages are structured the same but display one extra pair from the previous page. Participants are explicitly asked to give these duplicate pairs the same rating. We use them as quality control so that we can identify and exclude participants giving several inconsistent answers.

Checkpoint Questions The survey contains three control questions in which participants are asked to select the most similar pair out of three choices. For instance, the first checkpoint is: *Which of these pairs of words is the *most* similar? 1. to run / to jog 2. to run / to walk 3. to jog / to sweat.* One checkpoint occurs right after the instructions and the other two later in the survey. The purpose is to check that annotators have understood the guidelines and to have another quality control measure for ensuring that they are paying attention throughout the survey. If just one of the checkpoint questions is answered incorrectly, the survey ends immediately and all scores from the annotator in question are discarded.

Participants 843 raters participated in the study, producing over 65,000 ratings. Unlike other crowdsourcing platforms, PA collects and stores detailed demographic information from the participants upfront. This information was used to carefully select the pool of eligible participants. We restricted the pool to native English speakers with a 90% approval rate (maximum rate on PA), of age 18-50, born and currently residing in the US (45% out of 843 raters), UK (53%), or Ireland (2%). 54% of the raters were female and 46% male, with the average age of 30. Participants took 8 minutes on average to complete the survey containing 79 questions.

[11] https://prolific.ac/ (We chose PA for logistic reasons.)

4.2 Post-Processing

We excluded ratings of annotators who *(a)* answered one of the checkpoint questions incorrectly (75% of exclusions); *(b)* did not give equal ratings to duplicate pairs; *(c)* showed suspicious rating patterns (e.g., randomly alternating between two ratings or using one single rating throughout). The final acceptance rate was 84%. We then calculated the average of all ratings from the accepted raters (≥ 10) for each pair. The score was finally scaled linearly from the 0-6 to the 0-10 interval as in (Hill et al., 2015).

5 Analysis

Inter-Annotator Agreement We employ two measures. **IAA-1 (pairwise)** computes the average pairwise Spearman's ρ correlation between any two raters – a common choice in previous data collection in distributional semantics (Padó et al., 2007; Reisinger and Mooney, 2010a; Silberer and Lapata, 2014; Hill et al., 2015).

A complementary measure would smooth individual annotator effects. For this aim, our **IAA-2 (mean)** measure compares the average correlation of a human rater with the average of all the other raters. SimVerb-3500 obtains $\rho = 0.84$ (IAA-1) and $\rho = 0.86$ (IAA-2), a very good agreement compared to other benchmarks (see Tab. 2).

Vector Space Models We compare the performance of prominent representation models on SimVerb-3500. We include: (1) unsupervised models that learn from distributional information in text, including the skip-gram negative-sampling model (*SGNS*) with various contexts (*BOW = bag of words; DEPS = dependency contexts*) as in Levy and Goldberg (2014), the symmetric-pattern based vectors by Schwartz et al. (2015), and count-based PMI-weighted vectors (Baroni et al., 2014); (2) Models that rely on linguistic hand-crafted resources or curated knowledge bases. Here, we use sparse binary vectors built from linguistic resources (*Non-*

Eval set	IAA-1	IAA-2	ALL	TEXT
WSIM (203)	0.67	0.65	0.79 SGNS-BOW	0.79 SGNS-BOW
SIMLEX (999)	0.67	0.78	0.74 Paragram+CF	0.56 SymPat+SGNS
SL-222 (222)	0.72	-	0.73 Paragram+CF	0.58 SymPat
SIMVERB (3500)	0.84	0.86	0.63 Paragram+CF	0.36 SGNS-DEPS

Table 2: An overview of word similarity evaluation benchmarks. ALL is the current best reported score on each data set across all models (including the models that exploit curated knowledge bases and hand-crafted lexical resources, see supplementary material). TEXT denotes the best reported score for a model that learns solely on the basis of distributional information. All scores are Spearman's ρ correlations.

Distributional, (Faruqui and Dyer, 2015)), and vectors fine-tuned to a paraphrase database (*Paragram*, (Wieting et al., 2015)) further refined using linguistic constraints (*Paragram+CF*, (Mrkšić et al., 2016)). Descriptions of these models are in the supplementary material.

Comparison to SimLex-999 (SL-222) 170 pairs from SL-222 also appear in SimVerb-3500. The correlation between the two data sets calculated on the shared pairs is $\rho = 0.91$. This proves, as expected, that the ratings are consistent across the two data sets.

Tab. 3 shows a comparison of models' performance on SimVerb-3500 against SL-222. Since the number of evaluation pairs may influence the results, we ideally want to compare sets of equal size for a fair comparison. Picking one random subset of 222 pairs would bias the results towards the selected pairs, and even using 10-fold cross-validation we found variations up to 0.05 depending on which subsets were used. Therefore, we employ a 2-level 10-fold cross-validation where new random subsets are picked in each iteration of each model. The numbers reported as *CV-222* are averages of these ten 10-fold cross-validation runs. The reported results come very close to the correlation on the full data set for all models.

Most models perform much better on SL-222, especially those employing additional databases or linguistic resources. The performance of the best scoring Paragram+CF model is even on par with the IAA-1 of 0.72. The same model obtains the highest score on SV-3500 ($\rho = 0.628$), with a clear gap to IAA-1 of 0.84. We attribute these differences in performance largely to SimVerb-3500 being a more extensive and diverse resource in terms of verb pairs.

Development Set A common problem in scored word pair datasets is the lack of a standard split to development and test sets. Previous works often optimise models on the entire dataset, which leads to overfitting (Faruqui et al., 2016) or use custom splits, e.g., 10-fold cross-validation (Schwartz et al., 2015), which make results incomparable with others. The lack of standard splits stems mostly from small size and poor coverage – issues which we have solved with SimVerb-3500.

Our development set contains 500 pairs, selected to ensure a broad coverage in terms of similarity ranges (i.e., non-similar and highly similar pairs, as well as pairs of medium similarity are represented) and top-level VN classes (each class is represented by at least 1 member verb). The test set includes the remaining 3,000 verb pairs. The performances of representation learning architectures on the dev and test sets are reported in Tab. 3. The ranking of models is identical on the test and the full SV-3500 set, with slight differences in ranking on the development set.

6 Evaluating Subsets

The large coverage and scale of SimVerb-3500 enables model evaluation based on selected criteria. In this section, we showcase a few example analyses.

Frequency In the first analysis, we select pairs based on their lemma frequency in the BNC corpus and form three groups, with 390-490 pairs in each group (Fig. 1). The results from Fig. 1 suggest that the performance of all models improves as the frequency of the verbs in the pair increases, with much steeper curves for the purely distributional models (e.g., SGNS and SymPat). The non-distributional non data-driven model of Faruqui and Dyer (2015) is only slightly affected by frequency.

WordNet Synsets Intuitively, representations for verbs with more diverse usage patterns are more difficult to learn with statistical models. To examine this hypothesis, we resort to WordNet (Miller, 1995), where different semantic usages of words are listed as so-called *synsets*. Fig. 2 shows a clear downward trend for all models, confirming that polysemous

Model	SV-3500	CV-222	SL-222	DEV-500	TEST-3000
SGNS-BOW-PW (d=300)	0.274	0.279	0.328	0.333	0.265
SGNS-DEPS-PW (d=300)	0.313	0.314	0.390	0.401	0.304
SGNS-UDEPS-PW (d=300)	0.259	0.262	0.347	0.313	0.250
SGNS-BOW-8B (d=500)	0.348	0.343	0.307	0.378	0.350
SGNS-DEPS-8B (d=500)	0.356	0.347	0.385	0.389	0.351
SYMPAT-8B (d=500)	0.328	0.336	0.544	0.276	0.347
COUNT-SVD (d=500)	0.196	0.200	0.059	0.259	0.186
NON-DISTRIBUTIONAL	0.596	0.596	0.689	0.632	0.600
PARAGRAM (d=25)	0.418	0.432	0.531	0.443	0.433
PARAGRAM (d=300)	0.540	0.528	0.590	0.525	0.537
PARAGRAM+CF (d=300)	0.628	0.625	0.727	0.611	0.624

Table 3: Evaluation of state-of-the representation learning models on the full SimVerb-3500 set (SV-3500), the Simlex-999 verb subset containing 222 pairs (SL-222), cross-validated subsets of 222 pairs from SV-3500 (CV-222), and the SimVerb-3500 development (DEV-500) and test set (TEST-3000).

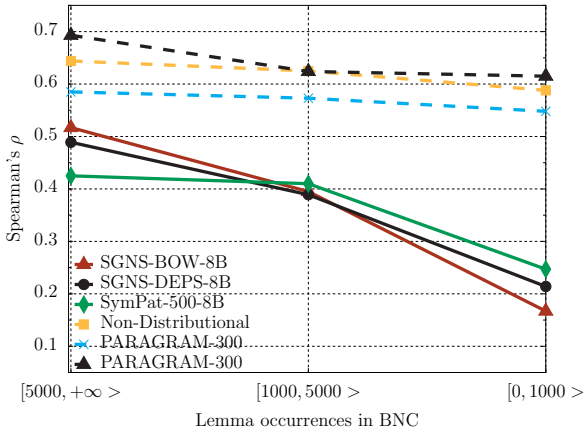

Figure 1: Subset-based evaluation, where subsets are created based on the frequency of verb lemmas in the BNC corpus. Each of the three frequency groups contains 390-490 verb pairs. To be included in each group it is required that both verbs in a pair are contained in the same frequency interval (x axis).

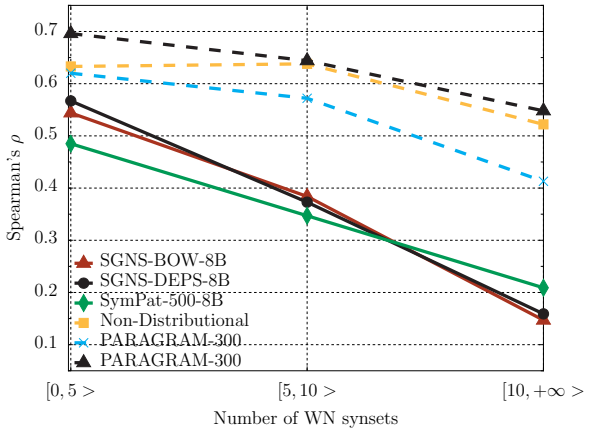

Figure 2: Subset-based evaluation, where subsets are created based on the number of synsets in WordNet (x axis). To be included in each subset it is required that both verbs in a pair have the number of synsets in the same interval.

verbs are more difficult for current verb representation models. Nevertheless, approaches which use additional information beyond corpus co-occurrence are again more robust. Their performance only drops substantially for verbs with more than 10 synsets, while the performance of other models deteriorates already when tackling verbs with more than 5 synsets.

VerbNet Classes Another analysis enabled by SimVerb-3500 is investigating the connection between VerbNet classes and human similarity judgments. We find that verbs in the same top-level VerbNet class are often not assigned high similarity score. Out of 1378 pairs where verbs share the top-level VerbNet class, 603 have a score lower than 5. Tab. 4 reports scores per VerbNet class. When a verb belongs to multiple classes, we count it for each class (see Footnote 2). We run the analysis on the five largest VN classes, each with more than 100 pairs with paired verbs belonging to the same class.

The results indicate clear differences between classes (e.g., Class 31 vs Class 51), and suggest that further developments in verb representation learning should also focus on constructing specialised representations at the finer-grained level of VN classes.

Lexical Relations SimVerb-3500 contains relation annotations (e.g., *antonyms*, *synonyms*, *hyper-/hyponyms*, *no relation*) for all pairs extracted automatically from WordNet. Evaluating per-relation subsets, we observe that some models draw their strength from good performance across different re-

Model	#13	#31	#37	#45	#51

Table 5: Spearman's ρ correlation between human judgments and model's cosine similarity based on pair relation type. Relations are based on WordNet, and included in the dataset. The classes are of different size, 373 pairs with no relation (*NR*), 306 synonym (*SYN*) pairs, and 800 hyper/hyponym (*HYP*) pairs. Frequencies of member verbs are distributed in a similar way.

lations. Others have low performance on these pairs, but do very well on synonyms and hyper-/hyponyms. Selected results of this analysis are in Tab. 5.[12]

Human Agreement Motivated by the varying performance of computational models regarding frequency and ambiguous words with many synsets, we analyse what disagreement effects may be captured in human ratings. We therefore compute the average standard deviation of ratings per subset: $avgstdd(S) = \frac{1}{n}\sum_{p \in S} \sigma(r_p)$, where *S* is one subset of pairs, *n* is the number of pairs in this subset, *p* is one pair, and r_p are all human ratings for this pair.

[12] Evaluation based on Spearman's ρ may be problematic with certain categories, e.g., with antonyms. It evaluates pairs according to their ranking; for antonyms the ranking is arbitrary - every antonym pair should have a very low rating, hence they are not included in Tab. 5. A similar effect occurs with highly ranked synonyms, but to a much lesser degree than with antonyms.

While the standard deviation of ratings is diverse for individual pairs, overall the average standard deviations per subset are almost identical. For both the frequency and the WordNet synset analyses it is around $\approx$1.3 across all subsets, and with only little difference for the subsets based on VerbNet. The only subsets where we found significant variations is the grouping by relations, where ratings tend to be more similar especially on antonyms (*0.86*) and pairs with no relation (*0.92*), much less similar on synonyms (*1.34*) and all other relations ($\approx$*1.4*). These findings suggest that humans are much less influenced by frequency or polysemy in their understanding of verb semantics compared to computational models.

7 Conclusions

SimVerb-3500 is a verb similarity resource for analysis and evaluation that will be of use to researchers involved in understanding how humans or machines represent the meaning of verbs, and, by extension, scenes, events and full sentences. The size and coverage of syntactico-semantic phenomena in SimVerb-3500 makes it possible to compare the strengths and weaknesses of various representation models via statistically robust analyses on specific word classes.

To demonstrate the utility of SimVerb-3500, we conducted a selection of analyses with existing representation-learning models. One clear conclusion is that distributional models trained on raw text (e.g. SGNS) perform very poorly on low frequency and highly polysemous verbs. This degradation in performance can be partially mitigated by focusing models on more principled distributional contexts, such as those defined by symmetric patterns. More generally, the finding suggests that, in order to model the diverse spectrum of verb semantics, we may require algorithms that are better suited to fast learning from few examples (Lake et al., 2011), and have some flexibility with respect to sense-level distinctions (Reisinger and Mooney, 2010b; Vilnis and McCallum, 2015). In future work we aim to apply such methods to the task of verb acquisition.

Beyond the preliminary conclusions from these initial analyses, the benefit of SimLex-3500 will become clear as researchers use it to probe the relationship between architectures, algorithms and representation quality for a wide range of verb classes. Better under-

standing of how to represent the full diversity of verbs should in turn yield improved methods for encoding and interpreting the facts, propositions, relations and events that constitute much of the important information in language.

Abstract

Language resources that systematically organize paraphrases for binary relations are of great value for various NLP tasks and have recently been advanced in projects like PATTY, WiseNet and DEFIE. This paper presents a new method for building such a resource and the resource itself, called POLY. Starting with a very large collection of multilingual sentences parsed into triples of phrases, our method clusters relational phrases using probabilistic measures. We judiciously leverage fine-grained semantic typing of relational arguments for identifying synonymous phrases. The evaluation of POLY shows significant improvements in precision and recall over the prior works on PATTY and DEFIE. An extrinsic use case demonstrates the benefits of POLY for question answering.

1 Introduction

Motivation. Information extraction from text typically yields relational triples: a binary relation along with its two arguments. Often the relation is expressed by a verb phrase, and the two arguments are named entities. We refer to the surface form of the relation in a triple as a *relational phrase*. Repositories of relational phrases are an asset for a variety of tasks, including information extraction, textual entailment, and question answering.

This paper presents a new method for systematically organizing a large set of such phrases. We aim to construct equivalence classes of synonymous phrases, analogously to how WordNet organizes unary predicates as noun-centric synsets (aka. semantic types). For example, the following relational phrases should be in the same equivalence class: *sings in, is vocalist in, voice in* denoting a relation between a musician and a song.

State of the Art and its Limitations. Starting with the seminal work on DIRT (Lin and Pantel, 2001), there have been various attempts on building comprehensive resources for relational phrases. Recent works include PATTY (Nakashole et al., 2012), WiseNet (Moro and Navigli, 2012) and DEFIE (Bovi et al., 2015). Out of these DEFIE is the cleanest resource. However, the equivalence classes tend to be small, prioritizing precision over recall. On the other hand, PPDB (Ganitkevitch et al., 2013) offers the largest repository of paraphrases. However, the paraphrases are not relation-centric and they are not semantically typed. So it misses out on the opportunity of using types to distinguish identical phrases with different semantics, for example, *performance in* with argument types *musician* and *song* versus *performance in* with types *athlete* and *competition*.

Our Approach. We start with a large collection of relational triples, obtained by shallow information extraction. Specifically, we use the collection of Faruqui and Kumar (2015), obtained by combining the OLLIE tool with Google Translate and projecting multilingual sentences back to English. Note that the task addressed in that work is relational triple extraction, which is orthogonal to our problem of organizing the relational phrases in these triples into synonymy sets.

We canonicalize the subject and object arguments

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2183–2192,
Austin, Texas, November 1-5, 2016.

of triples by applying named entity disambiguation and word sense disambiguation wherever possible. Using a knowledge base of entity types, we can then infer prevalent type signatures for relational phrases. Finally, based on a suite of judiciously devised probabilistic distance measures, we cluster phrases in a type-compatible way using a graph-cut technique. The resulting repository contains ca. 1 Million relational phrases, organized into ca. 160,000 clusters.

Contribution. Our salient contributions are: i) a novel method for constructing a large repository of relational phrases, based on judicious clustering and type filtering; ii) a new linguistic resource, coined POLY, of relational phrases with semantic typing, organized in equivalence classes; iii) an intrinsic evaluation of POLY, demonstrating its high quality in comparison to PATTY and DEFIE; iv) an extrinsic evaluation of POLY, demonstrating its benefits for question answering. The POLY resource is publicly available [1].

2 Method Overview

Our approach consists of two stages: *relational phrase typing* and *relational phrase clustering*. In Section 3, we explain how we infer semantic types of the arguments of a relational phrase. In Section 4, we present the model for computing synonyms of relational phrases (i.e., paraphrases) and organizing them into clusters.

A major asset for our approach is a large corpus of multilingual sentences from the work of Faruqui and Kumar (2015). That dataset contains sentences from Wikipedia articles in many languages. Each sentence has been processed by an Open Information Extraction method (Banko et al., 2007), specifically the OLLIE tool (Mausam et al., 2012), which produces a triple of surface phrases that correspond to a relational phrase candidate and its two arguments (subject and object). Each non-English sentence has been translated into English using Google Translate, thus leveraging the rich statistics that Google has obtained from all kinds of parallel multilingual texts. Altogether, the data from Faruqui and Kumar (2015) provides 135 million triples in 61 languages and in English (from the translations of the corresponding sentences). This is the noisy input to our method. Figure 1 shows two Spanish sentences, the extracted triples of Spanish phrases, the sentences' translations to English, and the extracted triples of English phrases.

The figure shows that identical phrases in the foreign language - "fue filmado por" - may be translated into different English phrases: "was shot by" vs. "was filmed by", depending on the context in the respective sentences. This is the main insight that our method builds on. The two resulting English phrases have a certain likelihood of being paraphrases of the same relation. However, this is an uncertain hypotheses only, given the ambiguity of language, the noise induced by machine translation and the potential errors of the triple extraction. Therefore, our method needs to de-noise these input phrases and quantify to what extent the the relational phrases are indeed synonymous. We discuss this in Sections 3 and 4.

3 Relation Typing

This section explains how we assign semantic types to relational phrases. For example, the relational phrase *wrote* could be typed as *<author> wrote <paper>*, as one candidate. The typing helps us to disambiguate the meaning of the relational phrase and later find correct synonyms. The relational phrase *shot* could have synonyms *directed* or *killed with a gun*. However, they represent different senses of the phrase *shot*. With semantic typing, we can separate these two meanings and determine that *<person> shot <person>* is a synonym of *<person> killed with a gun <person>*, whereas *<director> shot <movie>* is a synonym of *<director> directed <movie>*.

Relation typing has the following steps: argument extraction, argument disambiguation, argument typing and type filtering. The output is a set of candidate types for the left and right arguments of each English relational phrase.

3.1 Argument Extraction

For the typing of a relational phrase, we have to determine words in the left and right arguments that give cues for semantic types. To this end, we identify named entities, whose types can be looked up in a knowledge base, and the head words of common

[1] www.mpi-inf.mpg.de/yago-naga/poly/

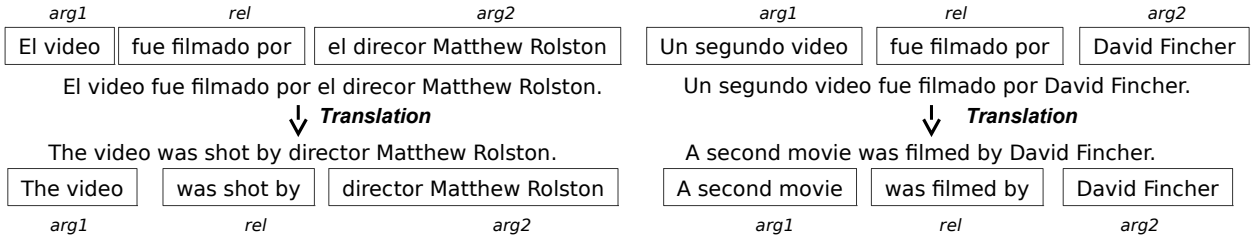

Figure 1: Multilingual input sentences and triples

noun phrases. As output, we produce a ranked list of entity mentions and common nouns.

To create this ranking, we perform POS tagging and noun phrase chunking using Stanford CoreNLP (Manning et al., 2014) and Apache OpenNLP [2]. For head noun extraction, we use the YAGO Javatools[3] and a set of manually crafted regular expressions. Since the input sentences result from machine translation, we could not use dependency parsing, because sentences are often ungrammatical.

Finally, we extract all noun phrases which contain the same head noun. These noun phrases are then sorted according to their lengths.

For example, for input phrase *contemporary British director who also created "Inception"*, our method would yield *contemporary British director*, *British director*, *director* in decreasing order.

3.2 Argument Disambiguation

The second step is responsible for the disambiguation of the noun phrase and named entity candidates. We use the YAGO3 knowledge base (Mahdisoltani et al., 2015) for named entities, and WordNet (Fellbaum, 1998) for noun phrases. We proceed in the ranking order of the phrases from the first step.

Candidate senses are looked up in YAGO3 and WordNet, respectively, and each candidate is scored. The scores are based on:

- Frequency count prior: This is the number of Wikipedia incoming links for named entities in YAGO3, or the frequency count of noun phrase senses in WordNet.
- Wikipedia prior: We increase scores of YAGO3 entities whose URL strings (i.e., Wikipedia titles) occur in the Wikipedia page from which the triple was extracted.
- Translation prior: We boost the scores of senses whose translations occur in the original input sentence. For example, the word *stage* is disambiguated as *opera stage* rather than *phase*, because the original German sentence contains the word *Bühne* (German word for a concert stage) and not *Phase*. The translations of word senses are obtained from Universal WordNet (de Melo and Weikum, 2009).

We prefer WordNet noun phrases over YAGO3 named entities since noun phrases have lower type ambiguity (fewer possible types). The final score of a sense s is:

$$score(\mathrm{s}) = \alpha freq(\mathrm{s}) + \beta wiki(\mathrm{s}) + \gamma trans(\mathrm{s}) \quad (1)$$

where $freq(\mathrm{s})$ is the frequency count of s, and $wiki(\mathrm{s})$ and $trans(\mathrm{s})$ equal maximal frequency count if the Wikipedia prior and Translation prior conditions hold (and otherwise set to 0). α, β, γ are tunable hyper-parameters (set using withheld data).

Finally, from the list of candidates, we generate a disambiguated argument: either a WordNet synset or a YAGO3 entity identifier.

3.3 Argument Typing

In the third step of relation typing, we assign candidate types to the disambiguated arguments. To this end, we query YAGO3 for semantic types (incl. transitive hypernyms) for a given YAGO3 or WordNet identifier.

The type system used in POLY consists of a subset of the WordNet noun hierarchy. We restrict ourselves to 734 types, chosen semi-automatically as follows. We selected the 1000 most frequent WordNet types in YAGO3 (incl. transitive hypernyms). Redundant and non-informative types were filtered out by the following technique: all types were organized into a directed acyclic graph (DAG), and

[2] opennlp.apache.org/

[3] mpi-inf.mpg.de/yago-naga/javatools/

we removed a type when the frequency count of some of its children was higher than 80% of the parent's count. For example, we removed type *trainer* since more than 80% of trainers in YAGO3 are also *coaches*. In addition, we manually removed a few non-informative types (e.g. *expressive style*).

As output, we obtain lists of semantic types for the two arguments of each relational phrase.

3.4 Type Filtering

In the last step, we filter types one more time. This time we filter candidate types separately for each distinct relational phrase, in order to choose the most suitable specific type signature for each phrase. This choice is made by type tree pruning.

For each relational phrase, we aggregate all types of the left arguments and all types of the right arguments, summing up their their frequency counts. This information is organized into a DAG, based on type hypernymy. Then we prune types as follows (similarly to Section 3.3): i) remove a parent type when the relative frequency count of one of the children types is larger than 80% of the parent's count; ii) remove a child type when its relative frequency count is smaller than 20% of the parent's count.

For each of the two arguments of the relational phrase we allow only those types which are left after the pruning. The final output is a set of relational phrases where each has a set of likely type signatures (i.e., pairs of types for the relation's arguments).

4 Relation Clustering

The second stage of POLY addresses the relation clustering. The algorithm takes semantically typed relational phrases as input, quantifies the semantic similarity between relational phrases, and organizes them into clusters of synonyms. The key insight that our approach hinges on is that synonymous phrases have similar translations in a different language. In our setting, two English phrases are semantically similar if they were translated from the same relational phrases in a foreign language and their argument types agree (see Figure 1 for an example). Similarities between English phrases are cast into edge weights of a graph with phrases as nodes. This graph is then partitioned to obtain clusters.

4.1 Probabilistic Similarity Measures

The phrase similarities in POLY are based on probabilistic measures. We use the notation:

- F: a set of relational phrases from a foreign language F
- E: a set of translations of relational phrases from language F to English
- $c(f, e)$: no. of times of translating relational phrase $f \in F$ into relational phrase $e \in E$
- $c(f)$, $c(e)$: frequency counts for relational phrase $f \in F$ and its translation $e \in E$
- $p(e|f) = \frac{c(f,e)}{c(f)}$: (estimator for the) probability of translating $f \in F$ into $e \in E$
- $p(f|e) = \frac{c(f,e)}{c(e)}$: (estimator for the) probability of $e \in E$ being a translation of $f \in F$

We define:

$$p(e_1|e_2) = \sum_f p(e_1|f) * p(f|e_2) \qquad (2)$$

as the probability of generating relational phrase $e_1 \in E$ from phrase $e_2 \in E$. Finally we define:

$$support(e_1, e_2) = \sum_{f \in F} c(f, e_1) * c(f, e_2) \qquad (3)$$

$$confidence(e_1, e_2) = \frac{2}{\frac{1}{p(e_1|e_2)} + \frac{1}{p(e_2|e_1)}} \qquad (4)$$

Confidence is the final similarity measure used in POLY. We use the harmonic mean in Equation 4 to dampen similarity scores that have big differences in their probabilities in Equation 2. Typically, pairs e_1, e_2 with such wide gaps in their probabilities come from subsumptions, not synonymous phrases. Finally, we compute the support and confidence for every pair of English relational phrases which have a common source phrase of translation. We prune phrase pairs with low support (below a threshold), and rank the remaining pairs by confidence.

4.2 Graph Clustering

To compute clusters of relational phrases, we use modularity-based graph partitioning. Specifically, we use the partitioning algorithm of Blondel et al. (2008). The resulting clusters (i.e., subgraphs) are

Cluster of relational phrases
<location> is the heart of <location>
<location> is situated in <location>
<location> is enclosed by <location>
<location> is located amidst <location>
<location> is surrounded by <location>

Table 1: Example of a cluster of relational phrases

then ranked by their weighted graph density multiplied by the graph size (Equation 5). The example of a cluster is shown in Table 1.

$$\frac{\sum_{(e_i,e_j)\in E} sim(e_i,e_j)}{|V| * |V-1|} * |V| \quad (5)$$

5 Evaluation

For the experimental evaluation, we primarily chose triples from the German language (and their English translations). With about 23 million triples, German is the language with the largest number of extractions in the dataset, and there are about 2.5 million distinct relational phrases from the German-to-English translation. The POLY method is implemented using Apache Spark, so it scales out to handle such large inputs.

After applying the relation typing algorithm, we obtain around 10 million typed relational phrases. If we ignored the semantic types, we would have about 950,000 distinct phrases. On this input data, POLY detected 1,401,599 pairs of synonyms. The synonyms were organized into 158,725 clusters.

In the following, we present both an intrinsic evaluation and an extrinsic use case. For the intrinsic evaluation, we asked human annotators to judge whether two typed relational phrases are synonymous or not. We also studied source languages other than German. In addition, we compared POLY against PATTY (Nakashole et al., 2012) and DEFIE (Bovi et al., 2015) on the relation paraphrasing task. For the extrinsic evaluation, we considered a simple question answering system and studied to what extent similarities between typed relational phrases can contribute to answering more questions.

5.1 Precision of Synonyms

To assess the precision of the discovered synonymy among relational phrases (i.e., clusters of paraphrases), we sampled POLY's output. We assessed the 250 pairs of synonyms with the highest similarity scores. We also assessed a sample of 250 pairs of synonyms, randomly drawn from POLY's output.

	Precision	Range
Top 250	0.91	$0.87 - 0.94$
Random	0.83	$0.78 - 0.87$

Table 2: Precision of synonym pairs in POLY

These pairs of synonyms were shown to several human annotators to check their correctness. Relational phrases were presented by showing the semantic types, the textual representation of the relational phrase and sample sentences where the phrase was found. The annotators were asked whether two relational phrases have the same meaning or not. They could also abstain.

The results of this evaluation are shown in Table 2 with (lower bounds and upper bounds of) the 0.95-confidence Wilson score intervals (Brown et al., 2001). This evaluation task had good inter-annotator agreement, with Fleiss' Kappa around 0.6. Table 3 shows anecdotal examples of synonymous pairs of relational phrases.

These results show that POLY's quality is comparable with state-of-the-art baselines resources. WiseNet (Moro and Navigli, 2012) is reported to have precision of 0.85 for 30,000 clusters. This is also the only prior work where the precision of synonymy of semantically typed relational phrases was evaluated. The other systems did not report that measure. However, they performed the evaluation of subsumption, entailment or hypernymy relationships which are related to synonymy. Subsumptions in PATTY have precision of 0.83 for top 100 and 0.75 for a random sample. Hypernyms in RELLY are reported to have precision of 0.87 for top 100 and 0.78 for a random sample. DEFIE performed separate evaluations for hypernyms generated directly from WordNet (precision 0.87) and hypernyms obtained through a substring generalization algorithm (precision 0.9).

Typical errors in the paraphrase discovery of POLY come from incorrect translations or extraction errors. For example, *heard* and *belongs to* were clustered together because they were translated from the

Id	Relation phrase	Synonymous Relational Phrase
1	<location> is surrounded by <region>	<location> is the heart of <region>
2	<artifact> is reminiscent of <time_period>	<artifact> recalls <time_period>
3	<painter> was a participant in <show>	<painter> has participated in <show>
4	<group> maintains a partnership with <district>	<group> has partnered with <district>
5	<movie> was shot at <location>	<movie> was filmed in <location>
6	<person> was shot by <group>	<person> was shot dead by <group>
7	<movie> was shot by <film_director>	<movie> was directed by <film_director>

Table 3: Examples of synonyms of semantically typed relational phrases

same semantically ambiguous German word *gehört*. An example for extraction errors is that *took* and *participated in* were clustered together because *took* was incorrectly extracted from a sentence with the phrase *took part in*. Other errors are caused by swapped order of arguments in a triple (i.e., mistakes in detecting passive form) and incorrect argument disambiguation.

5.2 Comparison to Competitors

To compare POLY with the closest competitors PATTY and DEFIE, we designed an experiment along the lines of the evaluation of Information Retrieval systems (e.g. TREC benchmarks). First, we randomly chose 100 semantically typed relational phrases with at least three words (to focus on the more interesting multi-word case, rather than single verbs). These relational phrases had to occur in all three resources. For every relational phrase we retrieved synonyms from all of the systems, forming a pool of candidates. Next, to remove minor syntactic variations of the same phrase, the relational phrases were lemmatized. In addition, we removed all leading prepositions, modal verbs, and adverbs.

We manually evaluated the correctness of the remaining paraphrase candidates for each of the 100 phrases. Precision was computed as the ratio of the correct synonyms by one system to the number of all synonyms provided by that system. Recall was computed as the ratio of the number of correct synonyms by one system to the number of all correct synonyms in the candidate pool from all three systems.

The results are presented in Table 4. All results are macro-averaged over the 100 sampled phrases. We performed a paired t-test for precision and recall of POLY against each of the systems and obtained p-values below 0.05. POLY and DEFIE offer much higher diversity of synonyms than PATTY. However, DEFIE's synonyms often do not fit the semantic type signature of the given relational phrase and are thus incorrect. For example, *was assumed by* was found to be a synonym of *<group> was acquired by <group>*. PATTY, on the other hand, has higher recall due to its variety of prepositions attached to relational phrases; however, these also include spurious phrases, leading to lower precision. For example, *succeeded in* was found to be a synonym of *<person> was succeeded by <leader>*. Overall, POLY achieves much higher precision and recall than both of these baselines.

	Precision	Recall	F1
PATTY	0.63	0.32	0.42
DEFIE	0.66	0.32	0.44
POLY	**0.79**	**0.46**	**0.58**

Table 4: Comparison to the competitors

5.3 Ablation Study

To evaluate the influence of different components, we performed an ablation study. We consider versions of POLY where Wikipedia prior and Translation prior (Section 3.2) are disregarded (*− disambiguation*), where the type system (Section 3.3) was limited to the 100 most frequent YAGO types (*Type system 100*) or to the 5 top-level types from the YAGO hierarchy (*Type system 5*), or where the type filtering parameter (Section 3.4) was set to 70% or 90% (*Type filtering 0.7/0.9*). The evaluation was done on random samples of 250 pairs of synonyms.

Table 5 shows the results with the 0.95-confidence Wilson score intervals. Without our argument disambiguation techniques, the precision drops heavily. When weakening the type system, our tech-

	Precision	Coverage
POLY	0.83	1,401,599
− disambiguation	0.66 ± 0.06	1,279,941
Type system 100	0.76 ± 0.05	858,053
Type system 5	0.62 ± 0.06	236,804
Type filtering 0.7	0.81 ± 0.05	192,117
Type filtering 0.9	0.73 ± 0.05	2,061,257

Table 5: Ablation Study

	Top 250	Random 250
French	0.93 ± 0.03	0.85 ± 0.04
Hindi	0.86 ± 0.05	0.71 ± 0.05
Russian	0.85 ± 0.05	0.77 ± 0.05

Table 6: Precision of synonyms (other languages)

niques for argument typing and type filtering are penalized, resulting in lower precision. So we see that all components of the POLY architecture are essential for achieving high-quality output. Lowering the type-filtering threshold yields results with comparable precision. However, increasing the threshold results in a worse noise filtering procedure.

5.4 Evaluation with Other Languages

In addition to paraphrases derived from German, we evaluated the relational phrase synonymy derived from a few other languages with lower numbers of extractions. We chose French, Hindi, and Russian (cf. (Faruqui and Kumar, 2015)). The results are presented in Table 6, again with the 0.95-confidence Wilson score intervals.

Synonyms derived from French have similar quality as those from German. This is plausible as one would assume that French and German have similar quality in translation to English. Synonyms derived from Russian and Hindi have lower precision due to the lower translation quality. The precision for Hindi is lower, as the Hindi input corpus has much fewer sentences than for the other languages.

5.5 Extrinsic Evaluation: Question Answering

As an extrinsic use case for the POLY resource, we constructed a simple Question Answering (QA) system over knowledge graphs such as Freebase, and determined the number of questions for which the system can find a correct answer. We followed the approach presented by Fader et al. (2014). The system consists of question parsing, query rewriting and database look-up stages. We disregard the stage of ranking answer candidates, and merely test whether the system could return the right answer (i.e., would return with the perfect ranking).

In the question parsing stage, we use 10 high-precision parsing operators by Fader et al. (2014), which map questions (e.g., *Who invented papyrus?*) to knowledge graph queries (e.g., *(?x, invented, papyrus)*). Additionally, we map question words to semantic types. For example, the word *who* is mapped to *person*, *where* to *location*, *when* to *abstract entity* and the rest of the question words are mapped to type *entity*.

We harness synonyms and hyponyms of relational phrases to paraphrase the predicate of the query. The paraphrases must be compatible with the semantic type of the question word. In the end, we use the original query, as well as found paraphrases, to query a database of subject, predicate, object triples. As the knowledge graph for this experiment we used the union of collections: a triples database from OpenIE (Fader et al., 2011), Freebase (Bollacker et al., 2008), Probase (Wu et al., 2012) and NELL (Carlson et al., 2010). In total, this knowledge graph contained more than 900 Million triples.

We compared six systems for paraphrasing semantically typed relational phrases:

- **Basic**: no paraphrasing at all, merely using the originally generated query.
- **DEFIE**: using the taxonomy of relational phrases by Bovi et al. (2015).
- **PATTY**: using the taxonomy of relational phrases by Nakashole et al. (2012).
- **RELLY**: using the subset of the PATTY taxonomy with additional entailment relationships between phrases (Grycner et al., 2015).
- **POLY_DE**: using synonyms of relational phrases derived from the German language.
- **POLY_ALL**: using synonyms of relational phrases derived from the 61 languages.

Since DEFIE's relational phrases are represented by BabelNet (Navigli and Ponzetto, 2012) word sense identifiers, we generated all possible lemmas for

each identifier.

We ran the paraphrase-enhanced QA system for three benchmark sets of questions:

- **TREC**: the set of questions used for the evaluation of information retrieval QA systems (Voorhees and Tice, 2000)
- **WikiAnswers**: a random subset of questions from WikiAnswers (Fader et al., 2013).
- **WebQuestions**: the set of questions about Freebase entities (Berant et al., 2013).

From these question sets, we kept only those questions which can be parsed by one of the 10 question parsing templates and have a correct answer in the gold-standard ground truth. In total, we executed 451 questions for TREC, 516 for WikiAnswers and 1979 for WebQuestions.

For every question, each paraphrasing system generates a set of answers. We measured for how many questions we could obtain at least one correct answer. Table 7 shows the results.

The best results were obtained by **POLY_ALL**. We performed a paired t-test for the results of POLY_DE and POLY_ALL against all other systems. The differences between POLY_ALL and the other systems are statistically significant with p-value below 0.05.

Additionally, we evaluated paraphrasing systems which consist of combination of all of the described datasets and all of the described datasets without POLY. The difference between these two versions suggest that POLY contains many paraphrases which are available in none of the competing resources.

	TREC	WikiAnswers	WebQuestions
Basic	193	144	365
DEFIE	197	147	394
RELLY	208	150	424
PATTY	213	155	475

6 Related Work

Knowledge bases (KBs) contribute to many NLP tasks, including Word Sense Disambiguation (Moro et al., 2014), Named Entity Disambiguation (Hoffart et al., 2011), Question Answering (Fader et al., 2014), and Textual Entailment (Sha et al., 2015). Widely used KBs are DBpedia (Lehmann et al., 2015), Freebase (Bollacker et al., 2008), YAGO (Mahdisoltani et al., 2015), Wikidata (Vrandecic and Krötzsch, 2014) and the Google Knowledge Vault (Dong et al., 2014). KBs have rich information about named entities, but are pretty sparse on relations. In the latter regard, manually created resources such as WordNet (Fellbaum, 1998), VerbNet (Kipper et al., 2008) or FrameNet (Baker et al., 1998) are much richer, but still face the limitation of labor-intensive input and human curation.

The paradigm of Open Information Extraction (OIE) was developed to overcome the weak coverage of relations in automatically constructed KBs. OIE methods process natural language texts to produce triples of surface forms for the arguments and relational phrase of binary relations. The first large-scale approach along these lines, TextRunner (Banko et al., 2007), was later improved by ReVerb (Fader et al., 2011) and OLLIE (Mausam et al., 2012). The focus of these methods has been on verbal phrases as relations, and there is little effort to determine lexical synonymy among them.

The first notable effort to build up a resource for relational paraphrases is DIRT (Lin and Pantel, 2001), based on Harris' Distributional Hypothesis to cluster syntactic patterns. RESOLVER (Yates and Etzioni, 2009) introduced a probabilistic relational model for predicting synonymy. Yao et al. (2012) incorporated latent topic models to resolve the ambiguity of relational phrases. Other probabilistic approaches employed matrix factorization for finding entailments between relations (Riedel et al., 2013; Petroni et al., 2015) or used probabilistic graphical models to find clusters of relations (Grycner et al., 2014). All of these approaches rely on the co-occurrence of the arguments of the relation.

Recent endeavors to construct large repositories of relational paraphrases are PATTY, WiseNet and DEFIE. PATTY (Nakashole et al., 2012) devised a sequence mining algorithm to extract relational

phrases with semantic type signatures, and organized them into synonymy sets and hypernymy hierarchies. WiseNet (Moro and Navigli, 2012) tapped Wikipedia categories for a similar way of organizing relational paraphrases. DEFIE (Bovi et al., 2015) went even further and used word sense disambiguation, anchored in WordNet, to group phrases with the same meanings.

Translation models have previously been used for paraphrase detection. Barzilay and McKeown (2001) utilized multiple English translations of the same source text for paraphrase extraction. Bannard and Callison-Burch (2005) used the bilingual pivoting method on parallel corpora for the same task. Similar methods were performed at a much bigger scale by the Paraphrase Database (PPDB) project (Pavlick et al., 2015). Unlike POLY, the focus of these projects was not on paraphrases of binary relations. Moreover, POLY considers the semantic type signatures of relations, which is missing in PPDB.

Research on OIE for languages other than English has received little attention. Kim et al. (2011) uses Korean-English parallel corpora for cross-lingual projection. Gamallo et al. (2012) developed an OIE system for Spanish and Portuguese using rules over shallow dependency parsing. The recent work of Faruqui and Kumar (2015) extracted relational phrases from Wikipedia in 61 languages using cross-lingual projection. Lewis and Steedman (2013) clustered semantically equivalent English and French phrases, based on the arguments of relations.

7 Conclusions

We presented POLY, a method for clustering semantically typed English relational phrases using a multilingual corpus, resulting in a repository of semantically typed paraphrases with high coverage and precision. Future work includes jointly processing all 61 languages in the corpus, rather than considering them pairwise, to build a resource for all languages. The POLY resource is publicly available at `www.mpi-inf.mpg.de/yago-naga/poly/`.

Exploiting Sentence Similarities for Better Alignments

Tao Li and **Vivek Srikumar**
University of Utah
{tli,svivek}@cs.utah.edu

Abstract

We study the problem of jointly aligning sentence constituents and predicting their similarities. While extensive sentence similarity data exists, manually generating reference alignments and labeling the similarities of the aligned chunks is comparatively onerous. This prompts the natural question of whether we can exploit easy-to-create sentence level data to train better aligners. In this paper, we present a model that learns to jointly align constituents of two sentences and also predict their similarities. By taking advantage of both sentence and constituent level data, we show that our model achieves state-of-the-art performance at predicting alignments and constituent similarities.

1 Introduction

The problem of discovering semantic relationships between two sentences has given birth to several NLP tasks over the years. Textual entailment (Dagan et al., 2013, *inter alia*) asks about the truth of a hypothesis sentence given another sentence (or more generally a paragraph). Paraphrase identification (Dolan et al., 2004, *inter alia*) asks whether two sentences have the same meaning. Foregoing the binary entailment and paraphrase decisions, the semantic textual similarity (STS) task (Agirre et al., 2012) asks for a numeric measure of semantic equivalence between two sentences. All three tasks have attracted much interest in the form of shared tasks.

While various approaches have been proposed to predict these sentence relationships, a commonly employed strategy (Das and Smith, 2009; Chang et al., 2010a) is to postulate an alignment between constituents of the sentences and use this alignment to make the final prediction (a binary decision or a numeric similarity score). The implicit assumption in such approaches is that better constituent alignments can lead to better identification of semantic relationships between sentences.

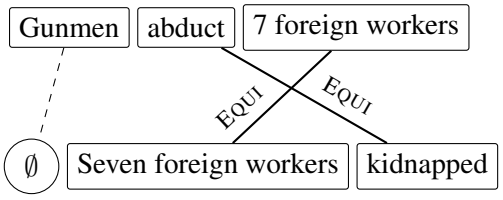

Figure 1: Example constituent alignment. The solid lines represent aligned constituents (here, both labeled equivalent). The chunk *Gunmen* is unaligned.

Constituent alignments serve two purposes. First, they act as an intermediate representation for predicting the final output. Second, the alignments help interpret (and debug) decisions made by the overall system. For example, the alignment between the sentences in Figure 1 can not only be useful to determine the equivalence of the two sentences, but also help reason about the predictions.

The importance of this intermediate representation led to the creation of the *interpretable* semantic textual similarity task (Agirre et al., 2015a) that focuses on predicting chunk-level alignments and similarities. However, while extensive resources exist for sentence-level relationships, human annotated chunk-aligned data is comparatively smaller.

In this paper, we address the following question: can we use sentence-level resources to better pre-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2193–2203,
Austin, Texas, November 1-5, 2016.

dict constituent alignments and similarities? To answer this question, we focus on the semantic textual similarity (STS) task and its interpretable variant. We propose a joint model that aligns constituents and integrates the information across the aligned edges to predict both constituent and sentence level similarity. The key advantage of modeling these two problems jointly is that, during training, the sentence-level information can provide feedback to the constituent-level predictions.

We evaluate our model on the SemEval-2016 task of interpretable STS. We show that even without the sentence information, our joint model that uses constituent alignments and similarities forms a strong baseline. Further, our easily extensible joint model can incorporate sentence-level similarity judgments to produce alignments and chunk similarities that are comparable to the best results in the shared task.

In summary, the contributions of this paper are:

1. We present the first joint model for predicting constituent alignments and similarities. Our model can naturally take advantage of the much larger sentence-level annotations.

2. We evaluate our model on the SemEval-2016 task of interpretable semantic similarity and show state-of-the-art results.

2 Problem Definition

In this section, we will introduce the notation used in the paper using the sentences in Figure 1 as a running example. The input to the problem is a pair of sentences, denoted by $\mathbf{x}$. We will assume that the sentences are chunked (Tjong Kim Sang and Buchholz, 2000) into constituents. We denote the chunks using subscripts. Thus, the input $\mathbf{x}$ consists of two sequences of chunks $\mathbf{s} = (s_1, s_2, \cdots)$ and $\mathbf{t} = (t_1, t_2, \cdots)$ respectively. In our running example, we have $\mathbf{s} =$ (*Gunmen*, *abduct*, *seven foreign workers*) and $\mathbf{t} =$ (*Seven foreign workers*, *kidnapped*).

The output consists of three components:

1. **Alignment**: The alignment between a pair of chunks is a labeled, undirected edge that explains the relation that exists between them. The labels can be one of EQUI (semantically equivalent), OPPO (opposite meaning in context), SPE1, SPE2 (the chunk from $\mathbf{s}$ is more specific than the one from $\mathbf{t}$ and vice versa), SIMI (similar meaning, but none of the previous ones) or REL (related, but none of the above)[1]. In Figure 1, we see two EQUI edges. A chunk from either sentence can be unaligned, as in the case of the chunk *Gunmen*.

   We will use $\mathbf{y}$ to denote the alignment for an input $\mathbf{x}$. The alignment $\mathbf{y}$ consists of a sequence of triples of the form (s_i, t_j, l). Here, s_i and t_j denote a pair of chunks that are aligned with a label l. For brevity, we will include unaligned chunks into this format using a special null chunk and label to indicate that a chunk is unaligned. Thus, the alignment for our running example contain the triple $(\textit{Gunmen}, \emptyset, \emptyset)$.

2. **Chunk similarity**: Every aligned chunk is associated with a relatedness score between zero and five, denoting the range from unrelated to equivalent. Note that even chunks labeled OPPO can be assigned a high score because the polarity is captured by the label rather than the score. We will denote the chunk similarities using $\mathbf{z}$, comprising of numeric $z_{i,j,l}$ for elements of the corresponding alignment $\mathbf{y}$. For an unaligned chunk, the corresponding similarity z is fixed to zero.

3. **Sentence similarity**: The pair of sentences is associated with a scalar score from zero to five, to be interpreted as above. We will use r to denote the sentence similarity for an input $\mathbf{x}$.

Thus, the prediction problem is the following: Given a pair of chunked sentences $\mathbf{x} = (\mathbf{s}, \mathbf{t})$, predict the alignment $\mathbf{y}$, the alignment similarities $\mathbf{z}$ and the sentence similarity r. Note that this problem definition integrates the canonical semantic textual similarity task (only predicting r) and its interpretable variant (predicting both $\mathbf{y}$ and $\mathbf{z}$) into a single task.

[1] We refer the reader to the guidelines of the task (Agirre et al., 2015a) for further details on these labels. Also, for simplicity, in this paper, we ignore the factuality and polarity tags from the interpretable task.

3 Predicting Alignments and Similarities

This section describes our model for predicting alignments, alignment scores, and the sentence similarity scores for a given pair of sentences. We will assume that learning is complete and we have all the scoring functions we need and defer discussing the parameterization and learning to Section 4.

We frame the problem of inference as an instance of an integer linear program (ILP). We will first see the scoring functions and the ILP formulation in Section 3.1. Then, in Section 3.2, we will see how we can directly read off the similarity scores at both chunk and sentence level from the alignment.

3.1 Alignment via Integer Linear Programs

We have two kinds of 0-1 inference variables to represent labeled aligned chunks and unaligned chunks.

We will use the inference variables $\mathbb{1}_{i,j,l}$ to denote the decision that chunks s_i and t_j are aligned with a label l. To allow chunks to be unaligned, the variables $\mathbb{1}_{i,0}$ and $\mathbb{1}_{0,j}$ denote the decisions that s_i and t_j are unaligned respectively.

Every inference decision is scored by the trained model. Thus, we have $\text{score}(i,j,l)$, $\text{score}(i,0)$ and $\text{score}(0,j)$ for the three kinds of inference variables respectively. All scores are of the form $A\left(\mathbf{w}^T\Phi\left(\cdot,\mathbf{s},\mathbf{t}\right)\right)$, where $\mathbf{w}$ is a weight vector that is learned, $\Phi\left(\cdot,\mathbf{s},\mathbf{t}\right)$ is a feature function whose arguments include the constituents and labels in question, and A is a sigmoidal activation function that flattens the scores to the range $[0,5]$. In all our experiments, we used the function $A(x)=\frac{5}{1+e^{-x}}$.

The goal of inference is to find the assignment to the inference variables that maximizes total score. That is, we seek to solve

$$\begin{aligned}\arg\max_{\mathbb{1}\in\mathcal{C}} \quad & \sum_{i,j,l}\text{score}(i,j,l)\mathbb{1}_{i,j,l} \\ & +\sum_{i}\text{score}(i,0)\mathbb{1}_{i,0} \\ & +\sum_{j}\text{score}(0,j)\mathbb{1}_{0,j} \qquad (1)\end{aligned}$$

Here $\mathbb{1}$ represents all the inference variables together and $\mathcal{C}$ denotes the set of all valid assignments to the variables, defined by the following set of constraints:

1. A pair of chunks can have *at most* one label.
2. Either a chunk can be unaligned or it should participate in a labeled alignment with exactly one chunk of the other sentence.

We can convert these constraints into linear inequalities over the inference variables using standard techniques for ILP inference (Roth and Yih, 2004)[2]. Note that, by construction, there is a one-to-one mapping from an assignment to the inference variables $\mathbb{1}$ and the alignment $\mathbf{y}$. In the rest of the paper, we use these two symbols interchangeably, using $\mathbb{1}$ referring details of inference and $\mathbf{y}$ referring to the alignment as a sequence of labeled edges.

3.2 From Alignments to Similarities

To complete the prediction, we need to compute the numeric chunk and sentence similarities given the alignment $\mathbf{y}$. In each case, we make modeling assumptions about how the alignments and similarities are related, as described below.

Chunk similarities To predict the chunk similarities, we assume that the label-specific chunk similarities of aligned chunks *are* the best edge-weights for the corresponding inference variables. That is, for a pair of chunks (s_i,t_j) that are aligned with a label l, the chunk pair similarity $z_{i,j,l}$ is the coefficient associated with the corresponding inference variable. If the alignment edge indicates an unaligned chunk, then the corresponding score is zero. That is,

$$z_{i,j,l}=\begin{cases}A\left(\mathbf{w}^T\Phi\left(s_i,t_j,l,\mathbf{s},\mathbf{t}\right)\right) & \text{if } l\neq\emptyset \\ 0 & \text{if } l=\emptyset.\end{cases} \qquad (2)$$

But can chunk similarities directly be used to find good alignments? To validate this assumption, we performed a pilot experiment on the chunk aligned part of our training dataset. We used the gold standard chunk similarities as scores of the inference variables in the integer program in Eq. 1, with the variables associated with unaligned chunks being scored zero. We found that this experiment gives a near-perfect typed alignment F-score of 0.9875.

[2]While it may be possible to find the score maximizing alignment in the presence of these constraints using dynamic programming (say, a variant of the Kuhn-Munkres algorithm), we model inference as an ILP to allow us the flexibility to explore more sophisticated output interactions in the future.

The slight disparity is because the inference only allows 1-to-1 matches between chunks (constraint 2), which does not hold in a small number of examples.

Sentence similarities Given the aligned chunks $\mathbf{y}$, the similarity between the sentences $\mathbf{s}$ and $\mathbf{t}$ (*i.e.*, in our notation, r) is the weighted average of the chunk similarities (*i.e.*, $z_{i,j,l}$). Formally,

$$r = \frac{1}{|\mathbf{y}|} \sum_{(s_i,t_j,l)\in\mathbf{y}} \alpha_l z_{i,j,l}. \quad (3)$$

Note that the weights α_l depend only on the labels associated with the alignment edge and are designed to capture the polarity and strength of the label. Eq. 3 bridges sentence similarities and chunk similarities. During learning, this provides the feedback from sentence similarities to chunk similarities. The values of the α's can be learned or fixed before learning commences. To simplify our model, we choose the latter approach . Section 5 gives more details.

Features To complete the description of the model, we now describe the features that define the scoring functions. We use standard features from the STS literature (Karumuri et al., 2015; Agirre et al., 2015b; Banjade et al., 2015).

For a pair of chunks, we extract the following similarity features: (1) Absolute cosine similarities of GloVe embeddings (Pennington et al., 2014) of head words, (2) WordNet based Resnik (Resnik, 1995), Leacock (Leacock and Chodorow, 1998) and Lin (Lin, 1998) similarities of head words, (3) Jaccard similarity of content words and lemmas. In addition, we also add indicators for: (1) the part of speech tags of the pair of head words, (2) the pair of head words being present in the lexical large section of the Paraphrase Database (Ganitkevitch et al., 2013), (3) a chunk being longer than the other while both are not named entity chunks, (4) a chunk having more content words than the other, (5) contents of one chunk being a part of the other, (6) having the same named entity type or numeric words, (7) sharing synonyms or antonyms, (8) sharing conjunctions or prepositions, (9) the existence of unigram/bigram/trigram overlap, (10) if only one chunk has a negation, and (11) a chunk having extra content words that are also present in the other sentence.

For a chunk being unaligned, we conjoin an indicator that the chunk is unaligned with the part of speech tag of its head word.

3.3 Discussion

In the model proposed above, by predicting the alignment, we will be able to deterministically calculate both chunk and sentence level similarities. This is in contrast to other approaches for the STS task, which first align constituents and then extract features from alignments to predict similarities in a pipelined fashion. The joint prediction of alignment and similarities allows us to address the primary motivation of the paper, namely using the abundant sentence level data to train the aligner and scorer.

The crucial assumption that drives the joint model is that the *same* set of parameters that can discover a good alignment can also predict similarities. This assumption – similar to the one made by Chang et al. (2010b) – and the associated model described above, imply that the goal of learning is to find parameters that drive the inference towards good alignments and similarities.

4 Learning the Alignment Model

Under the proposed model, the alignment directly predicts the chunk and sentence similarities as well. We utilize two datasets to learn the model:

1. The **alignment dataset** D_A consists of fully annotated aligned chunks and respective chunk similarity scores.

2. The **sentence dataset** D_S that consists of pairs of sentences where each pair is labeled with a numeric similarity score between zero and five.

The goal of learning is to use these two datasets to train the model parameters. Note that unlike standard multi-task learning problems, the two tasks in our case are tightly coupled both in terms of their definition and via the model described in Section 3.

We define three types of loss functions corresponding to the three components of the final output (*i.e.*, alignment, chunk similarity and sentence similarity). Naturally, for each kind of loss, we assume that we have the corresponding ground truth. We will denote ground truth similarity scores and alignments using asterisks. Also, the loss functions

defined below depend on the weight vector $\mathbf{w}$, but this is not shown to simplify notation.

1. The **alignment loss** L_a is a structured loss function that penalizes alignments that are far away from the ground truth. We used the structured hinge loss (Taskar et al., 2004; Tsochantaridis et al., 2005) for this purpose.

$$L_a(\mathbf{s}, \mathbf{t}, \mathbf{y}^*) = \max_{\mathbf{y}} \mathbf{w}^T \Phi(\mathbf{s}, \mathbf{t}, \mathbf{y}) + \Delta(\mathbf{y}, \mathbf{y}^*) - \mathbf{w}^T \Phi(\mathbf{s}, \mathbf{t}, \mathbf{y}^*).$$

   Here, Δ refers to the Hamming distance between the alignments.

2. The **chunk score loss** L_c is designed to penalize errors in predicted chunk level similarities. To account for cases where chunk boundaries may be incorrect, we define this loss as the sum of squared errors of token similarities. However, neither our output nor the gold standard similarities are at the granularity of tokens. Thus, to compute the loss, we project the chunk scores $z_{i,j,l}$ for an aligned chunk pair (s_i, t_j, l) to the tokens that constitute the chunks by equally partitioning the scores among all possible internal alignments. In other words, for a token w_i in the chunk s_i and token w_j in chunk s_j, we define token similarity scores as

$$z(w_i, w_j, l) = \frac{z_{i,j,l}}{N(s_i, t_j)}$$

   Here, the normalizing function N is the product of the number of tokens in the chunks[3]. Note that this definition of the token similarity scores applies to both predicted and gold standard similarities. Unaligned tokens are associated with a zero score.

   We can now define the loss for a token pair $(w_i, w_j) \in (\mathbf{s}, \mathbf{t})$ and a label l as the squared error of their token similarity scores:

$$l(w_i, w_j, l) = \left(z(w_i, w_j, l) - z^*(w_i, w_j, l)\right)^2$$

   The chunk loss score L_c for a sentence pair is the sum of all the losses over all pairs of tokens and labels.

$$L_c(\mathbf{s}, \mathbf{t}, \mathbf{y}, \mathbf{y}^*, \mathbf{z}, \mathbf{z}^*) = \sum_{w_i, w_j, l} l(w_i, w_j, l)$$

3. The **sentence similarity loss** L_s provides feedback to the aligner by penalizing alignments that are far away from the ground truth in their similarity assessments. For a pair of sentences $(\mathbf{s}, \mathbf{t})$, given the ground truth sentence similarity r^* and the predicted sentence similarity r (using Equation (3)), the sentence similarity loss is the squared error:

$$L_s(\mathbf{s}, \mathbf{t}, r^*) = (r - r^*)^2.$$

Our learning objective is the weighted combination of the above three components and a ℓ_2 regularizer on the weight vector. The importance of each type of loss is controlled by a corresponding hyperparameter: λ_a, λ_c and λ_s respectively.

Learning algorithm We have two scenarios to consider: with only alignment dataset D_A, and with both D_A and sentence dataset D_S. Note that even if we train only on the alignment dataset D_A, our learning objective is not convex because the activation function is sigmoidal (in Section 3.1).

In both cases, we use stochastic gradient descent with minibatch updates as the optimizer. In the first scenario, we simply perform the optimization using the alignment and the chunk score losses. We found by preliminary experiments on training data that initializing the weights to one performed best.

Algorithm 1 Learning alignments and similarities, given alignment dataset D_A and sentence similarity dataset D_S. See the text for more details.

1: Initialize all weights to one.
2: $\mathbf{w}^0 \leftarrow SGD(D_A)$: Train an initial model
3: Use $\mathbf{w}^0$ to predict alignments on examples in D_S. Call this $\widehat{D_S}$.
4: $\mathbf{w} \leftarrow SGD(D_A \cup \widehat{D_S})$: Train on both sets of examples.
5: **return** $\mathbf{w}$

When we have both D_A and D_S (Algorithm 1), we first initialize the model on the alignment data

[3] Following the official evaluation of the interpretable STS task, we also experimented with the $\max(|s_i|, |t_j|)$ for the normalizer, but we found via cross validation that the product performs better.

only. Using this initial model, we hypothesize alignments on all examples in D_S to get fully labeled examples. Then, we optimize the full objective (all three loss terms) on the combined dataset. Because our goal is to study the impact on the chunk level predictions, in the full model, the sentence loss does not play a part on examples from D_A.

5 Experiments and Results

The primary research question we seek to answer via experiments is: Can we better predict chunk alignments and similarities by taking advantage of sentence level similarity data?

Datasets We used the training and test data from the 2016 SemEval shared tasks of predicting semantic textual similarity (Agirre et al., 2016a) and interpretable STS (Agirre et al., 2016b), that is, tasks 1 and 2 respectively. For our experiments, we used the headlines and images sections of the data. The data for the interpretable STS task, consisting of manually aligned and scored chunks, provides the alignment datasets for training (D_A). The headlines section of the training data consists for 756 sentence pairs, while the images section consists for 750 sentence pairs. The data for the STS task acts as our sentence level training dataset (D_S). For the headlines section, we used the 2013 headlines test set consisting of 750 sentence pairs with gold sentence similarity scores. For the images section, we used the 2014 images test set consisting of 750 examples. We evaluated our models on the official Task 2 test set, consisting of 375 sentence pairs for both the headlines and images sections. In all experiments, we used gold standard chunk boundaries if they are available (*i.e.*, for D_A).

Pre-processing We pre-processed the sentences with parts of speech using the Stanford CoreNLP toolkit (Manning et al., 2014). Since our setting assumes that we have the chunks as input, we used the Illinois shallow parser (Clarke et al., 2012) to extract chunks from D_S. We post-processed the predicted chunks to correct for errors using the following steps: 1. Split on punctuation; 2. Split on verbs in NP; 3. Split on nouns in VP; 4. Merge PP+NP into PP; 5. Merge VP+PRT into VP if the PRT chunk is not a preposition or a subordinating conjunction; 6. Merge SBAR+NP into SBAR; and 7. Create new contiguous chunks using tokens that are marked as being outside a chunk by the shallow parser. We found that using the above post-processing rules, improved the F1 of chunk accuracy from 0.7865 to 0.8130. We also found via cross-validation that this post-processing improved overall alignment accuracy. The reader may refer to other STS resources (Karumuri et al., 2015) for further improvements along this direction.

Experimental setup We performed stochastic gradient descent for 200 epochs in our experiments, with a mini-batch size of 20. We determined the three λ's using cross-validation, with different hyperparameters for examples from D_A and D_S. Table 1 lists the best hyperparameter values. For performing inference, we used the Gurobi optimizer[4].

Setting	$\lambda_a, \lambda_c, \lambda_s$
headlines, D_A	100, 0.01, N/A
headlines, D_S	0.5, 1, 50
images, D_A	100, 0.01, N/A
images, D_S	5, 2.5, 50

Table 1: Hyperparameters for the various settings, chosen by cross-validation. The alignment dataset do not have a λ associated with the sentence loss.

As noted in Section 3.1, the parameter α_l combines chunk scores into sentence scores. To find these hyper-parameters, we used a set of 426 sentences from the from the headlines training data that had both sentence and chunk annotation. We simplified the search by assuming that α_{Equi} is always 1.0 and all labels other than OPPO have the same α. Using grid search over $[-1, 1]$ in increments of 0.1, we selected α's that gave us the highest Pearson correlation for sentence level similarities. The best α's (with a Pearson correlation of 0.7635) were:

$$\alpha_l = \begin{cases} 1, & l = \text{EQUI}, \\ -1, & l = \text{OPPO}, \\ 0.7, & \text{otherwise} \end{cases}$$

Results Following the official evaluation for the SemEval task, we evaluate both alignments and their

Table 2: F-score for headlines and images datasets. These tables show the result of our systems, baseline and top-ranked systems. D_A is our strong baseline trained on interpretable STS dataset; $D_A + D_S$ is trained on interpretable STS as well as STS dataset. The rank 1 system on headlines is Inspire (Kazmi and Schüller, 2016) and UWB (Konopik et al., 2016) on images. Bold are the best scores.

corresponding similarity scores. The typed alignment evaluation (denoted by **typed ali** in the results table) measures F1 over the alignment edges where the types need to match, but scores are ignored. The typed similarity evaluation (denoted by **typed score**) is the more stringent evaluation that measures F1 of the alignment edge labels, but penalizes them if the similarity scores do not match. The **untyped** versions of alignment and scored alignment evaluations ignore alignment labels. These metrics, based on Melamed (1997), are tailored for the interpretable STS task[5]. We refer the reader to the guidelines of the task for further details. We report both scores in Table 2. We also list the performance of the baseline system (Sultan et al., 2014a) and the top ranked systems from the 2016 shared task for each dataset[6].

By comparing the rows labeled D_A and $D_A + D_S$ in Table 2 (a) and Table 2 (b), we see that in both the headlines and the images datasets, adding sentence level information improves the untyped score, lifting the stricter typed score F1. On the headlines dataset, incorporating sentence-level information degrades both the untyped and typed alignment quality because we cross-validated on the typed score metric.

The typed score metric is the combination of untyped alignment, untyped score and typed alignment. From the row $D_A + D_S$ in Table 2(a), we observe that the typed score F1 is slightly behind that of rank 1 system while all other three metrics are significantly better, indicating that we need to improve our modeling of the intersection of the three aspects. However, this does not apply to images dataset where the improvement on the typed score F1 comes from the typed alignment.

Further, we see that even our base model that only depends on the alignment data offers strong alignment F1 scores. This validates the utility of jointly modeling alignments and chunk similarities. Adding sentence data to this already strong system leads to performance that is comparable to or better than the state-of-the-art systems. Indeed, our final results would have been ranked first on the images task and a close second on the headlines task in the official standings.

The most significant feedback coming from sentence-level information is with respect to the chunk similarity scores. While we observed slight change in the unscored alignment performance, for both the headlines and the images datasets, we saw improvements in both scored precision and recall when sentence level data was used.

6 Analysis and Discussion

In this section, first, we report the results of manual error analysis. Then, we study the ability of our model to handle data from different domains.

6.1 Error Analysis

To perform a manual error analysis, we selected 40 examples from the development set of the headlines section. We classified the errors made by the full model trained on the alignment and sentence datasets. Below, we report the four most significant types of errors:

1. **Contextual implication**: Chunks that are meant to be aligned are not synonyms by them-

[5]In the SemEval 2016 shared task, the typed score is the metric used for system ranking.

[6]http://alt.qcri.org/semeval2016/task2/

selves but are implied by the context. For instance, *Israeli forces* and *security forces* might be equivalent in certain contexts. Out of the 16 instances of EQUI being misclassified as SPE, eight were caused by the features' inability to ascertain contextual implications. This also accounted for four out of the 15 failures to identify alignments.

2. **Semantic phrase understanding**: These are the cases where our lexical resources failed, *e.g.*, *ablaze* and *left burning*. This accounted for ten of the 15 chunk alignment failures and nine of the 21 labeling errors. Among these, some errors (four alignment failures and four labeling errors) were much simpler than others that could be handled with relatively simple features (e.g. *family reunions* ↔ *family unions*).

3. **Preposition semantics**: The inability to account for preposition semantics accounts for three of the 16 cases where EQUI is mistaken as a SPE. Some examples include *at 91* ↔ *aged 91* and *catch fire* ↔ *after fire*.

4. **Underestimated** EQUI **score**: Ten out of 14 cases of score underestimation happened on EQUI label.

Our analysis suggests that we need better contextual features and phrasal features to make further gains in aligning constituents.

6.2 Does the text domain matter?

In all the experiments in Section 5, we used sentence datasets belonging to the same domain as the alignment dataset (either headlines or images). Given that our model can take advantage of two separate datasets, a natural question to ask is how the domain of the sentence dataset influences overall alignment performance. Additionally, we can also ask how well the trained classifiers perform on out-of-domain data. We performed a series of experiments to explore these two questions. Table 3 summarizes the results of these experiments.

The columns labeled Train and Test of the table show the training and test sets used. Each dataset can be either the headlines section (denoted by hdln), or the images section (img) or not used ($\emptyset$). The last two columns report performance on the test set. The rows 1 and 5 in the table correspond to the in-domain settings and match the results of typed alignment and score in Table 2.

Id	Train		Test	Typed F1	
	D_A	D_S		ali	score
1.	hdln	$\emptyset$	hdln	0.7350	0.6776
2.		img		0.6826	0.6347
3.		$\emptyset$	img	0.6547	0.5989
4.		img		0.6161	0.5854
5.	img	$\emptyset$	img	0.6933	0.6411
6.		hdln		0.7033	0.6793
7.		$\emptyset$	hdln	0.6702	0.6274
8.		hdln		0.6672	0.6445

Table 3: F-score for the domain adaptation experiments. This table shows the performance of training on different dataset combinations.

When the headlines data is tested on the images section, we see that there is the usual domain adaptation problem (row 3 vs row 1) and using target images sentence data does not help (row 4 vs row 3). In contrast, even though there is a domain adaptation problem when we compare the rows 5 and 7, we see that once again, using headlines sentence data improves the predicted scores (row 7 vs row 8). This observation can be explained by the fact that the images sentences are relatively simpler and headlines dataset can provide richer features in comparison, thus allowing for stronger feedback from sentences to constituents.

The next question concerns how the domain of the sentence dataset D_S influences alignment and similarity performance. To answer this, we can compare the results in every pair of rows (*i.e.*, 1 vs 2, 3 vs 4, etc.) We see that when the sentence data from the image data is used in conjunction to the headlines chunk data, it invariably makes the classifiers worse. In contrast, the opposite trend is observed when the headlines sentence data augments the images chunk data. This can once again be explained by relatively simpler sentence constructions in the images set, suggesting that we can leverage linguistically complex corpora to improve alignment on simpler ones. Indeed, surprisingly, we obtain marginally better performance on the images set when we use images chunk level data in conjunction

with the headlines sentence data (row 6 vs the row labeled $D_A + D_S$ in the Table 2(b)).

7 Related Work

Aligning words and phrases between pairs of sentences is widely studied in NLP. Machine translation has a rich research history of using alignments (for *e.g.*, (Koehn et al., 2003; Och and Ney, 2003)), going back to the IBM models (Brown et al., 1993). From the learning perspective, the alignments are often treated as latent variables during learning, as in this work where we treated alignments in the sentence level training examples as latent variables. Our work is also conceptually related to (Ganchev et al., 2008), which asked whether improved alignment error implied better translation.

Outside of machine translation, alignments are employed either explicitly or implicitly for recognizing textual entailment (Brockett, 2007; Chang et al., 2010a) and paraphrase recognition (Das and Smith, 2009; Chang et al., 2010a). Additionally, alignments are explored in multiple ways (tokens, phrases, parse trees and dependency graphs) as a foundation for natural logic inference (Chambers et al., 2007; MacCartney and Manning, 2007; MacCartney et al., 2008). Our proposed aligner can be used to aid such applications.

For predicting sentence similarities, in both variants of the task, word or chunk alignments have extensively been used (Sultan et al., 2015; Sultan et al., 2014a; Sultan et al., 2014b; Hänig et al., 2015; Karumuri et al., 2015; Agirre et al., 2015b; Banjade et al., 2015, and others). In contrast to these systems, we proposed a model that is trained jointly to predict alignments, chunk similarities and sentence similarities. To our knowledge, this is the first approach that combines sentence-level similarity data with fine grained alignments to train a chunk aligner.

8 Conclusion

In this paper, we presented the first joint framework for aligning sentence constituents and predicting constituent and sentence similarities. We showed that our predictive model can be trained using both aligned constituent data *and* sentence similarity data. Our jointly trained model achieves state-of-the-art performance on the task of predicting interpretable sentence similarities.

Abstract

We develop a novel bi-directional attention model for dependency parsing, which learns to agree on headword predictions from the forward and backward parsing directions. The parsing procedure for each direction is formulated as sequentially querying the memory component that stores continuous headword embeddings. The proposed parser makes use of *soft* headword embeddings, allowing the model to implicitly capture high-order parsing history without dramatically increasing the computational complexity. We conduct experiments on English, Chinese, and 12 other languages from the CoNLL 2006 shared task, showing that the proposed model achieves state-of-the-art unlabeled attachment scores on 6 languages.[1]

1 Introduction

Recently, several neural network models have been developed for efficiently accessing long-term memory and discovering dependencies in sequential data. The memory network framework has been studied in the context of question answering and language modeling (Weston et al., 2015; Sukhbaatar et al., 2015), whereas the neural attention model under the encoder-decoder framework has been applied to machine translation (Bahdanau et al., 2015) and constituency parsing (Vinyals et al., 2015b). Both frameworks learn the latent alignment between the source and target sequences, and the mechanism of attention over the *encoder* can be viewed as a soft operation on the *memory*. Although already used in the encoder for capturing global context information (Bahdanau et al., 2015), the bi-directional recurrent neural network (RNN) has yet to be employed in the decoder. Bi-directional decoding is expected to be advantageous over the previously developed uni-directional counterpart, because the former exploits richer contextual information. Intuitively, we can use two separate uni-directional RNNs where each one constructs its respective attended encoder context vectors for computing RNN hidden states. However, the drawback of this approach is that the decoder would often produce different alignments resulting in discrepancies for the forward and backward directions. In this paper, we design a training objective function to enforce attention agreement between both directions, inspired by the alignment-by-agreement idea from Liang et al. (2006). Specifically, we develop a dependency parser (BiAtt-DP) using a bi-directional attention model based on the memory network. Given that the golden alignment is observed for dependency parsing in the training stage, we further derive a simple and interpretable approximation for the agreement objective, which makes a natural connection between the latent and observed alignment cases.

The proposed BiAtt-DP parses a sentence in a linear order via sequentially querying the memory component that stores continuous embeddings for all headwords. In other words, we consider all possible arcs during the parsing. This formulation is adopted by graph-based parsers such as the MSTParser (McDonald et al., 2005). The consideration

[1] Our software and models are available at https://github.com/hao-cheng/biattdp.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2204–2214,
Austin, Texas, November 1-5, 2016.

of all possible arcs makes the proposed BiAtt-DP different from many recently developed neural dependency parsers (Chen and Manning, 2014; Weiss et al., 2015; Alberti et al., 2015; Dyer et al., 2015; Ballesteros et al., 2015), which use a transition-based algorithm by modeling the parsing procedure as a sequence of actions on buffers. Moreover, unlike most graph-based parsers which may suffer from high computational complexity when utilizing high-order parsing history (McDonald and Pereira, 2006), the proposed BiAtt-DP can implicitly inject such information into the model while keeping the computational complexity in the order of $\mathcal{O}(n^2)$ for a sentence with n words. This is achieved by feeding the RNN in the query component with a *soft* headword embedding, which is computed as the probability-weighted sum of all headword embeddings in the memory component.

To the best of our knowledge, this is the first attempt to apply memory network models to graph-based dependency parsing. Moreover, it is the first extension of neural attention models from uni-direction to multi-direction by enforcing agreement on alignments. Experiments on English, Chinese, and 12 languages from the CoNLL 2006 shared task show the BiAtt-DP can achieve competitive parsing accuracy with several state-of-the-art parsers. Furthermore, our model achieves the highest unlabeled attachment score (UAS) on Chinese, Czech, Dutch, German, Spanish and Turkish.

2 A MemNet-based Dependency Parser

The proposed parser first encodes each word in a sentence by continuous embeddings using a bi-directional RNN, and then performs two types of operations, *i.e.* 1) headword predictions based on bi-directional parsing history and 2) the relation prediction conditioned on the current modifier and its *predicted* headword both in the embedding space. In the following, we first present how the token embeddings are constructed. Then, the key components of the proposed parser, *i.e.* the memory component and the query component, are discussed in detail. Lastly, we describe the parsing algorithm using a bi-directional attention model with agreement.

2.1 Token Embeddings

In the proposed BiAtt-DP, the memory and query components share the same token embeddings. We use the notion of additive token embedding as in (Botha and Blunsom, 2014) to utilize the available information about the token, e.g., its word form, lemma, part-of-speech (POS) tag, and morphological features. Specifically, the token embedding is computed as

$$\mathbf{E}^{\text{form}}\mathbf{e}_i^{\text{form}} + \mathbf{E}^{\text{pos}}\mathbf{e}_i^{\text{pos}} + \mathbf{E}^{\text{lemma}}\mathbf{e}_i^{\text{lemma}} + \cdots,$$

where $\mathbf{e}_i$'s are one-hot encoding vectors for the i-th word, and $\mathbf{E}$'s are parameters to be learned that store the continuous embeddings for corresponding feature. Note those one-hot encoding vectors have different dimensions, depending on individual vocabulary sizes, and all $\mathbf{E}$'s have the same first dimension but different second dimension. The additive token embeddings allow us to easily integrate a variety of information. Moreover, we only need to make a single decision on the dimensionality of the token embedding, rather than a combination of decisions on word embeddings and POS tag embeddings as in concatenated token embeddings used by Chen and Manning (2014), Dyer et al. (2015) and Weiss et al. (2015). It reduces the number of model parameters to be tuned, especially when lots of different features are used. In our experiments, the word form and fine-grained POS tag are always used, whereas other features are used depending on their availability in the dataset. All singleton words, lemmas, and POS tags are replaced by special tokens.

The additive token embeddings are transformed into another space before they are used by the memory and query components, *i.e.*

$$\mathbf{x}_i = \text{LReL}\left[\mathbf{P}\left(\mathbf{E}^{\text{form}}\mathbf{e}_i^{\text{form}} + \cdots\right)\right],$$

where $\mathbf{P}$ is the projection matrix and is shared by the memory and query components as well. The activation function of this projection layer is the leaky rectified linear (LReL) function (Mass et al., 2013) with 0.1 as the slope of the negative part. In the remaining part of the paper, we refer to $\mathbf{x}_i \in \mathbb{R}^p$ as the token embedding for word at position i. Note the subscript i is substituted by j and t for the memory and query components, respectively.

2.2 Components

As shown in Figure 1, the proposed BiAtt-DP has three components, *i.e.* a memory component, a left-to-right query component, and a right-to-left query component. Given a sentence of length n, the parser first uses a bi-directional RNN to construct $n+1$ headword embeddings, $\mathbf{m}_0, \mathbf{m}_1, \ldots, \mathbf{m}_n \in \mathbb{R}^e$, with $\mathbf{m}_0$ reserved for the `ROOT` symbol. Each query component is an uni-directional attention model. In a query component, a sequence of n modifier embeddings $\mathbf{q}_1, \ldots, \mathbf{q}_n \in \mathbb{R}^d$ are constructed recursively by conditioning on all headword embeddings. To address the vanishing gradient issue in RNNs, we use the gated recurrent unit (GRU) proposed by Cho et al. (2014), where an update gate and a reset gate are employed to control the information flow. We replace the hyperbolic tangent function in GRU with the LReL function, which is faster to compute and achieves better parsing accuracy in our preliminary studies. In the following, we refer to headword and modifier embeddings as memory and query vectors, respectively.

Memory Component: The proposed BiAtt-DP uses a bi-directional RNN to obtain the memory vectors. At time step j, the current hidden state vector $\mathbf{h}^l_j \in \mathbb{R}^{e/2}$ (or $\mathbf{h}^r_j \in \mathbb{R}^{e/2}$) is computed as a non-linear transformation based on the current input vector $\mathbf{x}_j$ and the previous hidden state vector $\mathbf{h}^l_{j-1}$ (or $\mathbf{h}^r_{j+1}$), *i.e.* $\mathbf{h}^l_j = \mathrm{GRU}(\mathbf{h}^l_{j-1}, \mathbf{x}_j)$ (or $\mathbf{h}^r_j = \mathrm{GRU}(\mathbf{h}^r_{j+1}, \mathbf{x}_j)$). Ideally, the recursive nature of the RNN allows it to capture all context information from one-side, and a bi-directional RNN can thus capture context information from both sides. We concatenate the hidden layers of the left-to-right RNN and the right-to-left RNN for the word at position j as the memory vector $\mathbf{m}_j = \left[\mathbf{h}^l_j; \mathbf{h}^r_j\right]$. These memory vectors are expected to encode the words and their context information in the headword space.

Query Component: For each query component, we use a single-directional RNN with GRU to obtain the query vectors $\mathbf{q}_j$'s, which are the hidden state vectors of the RNN. Each $\mathbf{q}_t$ is used to query the memory component, returning association scores $s_{t,j}$'s between the word at position t and the headword at position j for $j \in \{0, \cdots, n\}$, *i.e.*

$$s_{t,j} = \mathbf{v}^T \phi\left(\mathbf{C}\mathbf{m}_j + \mathbf{D}\mathbf{q}_t\right), \tag{1}$$

where $\phi(\cdot)$ is the element-wise hyperbolic tangent function, and $\mathbf{C} \in \mathbb{R}^{h \times e}$, $\mathbf{D} \in \mathbb{R}^{h \times d}$ and $\mathbf{v} \in \mathbb{R}^h$ are model parameters. Then, we can obtain probabilities (aka attention weights), $a_{t,0}, \cdots, a_{t,n}$, over all headwords in the sentence by normalizing $s_{t,j}$'s, using a softmax function

$$\mathbf{a}_t = \mathrm{softmax}(\mathbf{s}_t). \tag{2}$$

The *soft* headword embedding is then defined as $\tilde{\mathbf{m}}_t = \sum_{j=1}^n a_{t,j}\mathbf{m}_j$. At each time step t, the

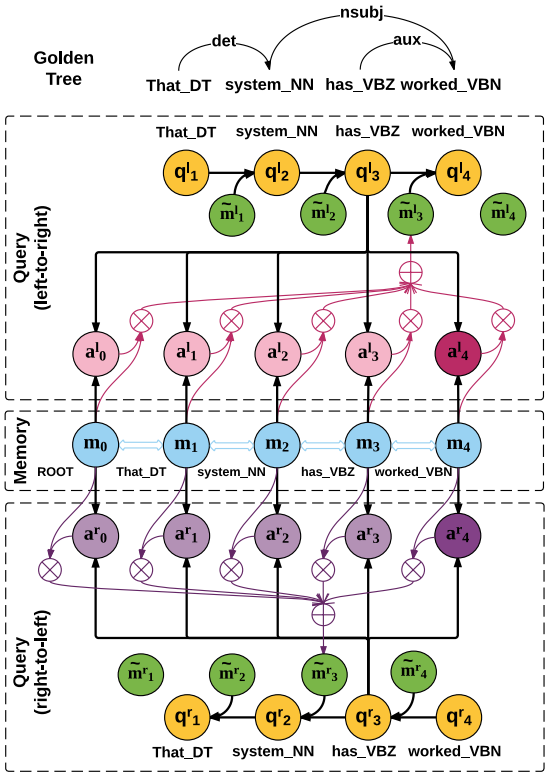

Figure 1: The structure of the BiAtt-DP. The figure only illustrates the parsing process at the time step for `has`. Blue and yellow circles are memory and query vectors, respectively. Red and purple circles represent headword probabilities predicted from corresponding query components. Green circles represent soft headword embeddings. Black arrowed lines are connections carrying weight matrices. $\otimes$ and $\oplus$ indicate element-wise multiplication and addition, respectively. For simplicity, we ignore the token embedding $\mathbf{x}_t$ connected to the RNN hidden layers $\mathbf{m}_j$, $\mathbf{q}^l_t$ and $\mathbf{q}^r_t$.

RNN takes the *soft* headword embedding $\tilde{\mathbf{m}}^l_{t-1}$ or $\tilde{\mathbf{m}}^r_{t+1}$ as the input, in addition to the token embedding $\mathbf{x}_t$. Formally, for the forward case, the $\mathbf{q}_t$ can be computed as $\mathbf{q}_t = \mathrm{GRU}\left(\mathbf{q}_{t-1}, [\tilde{\mathbf{m}}_t; \mathbf{x}_t]\right)$. Although the RNN is able to capture long-span context information to some extent, the local context may very easily dominate the hidden state. Therefore, this additional soft headword embedding allows the model to access long-span context information in a different channel. On the other hand, by recursively feeding both the query vector and the soft headword embedding into the RNN, the model *implicitly* captures high-order parsing history information, which can potentially improve the parsing accuracy (Yamada and Matsumoto, 2003; McDonald and Pereira, 2006). However, for a graph-based dependency parser, utilizing parsing history features is computationally expensive. For example, an k-th order MSTParser (McDonald and Pereira, 2006) has $\mathcal{O}(n^{k+1})$ complexity for a sentence of n words. In contrast, the BiAtt-DP *implicitly* captures high-order parsing history while keeping the complexity in the order of $\mathcal{O}(n^2)$, *i.e.* for each direction. we compute $n(n+1)$ pair-wise probabilities $a_{t,j}$ for $t = 1, \cdots, n$ and $j = 0, \cdots, n$.

In this paper, we choose to use soft headword embeddings rather than making hard decisions on headwords. In the latter case, beam search may potentially improve the parsing accuracy at the cost of higher computational complexity, *i.e.* $\mathcal{O}(Bn^2)$ with a beam width of B. When using soft headword embeddings, there is no need to perform beam search. Moreover, it is straightforward to incorporate parsing history from both directions by using two query components at the cost of $\mathcal{O}(2n^2)$, which cannot be easily achieved when using beam search. The parsing decision can be made directly based on attention weights from the two query components or further rescored by the maximum spanning tree (MST) search algorithm.

2.3 Parsing by Attention with Agreement

For the bi-directional attention model, the underlying probability distributions $\mathbf{a}^l_t$ and $\mathbf{a}^r_t$ may not agree with each other. In order to encourage the agreement, we use the mathematically convenient metric, *i.e.* the squared Hellinger distance $H^2\left(\mathbf{a}^l_t || \mathbf{a}^r_t\right)$, for quantifying the distance between these two distributions. For dependency parsing, when the golden alignment is known during training, we can derive an upper bound on the latent agreement objective as

$$H^2(\mathbf{a}^l_t, \mathbf{a}^r_t) \leq 2\sqrt{D(\mathbf{g}_t||\mathbf{a}^l_t) + D(\mathbf{g}_t||\mathbf{a}^r_t)},$$

where $D(\cdot||\cdot)$ is the KL-divergence. The complete derivation is provided in the Appendix A. During optimization, we can safely drop the constant scaler and the square root operation in the upper bound, leading to the following loss function

$$D(\mathbf{g}_t||\mathbf{a}^l_t) + D(\mathbf{g}_t||\mathbf{a}^r_t) = 2D(\mathbf{g}_t||\mathbf{a}^l_t \odot \mathbf{a}^r_t), \quad (3)$$

where $\odot$ indicates element-wise multiplication. The resulting loss function is equivalent to the cross-entropy loss, which is widely adopted for training neural networks.

As we can see, the loss function (3) tries to minimize the distance between the golden alignment and the intersection of the two directional attention alignments at every time step. Therefore, during inference, the headword prediction for the word at time step t can be obtained as

$$\underset{j}{\mathrm{argmax}} \quad \log a^l_{t,j} + \log a^r_{t,j},$$

seeking for agreement between both query components. This parsing procedure is also similar to the exhaustive left-to-right modifier-first search algorithm described in (Covington, 2001), but it is enhanced by an additional right-to-left search with the agreement enforcement. Alternatively, we can treat $(\log a^l_{t,j} + \log a^r_{t,j})$ as a score of the corresponding arc and then search for the MST to form a dependency parse tree, as proposed in (McDonald et al., 2005). The MST search is achieved via the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967), which can be implemented in $\mathcal{O}(n^2)$ for dense graphs according to Tarjan (1977). In practice, the MST search slows down the parsing speed by 6–10%. However, it forces the parser to produce a valid tree, and we observe a slight improvement on parsing accuracy in most cases.

After obtaining each modifier and its *soft* header embeddings, we use a single-layer perceptron to predict the head-modifier relation, *i.e.*

$$\mathbf{y}_t = \mathrm{softmax}\left(\mathbf{U}\left[\tilde{\mathbf{m}}^l_t;\, \tilde{\mathbf{m}}^r_t\right] + \mathbf{W}\left[\mathbf{q}^l_t;\, \mathbf{q}^r_t\right]\right), \quad (4)$$

where $y_{t,1}, \cdots, y_{t,m}$ are the probabilities of m possible relations, and $\mathbf{U} \in \mathbb{R}^{m \times 2e}$ and $\mathbf{W} \in \mathbb{R}^{m \times 2d}$ are model parameters.

3 Model Learning

For the t-th word (modifier) w_t in a sentence of length n, let H_t^l and H_t^r denote random variables representing the predicted headword from forward (left-to-right) and backward (right-to-left) parsing directions, respectively. Also let R_t denote the random variable representing the dependency relation for w_t. The joint probability of headword and relation predictions can be written as

$$\begin{aligned} & P(R_{1:n}, H_{1:n}^l, H_{1:n}^r | w_{1:n}) \\ = & \prod_{t=1}^{n} P(R_t | w_{1:n}) P(H_t^l | w_{1:n}) P(H_t^r | w_{1:n}) \\ = & \prod_{t=1}^{n} y_{t,R_t}^l \cdot a_{t,H_t^l}^l \cdot a_{t,H_t^r}^r \end{aligned} \quad (5)$$

where at each time step we assume head-modifier relations and headwords from both directions are independent with each other when conditioned on the global knowledge of the whole sentence. Note that the long-span context and high-order parsing history information are injected when we model $P(H_t^l | w_{1:n})$, $P(H_t^r | w_{1:n})$ and $P(R_t | w_{1:n})$, as discussed in Section 2.2.

As discussed in Section 2.3, the model can be trained by encouraging attention agreement between two query components. From (5), we observe that it is equivalent to maximizing the log-likelihood of the golden dependency tree (or minimizing the cross-entropy) for each training sentence, *i.e.*

$$\sum_{t=1}^{n} \left(\log y_{t,\text{relation}_t} + \log a_{t,\text{head}_t}^l + \log a_{t,\text{head}_t}^r \right),$$

where $a_{t,j}$ and $y_{t,r}$ are defined in (2) and (4), respectively, and $\texttt{relation}_t$ and $\texttt{head}_t$ are golden relation and headword labels, respectively. The gradients are computed via the back-propagation algorithm (Rumelhart et al., 1986). Errors of $\mathbf{y}_t$ come from the arc labels, whereas there are two source of errors for $\mathbf{a}_t$, one from the headword labels and the other back-propagated from errors of $\mathbf{y}_t$. We use stochastic gradient descent with the Adam algorithm proposed in (Kingma and Ba, 2015). The learning rate is halved at each iteration once the log-likelihood of the dev set decreases. The whole training procedure terminates when the log-likelihood decreases for the second time. All learning parameters except bias terms are initialized randomly according to the Gaussian distribution $\mathcal{N}(0, 10^{-2})$. In our experiments, we tune the initial learning rate with a step size of 0.0002, and choose the best one based on the log-likelihood on the dev set at the first epoch. Empirically, the selected initial learning rates fall in the range of $[0.0004, 0.0010]$ for hidden layer size $[128, 320]$, and tend to be larger when using a smaller hidden layer size, *i.e.* $[0.0016, 0.0034]$ for hidden layer size around 80. The training data are randomly shuffled at every epoch.

4 Experiments

In this section, we present the parsing accuracy of the proposed BiAtt-DP on 14 languages. We report both UAS and labeled attachment score (LAS), obtained by the CoNLL-X eval.pl script[2] which ignores punctuation symbols. The headword predictions are made through the MST search, which slightly improves both UAS and LAS (less than 0.3% absolutely). Overall, the proposed BiAtt-DP achieves competitive parsing accuracy on all languages as state-of-the-art parsers, and obtains better UAS in 6 languages. We also show the impact of using POS tags and pre-trained word embeddings. Moreover, different variants of the full model are compared in this section.

4.1 Data

We work on the English Treebank-3 (PTB) dataset (Marcus et al., 1999), the Chinese Treebank-5.1 (CTB) dataset (Palmer et al., 2005), and 12 other languages from the CoNLL 2006 shared task (Buchholz and Marsi, 2006). For PTB and CTB datasets, we use exactly the same setup as in (Chen and Manning, 2014; Dyer et al., 2015). Specifically, we convert the English and Chinese data using the Stanford parser v3.3.0 (de Marneffe et al., 2006) and the Penn2Malt tool (Zhang and Clark, 2008), respectively.

For English, POS tags are obtained using the Stanford POS tagger v3.3.0 (Toutanova et al., 2003),

[2] http://ilk.uvt.nl/conll/software.html

whereas for Chinese, we use gold segmentation and POS tags. When constructing the token embeddings for English and Chinese, both the word form and the POS tag are used. We also initialize $\mathbf{E}^{\text{form}}$ by pre-trained word embeddings[3].

For the 12 other languages, we randomly hold out 5% of the training data as the dev set. In addition to the word form and find-grained POS tags, we use extra features such as lemmas, coarse-grained POS tags, and morphemes when they are available in the dataset. No pre-trained word embeddings are used for these 12 languages.

4.2 Model Configurations

The hidden layer size is kept the same across all RNNs in the proposed BiAtt-DP. We also require the dimension of the token embeddings to be the same as the hidden layer size. Note that we concatenate the hidden layers of two RNNs for constructing $\mathbf{m}_j$, and thus we have $e = 2d$. The weight matrices $\mathbf{C}$ and $\mathbf{D}$ respectively project vectors $\mathbf{m}_j$ and $\mathbf{q}_t$ to the same dimension h, which is equivalent to d. For English and Chinese, since the dimension of pre-trained word embeddings are 300, we use $300 \times h$ as the dimension of embedding parameters $\mathbf{E}$'s. For the 12 other languages, we use square matrices for the embedding parameters $\mathbf{E}$'s. For all languages, We tune the hidden layer size and choose one according to UAS on the dev set. The selected hidden layer sizes for these languages are: 368 (English), 114 (Chinese), 128 (Arabic), 160 (Bulgarian), 224 (Czech), 176 (Danish), 220 (Dutch), 200 (German), 128 (Japanese), 168 (Portuguese), 128 (Slovene), 144 (Spanish), 176 (Swedish), and 128 (Turkish).

4.3 Results

We first compare our parser with state-of-the-art neural transition-based dependency parsers on PTB and CTB. For English, we also compare with state-of-the-art graph-based dependency parsers. The results are shown in Table 1 and Table 2, respectively. It can be seen that the BiAtt-DP outperforms all other graph-based parsers on PTB. Compared with the transition-based parsers, it achieves better accuracy than Chen and Manning (2014), which uses a feed-forward neural network, and Dyer et al. (2015), which uses three stack LSTM networks. Compared with the integrated parsing and tagging models, the BiAtt-DP outperforms Bohnet and Nivre (2012) but has a small gap to Alberti et al. (2015). On CTB, it achieves best UAS and similar LAS. This may be caused by that the relation vocabulary size is relatively smaller than the average sentence length, which biases the joint objective to be more sensitive to UAS. The parsing speed is around 50–60 sents/sec measured on a desktop with Intel Core i7 CPU @ 3.33GHz using single thread.

Next, in Table 3 we show the parsing accuracy of the proposed BiAtt-DP on 12 languages in the CoNLL 2006 shared task, including comparison with state-of-the-art parsers. Specifically, we show UAS of the 3rd-order RBGParser as reported in (Lei et al., 2014) since it also uses low-dimensional continuous embeddings. However, there are several major differences between the RBGParser and the BiAtt-DP. First, in (Lei et al., 2014), the low-dimensional continuous embeddings are derived

Table 3: UAS on 12 languages in the CoNLL 2006 shared task (Buchholz and Marsi, 2006). We also report corresponding LAS in squared brackets. The results of the 3rd-order RBGParser are reported in (Lei et al., 2014). Best published results on the same dataset in terms of UAS among (Pitler and McDonald, 2015), (Zhang and McDonald, 2014), (Zhang et al., 2013), (Zhang and McDonald, 2012), (Rush and Petrov, 2012), (Martins et al., 2013), (Martins et al., 2010), and (Koo et al., 2010). To study the effectiveness of the parser in dealing with non-projectivity, we follow (Pitler and McDonald, 2015), to compute the recall of crossed and uncrossed arcs in the gold tree, as well as the percentage of crossed arcs.

from low-rank tensors. Second, the RBGParser uses combined scoring of arcs by including traditional features from the MSTParser (McDonald and Pereira, 2006) / TurboParser (Martins et al., 2013). Third, the RBGParser employs a third-order parsing algorithm based on (Zhang et al., 2014), although it also implements a first-order parsing algorithm, which achieves lower UAS in general. In Table 3, we show that the proposed BiAtt-DP outperforms the RBGParser in most languages except Japanese, Slovene, and Swedish.

It can be observed from Table 3 that the BiAtt-DP has highly competitive parsing accuracy as state-of-the-art parsers. Moreover, it achieves best UAS for 5 out of 12 languages. For the remaining seven languages, the UAS gaps between the BiAtt-DP and state-of-the-art parsers are within 1.0%, except Swedish. An arguably fair comparison for the BiAtt-DP is the MSTParser (McDonald and Pereira, 2006), since the BiAtt-DP replaces the scoring function for arcs but uses exactly the same search algorithm. Due to the space limit, we refer readers to (Lei et al., 2014) for results of the MSTParsers (also shown in Appendix B). The BiAtt-DP consistently outperforms both parser by up to 5% absolute UAS score.

Finally, following (Pitler and McDonald, 2015), we also analyze the performance of the BiAtt-DP on both crossed and uncrossed arcs. Since the BiAtt-DP uses a graph-based non-projective parsing algorithm, it is interesting to evaluate the performance on crossed arcs, which result in the non-projectivity of the dependency tree. The last three columns of Table 3 show the recall of crossed arcs, that of uncrossed arcs, and the percentage of crossed arcs in the test set. Pitler and McDonald (2015) reported numbers on the same data for Dutch, German, Portuguese, and Slovene as in this paper. For these four languages, the BiAtt-DP achieves better UAS than that reported in (Pitler and McDonald, 2015). More importantly, we observe that the improvement on recall of crossed arcs (around 10–18% absolutely) is much more significant than that of uncrossed arcs (around 1–3% absolutely), which indicates the effectiveness of the BiAtt-DP in parsing languages with non-projective trees.

4.4 Ablative Study

Here we try to study the impact of using pre-trained word embeddings, POS tags, as well as the bi-directional query components on our model. First of all, we start from our best model (Model 1 in Table 4) on English, which uses 300 as the token embedding dimension and 368 as the hidden layer size. We keep those model parameter dimensions unchanged and analyze different factors by comparing the parsing accuracy on PTB dev set.

No.	INIT	POS	L2R	R2L	UAS	LAS
1	✓	✓	✓	✓	93.99	91.32
2		✓	✓	✓	93.36	90.42
3			✓	✓	91.87	87.85
4		✓		✓	92.64	89.66
5		✓	✓		92.47	89.47
6		✓	✓†	✓†	93.03	90.06

Table 4: Parsing accuracy on PTB dev set for different variants of the full model. `INIT` refers to using pre-trained word embddings to initialize $\mathbf{E}^{\text{form}}$. `POS` refers to using POS tags in token embeddings. `L2R` and `R2L` respectively indicate whether to use the left-to-right and right-to-left query components. † means the query component drops soft headword embeddings when constructing RNN hidden states.

The results are summarized in Table 4. Comparing Models 1–3, it can be observed that without using pre-trained word embeddings, both UAS and LAS drop by 0.6%, and without using POS tags in token embeddings, the numbers further drop by 1.6% in UAS and around 2.6% in LAS. In terms of query components, using single query component (Models 4–5) degrades UAS by 0.7–0.9% and LAS by around 1.0%, compared with Model 2. For Model 6, the soft headword embedding is only used for arc label predictions but not fed into the next hidden state, which is around 0.3% worse than Model 2. This supports the hypothesis about the usefulness of the parsing history information. We also implement a variant of Model 6 which produces one $\mathbf{a}_t$ instead two by using both $\mathbf{q}_t^l$ and $\mathbf{q}_t^r$ in (1). It gets 92.44% UAS and 89.26% LAS, indicating that naively applying a bi-directional RNN may not be enough.

5 Related Work

Neural Dependency Parsing: Recently developed neural dependency parsers are mostly transition-based models, which read words sequentially from a buffer into a stack and incrementally build a parse tree by predicting a sequence of transitions (Yamada and Matsumoto, 2003; Nivre, 2003; Nivre, 2004). A feed-forward neural network is used in (Chen and Manning, 2014), where they represent the current state with 18 selected elements such as the top words on the stack and buffer. Each element is encoded by concatenated embeddings of words, POS tags, and arc labels. Their dependency parser achieves improvement on both accuracy and parsing speed. Weiss et al. (2015) improve the parser using semi-supervised structured learning and unlabeled data. The model is extended to integrate parsing and tagging in (Alberti et al., 2015). On the other hand, Dyer et al. (2015) develop the stack LSTM architecture, which uses three LSTMs to respectively model the sequences of buffer states, stack states, and actions. Unlike the transition-based formulation, the proposed BiAtt-DP directly predicts the headword and the dependency relation at each time step. Specifically, there is no explicit representation of actions or headwords in our model. The model learns to retrieve the most relevant information from the input memory to make decisions on headwords and head-modifier relations.

Graph-based Dependency Parsing: In addition to the transition-based parsers, another line of research in dependency parsing uses graph-based models. Graph-based parser usually build a dependency tree from a directed graph and learns to scoring the possible arcs. Due to this nature, non-projective parsing can be done straightforwardly by most graph-based dependency parsers. The MSTParser (McDonald et al., 2005) and the TurboParser (Martins et al., 2010) are two examples of graph-based parsers. The MSTParser formulates the parsing as searching for the MST, whereas the TurboParser performs approximate variational inference over a factor graph. The RBGParser proposed in (Lei et al., 2014) can also be viewed as a graph-based parser, which scores arcs using low-dimensional continuous features derived from low-rank tensors as well as features used by MSTParser/TurboParser. It also employs a sampler-based algorithm for parsing (Zhang et al., 2014).

Neural Attention Model: The proposed BiAtt-DP is closely related to the memory network (Sukhbaatar et al., 2015) for question answering, as well as the neural attention models for machine translation (Bahdanau et al., 2015) and constituency parsing (Vinyals et al., 2015b). The way we query the memory component and obtain the soft headword embeddings is essentially the attention mechanism. However, different from the above studies where the alignment information is latent, in dependency parsing, the arc between the modifier and

headword is known during training. Thus, we can utilize these labels for attention weights. The similar idea is employed by the pointer network in (Vinyals et al., 2015a), which is used to solve three different combinatorial optimization problems.

6 Conclusion

In this paper, we develop a bi-directional attention model by encouraging agreement between the latent attention alignments. Through a simple and interpretable approximation, we make the connection between latent and observed alignments for training the model. We apply the bi-directional attention model incorporating the agreement objective during training to the proposed memory-network-based dependency parser. The resulting parser is able to implicitly capture the high-order parsing history without suffering from issue of high computational complexity for graph-based dependency parsing.

We have carried out empirical studies over 14 languages. The parsing accuracy of the proposed model is highly competitive with state-of-the-art dependency parsers. For English, the proposed BiAtt-DP outperforms all graph-based parsers. It also achieves state-of-the-art performance in 6 languages in terms of UAS, demonstrating the effectiveness of the proposed mechanism of bi-directional attention with agreement and its use in dependency parsing.

A Upper Bound on $H^2(\mathbf{p}, \mathbf{q})$

Here, we use the following definition of squared Hellinger distance for countable space

$$H^2(\mathbf{p}, \mathbf{q}) = \frac{1}{2} \sum_i (\sqrt{\mathbf{p}_i} - \sqrt{\mathbf{q}_i})^2$$

where $\mathbf{p}, \mathbf{q} \in \Delta^k$ are two k-simplexes. Introducing $\mathbf{g} \in \Delta^k$, the squared Hellinger distance can be upper bounded as

$$\begin{aligned} H^2(\mathbf{p}, \mathbf{q}) &\leq \sqrt{2} H(\mathbf{p}, \mathbf{q}) && (6) \\ &\leq \sqrt{2} \left[H(\mathbf{p}, \mathbf{g}) + H(\mathbf{q}, \mathbf{g}) \right] && (7) \\ &\leq 2\sqrt{H^2(\mathbf{p}, \mathbf{g}) + H^2(\mathbf{q}, \mathbf{g})} && (8) \end{aligned}$$

where (6), (7) and (8) follow the inequalities between the ℓ_1-norm and the ℓ_2-norm, the triangle inequality defined for a metric, and the Cauchy-Schwarz's inequality, respectively. Using the relationship between the KL-divergence and the squared Hellinger distance, (8) can be further bounded by

$$2\sqrt{D(\mathbf{g}||\mathbf{p}) + D(\mathbf{g}||\mathbf{q})}.$$

B UAS Scores of MSTParsers

Abstract

We present a study on two key characteristics of human syntactic annotations: anchoring and agreement. Anchoring is a well known cognitive bias in human decision making, where judgments are drawn towards pre-existing values. We study the influence of anchoring on a standard approach to creation of syntactic resources where syntactic annotations are obtained via human editing of tagger and parser output. Our experiments demonstrate a clear anchoring effect and reveal unwanted consequences, including overestimation of parsing performance and lower quality of annotations in comparison with human-based annotations. Using sentences from the Penn Treebank WSJ, we also report systematically obtained inter-annotator agreement estimates for English dependency parsing. Our agreement results control for parser bias, and are consequential in that they are *on par* with state of the art parsing performance for English newswire. We discuss the impact of our findings on strategies for future annotation efforts and parser evaluations.[1]

1 Introduction

Research in NLP relies heavily on the availability of human annotations for various linguistic prediction tasks. Such resources are commonly treated as de facto "gold standards" and are used for both training and evaluation of algorithms for automatic annotation. At the same time, human agreement on these annotations provides an indicator for the difficulty of the task, and can be instrumental for estimating upper limits for the performance obtainable by computational methods.

Linguistic gold standards are often constructed using pre-existing annotations, generated by automatic tools. The output of such tools is then manually corrected by human annotators to produce the gold standard. The justification for this annotation methodology was first introduced in a set of experiments on POS tag annotation conducted as part of the Penn Treebank project (Marcus et al., 1993). In this study, the authors concluded that tagger-based annotations are not only much faster to obtain, but also more consistent and of higher quality compared to annotations from scratch. Following the Penn Treebank, syntactic annotation projects for various languages, including German (Brants et al., 2002), French (Abeillé et al., 2003), Arabic (Maamouri et al., 2004) and many others, were annotated using automatic tools as a starting point. Despite the widespread use of this annotation pipeline, there is, to our knowledge, little prior work on syntactic annotation quality and on the reliability of system evaluations on such data.

In this work, we present a systematic study of the influence of automatic tool output on characteristics of annotations created for NLP purposes. Our investigation is motivated by the hypothesis that annotations obtained using such methodologies may be

[1] The experimental data in this study will be made publicly available.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2215–2224,
Austin, Texas, November 1-5, 2016.

subject to the problem of *anchoring*, a well established and robust cognitive bias in which human decisions are affected by pre-existing values (Tversky and Kahneman, 1974). In the presence of anchors, participants reason relative to the existing values, and as a result may provide different solutions from those they would have reported otherwise. Most commonly, anchoring is manifested as an alignment *towards* the given values.

Focusing on the key NLP tasks of POS tagging and dependency parsing, we demonstrate that the standard approach of obtaining annotations via human correction of automatically generated POS tags and dependencies exhibits a clear anchoring effect – a phenomenon we refer to as *parser bias*. Given this evidence, we examine two potential adverse implications of this effect on parser-based gold standards.

First, we show that parser bias entails substantial overestimation of parser performance. In particular, we demonstrate that bias towards the output of a specific tagger-parser pair leads to over-estimation of the performance of these tools relative to other tools. Moreover, we observe general performance gains for automatic tools relative to their performance on human-based gold standards. Second, we study whether parser bias affects the quality of the resulting gold standards. Extending the experimental setup of Marcus et al. (1993), we demonstrate that parser bias may lead to *lower* annotation quality for parser-based annotations compared to human-based annotations.

Furthermore, we conduct an experiment on inter-annotator agreement for POS tagging and dependency parsing which controls for parser bias. Our experiment on a subset of section 23 of the WSJ Penn Treebank yields agreement rates of 95.65 for POS tagging and 94.17 for dependency parsing. This result is significant in light of the state of the art tagging and parsing performance for English newswire. With parsing reaching the level of human agreement, and tagging surpassing it, a more thorough examination of evaluation resources and evaluation methodologies for these tasks is called for.

To summarize, we present the first study to measure and analyze anchoring in the standard parser-based approach to creation of gold standards for POS tagging and dependency parsing in NLP. We conclude that gold standard annotations that are based on editing output of automatic tools can lead to inaccurate figures in system evaluations and lower annotation quality. Our human agreement experiment, which controls for parser bias, yields agreement rates that are comparable to state of the art automatic tagging and dependency parsing performance, highlighting the need for a more extensive investigation of tagger and parser evaluation in NLP.

2 Experimental Setup

2.1 Annotation Tasks

We examine two standard annotation tasks in NLP, POS tagging and dependency parsing. In the POS tagging task, each word in a sentence has to be categorized with a Penn Treebank POS tag (Santorini, 1990) (henceforth POS). The dependency parsing task consists of providing a sentence with a labeled dependency tree using the Universal Dependencies (UD) formalism (De Marneffe et al., 2014), according to version 1 of the UD English guidelines[2]. To perform this task, the annotator is required to specify the head word index (henceforth HIND) and relation label (henceforth REL) of each word in the sentence.

We distinguish between three variants of these tasks, *annotation*, *reviewing* and *ranking*. In the annotation variant, participants are asked to conduct annotation from scratch. In the reviewing variant, they are asked to provide alternative annotations for all annotation tokens with which they disagree. The participants are not informed about the source of the given annotation, which, depending on the experimental condition can be either parser output or human annotation. In the ranking task, the participants rank several annotation options with respect to their quality. Similarly to the review task, the participants are not given the sources of the different annotation options. Participants performing the annotation, reviewing and ranking tasks are referred to as annotators, reviewers and judges, respectively.

2.2 Annotation Format

All annotation tasks are performed using a CoNLL style text-based template, in which each word appears in a separate line. The first two columns of each line contain the word index and the word, re-

[2] http://universaldependencies.org/#en

spectively. The next three columns are designated for annotation of POS, HIND and REL.

In the annotation task, these values have to be specified by the annotator from scratch. In the review task, participants are required to edit pre-annotated values for a given sentence. The sixth column in the review template contains an additional # sign, whose goal is to prevent reviewers from overlooking and passively approving existing annotations. Corrections are specified following this sign in a space separated format, where each of the existing three annotation tokens is either corrected with an alternative annotation value or approved using a * sign. Approval of all three annotation tokens is marked by removing the # sign. The example below presents a fragment from a sentence used for the reviewing task, in which the reviewer approves the annotations of all the words, with the exception of "help", where the POS is corrected from VB to NN and the relation label *xcomp* is replaced with *dobj*.

```
...
5   you         PRP   6    nsubj
6   need        VBP   3    ccomp
7   help        VB    6    xcomp  # NN * dobj
...
```

The format of the ranking task is exemplified below. The annotation options are presented to the participants in a random order. Participants specify the rank of each annotation token following the vertical bar. In this sentence, the label *cop* is preferred over *aux* for the word "be" and *xcomp* is preferred over *advcl* for the word "Common".

```
...
8   it          PRP   10   nsubjpass
9   is          VBZ   10   auxpass
10  planed      VBN   0    root
11  to          TO    15   mark
12  be          VB    15   aux-cop | 2-1
13  in          IN    15   case
14  Wimbledon   NNP   15   compound
15  Common      NNP   10   advcl-xcomp | 2-1
...
```

The participants used basic validation scripts which checked for typos and proper formatting of the annotations, reviews and rankings.

2.3 Evaluation Metrics

We measure both parsing performance and inter-annotator agreement using tagging and parsing evaluation metrics. This choice allows for a direct comparison between parsing and agreement results. In this context, POS refers to tagging accuracy. We utilize the standard metrics Unlabeled Attachment Score (UAS) and Label Accuracy (LA) to measure accuracy of head attachment and dependency labels. We also utilize the standard parsing metric Labeled Attachment Score (LAS), which takes into account both dependency arcs and dependency labels. In all our parsing and agreement experiments, we exclude punctuation tokens from the evaluation.

2.4 Corpora

We use sentences from two publicly available datasets, covering two different genres. The first corpus, used in the experiments in sections 3 and 4, is the First Certificate in English (FCE) Cambridge Learner Corpus (Yannakoudakis et al., 2011). This dataset contains essays authored by upper-intermediate level English learners[3].

The second corpus is the WSJ part of the Penn Treebank (WSJ PTB) (Marcus et al., 1993). Since its release, this dataset has been the most commonly used resource for training and evaluation of English parsers. Our experiment on inter-annotator agreement in section 5 uses a random subset of the sentences in section 23 of the WSJ PTB, which is traditionally reserved for tagging and parsing evaluation.

2.5 Annotators

We recruited five students at MIT as annotators. Three of the students are linguistics majors and two are engineering majors with linguistics minors. Prior to participating in this study, the annotators completed two months of training. During training, the students attended tutorials, and learned the annotation guidelines for PTB POS tags, UD guidelines, as well as guidelines for annotating challenging syntactic structures arising from grammatical errors. The students also annotated individually six

[3]The annotation bias and quality results reported in sections 3 and 4 use the original learner sentences, which contain grammatical errors. These results were replicated on the error corrected versions of the sentences.

practice batches of 20-30 sentences from the English Web Treebank (EWT) (Silveira et al., 2014) and FCE corpora, and resolved annotation disagreements during group meetings.

Following the training period, the students annotated a treebank of learner English (Berzak et al., 2016) over a period of five months, three of which as a full time job. During this time, the students continued attending weekly meetings in which further annotation challenges were discussed and resolved. The annotation was carried out for sentences from the FCE dataset, where both the original and error corrected versions of each sentence were annotated and reviewed. In the course of the annotation project, each annotator completed approximately 800 sentence annotations, and a similar number of sentence reviews. The annotations and reviews were done in the same format used in this study. With respect to our experiments, the extensive experience of our participants and their prior work as a group strengthen our results, as these characteristics reduce the effect of anchoring biases and increase inter-annotator agreement.

3 Parser Bias

Our first experiment is designed to test whether expert human annotators are biased towards POS tags and dependencies generated by automatic tools. We examine the common out-of-domain annotation scenario, where automatic tools are often trained on an existing treebank in one domain, and used to generate initial annotations to speed-up the creation of a gold standard for a new domain. We use the EWT UD corpus as the existing gold standard, and a sample of the FCE dataset as the new corpus.

Procedure

Our experimental procedure, illustrated in figure 1(a) contains a set of 360 sentences (6,979 tokens) from the FCE, for which we generate three gold standards: one based on human annotations and two based on parser outputs. To this end, for each sentence, we assign *at random* four of the participants to the following annotation and review tasks. The fifth participant is left out to perform the quality ranking task described in section 4.

The first participant annotates the sentence from scratch, and a second participant reviews this annotation. The overall agreement of the reviewers with the annotators is 98.24 POS, 97.16 UAS, 96.3 LA and 94.81 LAS. The next two participants review parser outputs. One participant reviews an annotation generated by the Turbo tagger and parser (Martins et al., 2013). The other participant reviews the output of the Stanford tagger (Toutanova et al., 2003) and RBG parser (Lei et al., 2014). The taggers and parsers were trained on the gold annotations of the EWT UD treebank, version 1.1. Both parsers use predicted POS tags for the FCE sentences.

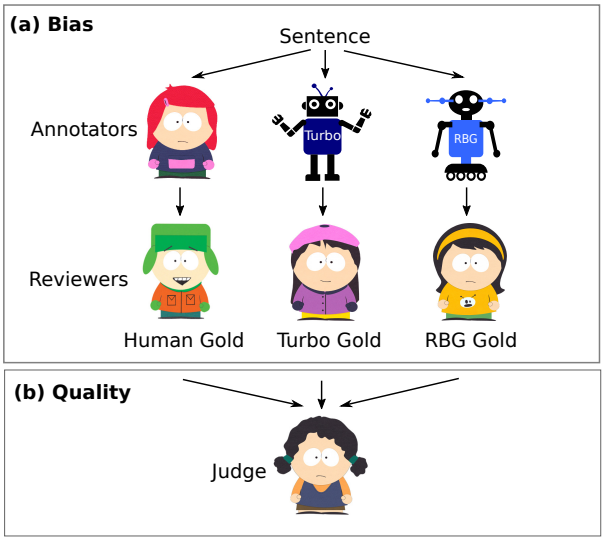

Figure 1: Experimental setup for parser bias (a) and annotation quality (b) on 360 sentences (6,979 tokens) from the FCE. For each sentence, five human annotators are assigned at random to one of three roles: annotation, review or quality assessment. In the bias experiment, presented in section 3, every sentence is annotated by a human, Turbo parser (based on Turbo tagger output) and RBG parser (based on Stanford tagger output). Each annotation is reviewed by a different human participant to produce three gold standards of each sentence: "Human Gold", "Turbo Gold" and "RBG Gold". The fifth annotator performs a quality assessment task described in section 4, which requires to rank the three gold standards in cases of disagreement.

Assigning the reviews to the human annotations yields a human based gold standard for each sentence called "Human Gold". Assigning the reviews to the tagger and parser outputs yields two parser-based gold standards, "Turbo Gold" and "RBG Gold". We chose the Turbo-Turbo and Stanford-RBG tagger-parser pairs as these tools obtain comparable performance on standard evaluation bench-

	Turbo				RBG			
	POS	UAS	LA	LAS	POS	UAS	LA	LAS
Human Gold	95.32	87.29	88.35	82.29	95.59	87.19	88.03	82.05
Turbo Gold	**97.62**	**91.86**	**92.54**	**89.16**	*96.64*	*89.16*	*89.75*	*84.86*
Error Reduction %	49.15	35.96	35.97	38.79	23.81	15.38	14.37	15.65
RBG Gold	96.43	*88.65*	*89.95*	*84.42*	**97.76**	**91.22**	**91.84**	**87.87**
Error Reduction %	23.72	10.7	13.73	12.03	49.21	31.46	31.83	32.42

Table 1: Annotator bias towards taggers and parsers on 360 sentences (6,979 tokens) from the FCE. Tagging and parsing results are reported for the Turbo parser (based on the output of the turbo Tagger) and RBG parser (based on the output of the Stanford tagger) on three gold standards. Human Gold are manual corrections of human annotations. Turbo Gold are manual corrections of the output of Turbo tagger and Turbo parser. RBG Gold are manual corrections of the Stanford tagger and RBG parser. Error reduction rates are reported relative to the results obtained by the two tagger-parser pairs on the Human Gold annotations. Note that (1) The parsers perform equally well on Human Gold. (2) Each parser performs better than the other parser on its own reviews. (3) Each parser performs better on the reviews of the other parser compared to its performance on Human Gold. The differences in (2) and (3) are statistically significant with $p \ll 0.001$ using McNemar's test.

marks, while yielding substantially different annotations due to different training algorithms and feature sets. For our sentences, the agreement between the Turbo tagger and Stanford tagger is 96.97 POS. The agreement between the Turbo parser and RBG parser based on the respective tagger outputs is 90.76 UAS, 91.6 LA and 87.34 LAS.

Parser Specific and Parser Shared Bias

In order to test for parser bias, in table 1 we compare the performance of the Turbo-Turbo and Stanford-RBG tagger-parser pairs on our three gold standards. First, we observe that while these tools perform equally well on Human Gold, each tagger-parser pair performs better than the other on its own reviews. These *parser specific* performance gaps are substantial, with an average of 1.15 POS, 2.63 UAS, 2.34 LA and 3.88 LAS between the two conditions. This result suggests the presence of a bias towards the output of specific tagger-parser combinations. The practical implication of this outcome is that a gold standard created by editing an output of a parser is likely to boost the performance of that parser in evaluations and over-estimate its performance relative to other parsers.

Second, we note that the performance of each of the parsers on the gold standard of the other parser is still higher than its performance on the human gold standard. The average performance gap between these conditions is 1.08 POS, 1.66 UAS, 1.66 LA and 2.47 LAS. This difference suggests an annotation bias towards *shared* aspects in the predictions of taggers and parsers, which differ from the human based annotations. The consequence of this observation is that irrespective of the specific tool that was used to pre-annotate the data, parser-based gold standards are likely to result in higher parsing performance relative to human-based gold standards.

Taken together, the parser specific and parser shared effects lead to a dramatic overall average error reduction of 49.18% POS, 33.71% UAS, 34.9% LA and 35.61% LAS on the parser-based gold standards compared to the human-based gold standard. To the best of our knowledge, these results are the first systematic demonstration of the tendency of the common approach of parser-based creation of gold standards to yield biased annotations and lead to overestimation of tagging and parsing performance.

4 Annotation Quality

In this section we extend our investigation to examine the impact of parser bias on the quality of parser-based gold standards. To this end, we perform a manual comparison between human-based and parser-based gold standards.

Our quality assessment experiment, depicted schematically in figure 1(b), is a ranking task. For each sentence, a randomly chosen judge, who did not annotate or review the given sentence, ranks disagreements between the three gold standards Human Gold, Turbo Gold and RBG Gold, generated in the parser bias experiment in section 3.

Table 2 presents the preference rates of judges

Human Gold Preference %	POS	HIND	REL
Turbo Gold	64.32*	63.96*	61.5*
# disagreements	199	444	439
RBG Gold	56.72	61.38*	57.73*
# disagreements	201	435	440

Table 2: Human preference rates for a human-based gold standard Human Gold over the two parser-based gold standards Turbo Gold and RBG Gold. # disagreements denotes the number of tokens that differ between Human Gold and the respective parser-based gold standard. Statistically significant values for a two-tailed Z test with $p < 0.01$ are marked with *. Note that for both tagger-parser pairs, human judges tend to prefer human-based over parser-based annotations.

for the human-based gold standard over each of the two parser-based gold standards. In all three evaluation categories, human judges tend to prefer the human-based gold standard over both parser-based gold standards. This result demonstrates that the initial reduced quality of the parser outputs compared to human annotations indeed percolates via anchoring to the resulting gold standards.

The analysis of the quality assessment experiment thus far did not distinguish between cases where the two parsers agree and where they disagree. In order to gain further insight into the relation between parser bias and annotation quality, we break down the results reported in table 2 into two cases which relate directly to the *parser specific* and *parser shared* components of the tagging and parsing performance gaps observed in the parser bias results reported in section 3. In the first case, called "parser specific approval", a reviewer approves a parser annotation which disagrees both with the output of the other parser and the Human Gold annotation. In the second case, called "parser shared approval", a reviewer approves a parser output which is shared by both parsers but differs with respect to Human Gold.

Table 3 presents the judge preference rates for the Human-Gold annotations in these two scenarios. We observe that cases in which the parsers disagree are of substantially worse quality compared to human-based annotations. However, in cases of agreement between the parsers, the resulting gold standards do not exhibit a clear disadvantage relative to the Human Gold annotations.

This result highlights the crucial role of parser

Human Gold Preference %	POS	HIND	REL
Turbo specific approval	85.42*	78.69*	80.73*
# disagreements	48	122	109
RBG specific approval	73.81*	77.98*	77.78*
# disagreements	42	109	108
Parser shared approval	51.85	58.49*	51.57
# disagreements	243	424	415

Table 3: Breakdown of the Human preference rates for the human-based gold standard over the parser-based gold standards in table 2, into cases of agreement and disagreement between the two parsers. Parser specific approval are cases in which a parser output approved by the reviewer differs from both the output of the other parser and the Human Gold annotation. Parser shared approval denotes cases where an approved parser output is identical to the output of the other parser but differs from the Human Gold annotation. Statistically significant values for a two-tailed Z test with $p < 0.01$ are marked with *. Note that parser specific approval is substantially more detrimental to the resulting annotation quality compared to parser shared approval.

specific approval in the overall preference of judges towards human-based annotations in table 2. Furthermore, it suggests that annotations on which multiple state of the art parsers agree are of sufficiently high accuracy to be used to save annotation time without substantial impact on the quality of the resulting resource. In section 7 we propose an annotation scheme which leverages this insight.

5 Inter-annotator Agreement

Agreement estimates in NLP are often obtained in annotation setups where both annotators edit the same automatically generated input. However, in such experimental conditions, anchoring can introduce cases of spurious disagreement as well as spurious agreement between annotators due to alignment of one or both participants towards the given input. The initial quality of the provided annotations in combination with the parser bias effect observed in section 3 may influence the resulting agreement estimates. For example, in Marcus et al. (1993) annotators were shown to produce POS tagging agreement of 92.8 on annotation from scratch, compared to 96.5 on reviews of tagger output.

Our goal in this section is to obtain estimates for inter-annotator agreement on POS tagging and dependency parsing that control for parser bias, and

as a result, reflect more accurately human agreement on these tasks. We thus introduce a novel pipeline based on human annotation only, which eliminates parser bias from the agreement measurements. Our experiment extends the human-based annotation study of Marcus et al. (1993) to include also syntactic trees. Importantly, we include an additional review step for the initial annotations, designed to increase the precision of the agreement measurements by reducing the number of errors in the original annotations.

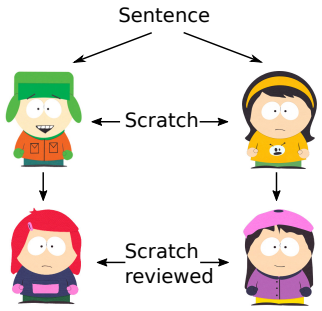

Figure 2: Experimental setup for the inter-annotator agreement experiment. 300 sentences (7,227 tokens) from section 23 of the PTB-WSJ are annotated and reviewed by four participants. The participants are assigned to the following tasks *at random* for each sentence. Two participants annotate the sentence from scratch, and the remaining two participants review one of these annotations each. Agreement is measured on the annotations ("scratch") as well after assigning the review edits ("scratch reviewed").

For this experiment, we use 300 sentences (7,227 tokens) from section 23 of the PTB-WSJ, the standard test set for English parsing in NLP. The experimental setup, depicted graphically in figure 2, includes four participants randomly assigned for each sentence to annotation and review tasks. Two of the participants provide the sentence with annotations from scratch, while the remaining two participants provide reviews. Each reviewer edits one of the annotations independently, allowing for correction of annotation errors while maintaining the independence of the annotation sources. We measure agreement between the initial annotations ("scratch"), as well as the agreement between the reviewed versions of our sentences ("scratch reviewed").

The agreement results for the annotations and the reviews are presented in table 4. The initial agreement rate on POS annotation from scratch is higher than in (Marcus et al., 1993). This difference is likely to arise, at least in part, due to the fact that their experiment was conducted at the beginning of the annotation project, when the annotators had a more limited annotation experience compared to our participants. Overall, we note that the agreement rates from scratch are relatively low. The review round raises the agreement on all the evaluation categories due to elimination of annotation errors present the original annotations.

	POS	UAS	LA	LAS
scratch	94.78	93.07	92.3	88.32
scratch reviewed	**95.65**	**94.17**	**94.04**	**90.33**

Table 4: Inter-annotator agreement on 300 sentences (7,227 tokens) from the PTB-WSJ section 23. "scratch" is agreement on independent annotations from scratch. "scratch reviewed" is agreement on the same sentences after an additional independent review round of the annotations.

Our post-review agreement results are consequential in light of the current state of the art performance on tagging and parsing in NLP. For more than a decade, POS taggers have been achieving over 97% accuracy with the PTB POS tag set on the PTB-WSJ test set. For example, the best model of the Stanford tagger reported in Toutanova et al. (2003) produces an accuracy of 97.24 POS on sections 22-24 of the PTB-WSJ. These accuracies are above the human agreement in our experiment.

With respect to dependency parsing, recent parsers obtain results which are on par or higher than our inter-annotator agreement estimates. For example, Weiss et al. (2015) report 94.26 UAS and Andor et al. (2016) report 94.61 UAS on section 23 of the PTB-WSJ using an automatic conversion of the PTB phrase structure trees to Stanford dependencies (De Marneffe et al., 2006). These results are not fully comparable to ours due to differences in the utilized dependency formalism and the automatic conversion of the annotations. Nonetheless, we believe that the similarities in the tasks and evaluation data are sufficiently strong to indicate that dependency parsing for standard English newswire may be reaching human agreement levels.

6 Related Work

The term "anchoring" was coined in a seminal paper by Tversky and Kahneman (1974), which demonstrated that numerical estimation can be biased by uninformative prior information. Subsequent work across various domains of decision making confirmed the robustness of anchoring using both informative and uninformative anchors (Furnham and Boo, 2011). Pertinent to our study, anchoring biases were also demonstrated when the participants were domain experts, although to a lesser degree than in the early anchoring experiments (Wilson et al., 1996; Mussweiler and Strack, 2000).

Prior work in NLP examined the influence of pre-tagging (Fort and Sagot, 2010) and pre-parsing (Skjærholt, 2013) on human annotations. Our work introduces a systematic study of this topic using a novel experimental framework as well as substantially more sentences and annotators. Differently from these studies, our methodology enables characterizing annotation bias as anchoring and measuring its effect on tagger and parser evaluations.

Our study also extends the POS tagging experiments of Marcus et al. (1993), which compared inter-annotator agreement and annotation quality on manual POS tagging in annotation from scratch and tagger-based review conditions. The first result reported in that study was that tagger-based editing increases inter-annotator agreement compared to annotation from scratch. Our work provides a novel agreement benchmark for POS tagging which reduces annotation errors through a review process while controlling for tagger bias, and obtains agreement measurements for dependency parsing. The second result reported in Marcus et al. (1993) was that tagger-based edits are of higher quality compared to annotations from scratch when evaluated against an additional independent annotation. We modify this experiment by introducing ranking as an alternative mechanism for quality assessment, and adding a review round for human annotations from scratch. Our experiment demonstrates that in this configuration, parser-based annotations are of *lower* quality compared to human-based annotations.

Several estimates of expert inter-annotator agreement for English parsing were previously reported. However, most such evaluations were conducted using annotation setups that can be affected by an anchoring bias (Carroll et al., 1999; Rambow et al., 2002; Silveira et al., 2014). A notable exception is the study of Sampson and Babarczy (2008) who measure agreement on annotation from scratch for English parsing in the SUSANNE framework (Sampson, 1995). The reported results, however, are not directly comparable to ours, due to the use of a substantially different syntactic representation, as well as a different agreement metric. Their study further suggests that despite the high expertise of the annotators, the main source of annotation disagreements was annotation errors. Our work alleviates this issue by using annotation reviews, which reduce the number of erroneous annotations while maintaining the independence of the annotation sources. Experiments on non-expert dependency annotation from scratch were previously reported for French, suggesting low agreement rates (79%) with an expert annotation benchmark (Gerdes, 2013).

7 Discussion

We present a systematic study of the impact of anchoring on POS and dependency annotations used in NLP, demonstrating that annotators exhibit an anchoring bias effect towards the output of automatic annotation tools. This bias leads to an artificial boost of performance figures for the parsers in question and results in lower annotation quality as compared with human-based annotations.

Our analysis demonstrates that despite the adverse effects of parser bias, predictions that are shared across different parsers do not significantly lower the quality of the annotations. This finding gives rise to the following *hybrid annotation* strategy as a potential future alternative to human-based as well as parser-based annotation pipelines. In a hybrid annotation setup, human annotators review annotations on which several parsers agree, and complete the remaining annotations from scratch. Such a strategy would largely maintain the annotation speed-ups of parser-based annotation schemes. At the same time, it is expected to achieve annotation quality comparable to human-based annotation by avoiding parser specific bias, which plays a pivotal role in the reduced quality of single-parser reviewing pipelines.

Further on, we obtain, to the best of our knowl-

edge for the first time, syntactic inter-annotator agreement measurements on WSJ-PTB sentences. Our experimental procedure reduces annotation errors and controls for parser bias. Despite the detailed annotation guidelines, the extensive experience of our annotators, and their prior work as a group, our experiment indicates rather low agreement rates, which are below state of the art tagging performance and on par with state of the art parsing results on this dataset. We note that our results do not necessarily reflect an upper bound on the achievable syntactic inter-annotator agreement for English newswire. Higher agreement rates could in principle be obtained through further annotator training, refinement and revision of annotation guidelines, as well as additional automatic validation tests for the annotations. Nonetheless, we believe that our estimates reliably reflect a realistic scenario of expert syntactic annotation.

The obtained agreement rates call for a more extensive examination of annotator disagreements on parsing and tagging. Recent work in this area has already proposed an analysis of expert annotator disagreements for POS tagging in the absence of annotation guidelines (Plank et al., 2014). Our annotations will enable conducting such studies for annotation with guidelines, and support extending this line of investigation to annotations of syntactic dependencies. As a first step towards this goal, we plan to carry out an in-depth analysis of disagreement in the collected data, characterize the main sources of inconsistent annotation and subsequently formulate further strategies for improving annotation accuracy. We believe that better understanding of human disagreements and their relation to disagreements between humans and parsers will also contribute to advancing evaluation methodologies for POS tagging and syntactic parsing in NLP, an important topic that has received only limited attention thus far (Schwartz et al., 2011; Plank et al., 2015).

Finally, since the release of the Penn Treebank in 1992, it has been serving as the standard benchmark for English parsing evaluation. Over the past few years, improvements in parsing performance on this dataset were obtained in small increments, and are commonly reported without a linguistic analysis of the improved predictions. As dependency parsing performance on English newswire may be reaching human expert agreement, not only new evaluation practices, but also more attention to noisier domains and other languages may be in place.

Tense Manages to Predict Implicative Behavior in Verbs

Ellie Pavlick

Abstract

Implicative verbs (e.g. *manage*) entail their complement clauses, while non-implicative verbs (e.g. *want*) do not. For example, while *managing to solve the problem* entails *solving the problem*, no such inference follows from *wanting to solve the problem*. Differentiating between implicative and non-implicative verbs is therefore an essential component of natural language understanding, relevant to applications such as textual entailment and summarization. We present a simple method for predicting implicativeness which exploits known constraints on the tense of implicative verbs and their complements. We show that this yields an effective, data-driven way of capturing this nuanced property in verbs.

1 Overview

Understanding language requires the ability to perform basic inference– to make conclusions about what is likely true or false based on what is said. For example, given the sentence *She fixed the bug*, we should almost certainly infer that *the bug is fixed*. However, rather than stating plainly that *She fixed the bug*, one might instead say:

(1a) She **managed to fix** the bug before midnight.

(1b) She **happened to fix** the bug while refactoring.

In either case, the hearer should still infer that *the bug is fixed*. But it is not as easy as always inferring that embedded clauses are true. By changing only one word, these sentence no longer give a clear indication as to whether or not the bug has been fixed:

(2a) She **wanted to fix** the bug before midnight.

(2b) She **planned to fix** the bug while refactoring.

Implicative verbs, like those in (1), give rise to entailments, while non-implicative verbs, like those in (2), do not. It is therefore vital to natural language understanding to differentiate between clauses that are embedded under implicatives, which we can often infer to be either true or false, and those which are embedded under non-implicatives, for which such inferences cannot be made. In this paper, we exploit a known linguistic property of implicative verbs– that their complement clause is constrained to be in the same tense as the main clause– in order to predict the tendency of verbs to behave implicatively. We show that our method almost perfectly separates non-implicatives from implicatives in a small hand-labeled dataset, and that it provides strong signal for predicting entailments in sentences involving implicative verbs.

2 Implicative Verbs

Some English verbs can take infinitival complements, meaning they can appear in constructions of the form VB_1^* *to* VB_2, where VB_1^* is the "main" verb (which can be conjugated[1]) and VB_2 is the "complement" verb (which is in infinitive form). Examples (1a)-(2b) illustrate verbs taking infinitive complements.

Implicative verbs are a special subclass[2] of such verbs which give rise to entailments involving their

[1]Here, * indicates that VB_1 can match any verb form, e.g. VB, VBD, VBP, etc. VB_2 can only match the base form VB.

[2]We note that *factive verbs* represent another special class of verbs which can take infinitival complements. Unlike implica-

Austin, Texas, November 1-5, 2016.

	Is the main verb negated?	Is the complement entailed?	Example
Implicative	−	Yes	I managed to solve the problem. ⇒ I solved the problem.
Implicative	+	No	I did not manage to solve the problem. ⇒ I did not solve the problem.
Implicative	−	No	I failed to solve the problem. ⇒ I did not solve the problem.
Implicative	+	Yes	I did not fail to solve the problem. ⇒ I solved the problem.
Non-Impl.	−	Unknown	I wanted to solve the problem. ⇏ I solved the problem.
Non-Impl.	+	Unknown	I did not want to solve the problem. ⇏ I did not solve the problem.

Table 1: Implicative verbs give rise to entailments involving their complement clauses. Non-implicatives entail neither the truth nor the falsity of their complements, and thus the truth/falsity of the complement is unaffected by negation of the main clause.

complement clauses. Individual implicatives can differ in the entailments they generate: e.g. while *manage* entails the truth of its complement, *fail* entails the falsity of its complement (*failed to solve the problem ⇒ didn't solve the problem*). Despite these differences, however, implicatives represent a coherent class of verbs in that they permit some inference to be made about their complements, and this inference is sensitive to the context (positive/negated) of the main clause. This contrasts with *non-implicative verbs*, like *want*, which do not permit any inference regarding their complements, and for which the truth of the complement is unaffected by negation in the main clause (Table 1).

The method described in this paper aims to separate implicatives from non-implicatives (*manage* vs. *want*), rather than to differentiate between types implicatives (*manage* vs. *fail*). Making this implicative/non-implicative distinction is a necessary first step toward handling inferences involving embedded clauses, and one that, to date, has only been performed using manually-constructed word lists (MacCartney, 2009; Recasens et al., 2013).

2.1 Tense Constraints on Complement Clauses

Karttunen (1971) observed that, in sentences involving implicatives, the tense of the main verb must necessarily match the tense of the complement clause. For example, (3), in which the main clause and the complement are both in the past tense, is acceptable but (4), in which the complement is in the future, is clearly not. For non-implicatives, however, no such constraint exists: (6) is perfectly felicitous.

(3) I managed to solve the problem last night.

(4) #I managed to solve the problem tomorrow.

(5) I planned to solve the problem last night.

(6) I planned to solve the problem tomorrow.

We exploit this property to predict *implicativeness*– whether the truth of a verb's complement can be inferred– by observing the verb's usage in practice.

3 Method

We hypothesize that, given a large corpus, we should be able to distinguish implicative verbs from non-implicative verbs by observing how often the main verb tense agrees/disagrees with the tense of the complement clause. Unfortunately, verbs in infinitival complement clauses are not conjugated, and so are not necessarily marked for tense. We therefore use the Stanford Temporal Tagger (TT) (Chang and Manning, 2012) in order to identify time-referring expressions (e.g. *tomorrow* or *last night*) and resolve them to either past, present, or future tense.

We find all sentences containing VB_1^* *to* VB_2 constructions in the Annotated Gigaword corpus (Napoles et al., 2012). We run the the TT over all of the sentences in order to identify time-referring expressions. We only consider sentences in which a time-referring expression appears and is in a direct dependency relationship with the complement verb (VB_2). We provide the TT with the document publication dates,[3] which are used to resolve each time mention to a specific calendar date and time. We then map these time expressions coarsely to either past, present, or future tense by comparing the

tives, factives presuppose, rather than entail, their complements. E.g. both *I was/was not glad to solve the problem* entail *I solved the problem*. We do not address factives here, as factives rarely take infinitival complements: more often, they take "that" complements (e.g. *know that, realize that*). Factives that do take infinitival complements are mostly phrasal (e.g. *be glad to*).

[3] Provided as metadata in the Annotated Gigaword.

resolved time to the document creation time. Because of the fact that days were often not resolved correctly, or at all, we eventually throw away sentences in which the complement clause is labeled as present tense, as these are rarely true references to the present, and rather the result of incorrect time resolution, or implicit future references (e.g. *I am going to solve the problem today* implies the future as in *later today*, but this is not captured by the TT). We also assign the main clause to past, present, or future tense by using the fine-grained POS tag and a set of heuristics (for example, to check for modals).[4]

We assign a *tense agreement* score to each verb v as follows. Let S be the set of all VB_1^* *to* VB_2 constructions in which $VB_1^* = v$. Then tense agreement is simply $\frac{1}{|S|} \times |\{s \in S \mid \text{complement tense = main tense}\}|$, i.e. the fraction of constructions in S in which the tenses of the main and complement clauses agree. We expect implicative verbs to occur mostly in agreeing constructions, and thus have high tense agreement, while non-implicatives may occur in both agreeing and non-agreeing constructions, and thus should have lower tense agreement. Note that while in theory, implicatives should never appear in non-agreeing constructions, the time annotation process is very imprecise, and thus we do not expect perfect results.

4 Evaluation

Recreating list from Karttunen (1971). Karttunen (1971) provides a short illustrative list of 7 known implicatives[5] and 8 non-implicatives (shown in Table 2). As a first evaluation, we test whether tense agreement can accurately separate the verbs in this list, such that the implicatives are assigned higher agreement scores than the non-implicatives. Table 2 shows that this is indeed the case. Tense agreement almost perfectly divides the list, with implicative verbs appearing above non-implicative verbs in all cases. The one exception is *decide* (reportedly non-implicative), which appears above *dare* (reportedly implicative). This error, however, seems understandable: while *decide* is not strictly implicative in the way *manage* is, it is often used as an implicative. E.g. the sentence *I decided to leave* would likely be taken to mean *I left*.

venture to	1.00	try to	0.42
forget to	0.80	agree to	0.34
manage to	0.79	promise to	0.22
bother to	0.61	want to	0.14
happen to	0.59	intend to	0.12
get to	0.52	plan to	0.10
decide to	0.45	hope to	0.03
dare to	0.44		

Table 2: Tense agreement scores for known implicatives (bold) and non-implicatives listed in Karttunen (1971). Ranking by tense agreement almost perfectly divides the two classes.

Predicting Entailment. Our interest is not in distinguishing implicatives from non-implicatives for its own sake, but rather to predict, based on the main verb, whether the truth of the complement can be inferred. We therefore conduct a second evaluation to assess how well tense agreement predicts this entailment property. We design our evaluation following the recognizing textual entailment (RTE) task (Dagan et al., 2006), in which two sentences are given, a premise p and a hypothesis h, and the goal is to determine whether p reasonably entails h. To construct our p/h pairs, we take all the verbs extracted in Section 3 which appear in at least 50 tense-labeled sentences. For each of these verbs, we choose 3 random sentences in which the verb appears as VB_1^* in a VB_1^* *to* VB_2 construction.[6] From each sentence, we extract the complement clause by deleting VB_1^* *to* from the sentence, and conjugating VB_2 to match the tense of VB_1^*. We then use the original sentence as p and the extracted complement as h: e.g. a p/h pair might look like *I get to interact with fellow professors/I interact with fellow professors*. We ask 5 independent annotators on Amazon Mechanical Turk to read each p and then determine whether h is true, false, or unclear given p.[7] We take the majority answer as the true label. We expect that implicative verbs should lead to judgements which are decidedly true or false while non-implicatives should lead

[4] Full set of heuristics in supplementary material.

[5] The original list had 8 implicatives, but we omit *remember* since, in our data, it occurred almost exclusively with recurring time expressions, which we were not able to map to a specific date/time and thus tense, e.g. *consumers must remember to make payments every 14 days*.

[6] These sentences can come from anywhere in the Gigaword corpus, they are not required to contain time expressions.

[7] Full annotation guidelines in supplementary material.

(**0.14**) UFJ **wants to merge** with Mitsubishi, a combination that'd surpass Citigroup as the world's biggest bank. $\not\Rightarrow$ The merger of Japanese Banks creates the world's biggest bank.
(**0.55**) After graduating, Gallager **chose to accept** a full scholarship to play football for Temple University. $\Rightarrow$ Gallager attended Temple University.
(**0.68**) Wilkins **was allowed to leave** in 1987 to join French outfit Paris Saint-Germain. $\Rightarrow$ Wilkins departed Milan in 1987.

Table 3: Examples from the RTE3 dataset (Giampiccolo et al., 2007) which require recognizing implicative behavior, even in verbs that are not implicative by definition. The tendency of certain verbs (e.g. *be allowed*) to behave as *de facto* implicatives is captured surprisingly well by the tense agreement score (shown in parentheses).

to mostly judgements of unclear.

Figure 1 shows that these expectations hold. When a verb with low tense agreement appeared as the main verb of a sentence, the truth of the complement could only be inferred 30% of the time. When a verb with high tense agreement appeared as the main verb, the truth of the complement could be inferred 91% of the time. This difference is significant at $p < 0.01$. That is, tense agreement provides a strong signal for identifying non-implicative verbs, and thus can help systems avoid false-positive entailment judgements, e.g. incorrectly inferring that *wanting to merge* $\Rightarrow$ *merging* (Table 3).

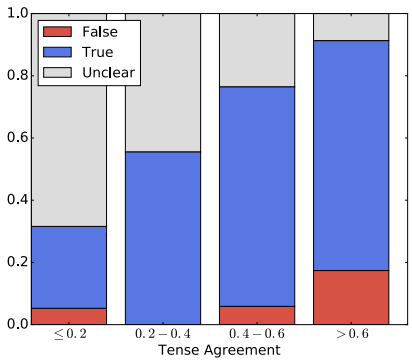

Figure 1: Whether or not complement is entailed for main verbs with varying levels of tense agreement. Verbs with high tense agreement yield more definitive judgments (true/false). Each bar represents aggregated judgements over approx. 20 verbs.

Interestingly, tense agreement accurately models verbs that are not implicative by definition, but which nonetheless tend to behave implicatively in practice. For example, our method finds high tense agreement for *choose to* and *be allowed to*, which are often used to communicate, albeit indirectly, that their complements did in fact happen. To convince ourselves that treating such verbs as implicatives makes sense in practice, we manually look through the RTE3 dataset (Giampiccolo et al., 2007) for examples containing high-scoring verbs according to our method. Table 3 shows some example inferences that hinge precisely on recognizing these types of *de facto* implicatives.

5 Discussion and Related Work

Language understanding tasks such as RTE (Clark et al., 2007; MacCartney, 2009) and bias detection (Recasens et al., 2013) have been shown to require knowledge of implicative verbs, but such knowledge has previously come from manually-built word lists rather than from data. Nairn et al. (2006) and Martin et al. (2009) describe automatic systems to handle implicatives, but require hand-crafted rules for each unique verb that is handled. The tense agreement method we present offers a starting point for acquiring such rules from data, and is well-suited for incorporating into statistical systems. The clear next step is to explore similar data-driven means for learning the specific behaviors of individual implicative verbs, which has been well-studied from a theoretical perspective (Karttunen, 1971; Nairn et al., 2006; Amaral et al., 2012; Karttunen, 2012). Another interesting extension concerns the role of tense in word representations. While currently, tense is rarely built directly into distributional representations of words (Mikolov et al., 2013; Pennington et al., 2014), our results suggest it may offer important insights into the semantics of individual words. We leave this question as a direction for future work.

6 Conclusion

Differentiating between implicative and non-implicative verbs is important for discriminating inferences that can and cannot be made in natural language. We have presented a data-driven method

that captures the implicative tendencies of verbs by exploiting the tense relationship between the verb and its complement clauses. This method effectively separates known implicatives from known non-implicatives, and, more importantly, provides good predictive signal in an entailment recognition task.

Abstract

We have constructed a new "Who-did-What" dataset of over 200,000 fill-in-the-gap (cloze) multiple choice reading comprehension problems constructed from the LDC English Gigaword newswire corpus. The WDW dataset has a variety of novel features. First, in contrast with the CNN and Daily Mail datasets (Hermann et al., 2015) we avoid using article summaries for question formation. Instead, each problem is formed from two independent articles — an article given as the passage to be read and a separate article on the same events used to form the question. Second, we avoid anonymization — each choice is a person named entity. Third, the problems have been filtered to remove a fraction that are easily solved by simple baselines, while remaining 84% solvable by humans. We report performance benchmarks of standard systems and propose the WDW dataset as a challenge task for the community.[1]

1 Introduction

Researchers distinguish the problem of general knowledge question answering from that of reading comprehension (Hermann et al., 2015; Hill et al., 2016). Reading comprehension is more difficult than knowledge-based or IR-based question answering in two ways. First, reading comprehension systems must infer answers from a given unstructured passage rather than structured knowledge sources such as Freebase (Bollacker et al., 2008) or the Google Knowledge Graph (Singhal, 2012). Second, machine comprehension systems cannot exploit the large level of redundancy present on the web to find statements that provide a strong syntactic match to the question (Yang et al., 2015). In contrast, a machine comprehension system must use the single phrasing in the given passage, which may be a poor syntactic match to the question.

In this paper, we describe the construction of a new reading comprehension dataset that we refer to as "Who-did-What". Two typical examples are shown in Table 1.[2] The process of forming a problem starts with the selection of a question article from the English Gigaword corpus. The question is formed by deleting a person named entity from the first sentence of the question article. An information retrieval system is then used to select a passage with high overlap with the first sentence of the question article, and an answer choice list is generated from the person named entities in the passage.

Our dataset differs from the CNN and Daily Mail comprehension tasks (Hermann et al., 2015) in that it forms questions from two distinct articles rather than summary points. This allows problems to be derived from document collections that do not contain manually-written summaries. This also reduces the syntactic similarity between the question and the relevant sentences in the passage, increasing the need for deeper semantic analysis.

To make the dataset more challenging we selectively remove problems so as to suppress four simple

[2] The passages here only show certain salient portions of the passage. In the actual dataset, the entire article is given. The correct answers are (3) and (2).

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2230–2235,
Austin, Texas, November 1-5, 2016.

Passage: Britain's decision on Thursday to drop extradition proceedings against Gen. Augusto Pinochet and allow him to return to Chile is understandably frustrating ... Jack Straw, the home secretary, said the 84-year-old former dictator's ability to understand the charges against him and to direct his defense had been seriously impaired by a series of strokes. ... Chile's president-elect, Ricardo Lagos, has wisely pledged to let justice run its course. But the outgoing government of President Eduardo Frei is pushing a constitutional reform that would allow Pinochet to step down from the Senate and retain parliamentary immunity from prosecution. ...

Question: Sources close to the presidential palace said that Fujimori declined at the last moment to leave the country and instead he will send a high level delegation to the ceremony, at which Chilean President Eduardo Frei will pass the mandate to XXX.

Choices: (1) Augusto Pinochet (2) Jack Straw (3) Ricardo Lagos

Passage: Tottenham won 2-0 at Hapoel Tel Aviv in UEFA Cup action on Thursday night in a defensive display which impressed Spurs skipper Robbie Keane. ... Keane scored the first goal at the Bloomfield Stadium with Dimitar Berbatov, who insisted earlier on Thursday he was happy at the London club, heading a second. The 26-year-old Berbatov admitted the reports linking him with a move had affected his performances ... Spurs manager Juande Ramos has won the UEFA Cup in the last two seasons ...

Question: Tottenham manager Juande Ramos has hinted he will allow XXX to leave if the Bulgaria striker makes it clear he is unhappy.

Choices: (1) Robbie Keane (2) Dimitar Berbatov

Table 1: Sample reading comprehension problems from our dataset.

baselines — selecting the most mentioned person, the first mentioned person, and two language model baselines. This is also intended to produce problems requiring deeper semantic analysis.

The resulting dataset yields a larger gap between human and machine performance than existing ones. Humans can answer questions in our dataset with an 84% success rate compared to the estimates of 75% for CNN (Chen et al., 2016) and 82% for the CBT named entities task (Hill et al., 2016). In spite of this higher level of human performance, various existing readers perform significantly worse on our dataset than they do on the CNN dataset. For example, the Attentive Reader (Hermann et al., 2015) achieves 63% on CNN but only 55% on Who-did-What and the Attention Sum Reader (Kadlec et al., 2016) achieves 70% on CNN but only 59% on Who-did-What.

In summary, we believe that our Who-did-What dataset is more challenging, and requires deeper semantic analysis, than existing datasets.

2 Related Work

Our Who-did-What dataset is related to several recently developed datasets for machine comprehension. The MCTest dataset (Richardson et al., 2013) consists of 660 fictional stories with 4 multiple choice questions each. This dataset is too small to train systems for the general problem of reading comprehension.

The bAbI synthetic question answering dataset (Weston et al., 2016) contains passages describing a series of actions in a simulation followed by a question. For this synthetic data a logical algorithm can be written to solve the problems exactly (and, in fact, is used to generate ground truth answers).

The Children's Book Test (CBT) dataset, created by Hill et al. (2016), contains 113,719 cloze-style named entity problems. Each problem consists of 20 consecutive sentences from a children's story, a 21st sentence in which a word has been deleted, and a list of ten choices for the deleted word. The CBT dataset tests story completion rather than reading comprehension. The next event in a story is often not determined — surprises arise. This may explain why human performance is lower for CBT than for our dataset — 82% for CBT vs. 84% for Who-did-What. The 16% error rate for humans on Who-did-What seems to be largely due to noise in problem formation introduced by errors in named entity recognition and parsing. Reducing this noise in future versions of the dataset should significantly improve human performance. Another difference compared to CBT is that Who-did-What has shorter choice lists on average. Random guessing achieves only 10% on CBT but 32% on Who-did-What. The reduction

in the number of choices seems likely to be responsible for the higher performance of an LSTM system on Who-did-What – contextual LSTMs (the attentive reader of Hermann et al., 2015) improve from 44% on CBT (as reported by Hill et al., 2016) to 55% on Who-did-What.

Above we referenced the comprehension datasets created from CNN and Daily Mail articles by Hermann et al. (2015). The CNN and Daily Mail datasets together consist of 1.4 million questions constructed from approximately 300,000 articles. Of existing datasets, these are the most similar to Who-did-What in that they consist of cloze-style question answering problems derived from news articles. As discussed in Section 1, our Who-did-What dataset differs from these datasets in not being derived from article summaries, in using baseline suppression, and in yielding a larger gap between machine and human performance. The Who-did-What dataset also differs in that the person named entities are not anonymized, permitting the use of external resources to improve performance while remaining difficult for language models due to suppression.

3 Dataset Construction

We now describe the construction of our Who-did-What dataset in more detail. To generate a problem we first generate the question by selecting a random article — the "question article" — from the Gigaword corpus and taking the first sentence of that article — the "question sentence" — as the source of the cloze question. The hope is that the first sentence of an article contains prominent people and events which are likely to be discussed in other independent articles. To convert the question sentence to a cloze question, we first extract named entities using the Stanford NER system (Finkel et al., 2005) and parse the sentence using the Stanford PCFG parser (Klein and Manning, 2003).

The person named entities are candidates for deletion to create a cloze problem. For each person named entity we then identify a noun phrase in the automatic parse that is headed by that person. For example, if the question sentence is "President Obama met yesterday with Apple Founder Steve Jobs" we identify the two person noun phrases "President Obama" and "Apple Founder Steve Jobs". When a person named entity is selected for deletion, the entire noun phrase is deleted. For example, when deleting the second named entity, we get "President Obama met yesterday with XXX" rather than "President Obama met yesterday with Apple founder XXX". This increases the difficulty of the problems because systems cannot rely on descriptors and other local contextual cues. About 700,000 question sentences are generated from Gigaword articles (8% of the total number of articles).

Once a cloze question has been formed we select an appropriate article as a passage. The article should be independent of the question article but should discuss the people and events mentioned in the question sentence. To find a passage we search the Gigaword dataset using the Apache Lucene information retrieval system (McCandless et al., 2010), using the question sentence as the query. The named entity to be deleted is included in the query and required to be included in the returned article. We also restrict the search to articles published within two weeks of the date of the question article. Articles containing sentences too similar to the question in word overlap and phrase matching near the blanked phrase are removed. We select the best matching article satisfying our constraints. If no such article can be found, we abort the process and move on to a new question.

Given a question and a passage we next form the list of choices. We collect all person named entities in the passage except unblanked person named entities in the question. Choices that are subsets of longer choices are eliminated. For example the choice "Obama" would be eliminated if the list also contains "Barack Obama". We also discard ambiguous cases where a part of a blanked NE appears in multiple candidate answers, e.g., if a passage has "Bill Clinton" and "Hillary Clinton" and the blanked phrase is "Clinton". We found this simple coreference rule to work well in practice since news articles usually employ full names for initial mentions of persons. If the resulting choice list contains fewer than two or more than five choices, the process is aborted and we move on to a new question.[3]

After forming an initial set of problems we then

[3]The maximum of five helps to avoid sports articles containing structured lists of results.

remove "duplicated" problems. Duplication arises because Gigaword contains many copies of the same article or articles where one is clearly an edited version of another. Our duplication-removal process ensures that no two problems have very similar questions. Here, similarity is defined as the ratio of the size of the bag of words intersection to the size of the smaller bag.

In order to focus our dataset on the most interesting problems, we remove some problems to suppress the performance of the following simple baselines:

- First person in passage: Select the person that appears first in the passage.
- Most frequent person: Select the most frequent person in the passage.
- n-gram: Select the most likely answer to fill the blank under a 5-gram language model trained on Gigaword minus articles which are too similar to one of the questions in word overlap and phrase matching.
- Unigram: Select the most frequent last name using the unigram counts from the 5-gram model.

To minimize the number of questions removed we solve an optimization problem defined by limiting the performance of each baseline to a specified target value while removing as few problems as possible, i.e.,

$$\max_{\alpha(C)} \sum_{C \in \{0,1\}^{|b|}} \alpha(C)|T(C)| \quad (1)$$

subject to

$$\forall i \quad \sum_{C:C_i=1} \frac{\alpha(C)|T(C)|}{N} \leq k$$

$$N = \sum_{C \in \{0,1\}^{|b|}} \alpha(C)|T(C)| \quad (2)$$

where $T(C)$ is the subset of the questions solved by the subset C of the suppressed baselines, $\alpha(C)$ is a keeping rate for question set $T(C)$, $C_i = 1$ indicates the i-th baseline is in the subset, $|b|$ is the number of baselines, N is a total number of questions, and k is the upper bound for the baselines after suppression. We choose k to yield random performance for the baselines. The performance of the baselines before and after suppression is shown in Table 2. The suppression removed 49.9% of the questions.

Baseline	Accuracy Before	Accuracy After
First person in passage	0.60	0.32
Most frequent person	0.61	0.33
n-gram	0.53	0.33
Unigram	0.43	0.32
Random*	0.32	0.32

Table 2: Performance of suppressed baselines. *Random performance is computed as a deterministic function of the number of times each choice set size appears. Many questions have only two choices and there are about three choices on average.

	relaxed train	train	valid	test
# questions	185,978	127,786	10,000	10,000
avg. # choices	3.5	3.5	3.4	3.4
avg. # tokens	378	365	325	326
vocab. size	347,406		308,602	

Table 3: Dataset statistics.

Table 3 shows statistics of our dataset after suppression. We split the final dataset into train, validation, and test by taking the validation and test to be a random split of the most recent 20,000 problems as measured by question article date. In this way there is very little overlap in semantic subject matter between the training set and either validation or test. We also provide a larger "relaxed" training set formed by applying less baseline suppression (a larger value of k in the optimization). The relaxed training set then has a slightly different distribution from the train, validation, and test sets which are all fully suppressed.

4 Performance Benchmarks

We report the performance of several systems to characterize our dataset:

- Word overlap: Select the choice c inserted to the question q which is the most similar to any sentence s in the passage, i.e., $\mathrm{CosSim}(\mathrm{bag}(c + q), \mathrm{bag}(s))$.
- Sliding window and Distance baselines (and their combination) from Richardson et al. (2013).
- Semantic features: NLP feature based system from Wang et al. (2015).

- Attentive Reader: LSTM with attention mechanism (Hermann et al., 2015).
- Stanford Reader: An attentive reader modified with a bilinear term (Chen et al., 2016).
- Attention Sum (AS) Reader: GRU with a point-attention mechanism (Kadlec et al., 2016).
- Gated-Attention (GA) Reader: Attention Sum Reader with gated layers (Dhingra et al., 2016).

Table 4 shows the performance of each system on the test data. For the Attention and Stanford Readers, we anonymized the Who-did-What data by replacing named entities with entity IDs as in the CNN and Daily Mail datasets.

We see consistent reductions in accuracy when moving from CNN to our dataset. The Attentive and Stanford Reader drop by up to 10% and the AS and GA readers drop by up to 17%. The ranking of the systems also changes. In contrast to the Attentive/Stanford readers, the AS/GA readers explicitly leverage the frequency of the answer in the passage, a heuristic which appears beneficial for the CNN and Daily Mail tasks. Our suppression of the most-frequent-person baseline appears to more strongly affect the performance of these latter systems.

System	WDW	CNN
Word overlap	0.47	–
Sliding window	0.48	–
Distance	0.46	–
Sliding window + Distance	0.51	–
Semantic features	0.52	–
Attentive Reader	0.53	0.63^{I}
Attentive Reader (relaxed train)	0.55	
Stanford Reader	0.64	0.73^{II}
Stanford Reader (relaxed train)	0.65	
AS Reader	0.57	0.70^{III}
AS Reader (relaxed train)	0.59	
GA Reader	0.57	0.74^{IV}
GA Reader (relaxed train)	0.60	
Human Performance	$84/100$	$0.75+^{II}$

Table 4: System performance on test set. Human performance was computed by two annotators on a sample of 100 questions. Result marked I is from (Hermann et al., 2015), results marked II are from (Chen et al., 2016), result marked III is from (Kadlec et al., 2016), and result marked IV is from (Dhingra et al., 2016).

5 Conclusion

We presented a large-scale person-centered cloze dataset whose scalability and flexibility is suitable for neural methods. This dataset is different in a variety of ways from existing large-scale cloze datasets and provides a significant extension to the training and test data for machine comprehension.

Abstract

This paper presents a system that compositionally maps outputs of a wide-coverage Japanese CCG parser onto semantic representations and performs automated inference in higher-order logic. The system is evaluated on a textual entailment dataset. It is shown that the system solves inference problems that focus on a variety of complex linguistic phenomena, including those that are difficult to represent in the standard first-order logic.

1 Introduction

Logic-based semantic representations have played an important role in the study of semantic parsing and inference. For English, several methods have been proposed to map outputs of parsers based on syntactic theories like CCG (Steedman, 2000) onto logical formulas (Bos, 2015). Output formulas have been used in various tasks, including Question Answering (Lewis and Steedman, 2013) and Recognizing Textual Entailment (RTE) (Bos and Markert, 2005; Beltagy et al., 2013; Bjerva et al., 2014).

Syntactic and semantic parsing for Japanese, by contrast, has been dominated by chunk-based dependency parsing and semantic role labelling (Kudo and Matsumoto, 2002; Kawahara and Kurohashi, 2011; Hayashibe et al., 2011). Recently, the method of inducing wide-coverage CCG resources for English (Hockenmaier and Steedman, 2007) has been applied to Japanese and a robust CCG parser based on it has been developed (Uematsu et al., 2015). However, building a method to map CCG trees in Japanese onto logical formulas is not a trivial task, mainly due to the differences in syntactic structures between English and Japanese (Section 3).

There are two primary contributions of this paper. First, based on an in-depth analysis of the syntax-semantics interface in Japanese, we present the first system that compositionally derives semantic representations for a wide-coverage Japanese CCG parser. Output representations are formulas in higher-order logic (HOL) combined with Neo-Davidsonian Event Semantics (Parsons, 1990). Second, we demonstrate the capacity of HOL for textual entailment. We evaluate the system on a Japanese textual entailment dataset (Kawazoe et al., 2015), a dataset constructed in a similar way to the FraCaS dataset for English (Cooper et al., 1994; MacCartney and Manning, 2007). Although it is usually thought that HOL is unfeasible for practical applications, the results show that the entire system is able to perform efficient logical inference on complex linguistic phenomena such as generalized quantifiers and intensional modifiers — phenomena that pose challenges to the standard first-order-logic-based approaches.

2 Background and system overview

This section provides a brief overview of the entire system as applied to RTE, a task of determining whether a given text (T) entails, contradicts, or is just consistent with, a given hypothesis (H). In logic-based approaches, the meanings of T and H are represented by logical formulas; whether the entailment relation holds is typically determined by checking whether $T \to H$ is a theorem in a logical system with the help of a knowledge base.

Currently, first-order logic (FOL) is the most pop-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2236–2242,
Austin, Texas, November 1-5, 2016.

ular logical system used for RTE (Bos and Markert, 2005; Lewis and Steedman, 2013; Bjerva et al., 2014). One advantage of systems based on FOL is that practical general-purpose theorem provers and model-builders are available. However, a drawback is that there are linguistic phenomena that cannot be represented in the standard FOL; a typical example is a generalized quantifier such as *most* (Barwise and Cooper, 1981). Accordingly, it has been standard in formal semantics of natural language to use HOL as a representation language (Montague, 1974). Although HOL does not have general-purpose theorem provers, there is room for developing an automated reasoning system specialized for natural language inference. In general, a higher-order representation makes the logical structure of a sentence more explicit than a first-order encoding does and hence can simplify the process of proof search (Miller and Nadathur, 1986). Recently, based on the evaluation on the FraCaS dataset (Cooper et al., 1994), Mineshima et al. (2015) showed that a higher-order inference system outperformed the Boxer/Nutcracker's first-order system (Bos, 2008) in both speed and accuracy. Likewise, Abzianidze (2015) developed a higher-order prover based on natural logic tableau system and showed that it achieved high accuracy comparable to state-of-the-art results on the SICK dataset (Marelli et al., 2014).

There are three main steps in our pipeline. The focus of this paper is on the last two components.

1. Syntactic parsing Input sentences are mapped onto CCG trees. We use a Japanese CCG parser Jigg (Noji and Miyao, 2016)[1], a statistical parser based on Japanese CCGbank (Uematsu et al., 2015).

2. Semantic parsing CCG derivation trees are compositionally mapped onto semantic representations in HOL. The compositional mapping is implemented via simply typed λ-calculus in the standard way (Bos, 2008; Martínez-Gómez et al., 2016).

3. Logical inference Theorem proving in HOL is performed to check for entailment and contradiction. Axioms and proof-search procedures are largely language-independent, so we use the higher-order inference system of Mineshima et al. (2015)[2] and adapt it for our purpose.

3 Compositional Semantics and HOL

3.1 CCG and semantic lexicon

Combinatory Categorial Grammar (CCG) (Steedman, 2000) is a lexicalized grammar formalism suitable for implementing a compositional mapping from syntax to semantics. A syntactic category of CCG is either a basic category such as *S* and *NP* or a functional category of the form X/Y or $X\backslash Y$. The meaning of a sentence is computed from a small number of combinatory rules and the meanings of constituent words. In addition to standard combinatory rules, the Japanese CCG parser uses a small number of unary type-shifting rules (e.g., the relativization rule that changes the category $S\backslash NP$ to NP/NP), to which suitable meaning composition rules are given.

We follow the standard method of building a semantic lexicon in CCG-based logical semantics (Bos, 2008). There are two kinds of lexical entries: (1) *semantic templates* that are schematic entries assigned to syntactic categories, possibly with syntactic features and (2) *lexical entries* directly assigned to a limited number of logical and functional expressions. Lexical entries can be sensitive to a POS tag, a surface form, and other information contained in the parser output. Table 1 shows semantic templates for main syntactic categories. More details will be provided in Section 3.2 and 3.3.

We use a language of standard higher-order logic (simple type theory) (Carpenter, 1997) as a representation language. Expressions in HOL are assigned semantic types. We use three basic types: E (Entity), Ev (Event), and Prop (Proposition). Thus, the semantic types of expressions in our system are defined by the rule

$$\mathsf{T} ::= \mathsf{E} \mid \mathsf{Ev} \mid \mathsf{Prop} \mid \mathsf{T}_1 \Rightarrow \mathsf{T}_2$$

where $\mathsf{T}_1 \Rightarrow \mathsf{T}_2$ is a function type.

First-order language can be taken as a fragment of this system; apart from logical connectives and

$NP^\bullet = ((\mathsf{E} \Rightarrow \mathsf{Prop}) \Rightarrow \mathsf{E} \Rightarrow \mathsf{Prop}) \Rightarrow (\mathsf{E} \Rightarrow \mathsf{Prop}) \Rightarrow \mathsf{Prop}$
$S^\bullet = ((\mathsf{Ev} \Rightarrow \mathsf{Prop}) \Rightarrow \mathsf{Ev} \Rightarrow \mathsf{Prop}) \Rightarrow \mathsf{Prop}$
$(C1/C2)^\bullet = (C1\backslash C2)^\bullet = C2^\bullet \Rightarrow C1^\bullet$

Figure 1: The mapping from syntactic categories to semantic types. $\Rightarrow$ is right-associative.

quantifiers, all primitive expressions in first-order logic are confined to constant symbols of type E and predicates of type $\mathsf{E} \Rightarrow \mathsf{Prop}$, $\mathsf{E} \Rightarrow \mathsf{E} \Rightarrow \mathsf{Prop}$, and so on. Thus, adopting higher-order language does not lead to the loss of the expressive power of first-order language.

The Japanese CCG parser simplifies the standard CCG and uses two basic categories, *S* and *NP*. Accordingly, a mapping $(\cdot)^\bullet$ from syntactic categories to semantic types can be defined as in Figure 1. Keeping the correspondence between syntactic categories and semantic types in the semantic lexicon guarantees that a well-formed formula is compositionally derived from the meaning assignment to each leaf of a CCG derivation tree.

3.2 Semantic composition for VPs

To model a semantics for VPs in Japanese, we adopt Neo-Davidsonian Event Semantics (Parsons, 1990; Jurafsky and Martin, 2009), which is widely used in the NLP field. For instance, the sentence (1) is analyzed as having the logical form in (2):

(1) ジョン が　ゆっくり 歩い た。
John NOM slowly walk PAST
'John walked slowly'

(2) $\exists v(\mathsf{walk}(v) \wedge (\mathsf{Nom}(v) = \mathsf{john}) \wedge \mathsf{slow}(v) \wedge \mathsf{Past}(v))$

In this approach, verbs are analyzed as 1-place predicates over events; arguments and adjuncts of VPs are also analyzed as event predicates. This semantic uniformity is suitable to handling Japanese syntactic structures in which the arguments of a VP is often implicit and thus the argument-adjunct distinction is less transparent than languages like English (Pietroski, 2005). As is seen in (2), we adopt the unique-role requirement for case markers (Carlson, 1984); for instance, the nominative case marker does not denote the relation $\mathsf{Nom}(v, x)$, as in the event semantics in Boxer (Bos, 2008), but the function $\mathsf{Nom}(v) = x$. This treatment allows us to make use of logical properties of equality and hence is more suited to theorem-proving in our setting.

To derive a semantic representation in event semantics compositionally, we adopt the compositional semantics of VPs in Champollion (2015) and analyze VPs themselves as introducing existential quantification over events. To derive the correct meaning for VP modifiers, the semantic type of a verb is raised so that the verb takes a modifier as argument but not vice versa. Figures 2 and 3 give example derivations.

VP modifiers such as *slowly* license an inference from *John walked slowly* to *John walked*, an inference correctly captured by the formula in (2). In English and Japanese, however, there are intensional VP modifiers that do not license this inference pattern. Thus, the sentence *John almost walked* does not entail *John walked* (Dowty, 1979). While it is not easy to provide a desirable analysis in first-order language (Hobbs, 1985), HOL gives a perspicuous representation:

(3) $\exists v(\mathsf{almost}(\mathsf{walk}, v) \wedge (\mathsf{Nom}(v) = \mathsf{john}) \wedge \mathsf{Past}(v))$

Here, almost is a higher-order predicate having the semantic type $(\mathsf{Ev} \Rightarrow \mathsf{Prop}) \Rightarrow \mathsf{Ev} \Rightarrow \mathsf{Prop}$. The meaning assignment to VP modifiers of category S/S in Table 1 is for extensional modifiers; an intensional modifier is assigned the representation $\lambda SK.S(\lambda Jv.K(\mathsf{Base}(J), v))$ in the lexical entry, which results in a representation as in (3).

3.3 Semantic composition for NPs

The quantificational structure of an NP plays a crucial role in capturing basic entailment patterns such as monotonicity inference. In the case of English, quantificational structures are specified by the type of determiners (e.g. *a, the, every, some, no*); together with the category distinction between *N* and *NP*, which is supported in English CCGbank (Hockenmaier and Steedman, 2007), one can provide a correct representation for NPs.

By contrast, Japanese is a classifier language, where NPs freely occur without determiners in argument position (Chierchia, 1998). For example, the subject in (4) appears in argument position without accompanying any determiner.

(4) 小さな 犬　が　吠え た。
small dog NOM bark PAST
'A small dog barked'

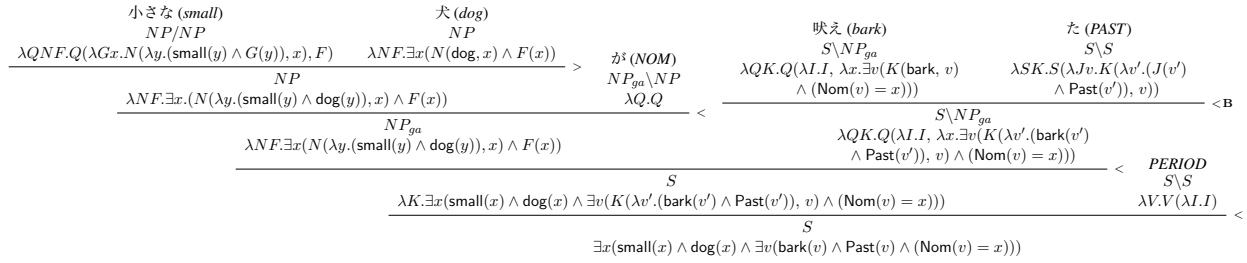

Figure 2: A CCG derivation tree for the sentence "A small dog barked".

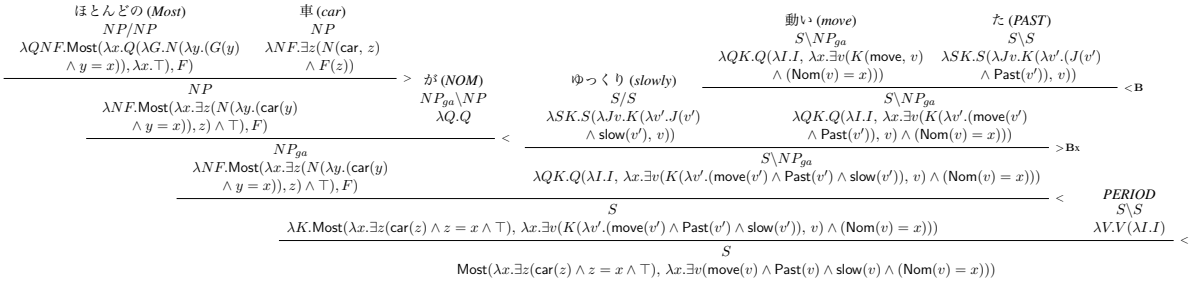

Figure 3: A CCG derivation tree for the sentence "Most cars moved slowly". $\top$ denotes the tautology.

Bekki (2010) provides a comprehensive CCG grammar for Japanese that adopts the *N-NP* distinction and analyzes Japanese bare NPs as accompanying the null determiner. The Japanese CCGbank, by contrast, simplifies Bekki's (2010) grammar and avoids the use of the null determiner; it does not use the category *N* and takes all NPs in Japanese to have the syntactic category *NP*. This discrepancy in NP-structure between English and Japanese poses a challenge to the standard approach to building compositional semantics.

To provide a compositional semantics adapted for the Japanese CCG, we take NPs themselves as introducing quantification over individuals, along the same lines as the semantics for VPs. The semantic type of NPs needs to be raised so that they take NP-modifiers as argument (cf. the template for *NP* in Table 1). Figure 2 shows a derivation for the sentence in (4), where the adjective *small* modifies the NP *dog* to form a bare NP *small dog*. It should be noted that the predicate $\mathsf{small}(x)$ is correctly inserted inside the scope of the existential quantification introduced by the NP *dog*. The so-called privative adjectives (e.g. *fake* and *former*) are analyzed in the same way as intensional VP modifiers.

Following the analysis in Mineshima et al. (2015), we analyze non-first-order generalized quantifier *most* as having the higher-order logical form $\mathsf{Most}(F, G)$, where Most has the type of generalized quantifier $(\mathsf{E} \Rightarrow \mathsf{Prop}) \Rightarrow (\mathsf{E} \Rightarrow \mathsf{Prop}) \Rightarrow \mathsf{Prop}$. Figure 3 shows an example derivation for a sentence containing a generalized quantifier *most*. Our system also handles floating quantifiers in Japanese.

4 Experiments

We evaluate our system[3] on Japanese Semantics test suite (JSeM)[4] (Kawazoe et al., 2015), a Japanese dataset for textual entailment designed in a similar way to the FraCaS dataset for English. These datasets focus on the types of logical inferences that do not require world knowledge. JSeM has Japanese translations of FraCaS problems and an extended set of problems focusing on Japanese syntax and semantics. Each problem has one or more premises, followed by a hypothesis. There are three types of answer: *yes* (entailment), *no* (contradiction), and *unknown* (neutral). Each problem is annotated with the types of inference (logical entailment, presupposition, etc.) and of linguistic phenomena.

We evaluate the system on 523 problems in the dataset. We focus on problems tagged with one of the five phenomena: generalized quantifier, plu-

Table 3: Accuracy, precision, recall, and average proof time.

ral, adjective, verb, and attitude. We use problems whose inference type is logical entailment, excluding anaphora and presupposition. We use Kuromoji[5] for morphological analysis. To focus on the evaluation of semantic parsing and inference, we use gold syntactic parses, which show an upper bound on the performance of the semantic component. Gold syntactic parses are manually selected from n-best outputs of the CCG parser. For the higher-order inference system, we use the axioms presented in Mineshima et al. (2015) adapted with the necessary modification for our event semantics.

Given premises $P_1, \ldots, P_n$ and a hypothesis H, the system outputs *yes* ($P_1 \wedge \cdots \wedge P_n \rightarrow H$ is proved), *no* ($P_1 \wedge \cdots \wedge P_n \rightarrow \neg H$ is proved), or *unknown* (neither is proved in a fixed proof-search space).[6] We set a 30 seconds timeout for each inference run; the system outputs *unknown* after it. The current semantic lexicon has 36 templates and 113 lexical entries.

Table 2 and 3 show the results. The system with gold syntactic parses achieved 86% accuracy on the total 523 problems, with high precision and reasonable speed. There was no timeout.[7] The accuracy dropped to 70% when ablating HOL axioms (Table 3). SLC refers to the performance of a supervised learning classifier[8] based on 5-fold cross-validation for each section. Although direct comparison is not possible, our system with gold parses outperforms it for all sections.

[5] http://www.atilika.org/

[6] Note that natural-logic-based systems (MacCartney and Manning, 2008) do not handle multi-premised problems.

[7] Our pipeline was run single-threaded on Ubuntu Linux 64 bits with a CPU at 2.67GHz.

Table 4: The results on a subset of JSeM that is a translation of FraCaS. M15 refers to the accuracy of Mineshima et al. (2015) on the corresponding sections of FraCaS.

Out of the 523 problems, 417 are Japanese translations of the FraCaS problems. Table 4 shows a comparison between the performance of our system on this subset of the JSeM problems and the performance of the RTE system for English in Mineshima et al. (2015) on the corresponding problems in the FraCaS dataset. Mineshima et al. (2015) used system parses of the English C&C parser (Clark and Curran, 2007). The total accuracy of our system is comparable to that of Mineshima et al. (2015).

Most errors we found are due to syntactic parse errors caused by the CCG parser, where no correct syntactic parses were found in n-best responses. Comparison between gold parses and system parses shows that correct syntactic disambiguation improves performance.

5 Conclusion

To our knowledge, this study provides the first semantic parsing system based on CCG that compositionally maps real texts in Japanese onto logical forms. We have also demonstrated the capacity of HOL for textual entailment. The evaluation on JSeM showed that our system performs efficient logical inference on various semantic phenomena, including those that challenge the standard FOL. The attractiveness of a logic-based system is that it is highly modular and can be extended with other components such as a robust knowledge base (Lewis and Steedman, 2013; Beltagy et al., 2013; Bjerva et al., 2014). Such an extension will be a focus of future work.

Acknowledgments We are grateful to the three anonymous reviewers for their helpful comments and suggestions. This research has been supported by the JST CREST program.

Abstract

The production of color language is essential for grounded language generation. Color descriptions have many challenging properties: they can be vague, compositionally complex, and denotationally rich. We present an effective approach to generating color descriptions using recurrent neural networks and a Fourier-transformed color representation. Our model outperforms previous work on a conditional language modeling task over a large corpus of naturalistic color descriptions. In addition, probing the model's output reveals that it can accurately produce not only basic color terms but also descriptors with non-convex denotations ("greenish"), bare modifiers ("bright", "dull"), and compositional phrases ("faded teal") not seen in training.

1 Introduction

Color descriptions represent a microcosm of grounded language semantics. Basic color terms like "red" and "blue" provide a rich set of semantic building blocks in a continuous meaning space; in addition, people employ compositional color descriptions to express meanings not covered by basic terms, such as "greenish blue" or "the color of the rust on my aunt's old Chevrolet" (Berlin and Kay, 1991). The production of color language is essential for referring expression generation (Krahmer and Van Deemter, 2012) and image captioning (Kulkarni et al., 2011; Mitchell et al., 2012), among other grounded language generation problems.

We consider color description generation as a grounded language modeling problem. We present an effective new model for this task that uses a long short-term memory (LSTM) recurrent neural network (Hochreiter and Schmidhuber, 1997; Graves, 2013) and a Fourier-basis color representation inspired by feature representations in computer vision.

Color	Top-1	Sample
(83, 80, 28)	"green"	"very green"
(232, 43, 37)	"blue"	"royal indigo"
(63, 44, 60)	"olive"	"pale army green"
(39, 83, 52)	"orange"	"macaroni"

Table 1: A selection of color descriptions sampled from our model that were not seen in training. Color triples are in HSL. *Top-1* shows the model's highest-probability prediction.

We compare our model with LUX (McMahan and Stone, 2015), a Bayesian generative model of color semantics. Our model improves on their approach in several respects, which we demonstrate by examining the meanings it assigns to various unusual descriptions: (1) it can generate compositional color descriptions not observed in training (Fig. 3); (2) it learns correct denotations for underspecified modifiers, which name a variety of colors ("dark", "dull"; Fig. 2); and (3) it can model non-convex denotations, such as that of "greenish", which includes both greenish yellows and blues (Fig. 4). As a result, our model also produces significant improvements on several grounded language modeling metrics.

2 Model formulation

Formally, a model of color description generation is a probability distribution $S(d \mid c)$ over sequences of

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2243–2248,
Austin, Texas, November 1-5, 2016.

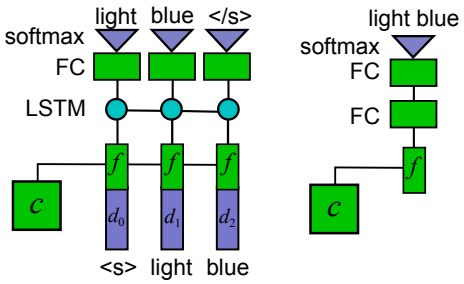

Figure 1: Left: sequence model architecture; right: atomic-description baseline. FC denotes fully connected layers.

tokens d conditioned on a color c, where c is represented as a 3-dimensional real vector in HSV space.[1]

Architecture Our main model is a recurrent neural network sequence decoder (Fig. 1, left panel). An input color $c = (h, s, v)$ is mapped to a representation f (see Color features, below). At each time step, the model takes in a concatenation of f and an embedding for the previous output token d_i, starting with the start token $d_0 =$ <s>. This concatenated vector is passed through an LSTM layer, using the formulation of Graves (2013). The output of the LSTM at each step is passed through a fully-connected layer, and a softmax nonlinearity is applied to produce a probability distribution for the following token.[2] The probability of a sequence is the product of probabilities of the output tokens up to and including the end token </s>.

We also implemented a simple feed-forward neural network, to demonstrate the value gained by modeling descriptions as sequences. This architecture (*atomic*; Fig. 1, right panel) consists of two fully-connected hidden layers, with a ReLU nonlinearity after the first and a softmax output over all full color descriptions seen in training. This model therefore treats the descriptions as atomic symbols rather than sequences.

Color features We compare three representations:

- *Raw*: The original 3-dimensional color vectors, in HSV space.
- *Buckets*: A discretized representation, dividing HSV space into rectangular regions at three resolutions ($90\times10\times10$, $45\times5\times5$, $1\times1\times1$) and assigning a separate embedding to each region.
- *Fourier*: Transformation of HSV vectors into a Fourier basis representation. Specifically, the representation f of a color (h, s, v) is given by

$$\hat{f}_{jk\ell} = \exp\left[-2\pi i \left(jh^* + ks^* + \ell v^*\right)\right]$$
$$f = \begin{bmatrix}\mathrm{Re}\{\hat{f}\} & \mathrm{Im}\{\hat{f}\}\end{bmatrix} \qquad j,k,\ell = 0..2$$

  where $(h^*, s^*, v^*) = (h/360, s/200, v/200)$.

The Fourier representation is inspired by the use of Fourier feature descriptors in computer vision applications (Zhang and Lu, 2002). It is a nonlinear transformation that maps the 3-dimensional HSV space to a 54-dimensional vector space. This representation has the property that most regions of color space denoted by some description are extreme along a single direction in Fourier space, thus largely avoiding the need for the model to learn non-monotonic functions of the color representation.

Training We train using Adagrad (Duchi et al., 2011) with initial learning rate $\eta = 0.1$, hidden layer size and cell size 20, and dropout (Hinton et al., 2012) with a rate of 0.2 on the output of the LSTM and each fully-connected layer. We identified these hyperparameters with random search, evaluating on a held-out subset of the training data.

We use random normally-distributed initialization for embeddings ($\sigma = 0.01$) and LSTM weights ($\sigma = 0.1$), except for forget gates, which are initialized to a constant value of 5. Dense weights use normalized uniform initialization (Glorot and Bengio, 2010).

3 Experiments

We demonstrate the effectiveness of our model using the same data and statistical modeling metrics as McMahan and Stone (2015).

Data The dataset used to train and evaluate our model consists of pairs of colors and descriptions collected in an open online survey (Munroe, 2010). Participants were shown a square of color and asked to write a free-form description of the color in a text box. McMahan and Stone filtered the responses to normalize spelling differences and exclude spam responses and descriptions that occurred

[1] HSV: hue-saturation-value. The visualizations and tables in this paper instead use HSL (hue-saturation-lightness), which yields somewhat more intuitive diagrams and differs from HSV by a trivial reparameterization.

[2] Our implementation uses Lasagne (Dieleman et al., 2015), a neural network library based on Theano (Al-Rfou et al., 2016).

Model	Feats.	Perp.	AIC	Acc.
atomic	raw	28.31	1.08×10^6	28.75%
atomic	buckets	16.01	1.31×10^6	38.59%
atomic	Fourier	15.05	8.86×10^5	38.97%
RNN	raw	13.27	8.40×10^5	40.11%
RNN	buckets	13.03	1.26×10^6	39.94%
RNN	Fourier	**12.35**	$\mathbf{8.33\times10^5}$	**40.40%**
HM	buckets	14.41	4.82×10^6	39.40%
LUX	raw	13.61	4.13×10^6	39.55%
RNN	Fourier	**12.58**	$\mathbf{4.03\times10^6}$	**40.22%**

Table 2: Experimental results. Top: development set; bottom: test set. AIC is not comparable between the two splits. HM and LUX are from McMahan and Stone (2015). We reimplemented HM and re-ran LUX from publicly available code, confirming all results to the reported precision except perplexity of LUX, for which we obtained a figure of 13.72.

very rarely. The resulting dataset contains 2,176,417 pairs divided into training (1,523,108), development (108,545), and test (544,764) sets.

Metrics We quantify model effectiveness with the following evaluation metrics:

- *Perplexity*: The geometric mean of the reciprocal probability assigned by the model to the descriptions in the dataset, conditioned on the respective colors. This expresses the same objective as log conditional likelihood. We follow McMahan and Stone (2015) in reporting perplexity per-description, not per-token as in the language modeling literature.
- *AIC*: The Akaike information criterion (Akaike, 1974) is given by AIC $= 2\ell + 2k$, where ℓ is log likelihood and k is the total number of real-valued parameters of the model (e.g., weights and biases, or bucket probabilities). This quantifies a tradeoff between accurate modeling and model complexity.
- *Accuracy*: The percentage of most-likely descriptions predicted by the model that exactly match the description in the dataset (recall@1).

Results The top section of Table 2 shows development set results comparing modeling effectiveness for atomic and sequence model architectures and different features. The Fourier feature transformation generally improves on raw HSV vectors and discretized embeddings. The value of modeling descriptions as sequences can also be observed in these results; the LSTM models consistently outperform their atomic counterparts.

Additional development set experiments (not shown in Table 2) confirmed smaller design choices for the recurrent architecture. We evaluated a model with two LSTM layers, but we found that the model with only one layer yielded better perplexity. We also compared the LSTM with GRU and vanilla recurrent cells; we saw no significant difference between LSTM and GRU, while using a vanilla recurrent unit resulted in unstable training. Also note that the color representation f is input to the model at every time step in decoding. In our experiments, this yielded a small but significant improvement in perplexity versus using the color representation as the initial state.

Test set results appear in the bottom section. Our best model outperforms both the histogram baseline (HM) and the improved LUX model of McMahan and Stone (2015), obtaining state-of-the-art results on this task. Improvements are highly significant on all metrics ($p < 0.001$, approximate permutation test, $R = 10{,}000$ samples; Padó, 2006).

4 Analysis

Given the general success of LSTM-based models at generation tasks, it is perhaps not surprising that they yield good raw performance when applied to color description. The color domain, however, has the advantage of admitting faithful visualization of descriptions' semantics: colors exist in a 3-dimensional space, so a two-dimensional visualization can show an acceptably complete picture of an entire distribution over the space. We exploit this to highlight three specific improvements our model realizes over previous ones.

We construct visualizations by querying the model for the probability $S(d \mid c)$ of the same description for each color in a uniform grid, summing the probabilities over the hue dimension (left cross-section) and the saturation dimension (right cross-section), normalizing them to sum to 1, and plotting the log of the resulting values as a grayscale image.

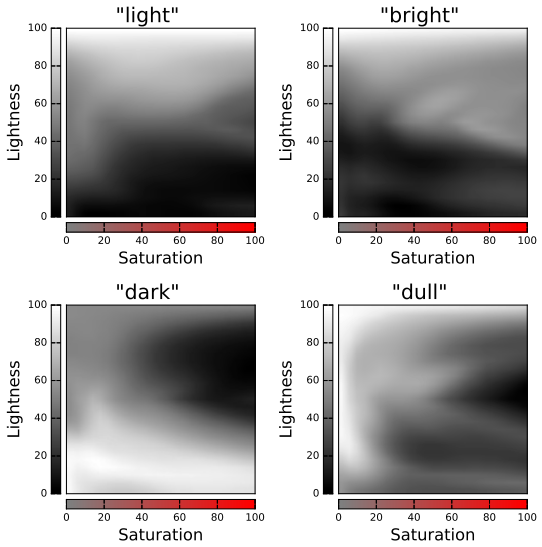

Figure 2: Conditional likelihood of bare modifiers according to our generation model as a function of color. White represents regions of high likelihood. We omit the hue dimension, as these modifiers do not express hue constraints.

Formally, each visualization is a pair of functions (L, R), where

$$L(s,\ell) = \log\left[\frac{\int dh\ S(d \mid c = (h,s,\ell))}{\int dc'\ S(d \mid c')}\right]$$

$$R(h,\ell) = \log\left[\frac{\int ds\ S(d \mid c = (h,s,\ell))}{\int dc'\ S(d \mid c')}\right]$$

The maximum value of each function is plotted as white, the minimum value is black, and intermediate values linearly interpolated.

Learning modifiers Our model learns accurate meanings of adjectival modifiers apart from the full descriptions that contain them. We examine this in Fig. 2, by plotting the probabilities assigned to the bare modifiers "light", "bright", "dark", and "dull". "Light" and "dark" unsurprisingly denote high and low lightness, respectively. Less obviously, they also exclude high-saturation colors. "Bright", on the other hand, features both high-lightness colors and saturated colors—"bright yellow" can refer to the prototypical yellow, whereas "light yellow" cannot. Finally, "dull" denotes unsaturated colors in a variety of lightnesses.

Compositionality Our model generalizes to compositional descriptions not found in the training set. Fig. 3 visualizes the probability assigned to the

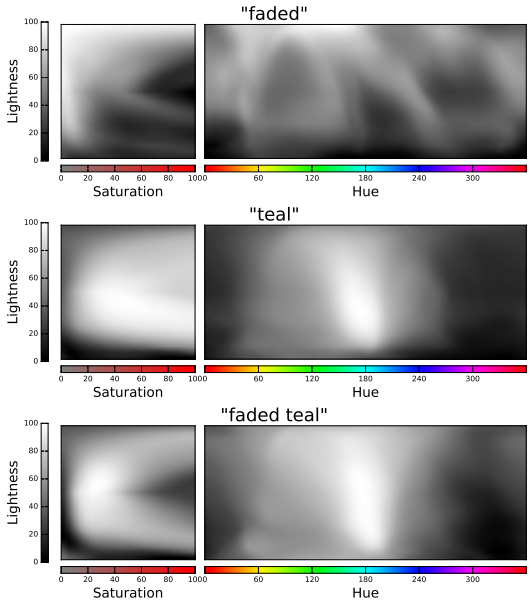

Figure 3: Conditional likelihood of "faded", "teal", and "faded teal". The two meaning components can be seen in the two cross-sections: "faded" denotes a low saturation value, and "teal" denotes hues near the center of the spectrum.

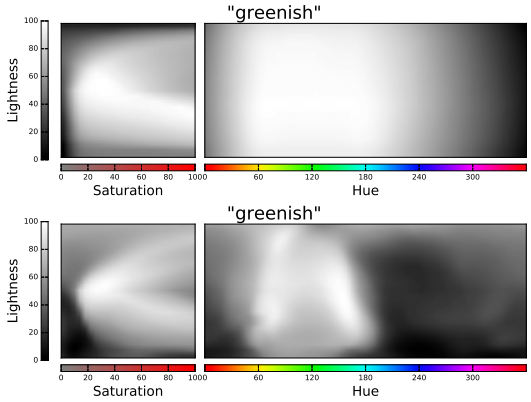

Figure 4: Conditional likelihood of "greenish" as a function of color. The distribution is bimodal, including greenish yellows and blues but not true greens. Top: LUX; bottom: our model.

novel utterance "faded teal", along with "faded" and "teal" individually. The meaning of "faded teal" is intersective: "faded" colors are lower in saturation, excluding the colors of the rainbow (the V on the right side of the left panel); and "teal" denotes colors with a hue near 180° (center of the right panel).

Non-convex denotations The Fourier feature transformation and the nonlinearities in the model allow it to capture a rich set of denotations. In particular, our model addresses the shortcoming identified by McMahan and Stone (2015) that their model cannot capture non-convex denotations. The description

Color	Top-1	Sample
(36, 86, 63)	"orange"	"ugly"
(177, 85, 26)	"teal"	"robin's"
(29, 45, 71)	"tan"	"reddish green"
(196, 27, 71)	"grey"	"baby royal"

Table 3: Error analysis: some color descriptions sampled from our model that are incorrect or incomplete.

"greenish" (Fig. 4) has such a denotation: "greenish" specifies a region of color space surrounding, but not including, true greens.

Error analysis Table 3 shows some examples of errors found in samples taken from the model. The main type of error the system makes is ungrammatical descriptions, particularly fragments lacking a basic color term (e.g., "robin's"). Rarer are grammatical but meaningless compositions ("reddish green") and false descriptions. When queried for its single most likely prediction, $\arg\max_d S(d \mid c)$, the result is nearly always an acceptable, "safe" description—manual inspection of 200 such top-1 predictions did not identify any errors.

5 Conclusion and future work

We presented a model for generating compositional color descriptions that is capable of producing novel descriptions not seen in training and significantly outperforms prior work at conditional language modeling.[3] One natural extension is the use of character-level sequence modeling to capture complex morphology (e.g., "-ish" in "greenish"). Kawakami et al. (2016) build character-level models for predicting colors given descriptions in addition to describing colors. Their model uses a *Lab*-space color representation and uses the color to initialize the LSTM instead of feeding it in at each time step; they also focus on visualizing point predictions of their description-to-color model, whereas we examine the full distributions implied by our color-to-description model.

Another extension we plan to investigate is modeling of context, to capture how people describe colors differently to contrast them with other colors via pragmatic reasoning (DeVault and Stone, 2007; Golland et al., 2010; Monroe and Potts, 2015).

[3]We release our code at `https://github.com/stanfordnlp/color-describer`.

Abstract

We propose a simple neural architecture for natural language inference. Our approach uses attention to decompose the problem into subproblems that can be solved separately, thus making it trivially parallelizable. On the Stanford Natural Language Inference (SNLI) dataset, we obtain state-of-the-art results with almost an order of magnitude fewer parameters than previous work and without relying on any word-order information. Adding intra-sentence attention that takes a minimum amount of order into account yields further improvements.

1 Introduction

Natural language inference (NLI) refers to the problem of determining entailment and contradiction relationships between a premise and a hypothesis. NLI is a central problem in language understanding (Katz, 1972; Bos and Markert, 2005; van Benthem, 2008; MacCartney and Manning, 2009) and recently the large SNLI corpus of 570K sentence pairs was created for this task (Bowman et al., 2015). We present a new model for NLI and leverage this corpus for comparison with prior work.

A large body of work based on neural networks for text similarity tasks including NLI has been published in recent years (Hu et al., 2014; Rocktäschel et al., 2016; Wang and Jiang, 2016; Yin et al., 2016, *inter alia*). The dominating trend in these models is to build complex, deep text representation models, for example, with convolutional networks (LeCun et al., 1990, CNNs henceforth) or long short-term memory networks (Hochreiter and Schmidhuber, 1997, LSTMs henceforth) with the goal of deeper sentence comprehension. While these approaches have yielded impressive results, they are often computationally very expensive, and result in models having millions of parameters (excluding embeddings).

Here, we take a different approach, arguing that for natural language inference it can often suffice to simply align bits of local text substructure and then aggregate this information. For example, consider the following sentences:

- *Bob is in his room, but because of the thunder and lightning outside, he cannot sleep.*
- *Bob is awake.*
- *It is sunny outside.*

The first sentence is complex in structure and it is challenging to construct a compact representation that expresses its entire meaning. However, it is fairly easy to conclude that the second sentence follows from the first one, by simply aligning *Bob* with *Bob* and *cannot sleep* with *awake* and recognizing that these are synonyms. Similarly, one can conclude that *It is sunny outside* contradicts the first sentence, by aligning *thunder and lightning* with *sunny* and recognizing that these are most likely incompatible.

We leverage this intuition to build a simpler and more lightweight approach to NLI within a neural framework; with considerably fewer parameters, our model outperforms more complex existing neural architectures. In contrast to existing approaches, our approach only relies on alignment and is fully computationally decomposable with respect to the input text. An overview of our approach is given in Figure 1. Given two sentences, where each word is repre-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2249–2255,
Austin, Texas, November 1-5, 2016.

sented by an embedding vector, we first create a soft alignment matrix using neural attention (Bahdanau et al., 2015). We then use the (soft) alignment to decompose the task into subproblems that are solved separately. Finally, the results of these subproblems are merged to produce the final classification. In addition, we optionally apply intra-sentence attention (Cheng et al., 2016) to endow the model with a richer encoding of substructures prior to the alignment step.

Asymptotically our approach does the same total work as a vanilla LSTM encoder, while being trivially parallelizable across sentence length, which can allow for considerable speedups in low-latency settings. Empirical results on the SNLI corpus show that our approach achieves state-of-the-art results, while using almost an order of magnitude fewer parameters compared to complex LSTM-based approaches.

2 Related Work

Our method is motivated by the central role played by alignment in machine translation (Koehn, 2009) and previous approaches to sentence similarity modeling (Haghighi et al., 2005; Das and Smith, 2009; Chang et al., 2010; Fader et al., 2013), natural language inference (Marsi and Krahmer, 2005; MacCartney et al., 2006; Hickl and Bensley, 2007; MacCartney et al., 2008), and semantic parsing (Andreas et al., 2013). The neural counterpart to alignment, *attention* (Bahdanau et al., 2015), which is a key part of our approach, was originally proposed and has been predominantly used in conjunction with LSTMs (Rocktäschel et al., 2016; Wang and Jiang, 2016) and to a lesser extent with CNNs (Yin et al., 2016). In contrast, our use of attention is purely based on word embeddings and our method essentially consists of feed-forward networks that operate largely independently of word order.

3 Approach

Let $\mathbf{a} = (a_1, \ldots, a_{\ell_a})$ and $\mathbf{b} = (b_1, \ldots, b_{\ell_b})$ be the two input sentences of length ℓ_a and ℓ_b, respectively. We assume that each a_i, $b_j \in \mathbb{R}^d$ is a word embedding vector of dimension d and that each sentence is prepended with a "NULL" token. Our training data comes in the form of labeled pairs $\{\mathbf{a}^{(n)}, \mathbf{b}^{(n)}, \mathbf{y}^{(n)}\}_{n=1}^{N}$, where $\mathbf{y}^{(n)} = (y_1^{(n)}, \ldots, y_C^{(n)})$ is an indicator vector encoding the label and C is the number of output classes. At test time, we receive a pair of sentences $(\mathbf{a}, \mathbf{b})$ and our goal is to predict the correct label $\mathbf{y}$.

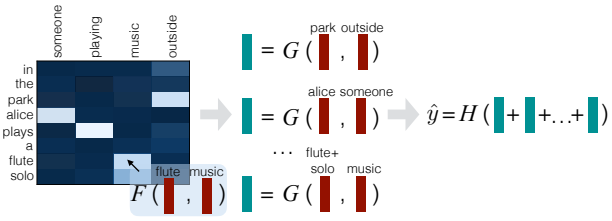

Figure 1: Pictoral overview of the approach, showing the *Attend* (left), *Compare* (center) and *Aggregate* (right) steps.

Input representation. Let $\bar{\mathbf{a}} = (\bar{a}_1, \ldots, \bar{a}_{\ell_a})$ and $\bar{\mathbf{b}} = (\bar{b}_1, \ldots, \bar{b}_{\ell_b})$ denote the input representation of each fragment that is fed to subsequent steps of the algorithm. The vanilla version of our model simply defines $\bar{\mathbf{a}} := \mathbf{a}$ and $\bar{\mathbf{b}} := \mathbf{b}$. With this input representation, our model does not make use of word order. However, we discuss an extension using intra-sentence attention in Section 3.4 that uses a minimal amount of sequence information.

The core model consists of the following three components (see Figure 1), which are trained jointly:

Attend. First, soft-align the elements of $\bar{\mathbf{a}}$ and $\bar{\mathbf{b}}$ using a variant of neural attention (Bahdanau et al., 2015) and decompose the problem into the comparison of aligned subphrases.

Compare. Second, separately compare each aligned subphrase to produce a set of vectors $\{\mathbf{v}_{1,i}\}_{i=1}^{\ell_a}$ for $\mathbf{a}$ and $\{\mathbf{v}_{2,j}\}_{j=1}^{\ell_b}$ for $\mathbf{b}$. Each $\mathbf{v}_{1,i}$ is a nonlinear combination of a_i and its (softly) aligned subphrase in $\mathbf{b}$ (and analogously for $\mathbf{v}_{2,j}$).

Aggregate. Finally, aggregate the sets $\{\mathbf{v}_{1,i}\}_{i=1}^{\ell_a}$ and $\{\mathbf{v}_{2,j}\}_{j=1}^{\ell_b}$ from the previous step and use the result to predict the label $\hat{y}$.

3.1 Attend

We first obtain unnormalized attention weights e_{ij}, computed by a function F', which decomposes as:

$$e_{ij} := F'(\bar{a}_i, \bar{b}_j) := F(\bar{a}_i)^T F(\bar{b}_j)\,. \qquad (1)$$

This decomposition avoids the quadratic complexity that would be associated with separately applying F' $\ell_a \times \ell_b$ times. Instead, only $\ell_a + \ell_b$ applications of F are needed. We take F to be a feed-forward neural network with ReLU activations (Glorot et al., 2011).

These attention weights are normalized as follows:

$$\beta_i := \sum_{j=1}^{\ell_b} \frac{\exp(e_{ij})}{\sum_{k=1}^{\ell_b} \exp(e_{ik})} \bar{b}_j \,,$$
$$\alpha_j := \sum_{i=1}^{\ell_a} \frac{\exp(e_{ij})}{\sum_{k=1}^{\ell_a} \exp(e_{kj})} \bar{a}_i \,. \quad (2)$$

Here β_i is the subphrase in $\bar{\mathbf{b}}$ that is (softly) aligned to $\bar{a}_i$ and vice versa for α_j.

3.2 Compare

Next, we separately compare the aligned phrases $\{(\bar{a}_i, \beta_i)\}_{i=1}^{\ell_a}$ and $\{(\bar{b}_j, \alpha_j)\}_{j=1}^{\ell_b}$ using a function G, which in this work is again a feed-forward network:

$$\mathbf{v}_{1,i} := G([\bar{a}_i, \beta_i]) \quad \forall i \in [1, \ldots, \ell_a] \,,$$
$$\mathbf{v}_{2,j} := G([\bar{b}_j, \alpha_j]) \quad \forall j \in [1, \ldots, \ell_b] \,. \quad (3)$$

where the brackets $[\cdot, \cdot]$ denote concatenation. Note that since there are only a linear number of terms in this case, we do not need to apply a decomposition as was done in the previous step. Thus G can jointly take into account both $\bar{a}_i$, and β_i.

3.3 Aggregate

We now have two sets of comparison vectors $\{\mathbf{v}_{1,i}\}_{i=1}^{\ell_a}$ and $\{\mathbf{v}_{2,j}\}_{j=1}^{\ell_b}$. We first aggregate over each set by summation:

$$\mathbf{v}_1 = \sum_{i=1}^{\ell_a} \mathbf{v}_{1,i} \quad , \quad \mathbf{v}_2 = \sum_{j=1}^{\ell_b} \mathbf{v}_{2,j} \,. \quad (4)$$

and feed the result through a final classifier H, that is a feed forward network followed by a linear layer:

$$\hat{\mathbf{y}} = H([\mathbf{v}_1, \mathbf{v}_2]) \,, \quad (5)$$

where $\hat{\mathbf{y}} \in \mathbb{R}^C$ represents the predicted (unnormalized) scores for each class and consequently the predicted class is given by $\hat{y} = \text{argmax}_i \hat{\mathbf{y}}_i$.

For training, we use multi-class cross-entropy loss with dropout regularization (Srivastava et al., 2014):

$$L(\theta_F, \theta_G, \theta_H) = \frac{1}{N} \sum_{n=1}^{N} \sum_{c=1}^{C} y_c^{(n)} \log \frac{\exp(\hat{y}_c)}{\sum_{c'=1}^{C} \exp(\hat{y}_{c'})} \,.$$

Here $\theta_F, \theta_G, \theta_H$ denote the learnable parameters of the functions F, G and H, respectively.

3.4 Intra-Sentence Attention (Optional)

In the above model, the input representations are simple word embeddings. However, we can augment this input representation with *intra-sentence attention* to encode compositional relationships between words within each sentence, as proposed by Cheng et al. (2016). Similar to Eqs. 1 and 2, we define

$$f_{ij} := F_{\text{intra}}(a_i)^T F_{\text{intra}}(a_j) \,, \quad (6)$$

where F_{intra} is a feed-forward network. We then create the self-aligned phrases

$$a'_i := \sum_{j=1}^{\ell_a} \frac{\exp(f_{ij} + d_{i-j})}{\sum_{k=1}^{\ell_a} \exp(f_{ik} + d_{i-k})} a_j \,. \quad (7)$$

The distance-sensitive bias terms $d_{i-j} \in \mathbb{R}$ provides the model with a minimal amount of sequence information, while remaining parallelizable. These terms are bucketed such that all distances greater than 10 words share the same bias. The input representation for subsequent steps is then defined as $\bar{a}_i := [a_i, a'_i]$ and analogously $\bar{b}_i := [b_i, b'_i]$.

4 Computational Complexity

We now discuss the asymptotic complexity of our approach and how it offers a higher degree of parallelism than LSTM-based approaches. Recall that d denotes embedding dimension and ℓ means sentence length. For simplicity we assume that all hidden dimensions are d and that the complexity of matrix($d \times d$)-vector($d \times 1$) multiplication is $O(d^2)$.

A key assumption of our analysis is that $\ell < d$, which we believe is reasonable and is true of the SNLI dataset (Bowman et al., 2015) where $\ell < 80$, whereas recent LSTM-based approaches have used $d \geq 300$. This assumption allows us to bound the complexity of computing the ℓ^2 attention weights.

Complexity of LSTMs. The complexity of an LSTM cell is $O(d^2)$, resulting in a complexity of $O(\ell d^2)$ to encode the sentence. Adding attention as in Rocktäschel et al. (2016) increases this complexity to $O(\ell d^2 + \ell^2 d)$.

Complexity of our Approach. Application of a feed-forward network requires $O(d^2)$ steps. Thus, the **Compare** and **Aggregate** steps have complexity $O(\ell d^2)$ and $O(d^2)$ respectively. For the **Attend** step,

Method	Train Acc	Test Acc	#Parameters
Lexicalized Classifier (Bowman et al., 2015)	99.7	78.2	–
300D LSTM RNN encoders (Bowman et al., 2016)	83.9	80.6	3.0M
1024D pretrained GRU encoders (Vendrov et al., 2015)	98.8	81.4	15.0M
300D tree-based CNN encoders (Mou et al., 2015)	83.3	82.1	3.5M
300D SPINN-PI encoders (Bowman et al., 2016)	89.2	83.2	3.7M
100D LSTM with attention (Rocktäschel et al., 2016)	85.3	83.5	252K
300D mLSTM (Wang and Jiang, 2016)	92.0	86.1	1.9M
450D LSTMN with deep attention fusion (Cheng et al., 2016)	88.5	86.3	3.4M
Our approach (vanilla)	89.5	86.3	382K
Our approach with intra-sentence attention	90.5	**86.8**	582K

Table 1: Train/test accuracies on the SNLI dataset and number of parameters (excluding embeddings) for each approach.

Method	**N**	**E**	**C**
Bowman et al. (2016)	80.6	88.2	85.5
Wang and Jiang (2016)	81.6	91.6	87.4
Our approach (vanilla)	83.6	91.3	85.8
Our approach w/ intra att.	83.7	92.1	86.7

Table 2: Breakdown of accuracy with respect to classes on SNLI development set. **N**=neutral, **E**=entailment, **C**=contradiction.

F is evaluated $O(\ell)$ times, giving a complexity of $O(\ell d^2)$. Each attention weight e_{ij} requires one dot product, resulting in a complexity of $O(\ell^2 d)$.

Thus the total complexity of the model is $O(\ell d^2 + \ell^2 d)$, which is equal to that of an LSTM with attention. However, note that with the assumption that $\ell < d$, this becomes $O(\ell d^2)$ which is the same complexity as a regular LSTM. Moreover, unlike the LSTM, our approach has the advantage of being parallelizable over ℓ, which can be useful at test time.

5 Experiments

We evaluate our approach on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015). Given a sentences pair $(\mathbf{a}, \mathbf{b})$, the task is to predict whether $\mathbf{b}$ is *entailed* by $\mathbf{a}$, $\mathbf{b}$ *contradicts* $\mathbf{a}$, or whether their relationship is *neutral*.

5.1 Implementation Details

The method was implemented in TensorFlow (Abadi et al., 2015).

Data preprocessing: Following Bowman et al. (2015), we remove examples labeled "–" (no gold label) from the dataset, which leaves 549,367 pairs for training, 9,842 for development, and 9,824 for testing. We use the tokenized sentences from the non-binary parse provided in the dataset and prepend each sentence with a "NULL" token. During training, each sentence was padded up to the maximum length of the batch for efficient training (the padding was explicitly masked out so as not to affect the objective/gradients). For efficient batching in TensorFlow, we semi-sorted the training data to first contain examples where both sentences had length less than 20, followed by those with length less than 50, and then the rest. This ensured that most training batches contained examples of similar length.

Embeddings: We use 300 dimensional GloVe embeddings (Pennington et al., 2014) to represent words. Each embedding vector was normalized to have ℓ_2 norm of 1 and projected down to 200 dimensions, a number determined via hyperparameter tuning. Out-of-vocabulary (OOV) words are hashed to one of 100 random embeddings each initialized to mean 0 and standard deviation 1. All embeddings remain fixed during training, but the projection matrix is trained. All other parameter weights (hidden layers etc.) were initialized from random Gaussians with mean 0 and standard deviation 0.01.

Each hyperparameter setting was run on a single machine with 10 asynchronous gradient-update threads, using Adagrad (Duchi et al., 2011) for optimization with the default initial accumulator value of 0.1. Dropout regularization (Srivastava et al., 2014) was used for all ReLU layers, but not for the final linear layer. We additionally tuned the following hyperparameters and present their chosen values in

ID	Sentence 1	Sentence 2	DA (vanilla)	DA (intra att.)	SPINN-PI	mLSTM	Gold
A	Two kids are standing in the ocean hugging each other.	Two kids enjoy their day at the beach.	**N**	**N**	E	E	**N**
B	A dancer in costumer performs on stage while a man watches.	the man is captivated	**N**	**N**	E	E	**N**
C	They are sitting on the edge of a fountain	The fountain is splashing the persons seated.	**N**	**N**	C	C	**N**
D	Two dogs play with tennis ball in field.	Dogs are watching a tennis match.	N	**C**	**C**	**C**	**C**
E	Two kids begin to make a snowman on a sunny winter day.	Two penguins making a snowman.	N	**C**	**C**	**C**	**C**
F	The horses pull the carriage, holding people and a dog, through the rain.	Horses ride in a carriage pulled by a dog.	E	E	**C**	**C**	**C**
G	A woman closes her eyes as she plays her cello.	The woman has her eyes open.	E	E	E	E	**C**
H	Two women having drinks and smoking cigarettes at the bar.	Three women are at a bar.	E	E	E	E	**C**
I	A band playing with fans watching.	A band watches the fans play	E	E	E	E	**C**

Table 3: Example wins and losses compared to other approaches. DA (Decomposable Attention) refers to our approach while SPINN-PI and mLSTM are previously developed methods (see Table 1).

parentheses: network size (2-layers, each with 200 neurons), batch size (4), [1] dropout ratio (0.2) and learning rate (0.05–vanilla, 0.025–intra-attention). All settings were run for 50 million steps (each step indicates one batch) but model parameters were saved frequently as training progressed and we chose the model that did best on the development set.

5.2 Results

Results in terms of 3-class accuracy are shown in Table 1. Our vanilla approach achieves state-of-the-art results with almost an order of magnitude fewer parameters than the LSTMN of Cheng et al. (2016). Adding intra-sentence attention gives a considerable improvement of 0.5 percentage points over the existing state of the art. Table 2 gives a breakdown of accuracy on the development set showing that most of our gains stem from *neutral*, while most losses come from *contradiction* pairs.

Table 3 shows some wins and losses. Examples A-C are cases where both variants of our approach are correct while both SPINN-PI (Bowman et al., 2016) and the mLSTM (Wang and Jiang, 2016) are incorrect. In the first two cases, both sentences contain phrases that are either identical or highly lexically related (e.g. "Two kids" and "ocean / beach") and our approach correctly favors neutral in these cases. In Example C, it is possible that relying on word-order may confuse SPINN-PI and the mLSTM due to how "fountain" is the object of a preposition in the first sentence but the subject of the second.

The second set of examples (D-F) are cases where our vanilla approach is incorrect but mLSTM and SPINN-PI are correct. Example F requires sequential information and neither variant of our approach can predict the correct class. Examples D-E are interesting however, since they don't require word order information, yet intra-attention seems to help. We suspect this may be because the word embeddings are not fine-grained enough for the algorithm to conclude that "play/watch" is a contradiction, but intra-attention, by adding an extra layer of composition/nonlinearity to incorporate context, compensates for this.

Finally, Examples G-I are cases that all methods get wrong. The first is actually representative of many examples in this category where there is one critical word that separates the two sentences (close vs open in this case) and goes unnoticed by the algorithms. Examples H requires inference about numbers and Example I needs sequence information.

6 Conclusion

We presented a simple attention-based approach to natural language inference that is trivially parallelizable. The approach outperforms considerably more complex neural methods aiming for text understanding. Our results suggest that, at least for this task, pairwise comparisons are relatively more important than global sentence-level representations.

Deep Reinforcement Learning for Mention-Ranking Coreference Models

Kevin Clark

Stanford University
manning@cs.stanford.edu

Abstract

Coreference resolution systems are typically trained with heuristic loss functions that require careful tuning. In this paper we instead apply reinforcement learning to directly optimize a neural mention-ranking model for coreference evaluation metrics. We experiment with two approaches: the REINFORCE policy gradient algorithm and a reward-rescaled max-margin objective. We find the latter to be more effective, resulting in a significant improvement over the current state-of-the-art on the English and Chinese portions of the CoNLL 2012 Shared Task.

1 Introduction

Coreference resolution systems typically operate by making sequences of local decisions (e.g., adding a coreference link between two mentions). However, most measures of coreference resolution performance do not decompose over local decisions, which means the utility of a particular decision is not known until all other decisions have been made.

Due to this difficulty, coreference systems are usually trained with loss functions that heuristically define the goodness of a particular coreference decision. These losses contain hyperparameters that are carefully selected to ensure the model performs well according to coreference evaluation metrics. This complicates training, especially across different languages and datasets where systems may work best with different settings of the hyperparameters.

To address this, we explore using two variants of reinforcement learning to directly optimize a coreference system for coreference evaluation metrics. In particular, we modify the max-margin coreference objective proposed by Wiseman et al. (2015) by incorporating the reward associated with each coreference decision into the loss's slack rescaling. We also test the REINFORCE policy gradient algorithm (Williams, 1992).

Our model is a neural mention-ranking model. Mention-ranking models score pairs of mentions for their likelihood of coreference rather than comparing partial coreference clusters. Hence they operate in a simple setting where coreference decisions are made independently. Although they are less expressive than entity-centric approaches to coreference (e.g., Haghighi and Klein, 2010), mention-ranking models are fast, scalable, and simple to train, causing them to be the dominant approach to coreference in recent years (Durrett and Klein, 2013; Wiseman et al., 2015). Having independent actions is particularly useful when applying reinforcement learning because it means a particular action's effect on the final reward can be computed efficiently.

We evaluate the models on the English and Chinese portions of the CoNLL 2012 Shared Task. The REINFORCE algorithm is competitive with a heuristic loss function while the reward-rescaled objective significantly outperforms both[1]. We attribute this to reward rescaling being well suited for a ranking task due to its max-margin loss as well as benefiting from directly optimizing for coreference metrics. Error analysis shows that using the reward-rescaling loss results in a similar number of mistakes as the heuristic loss, but the mistakes tend to be less severe.

2 Neural Mention-Ranking Model

We use the neural mention-ranking model described in Clark and Manning (2016), which we briefly go over in this section. Given a mention m and candidate antecedent c, the mention-ranking model produces a score for the pair $s(c, m)$ indicating their compatibility for coreference with a feedforward neural network. The candidate antecedent may be any mention that occurs before m in the document or NA, indicating that m has no antecedent.

Input Layer. For each mention, the model extracts various words (e.g., the mention's head word) and groups of words (e.g., all words in the mention's sentence) that are fed into the neural network. Each word is represented by a vector $\boldsymbol{w}_i \in \mathbb{R}^{d_w}$. Each group of words is represented by the average of the vectors of each word in the group. In addition to the embeddings, a small number of additional features are used, including distance, string matching, and speaker identification features. See Clark and Manning (2016) for the full set of features and an ablation study.

These features are concatenated to produce an I-dimensional vector $\boldsymbol{h}_0$, the input to the neural network. If $c = \text{NA}$, features defined over pairs of mentions are not included. For this case, we train a separate network with an identical architecture to the pair network except for the input layer to produce anaphoricity scores.

Hidden Layers. The input gets passed through three hidden layers of rectified linear (ReLU) units (Nair and Hinton, 2010). Each unit in a hidden layer is fully connected to the previous layer:

$$\boldsymbol{h}_i(c, m) = \max(0, \boldsymbol{W}_i \boldsymbol{h}_{i-1}(c, m) + \boldsymbol{b}_i)$$

where $\boldsymbol{W}_1$ is a $M_1 \times I$ weight matrix, $\boldsymbol{W}_2$ is a $M_2 \times M_1$ matrix, and $\boldsymbol{W}_3$ is a $M_3 \times M_2$ matrix.

Scoring Layer. The final layer is a fully connected layer of size 1:

$$s(c, m) = \boldsymbol{W}_4 \boldsymbol{h}_3(c, m) + b_4$$

where $\boldsymbol{W}_4$ is a $1 \times M_3$ weight matrix. At test time, the mention-ranking model links each mention with its highest scoring candidate antecedent.

3 Learning Algorithms

Mention-ranking models are typically trained with heuristic loss functions that are tuned via hyperparameters. These hyperparameters are usually given as costs for different error types, which are used to bias the coreference system towards making more or fewer coreference links. In this section we first describe a heuristic loss function incorporating this idea from Wiseman et al. (2015). We then propose new training procedures based on reinforcement learning that instead directly optimize for coreference evaluation metrics.

3.1 Heuristic Max-Margin Objective

The heuristic loss from Wiseman et al. is governed by the following error types, which were first proposed by Durrett et al. (2013).

Suppose the training set consists of N mentions $m_1, m_2, ..., m_N$. Let $\mathcal{C}(m_i)$ denote the set of candidate antecedents of a mention m_i (i.e., mentions preceding m_i and NA) and $\mathcal{T}(m_i)$ denote the set of true antecedents of m_i (i.e., mentions preceding m_i that are coreferent with it or $\{\text{NA}\}$ if m_i has no antecedent). Then we define the following costs for linking m_i to a candidate antecedent $c \in \mathcal{C}(m_i)$:

$$\Delta_h(c, m_i) = \begin{cases} \alpha_{\text{FN}} & \text{if } c = \text{NA} \ \wedge \mathcal{T}(m_i) \neq \{\text{NA}\} \\ \alpha_{\text{FA}} & \text{if } c \neq \text{NA} \ \wedge \mathcal{T}(m_i) = \{\text{NA}\} \\ \alpha_{\text{WL}} & \text{if } c \neq \text{NA} \ \wedge a \notin \mathcal{T}(m_i) \\ 0 & \text{if } a \in \mathcal{T}(m_i) \end{cases}$$

for "false new," "false anaphor," "wrong link", and correct coreference decisions.

The heuristic loss is a slack-rescaled max-margin objective parameterized by these error costs. Let $\hat{t}_i$ be the highest scoring true antecedent of m_i:

$$\hat{t}_i = \underset{c \in \mathcal{C}(m_i) \wedge \Delta_h(c, m_i) = 0}{\text{argmax}} s(c, m_i)$$

Then the heuristic loss is given as

$$\mathcal{L}(\theta) = \sum_{i=1}^{N} \max_{c \in \mathcal{C}(m_i)} \Delta_h(c, m_i)(1 + s(c, m_i) - s(\hat{t}_i, m_i))$$

Finding Effective Error Penalties. We fix $\alpha_{\text{WL}} = 1.0$ and search for α_{FA} and α_{FN} out of $\{0.1, 0.2, ..., 1.5\}$ with a variant of grid search. Each new trial uses the unexplored set of hyperparame-

ters that has the closest Manhattan distance to the best setting found so far on the dev set. The search is halted when all immediate neighbors (within 0.1 distance) of the best setting have been explored. We found $(\alpha_{\text{FN}}, \alpha_{\text{FA}}, \alpha_{\text{WL}}) = (0.8, 0.4, 1.0)$ to be best for English and $(\alpha_{\text{FN}}, \alpha_{\text{FA}}, \alpha_{\text{WL}}) = (0.8, 0.5, 1.0)$ to be best for Chinese on the CoNLL 2012 data.

3.2 Reinforcement Learning

Finding the best hyperparameter settings for the heuristic loss requires training many variants of the model, and at best results in an objective that is correlated with coreference evaluation metrics. To address this, we pose mention ranking in the reinforcement learning framework (Sutton and Barto, 1998) and propose methods that directly optimize the model for coreference metrics.

We can view the mention-ranking model as an *agent* taking a series of *actions* $a_{1:T} = a_1, a_2, ..., a_T$, where T is the number of mentions in the current document. Each action a_i links the ith mention in the document m_i to a candidate antecedent. Formally, we denote the set of actions available for the ith mention as $\mathcal{A}_i = \{(c, m_i) : c \in \mathcal{C}(m_i)\}$, where an action (c, m) adds a coreference link between mentions m and c. The mention-ranking model assigns each action the score $s(c, m)$ and takes the highest-scoring action at each step.

Once the agent has executed a sequence of actions, it observes a *reward* $R(a_{1:T})$, which can be any function. We use the B^3 coreference metric for this reward (Bagga and Baldwin, 1998). Although our system evaluation also includes the MUC (Vilain et al., 1995) and CEAF_{ϕ_4} (Luo, 2005) metrics, we do not incorporate them into the loss because MUC has the flaw of treating all errors equally and CEAF_{ϕ_4} is slow to compute.

Reward Rescaling. Crucially, the actions taken by a mention-ranking model are independent. This means it is possible to change any action a_i to a different one $a'_i \in \mathcal{A}_i$ and see what reward the model would have gotten by taking that action instead: $R(a_1, ..., a_{i-1}, a'_i, a_{i+1}, ..., a_T)$. We use this idea to improve the slack-rescaling parameter Δ in the max-margin loss $\mathcal{L}(\theta)$. Instead of setting its value based on the error type, we compute exactly how much each action hurts the final reward:

$$\Delta_r(c, m_i) = -R(a_1, ..., (c, m_i), ..., a_T) + \max_{a'_i \in \mathcal{A}_i} R(a_1, ..., a'_i, ..., a_T)$$

where $a_{1:T}$ is the highest scoring sequence of actions according to the model's current parameters. Otherwise the model is trained in the same way as with the heuristic loss.

The REINFORCE Algorithm. We also explore using the REINFORCE policy gradient algorithm (Williams, 1992). We can define a probability distribution over actions using the mention-ranking model's scoring function as follows:

$$p_\theta(a) \propto e^{s(c,m)}$$

for any action $a = (c, m)$. The REINFORCE algorithm seeks to maximize the expected reward

$$J(\theta) = \mathbb{E}_{[a_{1:T} \sim p_\theta]} R(a_{1:T})$$

It does this through gradient ascent. Computing the full gradient is prohibitive because of the expectation over all possible action sequences, which is exponential in the length of the sequence. Instead, it gets an unbiased estimate of the gradient by sampling a sequence of actions $a_{1:T}$ according to p_θ and computing the gradient only over the sample.

We take advantage of the independence of actions by using the following gradient estimate, which has lower variance than the standard REINFORCE gradient estimate.

$$\nabla_\theta J(\theta) \approx \sum_{i=1}^{T} \sum_{a'_i \in \mathcal{A}_i} [\nabla_\theta p_\theta(a'_i)](R(a_1, ..., a'_i, ..., a_T) - b_i)$$

where b_i is a baseline used to reduce the variance, which we set to $\mathbb{E}_{a'_i \in \mathcal{A}_i \sim p_\theta} R(a_1, ..., a'_i, ..., a_T)$.

4 Experiments and Results

We run experiments on the English and Chinese portions of the CoNLL 2012 Shared Task data (Pradhan et al., 2012) and evaluate with the MUC, B^3, and CEAF_{ϕ_4} metrics. Our experiments were run using predicted mentions from Stanford's rule-based coreference system (Raghunathan et al., 2010).

We follow the training methodology from Clark and Manning (2016): hidden layers of sizes M_1 = 1000, M_2 = M_3 = 500, the RMSprop optimizer

(Hinton and Tieleman, 2012), dropout (Hinton et al., 2012) with a rate of 0.5, and pretraining with the all pairs classification and top pairs classification tasks. However, we improve on the previous system by using using better mention detection, more effective hyperparameters, and more epochs of training.

4.1 Results

We compare the heuristic loss, REINFORCE, and reward rescaling approaches on both datasets. We find that REINFORCE does slightly better than the heuristic loss, but reward rescaling performs significantly better than both across both languages.

We attribute the modest improvement of REINFORCE to it being poorly suited for a ranking task. During training it optimizes the model's performance in expectation, but at test-time it takes the most probable sequence of actions. This mismatch occurs even at the level of an individual decision: the model only links the current mention to a single antecedent, but is trained to assign high probability to all correct antecedents. We believe the benefit of REINFORCE being guided by coreference evaluation metrics is offset by this disadvantage, which does not occur in the max-margin approaches. The reward-rescaled max-margin loss combines the best of both worlds, resulting in superior performance.

4.2 The Benefits of Reinforcement Learning

In this section we examine the reward-based cost function Δ_r and perform error analysis to determine how reward rescaling improves the mention-ranking model's accuracy.

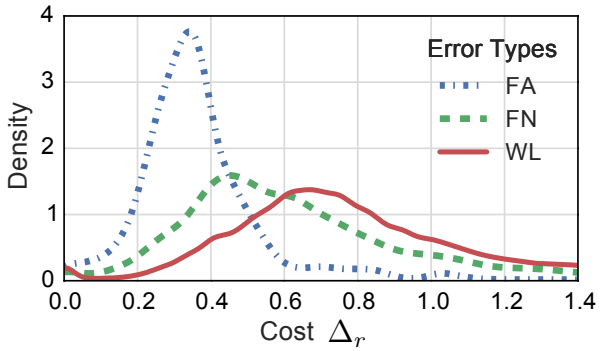

Figure 1: Density plot of the costs Δ_r associated with different error types on the English CoNLL 2012 test set.

Comparison with Heuristic Costs. We compare the reward-based cost function Δ_r with the error types used in the heuristic loss. For English, the average value of Δ_r is 0.79 for FN errors and 0.38 for FA errors when the costs are scaled so the average value of a WL error is 1.0. These are very close to the hyperparameter values $(\alpha_{\text{FN}}, \alpha_{\text{FA}}, \alpha_{\text{WL}}) = (0.8, 0.4, 1.0)$ found by grid search. However, there is a high variance in costs for each error type, suggesting that using a fixed penalty for each type as in the heuristic loss is insufficient (see Figure 1).

Avoiding Costly Mistakes. Embedding the costs of actions into the loss function causes the reward-rescaling model to prioritize getting the more important coreference decisions (i.e., the ones with the biggest impact on the final score) correct. As a

Class of Mentions	Average Cost $\overline{\Delta}_r$			# Heuristic Loss Errors			# Reward Rescaling Errors		
	FN	FA	WL	FN	FA	WL	FN	FA	WL
Proper nouns	0.90	0.38	1.02	403	597	221	334	660	233
Pronouns in phone conversations	0.86	0.39	1.21	82	85	81	90	78	67

Table 3: Examples of classes of mention on which the reward-rescaling loss significantly improves upon the heuristic loss due to its reward-based cost function. Reported numbers are from the English CoNLL 2012 test set.

Model	FN	FA	WL
Heuristic Loss	1719	1956	1258
Reward Rescaling	1725	1994	1247

Table 2: Number of "false new," "false anaphoric," and "wrong link" errors produced by the models on the English CoNLL 2012 test set.

result, it makes fewer costly mistakes at test time. Costly mistakes often involve large clusters of mentions: incorrectly combining two coreference clusters of size ten is much worse than incorrectly combining two clusters of size one. However, the cost of an action also depends on other factors like the number of errors already present in the clusters and the utilities of the other available actions.

Table 2 shows the breakdown of errors made by the heuristic and reward-rescaling models on the test set. The reward-rescaling model makes slightly more errors, meaning its improvement in performance must come from its errors being less severe.

Example Improvements. Table 3 shows two classes of mentions where the reward-rescaling loss particularly improves over the heuristic loss.

Proper nouns have a higher average cost for "false new" errors (0.90) than other mentions types (0.77). This is perhaps because proper nouns are important for connecting clusters of mentions far apart in a document, so incorrectly linking a proper noun to NA could result in a large decrease in recall. Because it more heavily weights these high-cost errors during training, the reward-rescaling model makes fewer "false new" errors for proper nouns than the heuristic loss. Although there is an increase in other kinds of errors as a result, most of these are low-cost "false anaphoric" errors.

The pronouns in the "telephone conversation" genre often group into extremely large coreference clusters, which means a "wrong link" error can have a very large negative effect on the score. This is reflected in its high average cost of 1.21. After prioritizing these examples during training, the reward-rescaling model creates significantly fewer wrong links than the heuristic loss, which is trained using a fixed cost of 1.0 for all wrong links.

5 Related Work

Mention-ranking models have been widely used for coreference resolution (Denis and Baldridge, 2007; Rahman and Ng, 2009; Durrett and Klein, 2013). These models are typically trained with heuristic loss functions that assign costs to different error types, as in the heuristic loss we describe in Section 3.1 (Fernandes et al., 2012; Durrett et al., 2013; Björkelund and Kuhn, 2014; Wiseman et al., 2015; Martschat and Strube, 2015; Wiseman et al., 2016).

To the best of our knowledge reinforcement learning has not been applied to coreference resolution before. However, imitation learning algorithms such as SEARN (Daumé III et al., 2009) have been used to train coreference resolvers (Daumé III, 2006; Ma et al., 2014; Clark and Manning, 2015). These algorithms also directly optimize for coreference evaluation metrics, but they require an expert policy to learn from instead of relying on rewards alone.

6 Conclusion

We propose using reinforcement learning to directly optimize mention-ranking models for coreference evaluation metrics, obviating the need for hyperparameters that must be carefully selected for each particular language, dataset, and evaluation metric. Our reward-rescaling approach also increases the model's accuracy, resulting in significant gains over the current state-of-the-art.

Abstract

Discourse parsing is considered as one of the most challenging natural language processing (NLP) tasks. Implicit discourse relation classification is the bottleneck for discourse parsing. Without the guide of explicit discourse connectives, the relation of sentence pairs are very hard to be inferred. This paper proposes a stacking neural network model to solve the classification problem in which a convolutional neural network (CNN) is utilized for sentence modeling and a collaborative gated neural network (CGNN) is proposed for feature transformation. Our evaluation and comparisons show that the proposed model outperforms previous state-of-the-art systems.

1 Introduction

As a fundamental task in natural language processing (NLP), discourse parsing entails the discovery of the latent relational structure in multi-sentence level analysis. It is also central to many practical tasks such as question answering (Liakata et al., 2013; Jansen et al., 2014), machine translation (Meyer and Popescu-Belis, 2012; Meyer and Webber, 2013) and automatic summarization (Murray et al., 2006; Yoshida et al., 2014). Discourse parsing is also the shared task of CoNLL 2015 and 2016 (Xue et al., 2015; Xue et al., 2016), and many previous works previous on this task (Qin et al., 2016b; Li et al., 2016; Chen et al., 2015; Wang and Lan, 2016). In a discourse parser, implicit relation recognition has been the bottleneck due to lack of explicit connectives (like *"because"* or *"and"*) that can be strong indicators for the senses between adjacent clauses (Qin et al., 2016b; Pitler et al., 2009; Lin et al., 2014). This work therefore focuses on implicit relation recognition that infers the senses of the discourse relations within adjacent sentence pairs.

Most previous works on PDTB implicit relation recognition only focus on one-versus-others binary classification problems of the top level four classes (Pitler et al., 2009; Zhou et al., 2010; Park and Cardie, 2012; Biran and McKeown, 2013; Rutherford and Xue, 2014; Braud and Denis, 2015). Traditional classification methods directly rely on feature engineering, based on bag-of-words, production rules, and some linguistically-informed features (Zhou et al., 2010; Rutherford and Xue, 2014). However, discourse relations root in semantics, which may be hard to recover from surface level feature, thus these methods did not report satisfactory performance. Recently, neural network (NN) models have shown competitive or even better results than traditional linear models with handcrafted sparse features (Wang et al., 2016b; Zhang et al., 2016a; Jia and Zhao, 2014). They have been proved to be effective for many tasks (Qin et al., 2016a; Wang et al., 2016a; Zhang et al., 2016b; Wang et al., 2015; Wang et al., 2014; Cai and

Zhao, 2016), also including discourse parsing. Ji and Eisenstein (2015) adopt recursive neural network and incorporate with entity-augmented distributed semantics. Zhang et al. (2015) explore a shallow convolutional neural network and achieve competitive performance. Although simple neural network has been shown effective, the result has not been quite satisfactory which suggests that there is still space for improving.

The concerned task could be straightforwardly formalized as a sentence-pair classification problem, which needs inferring senses solely based on the two arguments without cues of connectives. Two problems should be carefully handled in this task: how to model sentences and how to capture the interactions between the two arguments. The former could be addressed by Convolutional Neural Network (CNN) which has been proved effective for sentence modeling (Kalchbrenner et al., 2014; Kim, 2014), while the latter is the key problem, which might need deep semantic analysis for the interaction of two arguments. To solve the latter problem, we propose collaborative gated neural network (CGNN) which is partially inspired by Highway Network whose gate mechanism achieves success (Srivastava et al., 2015). Our method will be evaluated on the benchmark dataset against state-of-the-art methods.

The rest of the paper is organized as follows: Section 2 briefly describes our model, introducing the stacking architecture of CNN and CGNN, Section 3 shows the experiments and analysis, and Section 4 concludes this paper.

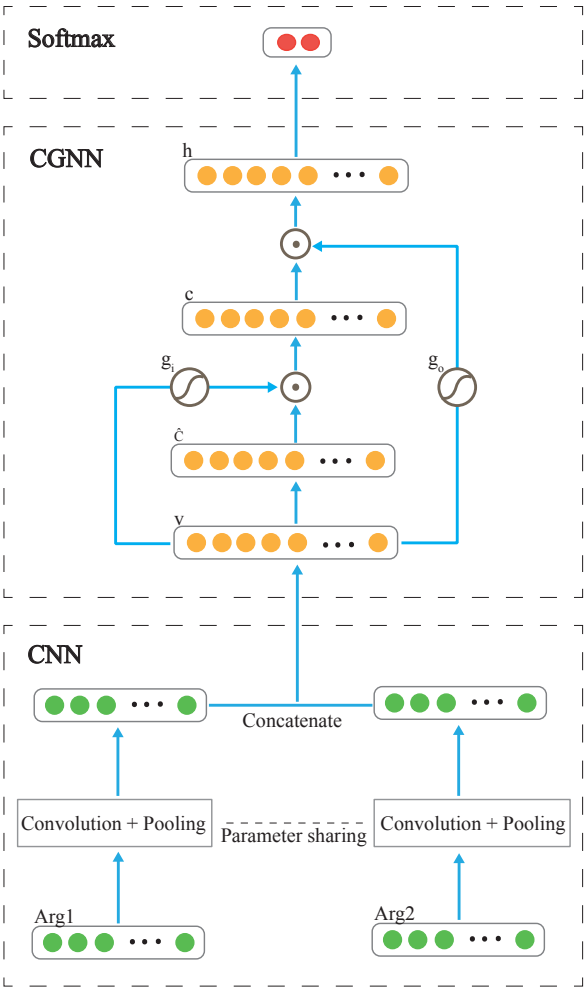

Figure 1: Model Architecture

2 Method

The architecture of the model, as shown in Figure 1, is straightforward. It can be divided into three parts: 1) CNN for modeling arguments; 2) CGNN unit for feature transformation; 3) a conventional softmax layer for the final classification. CNN is used to obtain the vector representations for the sentences, CGNN further captures and transforms the features for the final classification.

2.1 Convolutional Neural Network

As CNN has been broadly adopted for modeling sentences, we will explain it in brevity. For two arguments, typical sentence modeling process will be applied: sentence embedding (including embeddings for words and part-of-speech (POS) tags) through projection layer, convolution operations (with multiple groups of filters) through the convolution layer, obtaining the sentence representation through one-max-pooling. The two arguments will get their sentence vectors independently without any interfering, and the convolution operation will be the same by sharing parameters. The final argument-pair representation will be the vector $\mathbf{v}$ which is concatenated from two sentence vectors and this vector will be used as the input of the CGNN unit.

	COMP.	CONT.	EXP.	TEMP.	AVG

Table 1: F_1 scores (%) with different models.

2.2 Collaborative Gated Neural Network

For implicit sense classification, the key is how to effectively capture the interactions between the two arguments. The interactions could be word pairs, phrase pairs or even the latent meaning of the two full arguments. Pitler et al. (2009) has shown that word pair features are helpful. To model these interactions, we have to make a full use of the sentence vectors obtained from CNN. However, common neural hidden layers might be insufficient to deal with the challenge. We need to seek more powerful neural models, i.e., gated neural network.

In recent years, gated mechanism has gained popularity in neural models. Although it is first introduced in the cells of recurrent neural networks, like Long-Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Chung et al., 2014), traditional feed-forward neural models such as the Highway Network could also benefit from it (Srivastava et al., 2015). The existing studies show that the gated mechanism in highway network serves not only a means for easier training, but also a tool to route information in a trained network.

Motivated by the idea of highway network, we propose a collaborative gated neural network (CGNN) for this task. The architecture of CGNN is illustrated in Figure 1, and it contains a sequence of transformations. First, the inner-cell $\hat{\mathbf{c}}$ is obtained through linear transformation and non-linear activation on the input $\mathbf{v}$, and this process is exactly the operation of an ordinary neural layer.

$$\hat{\mathbf{c}} = \tanh(\mathbf{W}^c \cdot \mathbf{v} + \mathbf{b}^c)$$

Meanwhile, the two gates $\mathbf{g}_i$ and $\mathbf{g}_o$ are calculated independently because they are only influenced by the original input through different parameters:

$$\mathbf{g}_i = \sigma(\mathbf{W}^i \cdot \mathbf{v} + \mathbf{b}^i)$$
$$\mathbf{g}_o = \sigma(\mathbf{W}^o \cdot \mathbf{v} + \mathbf{b}^o)$$

where the σ denotes sigmoid function which guarantees the values in the gates are in [0,1]. Two gated operations are applied sequentially, where a gated operation indicates the element-wise multiplication of an inner-cell and a gate. Between the two gated operations, a non-linear activation operation is applied. The procedure could be formulated as follows:

$$\mathbf{c} = \hat{\mathbf{c}} \odot \mathbf{g}_i$$
$$\mathbf{h} = \tanh(\mathbf{c}) \odot \mathbf{g}_o$$

where $\odot$ denotes element-wise multiplication, $\mathbf{c}$ is the second inner-cell and $\mathbf{h}$ is the output of CGNN unit.

Although the two gates are generated independently, they will work collaboratively because they control the information flow of the inner-cells sequentially which resembles logical AND operation in a probabilistic version. In fact, the transformations after $\hat{\mathbf{c}}$ will concern only element-wise operations which might give finer controls for each dimension, and the information can only flow on the dimensions where both gates are "open". This procedure will help select the most crucial features.

The gates in this model are mainly used for routing information from sentence-pairs vectors. When there is only one gate in our network, the model works similar to the highway network (Srivastava et al., 2015).

2.3 Output and Training

After the transformation of the CGNN unit, the transformed vector $\mathbf{h}$ will be sent to a conventional softmax for classification.

The training object *J* will be the cross-entropy error *E* with *L2* regularization:

$$E(\hat{y}, y) = -\sum_{j}^{l} y_j \times \log(Pr(\hat{y}_j))$$

$$J(\theta) = \frac{1}{m}\sum_{k}^{m} E(\hat{y}^{(k)}, y^{(k)}) + \frac{\lambda}{2}\|\theta\|^2$$

where y_j is the gold label and $\hat{y}_j$ is the predicted one. We adopt the diagonal variant of AdaGrad (Duchi et al., 2011) for the optimization process.

3 Experiments

3.1 Setting

As for the benchmark dataset, Penn Discourse Treebank (PDTB) (Prasad et al., 2008) corpus[1] is used for evaluation. In the PDTB, each discourse relation is annotated between two argument spans.

To be consistent with the setups of prior works, we formulate the implicit relation classification task as four one-versus-other binary classification problems only using the four top level classes: COMPARISON (COMP.), CONTINGENCY (CONT.), EXPANSION (EXP.) and TEMPORAL (TEMP.). While different works include different relations of varying specificities, all of them include these four core relations (Pitler et al., 2009). Following dataset splitting convention of the previous works, we use sections 2-20 for training, sections 21-22 for testing and sections 0-1 for development set. The proposed model is possible to be extended for multi-class classification of discourse parsing, but for the comparisons with most of previous works, we will follow them and focus on the binary classification problems.

For other hyper-parameters of the model and training process, we fix the lengths of both the input arguments to be 80, and apply truncating or zero-padding when necessary. The dimensions for word embeddings and POS embeddings are respectively 300 and 50, and the embedding layer adopts a dropout of 0.2. The word embeddings are initialized with pre-trained word vectors using *word2vec* [2] (Mikolov et al., 2013) and other parameters are randomly initialized including POS embeddings. We set the starting learning rate to 0.001. For CNN model, we utilize three groups of filters with window widths of (2, 2, 2) and their filter numbers are all set to 1024. The hyper-parameters are the same for all models and we do not tune them individually.

3.2 Model Analysis

For transformation of sentence vectors, a simple Multilayer Perceptron (MLP) layer could be a straightforward choice, while more complex neural modules, such as LSTM and highway network, could also be considered. Our model utilizes a CGNN unit with refined gated mechanism for the transformation. Will the proposed CGNN really bring about further performance improvement? We now answer this question empirically.

As shown in Table 1, CNN model usually performs well on its own. Utilizing an MLP layer or a Highway layer could improve the accuracies on CONTINGENCY, EXPANSION, TEMPORARY except for COMPARISON. Though the primary motivation of Highway is to ease gradient-based training of highly deep networks through utilizing gated units, it works merely as an ordinary MLP in the proposed model, which explains the reason that it performs like MLP. Despite one of four classes, COMPARISON, not receiving performance improvement, introducing a non-linear transformation layer lets the classification benefit as a whole. "CNN+LSTM" denotes the method of using LSTM to read the convolution sequence (without pooling operation), and it even does not perform better than MLP.

The CGNN achieves the best performance on all classes including COMPARISON. It gains 3.97% imrovement on average F1 score using CNN only model. We assume that CGNN is well-suited to work with CNN, adaptively transforming and combining local features detected by the individual filters.

3.3 Results

We show the main results in Tables 2 and 3. The metrics include precision (P), recall (R), accuracy (Acc) and F1 score. Since not all of these metrics are reported in previous work, the comparisons are correspondingly in Table 2 and 3. Some previous work merges *Entrel* with *Expansion*, which is also explored in our study and noted as EXP.+.

Table 3: Comparisons of F_1 scores (%) (EXP. without *Entrel*).

We compare with best-performed or competitive models including both traditional linear methods and recent neural methods. For traditional methods: Pitler et al. (2009) use several linguistically informed features, including polarity tags, Levin verb classes, length of verb phrases, modality, context, and lexical features; Zhou et al. (2010) improve the performance through predicting connective words as features; Park and Cardie (2012) propose a locally-optimal feature set and further identify factors for feature extraction that can have a major impact performance, including stemming and lexicon look-up; Biran and McKeown (2013) collect word pairs from arguments of explicit examples to help the learning; Rutherford and Xue (2014) employ Brown cluster pair and coreference patterns for performance enhancement. Several neural methods have also been included for comparison: Zhang et al. (2015) propose a simplified neural network which has only three different pooling operations (max, min, average); Ji and Eisenstein (2015) compute distributed semantics representation by composition up the syntactic parse tree through recursive neural network; Braud and Denis (2015) consider shallow lexical features and word embeddings. Chen et al. (2016) replace the original words by word embeddings to overcome the data sparsity problem and they also utilize gated relevance network to capture the semantic interaction between word pairs. The gated network is different from ours but also works well.

Our model achieves F-measure improvements of 1.85% on COMPARISON, 1.56% on CONTINGENCY, 1.27% on EXPANSION, 0.94% on EXPANSION+, 4.89% on TEMPORAL, against the state-of-the-art of each class. We improve by 4.73% on average F1 score when not including ENTREL in EXPANSION as reported in Table 2 and 3.19% on average F1 score otherwise as reported in Table 3. The results show that our model achieves the best performance and especially makes the most remarkable progress on TEMPORAL.

4 Conclusion

In this paper, we propose a stacking gated neural architecture for implicit discourse relation classification. Our model includes convolution and collaborative gated neural network. The analysis and experiments show that CNN performs well on its own and combining CGNN provides further gains. Our evaluation on PTDB shows that the proposed model outperforms previous state-of-the-art systems.

Abstract

Dependency tree-to-tree translation models are powerful because they can naturally handle long range reorderings which is important for distant language pairs. The translation process is easy if it can be accomplished only by replacing non-terminals in translation rules with other rules. However it is sometimes necessary to adjoin translation rules. Flexible non-terminals have been proposed as a promising solution for this problem. A flexible non-terminal provides several insertion position candidates for the rules to be adjoined, but it increases the computational cost of decoding. In this paper we propose a neural network based insertion position selection model to reduce the computational cost by selecting the appropriate insertion positions. The experimental results show the proposed model can select the appropriate insertion position with a high accuracy. It reduces the decoding time and improves the translation quality owing to reduced search space.

1 Introduction

Tree-to-tree machine translation models currently receive limited attention. However, we believe that using target-side syntax is important to achieve high-quality translations between distant language pairs which require long range reorderings. Especially, using dependency trees on both source and target sides is promising for this purpose (Menezes and Quirk, 2007; Nakazawa and Kurohashi, 2010; Richardson et al., 2014). Tree-based translation models naturally realize word reorderings using the non-terminals or anchors for the attachment in the translation rules: therefore they do not need a reordering model which string-based models require. For example, suppose we have a translation rule with the word alignment shown in Figure 1, it is easy to translate a new input sentence which has "図書館 (*library*)" instead of "公園 (*park*)" because we can accomplish it by simply substituting "library" for the target word "park" without considering the reordering. In this case, the source word "公園" and target word "park" work as the non-terminals.

On the other hand, it is problematic when we need to adjoin a subtree which is not presented in training sentences, which we call *floating* subtree in this paper. The floating subtrees are not necessarily adjuncts, but any words or phrases. For example, suppose the Japanese input sentence in Figure 1 has "突然 (*suddenly*)", but the training corpus provides only a translation rule without the word. In this case we cannot directly use the rule for the translation because it does not know where to insert the translation of the floating word in the output. As another example, there is no context information available for the children of the OOV word in the input sentence, so we need some special process to translate them.

Previous work deals with this problem by using glue rules (Chiang, 2005) or limiting the dependency structures to be well-formed (Shen et al., 2008). Richardson et al. (2016) introduces the concept of *flexible* non-terminals. It provides multiple possible insertion positions for the floating subtree rather than fixed insertion positions. A possible insertion position must satisfy the following conditions:

- it must be a child of the aligned word of the parent of the floating subtree

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2271–2277,
Austin, Texas, November 1-5, 2016.

- it must not violate the projectivity of the dependency tree

For example, possible insertion positions for the floating word "突然" are shown in gray arrows in Figure 1. Since "突然" is a child of "電話する", and the translation of "電話する" is "called", insertion positions must be a child of "called". Also, insertion positions do not violate the projectivity of the target tree. Flexible non-terminals are analogous to the *auxiliary tree* of the tree adjoining grammars (TAG) (Joshi, 1985), which is successfully adopted in machine translation (DeNeefe and Knight, 2009). The difference is that TAG is defined on the constituency trees rather than the dependency trees.

Flexible non-terminals are powerful to handle floating subtrees and it achieve better translation quality. However the computational cost of decoding becomes high even though they are compactly represented in the lattice form (Cromieres and Kurohashi, 2014). In our experiments, using flexible non-terminals causes the decoding to be 3 to 6 times slower than when they are not used. Flexible non-terminals increase the number of translation rules because the insertion positions are selected during the decoding. However, we think it is possible to restrict possible insertion positions or even select only one insertion position by looking at the tree structures on both sides.

In this paper, we propose a method to select the appropriate insertion position before decoding. This can not only reduce the decoding time but also improve the translation quality because of reduced search space.

2 Insertion Position Selection

We assume that correct insertion positions can be determined before decoding, using the word to be inserted (I) with the context on the source side and the context of the insertion positions on the target side. On the source side, we use the parent of I (P_s) and the distance of I from P_s (D_s). On the target side, we use the previous (S_p) and next (S_n) sibling of the insertion position, the parent of the insertion position (P_t) and the distance of the insertion position from P_t (D_t). The distances are calculated on the siblings rather than the words in the sentence, and it is a positive or negative value if the insertion position is to the left or to the right of the parent respectively.

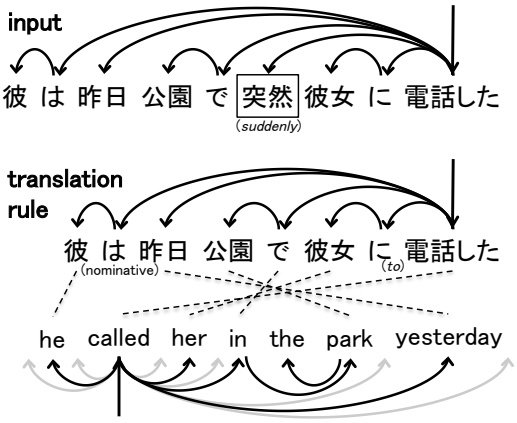

Figure 1: Example of an input sentence and a translation rule. We want to insert "突然 (*suddenly*)" which is not in the translation rule. The possible insertion positions in the target sentence are shown in gray arrows.

Taking the insertion position between "park" and "yesterday" in Figure 1 as an example, I = "突然", P_s = "電話した", D_s = +2, S_p = "park", S_n = "yesterday", P_t = "called" and D_t = -3. In cases where S_p or S_n is empty, we use special words "[[LEFT-START]]", "[[LEFT-END]]", "[[RIGHT-START]]" and "[[RIGHT-END]]". In the case of "yesterday" in Figure 1, S_p = "in" and S_n = "[[RIGHT-END]]". These clues are fed into the neural network model to solve the insertion position selection problem.

2.1 Neural Network Model

Figure 2 shows the neural network model for the insertion position selection. Given an insertion position candidate with an index k, the words (I, P_s, S_p^k, S_n^k, P_t) are first converted into vector representations through the same three embedding layers: surface form embedding (200 dimensions.), part-of-speech embedding (10 dimensions) and dependency type (or phrase category) embedding (10 dimensions), and they are concatenated to create the 220-dimension vectors. The word embedding is a randomly initialized transformation from an one-hot vector to a 200 or 10-dimensional vector, and it is learned during the whole network training.

Using these words and the distances, we create source and target context vectors c_s^k and c_t^k which represent the information of source and target sides, respectively. The distances (integer values) are directly inputted to the network. Then the context vec-

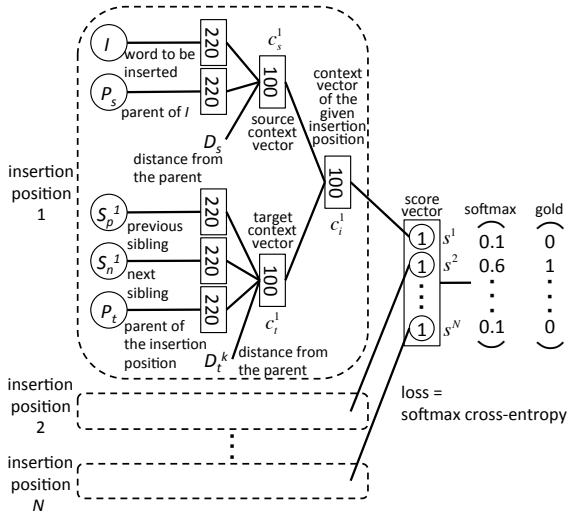

Figure 2: The neural network for the insertion position selection. The numbers inside the boxes show the dimensions of the vectors.

tor of the given insertion position c_i^k is created using c_s^k and c_t^k. Finally we get the score of the given insertion position s^k from c_i^k. These vectors are calculated as follows:

$$\begin{aligned} c_s^k &= \tanh(W_{c_s}[I; P_s; D_s]) \\ c_t^k &= \tanh(W_{c_t}[S_p; S_n; P_t; D_t^k]) \\ c_i^k &= \tanh(W_{c_i}[c_s^k; c_t^k]) \\ s^k &= W_s c_i^k \end{aligned}$$

where ";" means concatenation of the vectors. The size of c_s^k, c_t^k and c_i^k is 100 in our experiments.

The same network is applied to all the other insertion positions and get their scores. Finally the scores are normalized by the softmax function, and the loss is calculated by the softmax cross-entropy as the loss function. All the links between layers are fully-connected. We use dropout (50%) to avoid overfitting.

2.2 Training Data Generation

The data for training the neural network model can be automatically generated from the word-aligned parallel corpus with dependency parses in both sides by Algorithm 1. The ALIGNMENT function returns the aligned word in the target tree for the given source word[1], and the ISPARENTCHILD function returns TRUE if P_t is the parent of C_t.

[1]In case of the multiple word alignment, we only use the root word of them in both source and target sides.

Algorithm 1 Training Data Generation for NN

```
for all P_s ∈ words in source tree do
    P_t = ALIGNMENT(P_s)
    for all C_s ∈ CHILDREN(P_s) do
        C_t = ALIGNMENT(C_s)
        if ISPARENTCHILD(P_t, C_t) then
            GENERATEDATA(P_s, C_s, P_t, C_t)
        end if
    end for
end for
```

	Ja ↔ En	Ja ↔ Zh
Training	2,020,106	667,520
Development	1,789	2,115
Test	1,812	2,174

Table 1: The number of sentences in ASPEC used in our experiments.

The GENERATEDATA function generates one instance of training data to predict the position of C_t from P_s, C_s and P_t with their contexts by removing C_t in the target tree. The position where C_t exists is regarded as the correct insertion position, and others as incorrect insertion positions. Note that C_s corresponds to I in Figure 2.

2.3 Insertion Position Selection in Translation

Once the neural network model is trained, it can be applied to select the most appropriate insertion positions in the translation rules for the given floating subtree by looking at the score of each insertion position. Translation rules only contain part of the original parallel sentence in most of the cases. This means that the context used for selecting the insertion position is different from that in the training data for the neural network. For example, if the input sentence does not have "公園 で (*in the park*)" in Figure 1, the number of possible insertion positions is 6 and we do not use "in" as the context. However, this is not so problematic because similar or same context may appear in the different part of the corpus.

3 Experiments

We conducted two kinds of experiments: the insertion position selection and translation. We used ASPEC (Nakazawa et al., 2016) as the dataset and the numbers of the sentences of the corpus are shown in Table 1. The Japanese morphological analyzer (Kurohashi et al., 1994) and dependency parser (Kurohashi and Nagao, 1994) are used for Japanese

	Ja → En	En → Ja	Ja → Zh	Zh → Ja
Training	15.7M		5.7M	
Development	160K		58K	
Test	160K		58K	
ave. # IP	3.39	3.15	3.72	3.41
best epoch	89	71	61	79
mean loss	0.089	0.058	0.105	0.056
Accuracy (%)	97.08	97.72	96.51	97.99
Logit Accuracy (%)	55.00	89.03	68.04	83.16

Table 2: The statistics of the data and results of the insertion position selection experiments.

sentences. English sentences are first parsed by nlparser (Charniak and Johnson, 2005) and then converted into word dependency trees using Collins' head percolation table (Collins, 1999). We used Chinese word segmenter KKN (Shen et al., 2014) and dependency parser SKP (Shen et al., 2012) for Chinese sentences. The supervised word alignment Nile (Riesa et al., 2011) was used.

We used a state-of-the-art dependency tree-to-tree decoder (Richardson et al., 2014) with the default settings. The neural network is constructed and trained using the Chainer (Tokui et al., 2015).

3.1 Insertion Position Selection

The training, development and test data for the neural network is automatically generated by the procedure explained in Section 2.2. The size of the generated data from the ASPEC and the average number of insertion positions for each floating subtree are shown in Table 2. We trained the model for 100 epochs and used the best model on the development data for testing. The vocabulary size for the surface form was 50,000.

For comparison, we also tried the logistic regression to predict the correct insertion positions. Because our training data is huge, we used Multi-core LIBLINEAR[2] with L2-regularized logistic regression (primal) solver. The format of training instances are: one-hot (binary) vectors for surface form, POS and dependency type, and distances scaled to [0, 1]. We first find the best value for the C parameter, then train the model. The best insertion position is selected using the estimated probabilities for each insertion position.

The experimental results are also shown in Table 2. We evaluated the results by the mean loss of the model and the accuracy on the test data. The result shows that our model can select the correct insertion position with very high accuracy for every language pair while the classical logistic regression model cannot. This supports our claim stated in the beginning of Section 2.

X → Ja is easier and achieved slightly better accuracy than the reverse direction because Japanese is a head-final language and all children are generally put on the left of their parents. There are some cases judged as incorrect but acceptable insertion positions, and hence the true accuracies are higher than the ones reported above. We also investigated the top-2 accuracy and found that it is above 99.0% for Ja → X and 99.5% for X → Ja.

Table 3 shows the detailed result of Ja $rightarrow$ En experiment. The number of insertion-position is at least 2 (left/right of the parent) and it is easy to solve (more than 99% accuracy). 3 is a situation where the parent has one child, and it is still not so difficult (97-98% accuracy). About 70% of the test data have only 2 or 3 insertion-positions. Difficult cases are the sentences which have many adjuncts as in Figure 1, but we used the scientific paper corpora, where not so many adjuncts appear.

3.2 Translation

We conducted translation experiment using the ASPEC in 3 settings:

- No Flexible: not using the flexible non-terminals and using simple glue rules as in the baseline model of (Richardson et al., 2016) [3]
- Baseline: using the flexible non-terminals without the insertion position selection
- Proposed: using only the most appropriate insertion position for the flexible non-terminals

We also report the translation quality of conventional models for comparison: phrase-based SMT (PBSMT) and hierarchical phrase-based SMT (Hiero). We used the default settings of Moses except -distortion-limit=20 for PBSMT.

The translation quality is evaluated by the automatic evaluation measures BLEU (Papineni et al.,

[2]https://www.csie.ntu.edu.tw/∼cjlin/libsvmtools/multicore-liblinear/

[3]52.5% of all the translation rules require glue rule, but it is applied to 22.6% of the rules actually used in the translation.

# of ins. pos. and ratio	Top N accuracy (%)								
	1	2	3	4	5	6	7	8	9
2 (49.39%)	99.22

Table 4: The results of the translation experiments. † means the Proposed method achieved significantly better score than the Baseline ($p < 0.01$).

2002) and RIBES (Isozaki et al., 2010) with the significance testing by bootstrap resampling (Koehn, 2004). RIBES is more sensitive to word order than BLEU, so we expect an improvement in RIBES. We also investigated relative decoding time compared to the No Flexible setting. Note that we used the word "decoding" for only exploring the search space, and it does not include constructing the search space (as the table lookup in Phrase-based SMT). Our whole translation process is:

1. translation rule extraction
2. insertion-position selection
3. decoding

At the time of the second step, we have all the translation rules applicable to the input sentence. The computation time for each step is $3 \gg 1 \gg 2$ so we only focus on the time for step 3 in the experiments (the computation time for step 2 is negligibly small).

The results are shown in Table 4. The Proposed method achieved significantly better automatic evaluation scores than the Baseline for all the language pairs except the BLEU score of En → Ja direction. Also, the decoding time is reduced by about 60% relative to that of the Baseline.

Our tree-based model is better than the conventional models except C → J, where the accuracy of Chinese parsing for the input sentences has a bad effect.

4 Conclusion

In this paper we have proposed a neural network based insertion position selection model to reduce the computational cost of the decoding for dependency tree-to-tree translation with flexible non-terminals. The model successfully finds the appropriate insertion position from the candidates and it leads to faster translation speed and better translation quality due to the reduced search space.

Currently, we use only words as the context but it seems promising to use subtrees as well. For example, using the information of the subtree "in the park" is more informative than using only "in" in Figure 1. This is especially important for Japanese as the target language because children of verbs are often case markers and they do not provide enough information when selecting the appropriate insertion position. It is possible to adopt existing models of creating vector representation of dependency subtrees such as the model using recursive neural networks (Liu et al., 2015) and convolutional neural networks (Mou et al., 2015).

Abstract

We investigate how neural, encoder-decoder translation systems output target strings of appropriate lengths, finding that a collection of hidden units learns to explicitly implement this functionality.

1 Introduction

The neural encoder-decoder framework for machine translation (Neco and Forcada, 1997; Castaño and Casacuberta, 1997; Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015) provides new tools for addressing the field's difficult challenges. In this framework (Figure 1), we use a recurrent neural network (*encoder*) to convert a source sentence into a dense, fixed-length vector. We then use another recurrent network (*decoder*) to convert that vector into a target sentence. In this paper, we train long short-term memory (LSTM) neural units (Hochreiter and Schmidhuber, 1997) trained with back-propagation through time (Werbos, 1990).

A remarkable feature of this simple neural MT (NMT) model is that it produces translations of the right length. When we evaluate the system on previously unseen test data, using BLEU (Papineni et al., 2002), we consistently find the length ratio between MT outputs and human references translations to be very close to 1.0. Thus, no brevity penalty is incurred. This behavior seems to come for free, without special design.

By contrast, builders of standard statistical MT (SMT) systems must work hard to ensure correct length. The original mechanism comes from the IBM SMT group, whose famous Models 1-5 included a learned table $\epsilon(y|x)$, with x and y being the lengths of source and target sentences (Brown et al., 1993). But they did not deploy this table when decoding a foreign sentence f into an English sentence e; it did not participate in incremental scoring and pruning of candidate translations. As a result (Brown et al., 1995):

"However, for a given f, if the goal is to discover the most probable e, then the product P(e) P(f|e) is too small for long English strings as compared with short ones. As a result, short English strings are improperly favored over longer English strings. This tendency is counteracted in part by the following modification: Replace P(f|e) with $c^{length(e)} \cdot P(f|e)$ *for some empirically chosen constant c. This modification is treatment of the symptom rather than treatment of the disease itself, but it offers some temporary relief. The cure lies in better modeling."*

More temporary relief came from Minimum Error-Rate Training (MERT) (Och, 2003), which automatically sets c to maximize BLEU score. MERT also sets weights for the language model P(e), translation model P(f|e), and other features. The length feature combines so sensitively with other features that MERT frequently returns to it as it revises one weight at a time.

NMT's ability to correctly model length is remarkable for these reasons:

- SMT relies on maximum BLEU training to obtain a length ratio that is prized by BLEU, while NMT obtains the same result through generic maximum likelihood training.
- Standard SMT models explicitly "cross off"

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2278–2282,
Austin, Texas, November 1-5, 2016.

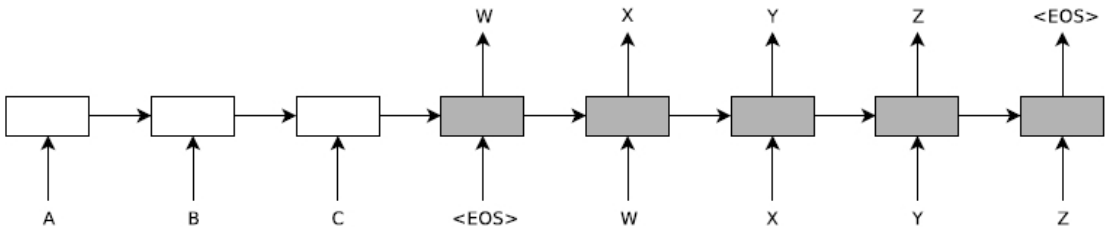

Figure 1: The encoder-decoder framework for neural machine translation (NMT) (Sutskever et al., 2014). Here, a source sentence C B A (fed in reverse as A B C) is translated into a target sentence W X Y Z. At each step, an evolving real-valued vector summarizes the state of the encoder (left half) and decoder (right half).

source words and phrases as they are translated, so it is clear when an SMT decoder has finished translating a sentence. NMT systems lack this explicit mechanism.

- SMT decoding involves heavy search, so if one MT output path delivers an infelicitous ending, another path can be used. NMT decoding explores far fewer hypotheses, using a tight beam without recombination.

In this paper, we investigate how length regulation works in NMT.

2 A Toy Problem for Neural MT

We start with a simple problem in which source strings are composed of symbols *a* and *b*. The goal of the translator is simply to copy those strings. Training cases look like this:

a a a b b a <EOS>	→ *a a a b b a* <EOS>
b b a <EOS>	→ *b b a* <EOS>
a b a b a b a a <EOS>	→ *a b a b a b a a* <EOS>
b b a b b a b b a <EOS>	→ *b b a b b a b b a* <EOS>

The encoder must summarize the content of any source string into a fixed-length vector, so that the decoder can then reconstruct it.[1] With 4 hidden LSTM units, our NMT system can learn to solve this problem after being trained on 2500 randomly chosen strings of lengths up to 9.[2] [3]

To understand how the learned system works, we encode different strings and record the resulting LSTM cell values. Because our LSTM has four hidden units, each string winds up at some point in four-dimensional space. We plot the first two dimensions (unit_1 and unit_2) in the left part of Figure 2, and we plot the other two dimensions (unit_3 and unit_4) in the right part. There is no dimension reduction in these plots. Here is what we learn:

- unit_1 records the approximate length of the string. Encoding a string of length 7 may generate a value of -6.99 for unit_1.
- unit_2 records the number of *b*'s minus the number of *a*'s, thus assigning a more positive value to *b*-heavy strings. It also includes a +1 bonus if the string ends with *a*.
- unit_3 records a prefix of the string. If its value is less than 1.0, the string starts with *b*. Otherwise, it records the number of leading *a*'s.
- unit_4 has a more diffuse function. If its value is positive, then the string consists of all *b*'s (with a possible final *a*). Otherwise, its value correlates with both negative length and the preponderance of *b*'s.

For our purposes, unit_1 is the interesting one. Figure 3 shows the progression of "*a b a b b b*" as it gets encoded (top figure), then decoded (bottom two figures). During encoding, the value of unit_1 decreases by approximately 1.0 each time a letter is read. During decoding, its value increases each time a letter is written. When it reaches zero, it signals the decoder to output <EOS>.

The behavior of unit_1 shows that the translator incorporates explicit length regulation. It also explains two interesting phenomena:

- When asked to transduce previously-unseen strings up to length 14, the system occasionally makes a mistake, mixing up an *a* or *b*. However, the output length is never wrong.[4]

[1] We follow Sutskever et al. (2014) in feeding the input string backwards to the encoder.

[2] Additional training details: 100 epochs, 100 minibatch size, 0.7 learning rate, 1.0 gradient clipping threshold.

[3] We use the toolkit: https://github.com/isi-nlp/Zoph_RNN

[4] Machine translation researchers have also noticed that

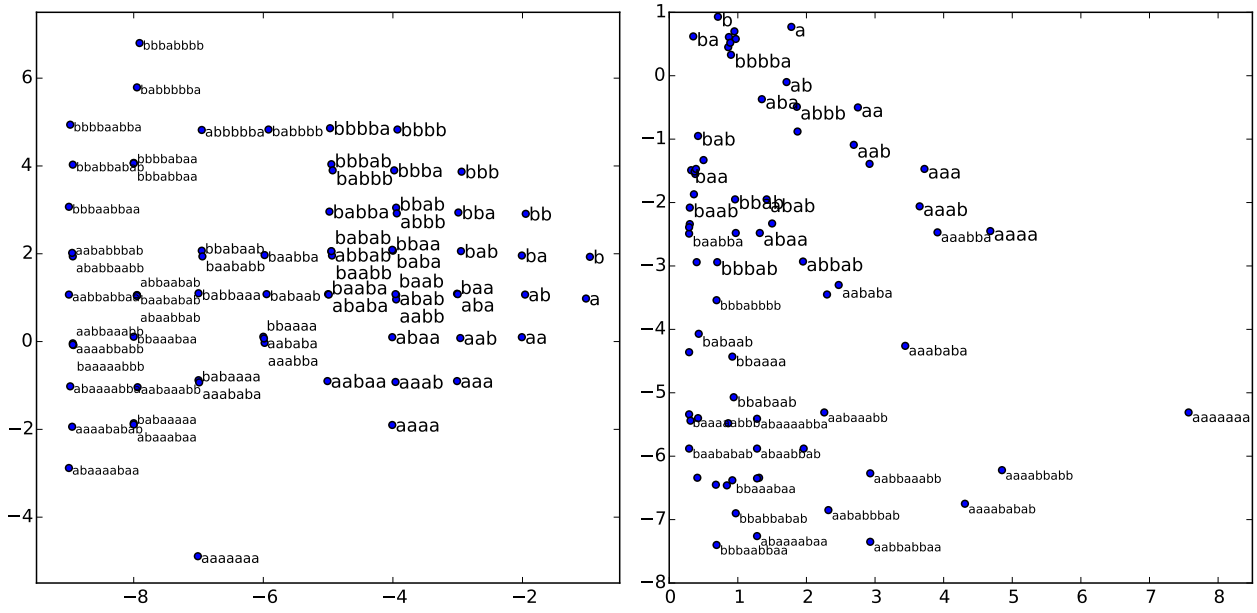

Figure 2: After learning, the recurrent network can convert any string of *a*'s and *b*'s into a 4-dimensional vector. The left plot shows the encoded strings in dimensions described by the cell states of LSTM unit_1 (x-axis) and unit_2 (y-axis). unit_1 learns to record the length of the string, while unit_2 records whether there are more *b*'s than *a*'s, with a +1 bonus for strings that end in *a*. The right plot shows the cell states of LSTM unit_3 (x-axis) and unit_4 (y-axis). unit_3 records how many *a*'s the string begins with, while unit_4 correlates with both length and the preponderance of *b*'s. Some text labels are omitted for clarity.

- When we ask the system to transduce very long strings, beyond what it has been trained on, its output length may be slightly off. For example, it transduces a string of 28 *b*'s into a string of 27 *b*'s. This is because unit_1 is not incremented and decremented by exactly 1.0.

3 Full-Scale Neural Machine Translation

Next we turn to full-scale NMT. We train on data from the WMT 2014 English-to-French task, consisting of 12,075,604 sentence pairs, with 303,873,236 tokens on the English side, and 348,196,030 on the French side. We use 1000 hidden LSTM units. We also use *two layers* of LSTM units between source and target.[5]

After the LSTM encoder-decoder is trained, we send test-set English strings through the encoder portion. Every time a word token is consumed, we record the LSTM cell values and the length of the string so far. Over 143,379 token observations, we investigate how the LSTM encoder tracks length.

Top 10 units by ...	1st layer	2nd layer
Individual R^2	0.868	0.947
Greedy addition	0.968	0.957
Beam search	0.969	0.958

Table 1: R^2 values showing how differently-chosen sets of 10 LSTM hidden units correlate with length in the NMT encoder.

With 1000 hidden units, it is difficult to build and inspect a heat map analogous to Figure 3. Instead, we seek to predict string length from the cell values, using a weighted, linear combination of the 1000 LSTM cell values. We use the least-squares method to find the best predictive weights, with resulting R^2 values of 0.990 (for the first layer, closer to source text) and 0.981 (second layer). So the entire network records length very accurately.

However, unlike in the toy problem, no single unit tracks length perfectly. The best unit in the second layer is unit_{109}, which correlates with R^2=0.894.

We therefore employ three mechanisms to locate

when the translation is completely wrong, the length is still correct (anonymous).

[5]Additional training details: 8 epochs, 128 minibatch size, 0.35 learning rate, 5.0 gradient clipping threshold.

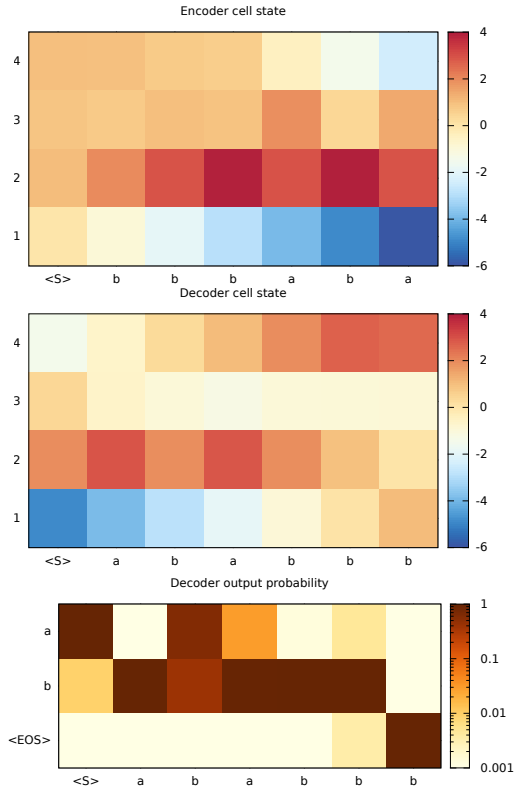

Figure 3: The progression of LSTM state as the recurrent network encodes the string "*a b a b b b*". Columns show the inputs over time and rows show the outputs. Red color indicates positive values, and blue color indicates negative. The value of unit$_1$ decreases during the encoding phase (top figure) and increases during the decoding phase (middle figure). The bottom figure shows the decoder's probability of ending the target string (<EOS>).

k	Best subset of LSTM's 1000 units	R^2
1	109	0.894
2	334, 109	0.936
3	334, 442, 109	0.942
4	334, 442, 109, 53	0.947
5	334, 442, 109, 53, 46	0.951
6	334, 442, 109, 53, 46, 928	0.953
7	334, 442, 109, 53, 46, 433, 663	0.955

Table 2: Sets of k units chosen by beam search to optimally track length in the NMT encoder. These units are from the LSTM's second layer.

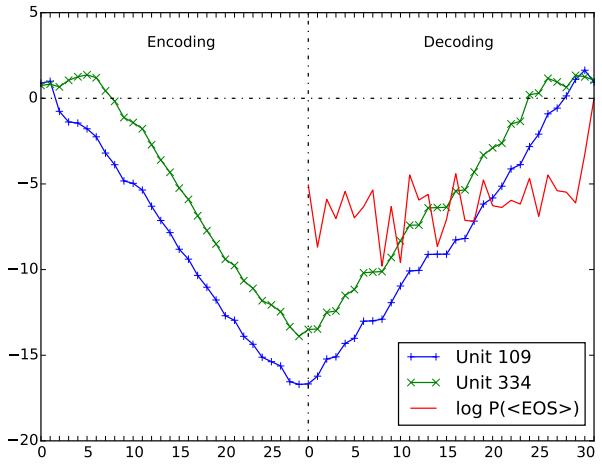

Figure 4: Action of translation unit$_{109}$ and unit$_{334}$ during the encoding and decoding of a sample sentence. Also shown is the softmax log-prob of output <EOS>.

a subset of units responsible for tracking length. We select the top k units according to: (1) individual R^2 scores, (2) greedy search, which repeatedly adds the unit which maximizes the set's R^2 value, and (3) beam search. Table 1 shows different subsets we obtain. These are quite predictive of length. Table 2 shows how R^2 increases as beam search augments the subset of units.

4 Mechanisms for Decoding

For the toy problem, Figure 3 (middle part) shows how the cell value of unit$_1$ moves back to zero as the target string is built up. It also shows (lower part) how the probability of target word <EOS> shoots up once the correct target length has been achieved.

MT decoding is trickier, because source and target strings are not necessarily the same length, and

target length depends on the words chosen. Figure 4 shows the action of unit_{109} and unit_{334} for a sample sentence. They behave similarly on this sentence, but not identically. These two units do not form a simple switch that controls length—rather, they are high-level features computed from lower/previous states that contribute quantitatively to the decision to end the sentence.

Figure 4 also shows the log P(<EOS>) curve, where we note that the probability of outputting <EOS> rises sharply (from 10^{-8} to 10^{-4} to 0.998), rather than gradually.

5 Conclusion

We determine how target length is regulated in NMT decoding. In future work, we hope to determine how other parts of the translator work, especially with reference to grammatical structure and transformations.

Abstract

In this paper, we improve the attention or alignment accuracy of neural machine translation by utilizing the alignments of training sentence pairs. We simply compute the distance between the machine attentions and the "true" alignments, and minimize this cost in the training procedure. Our experiments on large-scale Chinese-to-English task show that our model improves both translation and alignment qualities significantly over the large-vocabulary neural machine translation system, and even beats a state-of-the-art traditional syntax-based system.

1 Introduction

Neural machine translation (NMT) has gained popularity in recent two years (e.g. (Bahdanau et al., 2014; Jean et al., 2015; Luong et al., 2015; Mi et al., 2016b; Li et al., 2016), especially for the attention-based models of Bahdanau et al. (2014).

The attention model plays a crucial role in NMT, as it shows which source word(s) the model should focus on in order to predict the next target word. However, the attention or alignment quality of NMT is still very low (Mi et al., 2016a; Tu et al., 2016).

In this paper, we alleviate the above issue by utilizing the *alignments* (human annotated data or machine alignments) of the training set. Given the alignments of all the training sentence pairs, we add an alignment distance cost to the objective function. Thus, we not only maximize the log translation probabilities, but also minimize the alignment distance cost. Large-scale experiments over Chinese-to-English on various test sets show that our best method for a single system improves the translation quality significantly over the large vocabulary NMT system (Section 5) and beats the state-of-the-art syntax-based system.

2 Neural Machine Translation

As shown in Figure 1, attention-based NMT (Bahdanau et al., 2014) is an encoder-decoder network. the encoder employs a bi-directional recurrent neural network to encode the source sentence $\mathbf{x} = (x_1, ..., x_l)$, where l is the sentence length (including the end-of-sentence $\langle$eos$\rangle$), into a sequence of hidden states $\mathbf{h} = (h_1, ..., h_l)$, each h_i is a concatenation of a left-to-right $\overrightarrow{h_i}$ and a right-to-left $\overleftarrow{h_i}$.

Given $\mathbf{h}$, the decoder predicts the target translation by maximizing the conditional log-probability of the correct translation $\mathbf{y}^* = (y_1^*, ...y_m^*)$, where m is the sentence length (including the end-of-sentence). At each time t, the probability of each word y_t from a target vocabulary V_y is:

$$p(y_t|\mathbf{h}, y_{t-1}^*..y_1^*) = g(s_t, y_{t-1}^*), \tag{1}$$

where g is a two layer feed-forward neural network over the embedding of the previous word y_{t-1}^*, and the hidden state s_t. The s_t is computed as:

$$s_t = q(s_{t-1}, y_{t-1}^*, H_t) \tag{2}$$

$$H_t = \begin{bmatrix} \sum_{i=1}^{l} (\alpha_{t,i} \cdot \overleftarrow{h}_i) \\ \sum_{i=1}^{l} (\alpha_{t,i} \cdot \overrightarrow{h}_i) \end{bmatrix}, \tag{3}$$

where q is a gated recurrent units, H_t is a weighted sum of $\mathbf{h}$; the weights, α, are computed with a two layer feed-forward neural network r:

$$\alpha_{t,i} = \frac{\exp\{r(s_{t-1}, h_i, y_{t-1}^*)\}}{\sum_{k=1}^{l} \exp\{r(s_{t-1}, h_k, y_{t-1}^*)\}} \tag{4}$$

We put all $\alpha_{t,i}$ ($t = 1...m$, $i = 1...l$) into a matrix $\mathcal{A}'$, we have a matrix (alignment) like (c) in Figure 2, where each row (for each target word) is a probability distribution over the source sentence $\mathbf{x}$.

The training objective is to maximize the conditional log-probability of the correct translation y^*

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2283–2288,
Austin, Texas, November 1-5, 2016.

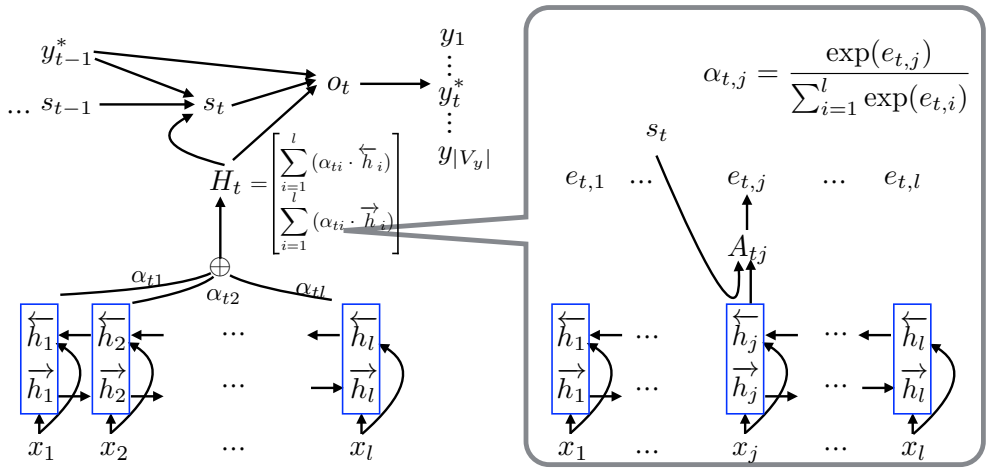

Figure 1: The architecture of attention-based NMT (Bahdanau et al., 2014). The source sentence $\mathbf{x} = (x_1, ..., x_l)$ with length l, x_l is an end-of-sentence token $\langle$eos$\rangle$ on the source side. The reference translation is $\mathbf{y}^* = (y^*_1, ..., y^*_m)$ with length m, similarly, y^*_m is the target side $\langle$eos$\rangle$. $\overleftarrow{h_i}$ and $\overrightarrow{h_i}$ are bi-directional encoder states. $\alpha_{t,j}$ is the attention probability at time t, position j. H_t is the weighted sum of encoding states. s_t is a hidden state. o_t is an output state. Another one layer neural network projects o_t to the target output vocabulary, and conducts softmax to predict the probability distribution over the output vocabulary. The attention model (the right box) is a two layer feedforward neural network, $A_{t,j}$ is an intermediate state, then another layer converts it into a real number $e_{t,j}$, the final attention probability at position j is $\alpha_{t,j}$.

given x with respect to the parameters θ

$$\theta^* = \arg\max_{\theta} \sum_{n=1}^{N}\sum_{t=1}^{m} \log p(y^{*n}_t | \mathbf{x}^n, y^{*n}_{t-1}..y^{*n}_1), \tag{5}$$

where n is the n-th sentence pair $(\mathbf{x}^n, \mathbf{y}^{*n})$ in the training set, N is the total number of pairs.

3 Alignment Component

The attentions, $\alpha_{t,1}...\alpha_{t,l}$, in each step t play an important role in NMT. However, the accuracy is still far behind the traditional MaxEnt alignment model in terms of alignment F1 score (Mi et al., 2016b; Tu et al., 2016). Thus, in this section, we explicitly add an alignment distance to the objective function in Eq. 5. The "truth" alignments for each sentence pair can be from human annotated data, unsupervised or supervised alignments (e.g. GIZA++ (Och and Ney, 2000) or MaxEnt (Ittycheriah and Roukos, 2005)).

Given an alignment matrix $\mathcal{A}$ for a sentence pair $(\mathbf{x}, \mathbf{y})$ in Figure 2 (a), where we have an end-of-source-sentence token $\langle$eos$\rangle = x_l$, and we align all the unaligned target words (y^*_3 in this example) to $\langle$eos$\rangle$, also we force y^*_m (end-of-target-sentence) to be aligned to x_l with probability one. Then we conduct two transformations to get the probability distribution matrices ((b) and (c) in Figure 2).

3.1 Simple Transformation

The first transformation simply normalizes each row. Figure 2 (b) shows the result matrix $\mathcal{A}^*$. The last column in red dashed lines shows the alignments of the special end-of-sentence token $\langle$eos$\rangle$.

3.2 Smoothed Transformation

Given the original alignment matrix $\mathcal{A}$, we create a matrix $\mathcal{A}^*$ with all points initialized with zero. Then, for each alignment point $\mathcal{A}_{t,i} = 1$, we update $\mathcal{A}^*$ by adding a Gaussian distribution, $g(\mu, \sigma)$, with a window size w (t-w, ... t ... t+w). Take the $\mathcal{A}_{1,1} = 1$ for example, we have $\mathcal{A}^*_{1,1}$ += 1, $\mathcal{A}^*_{1,2}$ += 0.61, and $\mathcal{A}^*_{1,3}$ += 0.14 with w=2, $g(\mu, \sigma)$=$g(0, 1)$. Then we normalize each row and get (c). In our experiments, we use a shape distribution, where σ = 0.5.

3.3 Objectives

Alignment Objective: Given the "true" alignment $\mathcal{A}^*$, and the machine attentions $\mathcal{A}'$ produced by NMT model, we compute the Euclidean distance bewteen $\mathcal{A}^*$ and $\mathcal{A}'$.

$$d(\mathcal{A}', \mathcal{A}^*) = \sqrt{\sum_{t=1}^{m}\sum_{i=1}^{l}(\mathcal{A}'_{t,i} - {\mathcal{A}^*}_{t,i})^2}. \tag{6}$$

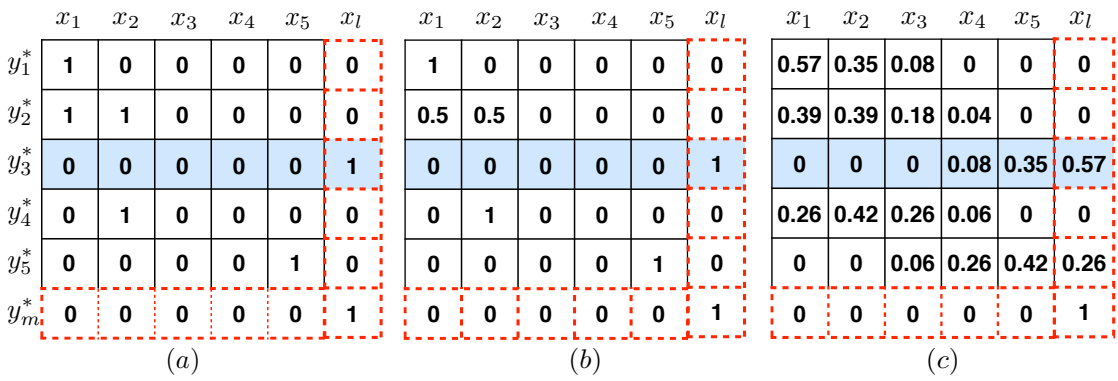

Figure 2: Alignment transformation. A special token, $\langle \text{eos} \rangle$, is introduced to the source sentence, we align all the unaligned target words (y_3^* in this case) to $\langle \text{eos} \rangle$. (a): the original alignment matrix $\mathcal{A}$ from GIZA++ or MaxEnt aligner. (b): simple normalization by rows (probability distribution over the source sentence $\mathbf{x}$). (c): smoothed transformation followed by normalization by rows, and typically, we always align end-of-source-sentence x_l to end-of-target-sentence y_m by probability one.

NMT Objective: We plug Eq. 6 to Eq. 5, we have

$$\theta^* = \arg\max_{\theta} \sum_{n=1}^{N} \Big\{ \sum_{t=1}^{m} \log p(y_t^{*n} | \mathbf{x}^n, y_{t-1}^{*n} .. y_1^{*n}) - d(\mathcal{A}'^n, \mathcal{A}^{*n}) \Big\}. \tag{7}$$

There are two parts: translation and alignment, so we can optimize them jointly, or separately (e.g. we first optimize alignment only, then optimize translation). Thus, we divide the network in Figure 1 into alignment **A** and translation **T** parts:

- **A**: all networks before the hidden state s_t,
- **T**: the network $g(s_t, y_{t-1}^*)$.

If we only optimize **A**, we keep the parameters in **T** unchanged. We can also optimize them jointly **J**. In our experiments, we test different optimization strategies.

4 Related Work

In order to improve the attention or alignment accuracy, Cheng et al. (2016) adapted the agreement-based learning (Liang et al., 2006; Liang et al., 2008), and introduced a combined objective that takes into account both translation directions (source-to-target and target-to-source) and an agreement term between the two alignment directions. By contrast, our approach directly uses and optimizes NMT parameters using the "supervised" alignments.

5 Experiments

5.1 Data Preparation

We run our experiments on Chinese to English task. The training corpus consists of approximately 5 million sentences available within the DARPA BOLT Chinese-English task. The corpus includes a mix of newswire, broadcast news, and webblog. We do not include HK Law, HK Hansard and UN data. The Chinese text is segmented with a segmenter trained on CTB data using conditional random fields (CRF). Our development set is the concatenation of several tuning sets (GALE Dev, P1R6 Dev, and Dev 12) initially released under the DARPA GALE program. The development set is 4491 sentences in total. Our test sets are NIST MT06 (1664 sentences) , MT08 news (691 sentences), and MT08 web (666 sentences).

For all NMT systems, the full vocabulary size of the training set is $300k$. In the training procedure, we use AdaDelta (Zeiler, 2012) to update model parameters with a mini-batch size 80. Following Mi et al. (2016a), the output vocabulary for each mini-batch or sentence is a sub-set of the full vocabulary. For each source sentence, the sentence-level target vocabularies are union of top $2k$ most frequent target words and the top 10 candidates of the word-to-word/phrase translation tables learned

Table 1: Single system results in terms of (TER-BLEU)/2 (T-B, the lower the better) on 5 million Chinese to English training set. BP denotes the brevity penalty. NMT results are on a large vocabulary ($300k$) and with UNK replaced. The second column shows different alignments (**Zh → En** (one direction), **GDFA** ("grow-diag-final-and"), and **MaxEnt** (Ittycheriah and Roukos, 2005). **A**, **T**, and **J** mean optimize alignment only, translation only, and jointly. **Gau.** denotes the smoothed transformation.

from 'fast_align' (Dyer et al., 2013). The maximum length of a source phrase is 4. In the training time, we add the reference in order to make the translation reachable.

The Cov. LVNMT system is a re-implementation of the enhanced NMT system of Mi et al. (2016a), which employs a coverage embedding model and achieves better performance over large vocabulary NMT Jean et al. (2015). The coverage embedding dimension of each source word is 100.

Following Jean et al. (2015), we dump the alignments, attentions, for each sentence, and replace UNKs with the word-to-word translation model or the aligned source word.

Our SMT system is a hybrid syntax-based tree-to-string model (Zhao and Al-onaizan, 2008), a simplified version of the joint decoding (Liu et al., 2009; Cmejrek et al., 2013). We parse the Chinese side with Berkeley parser, and align the bilingual sentences with GIZA++ and MaxEnt. and extract Hiero and tree-to-string rules on the training set. Our two 5-gram language models are trained on the English side of the parallel corpus, and on monolingual corpora (around 10 billion words from Gigaword (LDC2011T07), respectively.As suggested by Zhang (2016), NMT systems can achieve better results with the help of those monolingual corpora. In this paper, our NMT systems only use the bilingual data. We tune our system with PRO (Hopkins and May, 2011) to minimize (TER- BLEU)/2 [1] on the development set.

5.2 Translation Results

Table 1 shows the translation results of all systems. The syntax-based statistical machine translation model achieves an average (TER-BLEU)/2 of 13.36 on three test sets. The Cov. LVNMT system achieves an average (TER-BLEU)/2 of 14.24, which is about 0.9 points worse than Tree-to-string SMT system. Please note that all systems are single systems. It is highly possible that ensemble of NMT systems with different random seeds can lead to better results over SMT.

We test three different alignments:

- **Zh → En** (one direction of GIZA++),
- **GDFA** (the "grow-diag-final-and" heuristic merge of both directions of GIZA++),
- **MaxEnt** (trained on $67k$ hand-aligned sentences).

[1]The metric used for optimization in this work is (TER-BLEU)/2 to prevent the system from using sentence length alone to impact BLEU or TER. Typical SMT systems use target word count as a feature and it has been observed that BLEU can be optimized by tweaking the weighting of the target word count with no improvement in human assessments of translation quality. Conversely, in order to optimize TER shorter sentences can be produced. Optimizing the combination of metrics alleviates this effect (Arne Mauser and Ney, 2008).

The alignment quality improves from **Zh** $\rightarrow$ **En** to **MaxEnt**. We also test different optimization strategies: **J** (jointly), **A** (alignment only), and **T** (translation model only). A combination, **A** $\rightarrow$ **T**, shows that we optimize **A** only first, then we fix **A** and only update **T** part. **Gau.** denotes the smoothed transformation (Section 3.2). Only the last row uses the smoothed transformation, all others use the simple transformation.

Experimental results in Table 1 show some interesting results. First, with the same alignment, **J** joint optimization works best than other optimization strategies (lines 3 to 6). Unfortunately, breaking down the network into two separate parts (**A** and **T**) and optimizing them separately do not help (lines 3 to 5). We have to conduct joint optimization **J** in order to get a comparable or better result (lines 3, 5 and 6) over the baseline system.

Second, when we change the training alignment seeds (**Zh** $\rightarrow$ **En**, **GDFA**, and **MaxEnt**) NMT model does not yield significant different results (lines 6 to 8).

Third, the smoothed transformation (**J + Gau.**) gives some improvements over the simple transformation (the last two lines), and achieves the best result (1.2 better than LVNMT, and 0.3 better than Tree-to-string). In terms of BLEU scores, we conduct the statistical significance tests with the sign-test of Collins et al. (2005), the results show that the improvements of our **J + Gau.** over LVNMT are significant on three test sets ($p < 0.01$).

At last, the brevity penalty (BP) consistently gets better after we add the alignment cost to NMT objective. Our alignment objective adjusts the translation length to be more in line with the human references accordingly.

5.3 Alignment Results

Table 2 shows the alignment F1 scores on the alignment test set (447 hand aligned sentences). The MaxEnt model is trained on $67k$ hand-aligned sentences, and achieves an F1 score of 75.96. For NMT systems, we dump the alignment matrixes and convert them into alignments with following steps. For each target word, we sort the alphas and add the max probability link if it is higher than 0.2. If we only tune the alignment component (**A** in line 3), we improve the alignment F1 score from 45.76 to 47.87.

system			pre.	rec.	F1
MaxEnt			74.86	77.10	75.96
Cov LVNMT (Mi et al., 2016b)			51.11	41.42	45.76
+Alignment	**Zh** $\rightarrow$ **En**	**A**	50.88	45.19	47.87
		A $\rightarrow$ **J**	53.18	49.37	51.21
		A $\rightarrow$ **T**	50.29	44.90	47.44
		A $\rightarrow$ **T** $\rightarrow$ **J**	53.71	49.33	51.43
		J	**54.29**	48.02	50.97
	GDFA	**J**	53.88	48.25	50.91
	MaxEnt	**J**	44.42	55.25	49.25
		J + Gau.	48.90	**55.38**	**51.94**

Table 2: Alignment F1 scores of different models.

And we further boost the score to 50.97 by tuning alignment and translation jointly (**J** in line 7). Interestingly, the system using **MaxEnt** produces more alignments in the output, and results in a higher recall. This suggests that using **MaxEnt** can lead to a sharper attention distribution, as we pick the alignment links based on the probabilities of attentions, the sharper the distribution is, more links we can pick. We believe that a sharp attention distribution is a great property of NMT.

Again, the best result is **J + Gau.** in the last row, which significantly improves the F1 by 5 points over the baseline Cov. LVNMT system. When we use **MaxEnt** alignments, **J + Gau.** smoothing gives us about 1.7 points gain over **J** system. So it looks interesting to run another **J + Gau.** over **GDFA** alignment.

Together with the results in Table 1, we conclude that adding the alignment cost to the training objective helps both translation and alignment significantly.

6 Conclusion

In this paper, we utilize the "supervised" alignments, and put the alignment cost to the NMT objective function. In this way, we directly optimize the attention model in a supervised way. Experiments show significant improvements in both translation and alignment tasks over a very strong LVNMT system.

Abstract

Mapping word embeddings of different languages into a single space has multiple applications. In order to map from a source space into a target space, a common approach is to learn a linear mapping that minimizes the distances between equivalences listed in a bilingual dictionary. In this paper, we propose a framework that generalizes previous work, provides an efficient exact method to learn the optimal linear transformation and yields the best bilingual results in translation induction while preserving monolingual performance in an analogy task.

1 Introduction

Bilingual word embeddings have attracted a lot of attention in recent times (Zou et al., 2013; Kočiský et al., 2014; Chandar A P et al., 2014; Gouws et al., 2014; Gouws and Søgaard, 2015; Luong et al., 2015; Wick et al., 2016). A common approach to obtain them is to train the embeddings in both languages independently and then learn a mapping that minimizes the distances between equivalences listed in a bilingual dictionary. The learned transformation can also be applied to words missing in the dictionary, which can be used to induce new translations with a direct application in machine translation (Mikolov et al., 2013b; Zhao et al., 2015).

The first method to learn bilingual word embedding mappings was proposed by Mikolov et al. (2013b), who learn the linear transformation that minimizes the sum of squared Euclidean distances for the dictionary entries. Subsequent work has proposed alternative optimization objectives to learn better mappings. Xing et al. (2015) incorporate length normalization in the training of word embeddings and try to maximize the cosine similarity instead, introducing an orthogonality constraint to preserve the length normalization after the projection. Faruqui and Dyer (2014) use canonical correlation analysis to project the embeddings in both languages to a shared vector space.

Beyond linear mappings, Lu et al. (2015) apply deep canonical correlation analysis to learn a non-linear transformation for each language. Finally, additional techniques have been used to address the hubness problem in Mikolov et al. (2013b), both through the neighbor retrieval method (Dinu et al., 2015) and the training itself (Lazaridou et al., 2015). We leave the study of non-linear transformation and other additions for further work.

In this paper, we propose a general framework to learn bilingual word embeddings. We start with a basic optimization objective (Mikolov et al., 2013b) and introduce several meaningful and intuitive constraints that are equivalent or closely related to previously proposed methods (Faruqui and Dyer, 2014; Xing et al., 2015). Our framework provides a more general view of bilingual word embedding mappings, showing the underlying connection between the existing methods, revealing some flaws in their theoretical justification and providing an alternative theoretical interpretation for them. Our experiments on an existing English-Italian word translation induction and an English word analogy task give strong empirical evidence in favor of our theoretical reasoning, while showing that one of our models clearly outperforms previous alternatives.

Austin, Texas, November 1-5, 2016.

2 Learning bilingual mappings

Let X and Z denote the word embedding matrices in two languages for a given bilingual dictionary so that their ith row X_{i*} and Z_{i*} are the word embeddings of the ith entry in the dictionary. Our goal is to find a linear transformation matrix W so that XW best approximates Z, which we formalize minimizing the sum of squared Euclidean distances following Mikolov et al. (2013b):

$$\arg\min_W \sum_i \|X_{i*}W - Z_{i*}\|^2$$

Alternatively, this is equivalent to minimizing the (squared) Frobenius norm of the residual matrix:

$$\arg\min_W \|XW - Z\|_F^2$$

Consequently, W will be the so called least-squares solution of the linear matrix equation $XW = Z$. This is a well-known problem in linear algebra and can be solved by taking the Moore-Penrose pseudoinverse $X^+ = \left(X^T X\right)^{-1} X^T$ as $W = X^+ Z$, which can be computed using SVD.

2.1 Orthogonality for monolingual invariance

Monolingual invariance is needed to preserve the dot products after mapping, avoiding performance degradation in monolingual tasks (e.g. analogy). This can be obtained requiring W to be an orthogonal matrix ($W^T W = I$). The exact solution under such orthogonality constraint is given by $W = VU^T$, where $Z^T X = U\Sigma V^T$ is the SVD factorization of $Z^T X$ (cf. Appendix A). Thanks to this, the optimal transformation can be efficiently computed in linear time with respect to the vocabulary size. Note that orthogonality enforces an intuitive property, and as such it could be useful to avoid degenerated solutions and learn better bilingual mappings, as we empirically show in Section 3.

2.2 Length normalization for maximum cosine

Normalizing word embeddings in both languages to be unit vectors guarantees that all training instances contribute equally to the optimization goal. As long as W is orthogonal, this is equivalent to maximizing the sum of cosine similarities for the dictionary entries, which is commonly used for similarity computations:

$$\begin{aligned}&\arg\min_W \sum_i \left\| \frac{X_{i*}}{\|X_{i*}\|} W - \frac{Z_{i*}}{\|Z_{i*}\|} \right\|^2 \\ &= \arg\max_W \sum_i \cos\left(X_{i*}W, Z_{i*}\right)\end{aligned}$$

This last optimization objective coincides with Xing et al. (2015), but their work was motivated by an hypothetical inconsistency in Mikolov et al. (2013b), where the optimization objective to learn word embeddings uses dot product, the objective to learn mappings uses Euclidean distance and the similarity computations use cosine. However, the fact is that, as long as W is orthogonal, optimizing the squared Euclidean distance of length-normalized embeddings is equivalent to optimizing the cosine, and therefore, the mapping objective proposed by Xing et al. (2015) is equivalent to that used by Mikolov et al. (2013b) with orthogonality constraint and unit vectors. In fact, our experiments show that orthogonality is more relevant than length normalization, in contrast to Xing et al. (2015), who introduce orthogonality only to ensure that unit length is preserved after mapping.

2.3 Mean centering for maximum covariance

Dimension-wise mean centering captures the intuition that two randomly taken words would not be expected to be semantically similar, ensuring that the expected product of two random embeddings in any dimension and, consequently, their cosine similarity, is zero. As long as W is orthogonal, this is equivalent to maximizing the sum of dimension-wise covariance for the dictionary entries:

$$\begin{aligned}&\arg\min_W \|C_m X W - C_m Z\|_F^2 \\ &= \arg\max_W \sum_i \operatorname{cov}\left(XW_{*i}, Z_{*i}\right)\end{aligned}$$

where C_m denotes the centering matrix

This equivalence reveals that the method proposed by Faruqui and Dyer (2014) is closely related to our framework. More concretely, Faruqui and Dyer (2014) use Canonical Correlation Analysis (CCA) to project the word embeddings in both languages to a shared vector space. CCA maximizes

the dimension-wise covariance of both projections (which is equivalent to maximizing the covariance of a single projection if the transformations are constrained to be orthogonal, as in our case) but adds an implicit restriction to the two mappings, making different dimensions have the same variance and be uncorrelated among themselves[1]:

$$\arg\max_{A,B} \sum_i \mathrm{cov}\left(XA_{*i}, ZB_{*i}\right)$$
$$\text{s.t.} \quad A^T X^T C_m X A = B^T Z^T C_m Z B = I$$

Therefore, the only fundamental difference between both methods is that, while our model enforces monolingual invariance, Faruqui and Dyer (2014) do change the monolingual embeddings to meet this restriction. In this regard, we think that the restriction they add could have a negative impact on the learning of the bilingual mapping, and it could also degrade the quality of the monolingual embeddings. Our experiments (cf. Section 3) show empirical evidence supporting this idea.

3 Experiments

In this section, we experimentally test the proposed framework and all its variants in comparison with related methods. For that purpose, we use the translation induction task introduced by Mikolov et al. (2013b), which learns a bilingual mapping on a small dictionary and measures its accuracy on predicting the translation of new words. Unfortunately, the dataset they use is not public. For that reason, we use the English-Italian dataset on the same task provided by Dinu et al. (2015)[2]. The dataset contains monolingual word embeddings trained with the word2vec toolkit using the CBOW method with negative sampling (Mikolov et al., 2013a)[3]. The English embeddings were trained on a 2.8 billion word corpus (ukWaC + Wikipedia + BNC), while the 1.6 billion word corpus itWaC was used to train the Italian embeddings. The dataset also contains a bilingual dictionary learned from Europarl, split into a training set of 5,000 word pairs and a test set of 1,500 word pairs, both of them uniformly distributed in frequency bins. Accuracy is the evaluation measure.

Apart from the performance of the projected embeddings in bilingual terms, we are also interested in the monolingual quality of the source language embeddings after the projection. For that purpose, we use the word analogy task proposed by Mikolov et al. (2013a), which measures the accuracy on answering questions like "what is the word that is similar to *small* in the same sense as *biggest* is similar to *big*?" using simple word vector arithmetic. The dataset they use consists of 8,869 semantic and 10,675 syntactic questions of this type, and is publicly available[4]. In order to speed up the experiments, we follow the authors and perform an approximate evaluation by reducing the vocabulary size according to a frequency threshold of 30,000 (Mikolov et al., 2013a). Since the original embeddings are the same in all the cases and it is only the transformation that is applied to them that changes, this affects all the methods in the exact same way, so the results are perfectly comparable among themselves. With these settings, we obtain a coverage of 64.98%.

We implemented the proposed method in Python using NumPy, and make it available as an open source project[5]. The code for Mikolov et al. (2013b) and Xing et al. (2015) is not publicly available, so we implemented and tested them as part of the proposed framework, which only differs from the original systems in the optimization method (exact solution instead of gradient descent) and the length normalization approach in the case of Xing et al. (2015) (postprocessing instead of constrained training). As for the method by Faruqui and Dyer (2014), we used their original implementation in Python and MATLAB[6], which we extended to cover cases where the dictionary contains more than one entry for the same word.

[1] While CCA is typically defined in terms of correlation (thus its name), correlation is invariant to the scaling of variables, so it is possible to constrain the canonical variables to have a fixed variance, as we do, in which case correlation and covariance become equivalent

Table 2: Comparison of our method to other work.

3.1 Results of our framework

The rows in Table 1 show, respectively, the results for the original embeddings, the basic mapping proposed by Mikolov et al. (2013b) (cf. Section 2) and the addition of orthogonality constraint (cf. Section 2.1), with and without length normalization and, incrementally, mean centering. In all the cases, length normalization and mean centering were applied to all embeddings, even if missing from the dictionary.

The results show that the orthogonality constraint is key to preserve monolingual performance, and it also improves bilingual performance by enforcing a relevant property (monolingual invariance) that the transformation to learn should intuitively have. The contribution of length normalization alone is marginal, but when followed by mean centering we obtain further improvements in bilingual performance without hurting monolingual performance.

3.2 Comparison to other work

Table 2 shows the results for our best performing configuration in comparison to previous work. As discussed before, (Mikolov et al., 2013b) and (Xing et al., 2015) were implemented as part of our framework, so they correspond to our uncostrained mapping with no preprocessing and orthogonal mapping with length normalization, respectively.

As it can be seen, the method by Xing et al. (2015) performs better than that of Mikolov et al. (2013b) in the translation induction task, which is in line with what they report in their paper. Moreover, thanks to the orthogonality constraint their monolingual performance in the word analogy task does not degrade, whereas the accuracy of Mikolov et al. (2013b) drops by 2.86% in absolute terms with respect to the original embeddings.

Since Faruqui and Dyer (2014) take advantage of CCA to perform dimensionality reduction, we tested several values for it and report the best (180 dimensions). This beats the method by Xing et al. (2015) in the bilingual task, although it comes at the price of a considerable degradation in monolingual quality.

In any case, it is our proposed method with the orthogonality constraint and a global preprocessing with length normalization followed by dimension-wise mean centering that achieves the best accuracy in the word translation induction task. Moreover, it does not suffer from any considerable degradation in monolingual quality, with an anecdotal drop of only 0.07% in contrast with 2.86% for Mikolov et al. (2013b) and 7.02% for Faruqui and Dyer (2014).

When compared to Xing et al. (2015), our results in Table 1 reinforce our theoretical interpretation for their method (cf. Section 2.2), as it empirically shows that its improvement with respect to Mikolov et al. (2013b) comes solely from the orthogonality constraint, and not from solving any inconsistency.

It should be noted that the implementation by Faruqui and Dyer (2014) also length-normalizes the word embeddings in a preprocessing step. Following the discussion in Section 2.3, this means that our best performing configuration is conceptually very close to the method by Faruqui and Dyer (2014), as they both coincide on maximizing the average dimension-wise covariance and length-normalize the embeddings in both languages first, the only difference being that our model enforces monolingual invariance after the normalization while theirs does change the monolingual embeddings to make different dimensions have the same variance and be uncorrelated among themselves. However, our model performs considerably better than any configuration from Faruqui and Dyer (2014) in both the monolingual and the bilingual task, supporting our hypothesis that these two constraints that are implicit in their method are not only conceptually confusing,

but also have a negative impact.

4 Conclusions

This paper develops a new framework to learn bilingual word embedding mappings, generalizing previous work and providing an efficient exact method to learn the optimal transformation. Our experiments show the effectiveness of the proposed model and give strong empirical evidence in favor of our reinterpretation of Xing et al. (2015) and Faruqui and Dyer (2014). It is the proposed method with the orthogonality constraint and a global preprocessing with length normalization and dimension-wise mean centering that achieves the best overall results both in monolingual and bilingual terms, surpassing those previous methods. In the future, we would like to study non-linear mappings (Lu et al., 2015) and the additional techniques in (Lazaridou et al., 2015).

A Proof of solution under orthogonality

Constraining W to be orthogonal ($W^TW = I$), the original minimization problem can be reformulated as follows (cf. Section 2.1):

$$\begin{aligned}
&\arg\min_W \sum_i \|X_{i*}W - Z_{i*}\|^2 \\
&= \arg\min_W \sum_i \left(\|X_{i*}W\|^2 + \|Z_{i*}\|^2 - 2X_{i*}WZ_{i*}^T\right) \\
&= \arg\max_W \sum_i X_{i*}WZ_{i*}^T \\
&= \arg\max_W \operatorname{Tr}\left(XWZ^T\right) \\
&= \arg\max_W \operatorname{Tr}\left(Z^TXW\right)
\end{aligned}$$

In the above expression, $\operatorname{Tr}(\cdot)$ denotes the trace operator (the sum of all the elements in the main diagonal), and the last equality is given by its cyclic property. At this point, we can take the SVD of Z^TX as $Z^TX = U\Sigma V^T$, so $\operatorname{Tr}\left(Z^TXW\right) = \operatorname{Tr}\left(U\Sigma V^TW\right) = \operatorname{Tr}\left(\Sigma V^TWU\right)$. Since V^T, W and U are orthogonal matrices, their product V^TWU will also be an orthogonal matrix. In addition to that, given that Σ is a diagonal matrix, its trace after an orthogonal transformation will be maximal when the values in its main diagonal are preserved after the mapping, that is, when the orthogonal transformation matrix is the identity matrix. This will happen when $V^TWU = I$ in our case, so the optimal solution will be $W = VU^T$.

Measuring the behavioral impact of machine translation quality improvements with A/B testing

Benjamin Russell and **Duncan Gillespie**
Etsy
{brussell, dgillespie}@etsy.com

Abstract

In this paper we discuss a process for quantifying the behavioral impact of a domain-customized machine translation system deployed on a large-scale e-commerce platform. We discuss several machine translation systems that we trained using aligned text from product listing descriptions written in multiple languages. We document the quality improvements of these systems as measured through automated quality measures and crowdsourced human quality assessments. We then measure the effect of these quality improvements on user behavior using an automated A/B testing framework. Through testing we observed an increase in key e-commerce metrics, including a significant increase in purchases.

1 Introduction

Quality evaluation is an essential task when training a machine translation (MT) system. While automatic evaluation methods like BLEU (Papineni et al., 2002) can be useful for estimating translation quality, a higher score is no guarantee of quality improvement (Callison-Burch et al., 2006). Previous studies (e.g. Coughlin, 2003) have compared human evaluations of MT to metrics like BLEU and found close correspondence between the two. Koehn (2004) argued that relatively small differences in BLEU can indicate significant MT quality differences and suggested that human evaluation, the traditional alternative to automated metrics like BLEU, is therefore unnecessarily time-consuming and costly. Callison-Burch (2009) explored the use of crowdsourcing platforms for evaluating MT quality, with good results. However, we are not aware of any research that investigates the effect of improved MT on human behavior. In a commercial application, like an e-commerce platform, it is desirable to have a high degree of confidence in the material effect of MT quality differences: any MT system change should positively impact user experiences.

Etsy is an online marketplace for handmade and vintage items, with over 40 million active listings and a community of buyers and sellers located around the world. Visitors can use MT to translate the text of product descriptions, product reviews, and private messages, making it possible for members to communicate effectively with one another, even when they speak different languages. These multilingual interactions facilitated by MT, such as reading nonnative listing descriptions or conversing with a foreign seller, are integral to the user experience.

However, due to the unique nature of the products available in the marketplace, a generic third party MT system[1] often falls short when translating user-generated content. One challenging lexical item is "clutch." A generic engine, trained on commonly available parallel text, translates clutch as an "automotive clutch." In this marketplace, however, clutch almost always means "purse." A mistake like this is problematic: a user who sees this incorrect machine translation may lose confidence in that listing and possibly in the marketplace as a whole.

[1] We use Microsoft's Bing Translator for our machine translations.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2295–2299,
Austin, Texas, November 1-5, 2016.

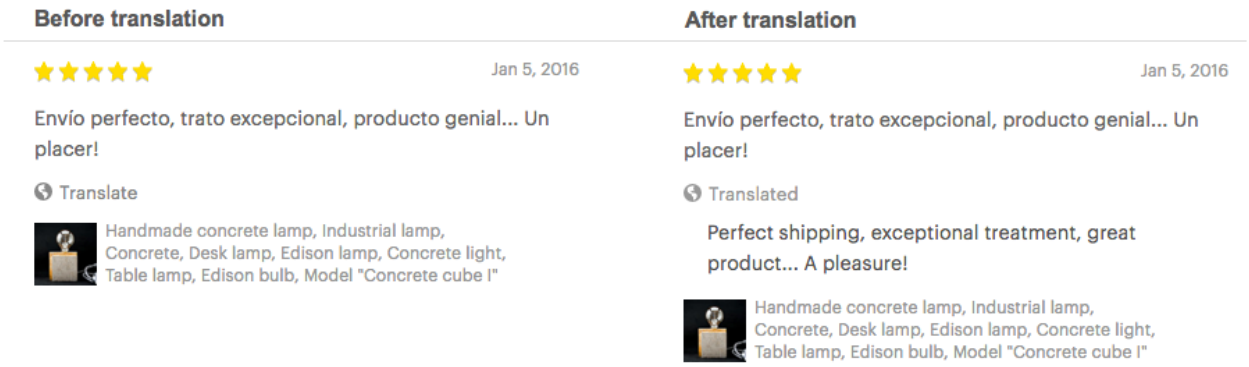

Figure 1: An example review translation on the website.

To improve the translation quality for terms like clutch, we used an interface provided by a third party machine translation service[2] to train a custom MT engine for English to French translations. To validate that the retrained MT systems were materially improved, we used a two step validation process, first using crowd-sourced evaluations with Amazon's Mechanical Turk, and secondly using A/B testing, a way of conducting randomized experiments on web sites, to measure the effect of the trained system on user behavior.

2 Data Collection

Our online marketplace contains millions of listing descriptions posted by tens of thousands of multilingual sellers. We conducted an MT system training using aligned texts from these product listings. We used our third-party translation service's automated retraining framework to train multiple MT systems that were specifically tuned to the marketplace's corpus. To gather this data, we used a Hadoop job to parse through 130 million active and expired product listings to find listing descriptions that were written in both English and French. Once we found these listing descriptions, we tokenized the text on sentence boundary. We removed any descriptions where there was a mismatch in the number of sentences between the source and target descriptions.

Next, we used a language detection service to ensure the source and target strings were the correct languages (source: English, target: French). After language detection, we removed all sentences where the ratio of alphabetic characters to total characters was below 70%. This 70% threshold was determined through manual assessment of the result set, and was used to eliminate strings with low numbers of alphabetic characters, such as "25.5 in x 35.5 in".

After these preliminary filtering steps, our training set consisted of 885,732 aligned sentences. To supplement the aligned text, we also collected 2,625,162 monolingual French sentences for the training. The monolingual text was parsed and cleaned in the same manner as the aligned sentences.

The commercial MT system's automatic training framework provides tools for the upload of bilingual and monolingual training data, tuning data, and testing data for customization of the underlying statistical MT system. Bilingual training data is used to modify the base translation model; monolingual data customizes the language model; the system is optimized for the tuning data; and the testing data is used to calculate a BLEU score. We trained over a dozen systems with a variety of datasets and selected the three systems that had the highest BLEU scores.

System 1 was trained using the aligned sentences, along with the 2.6 million monolingual sentences. The system was tuned using 2,500 sentences automatically separated from the training sentences by the third party's training system, and used an additional 2,500 automatically separated sentences for testing.

For System 2, we used a variation of the Gale-Church alignment algorithm (1993) to remove sentences predicted to be misaligned based on their length differences. The subject of sentence alignment in parallel texts has been researched exten-

[2] http://hub.microsofttranslator.com

Training Data	Sys. 1	Sys. 2	Sys. 3
886K aligned sentences	x		
766K aligned sentences after Gale-Church applied		x	x
2.6M monolingual segments	x	x	x
Auto tuning*	x	x	
Tuning with 2K in-domain sentences			x

sively (e.g. Brown et al., 1991; Gale and Church, 1993). Although more sophisticated methods exist (e.g. Chen, 1993; Wu, 1994; Melamed, 1996; Munteanu and Marcu, 2005), we used Gale-Church due to its relatively high accuracy and low implementation overhead. Misalignment between the same listing descriptions written in multiple languages could be caused by several factors, the most common problem being that sellers do not translate descriptions sentence for sentence from one language to the next. We detected possible misalignments in 13.5% of the original 886K aligned sentences, leaving 776K sentences to use for training System 2. We used auto-tuning and auto-testing for this engine, as we did for System 1.

System 3 was trained using the same training data as the second engine, but was tuned using 2,000 professionally-translated sentences taken from listing descriptions. Two hundred of these sentences were drawn semi-randomly to represent a general sample of listing description text; the remaining 1,800 contained terms, like "clutch," that were being mistranslated by the generic system. This system used the same automatically-generated testing data as the other two to calculate a BLEU score. Table 1 shows the training and tuning data used for the three systems.

3 Crowdsourced Evaluation

For evaluation of the trained translation systems, we generated translations of sentences drawn randomly from our monolingual English corpus (product listings that sellers had not translated into languages other than English). We excluded segments that were translated the same by both the trained and generic systems. (For System 1, 48 of 2,000 test sentences had the same translation as the generic system, for System 2 that number was 42, and for System 3 that number was 148.)

	BLEU Score	BLEU Score Improvement Over Generic System
System 1	48.16	+9.82
System 2	50.36	+12.02
System 3	46.85	+8.51

Table 2: BLEU score improvements for three translation systems over a baseline BLEU for the generic system of 38.34.

To obtain judgments about the quality of these translations, we used Mechanical Turk to obtain human evaluations of our candidate translation systems (Callison-Burch, 2009). To recruit Mechanical Turk workers with bilingual competence, we required workers to achieve at least 80% accuracy in a binary translation judgment task (workers were asked to judge whether each of 20 translations was "Good" or "Bad"; their answers were compared with those of professional translators).

Qualified workers completed a survey indicating their preference for the translation of a particular trained system compared to the generic commercial translation system. Translation pairs were presented in random order with no indication of whether a translation was produced by a human, a generic translation system, or an untrained translation system. Workers were asked to choose the better of the two translations or to indicate, "Neither is better". Workers were offered $2.00 to complete a 50-question survey. Each survey contained five hidden questions with known answers (translation pairs judged by professional translators) for quality control (we excluded responses from workers who did not answer the hidden questions with at least 80% accuracy).

4 Results

4.1 BLEU Evaluation

We used the automated BLEU calculation provided by the third-party translation service to obtain scores for each of the three translation systems.

All three systems had significant BLEU improvements after retraining, as shown in Table 2. We be-

	Trained	Generic	Neither	Ratio
Sys. 1	129 (34%)	109 (29%)	138 (36%)	1.18
Sys. 2	71 (25%)	85 (31%)	123 (44%)	0.84
Sys. 3	203 (36%)	150 (27%)	205 (37%)	1.35

Table 3: Results from crowdsourced evaluations of three translation systems. Columns labeled **Trained**, **Generic**, and **Neither** include the number of responses and percentage of total responses for each response type. The **Ratio** column shows the number of responses that favored the trained system to the number of responses that favored the generic system.

lieve System 3 has a lower BLEU score than the others because it was tuned on a different data set: the professionally-translated, in-domain sentences from product listing descriptions. This made the system's output less like the automatically-selected test set than the others, but closer, presumably, to the high-quality, low-noise tuning translations sourced from professional translators.

4.2 Crowdsourced evaluation

The crowdsourced evaluation of the three systems favored System 3. Table 3 provides a summary of the results. Neither System 1 nor System 2 showed a significant difference between selection of translations provided by the trained or untrained system: chi-squared tests did not detect a significant difference between number of responses favoring the trained system and number of responses favoring the generic system ($p = 0.1948$ and $p = 0.26$, respectively, for the two systems). However, a chi-squared test indicated a significant preference for System 3, which was chosen 35% more often than the generic system ($p = 0.0048$). Based on the crowd-sourced results, we proceeded to A/B test System 3 against the generic translation system baseline.

The lack of improvements for System 1 and System 2 detected using the crowd-sourcing methods was somewhat surprising, given the large BLEU score improvements observed for all three systems. We believe this lends further support to Callison-Burch, et al.'s (2006) critiques of BLEU as a standalone machine translation quality metric. In this case, it is possible that Systems 1 and 2 achieved high BLEU improvements due to over-fitting the training data from which the test set was drawn. We might speculate that this is due to the presence of low-quality translations from limited-bilingual sellers, or the presence of MT generated by a different online tool in some sellers' translations. By tuning the system using a high-quality, professionally-translated test set, we reduced overall BLEU but increased quality as judged by bilingual evaluators.

4.3 A/B testing

A/B testing is a strategy for comparing two different versions of a website to see which one performs better. Traditionally, one of these experiences is the existing, A, control experience, and the other experience is a new, B, variant experience. By randomly grouping users into one of the two experiences, and measuring the on-site behavior (e.g., clicks on a listing or items purchased) of each group, we can make data-driven decisions about whether new experiences are actually an improvement for our users. For our use case, the control experience is showing users content machine translated with the generic engine, and the variant experience is showing content translated with the retrained engine. A/B testing allows us to answer the following question: will users who read a product description translated by a domain-customized translation engine be more or less likely to purchase a product?

To test the effects of the quality improvement obtained, we used our in-house automated A/B testing framework to compare the behavioral effects on users who translated text using the generic engine and those who translated using System 3. Visitors to the online marketplace were randomly "bucketed" into an experimental group or a control group. Random bucketing was achieved via a hash of a user's browser ID, which allows users who return to the site during the experimental period to be bucketed consistently across visits. For visitors who requested translations from English into French, the generic system's translations were displayed to visitors in the control group, and System 3 translations were displayed to visitors in the experimental group.

The experiment ran for 66 days for a total of 88,106 visitors (43,306 control and 44,800 experimental). The key metrics tracked were pages per visit (the number of pages seen in one user session), conversion rate (the percent of visits that include at least one purchase), and add-to-cart rate (the percent of visits in which a user adds an item to their shopping cart). We observed a significant positive

Metric	Trained engine
Conversion rate	+8.72%
Visit add-to-cart rate	+2.92%
Pages per visit	+3.37%

Table 4: The trained translation system's (System 3) improvement over the generic engine on key business metrics. All differences are statistically significant ($p < 0.05$). Base rates are omitted for data privacy reasons.

effect of the trained system on all three metrics, as shown in Table 4: a 3.37% increase in pages per visit ($p = 0.00153$ 95% CI $[1.29, 5.46]$), an 8.72% increase in purchase rate ($p = 0.00513$ 95% CI $[2.61, 14.82]$), and a 2.92% increase in add-to-cart ($p = 0.04689$ 95% CI $[0.04, 5.8]$).

5 Conclusion

Numerous studies have shown that automatic machine translation quality estimates, such as BLEU, are correlated with human evaluations of translation quality. Our work shows that those improvements in translation quality can have a positive effect on user behavior in a commercial setting, as measured through conversion rate. These considerations suggest that, in domains where machine translation conveys information upon which individuals base decisions, the effort needed to gather and process data to customize a machine translation system can be worthwhile. Additionally, our experiments show A/B testing can be a valuable tool to evaluate machine translation quality. A/B testing goes beyond measuring the quality of translation improvements: it allows us to see the positive impact that quality improvements are having on users' purchase behavior in a measurable way.

Creating a Large Benchmark for Open Information Extraction

dagan@cs.biu.ac.il

Abstract

Open information extraction (Open IE) was presented as an unrestricted variant of traditional information extraction. It has been gaining substantial attention, manifested by a large number of automatic Open IE extractors and downstream applications. In spite of this broad attention, the Open IE task definition has been lacking – there are no formal guidelines and no large scale gold standard annotation. Subsequently, the various implementations of Open IE resorted to small scale post-hoc evaluations, inhibiting an objective and reproducible cross-system comparison. In this work, we develop a methodology that leverages the recent QA-SRL annotation to create a first independent and large scale Open IE annotation,[1] and use it to automatically compare the most prominent Open IE systems.

1 Introduction

Open Information Extraction (Open IE) was originally formulated as a function from a document to a set of tuples indicating a semantic relation between a predicate phrase and its arguments (Banko et al., 2007). Wu and Weld (2008) further defined that an Open IE extractor should "produce one triple for every relation stated explicitly in the text, but is not required to infer implicit facts". For example, given the sentence "*John managed to open the door*" an Open IE extractor should produce the tuple *(John;* **managed to open***; the door)* but is *not* required to produce the extraction *(John;* **opened***; the door)*.

[1]Publicly available at `http://www.cs.biu.ac.il/nlp/resources/downloads`

Following this initial presentation of the task, Open IE has gained substantial and consistent attention. Many automatic extractors were created (e.g., (Fader et al., 2011; Mausam et al., 2012; Del Corro and Gemulla, 2013)) and were put to use in various downstream applications.

In spite of this wide attention, Open IE's formal definition is lacking. There are no clear guidelines as to what constitutes a valid proposition to be extracted, and subsequently there is no large scale benchmark annotation. Open IE evaluations therefore usually consist of a post-hoc manual evaluation of a small output sample.

This evaluation practice lacks in several respects: (1) Most works provide a precision oriented metric, whereas recall is often not measured, (2) the numbers are not comparable across systems, as they use different guidelines and datasets, and (3) the experiments are hard to replicate.

In this work, we aim to contribute to the standardization of Open IE evaluation by providing a large gold benchmark corpus. For that end, we first identify consensual guiding principles across prominent Open IE systems, resulting in a clearer formulation of the Open IE task. Following, we find that the recent formulation of QA-SRL (He et al., 2015) in fact subsumes these requirements for Open IE. This enables us to automatically convert the annotations of QA-SRL to a high-quality Open IE corpus of more than 10K extractions, 13 times larger than the previous largest Open IE annotation.

Finally, we automatically evaluate the performance of various Open IE systems against our corpus, using a soft matching criterion. This is the first

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2300–2305,
Austin, Texas, November 1-5, 2016.

time such a comparative evaluation is performed on a large scale gold corpus.

Future Open IE systems (and its applicative users) can use this large benchmark, along with the automatic evaluation measure, to easily compare their performance against previous baselines, alleviating the current need for ad-hoc evaluation.

2 Background

2.1 Open IE

Open Information Extraction (Open IE) was introduced as an open variant of traditional Information Extraction (Etzioni et al., 2008). As mentioned in the Introduction, its primary goal is to extract coherent propositions from a sentence, each comprising of a relation phrase and two or more argument phrases (e.g., (Barack Obama, **born in**, Hawaii)). Since its inception, Open IE has gained consistent attention, mostly used as a component within larger frameworks (Christensen et al., 2013; Balasubramanian et al., 2013).

In parallel, many Open IE extractors were developed. TextRunner (Banko et al., 2007) and WOE (Wu and Weld, 2010) take a self-supervised approach over automatically produced dependency parses. Perhaps more dominant is the rule based approach taken by ReVerb (Fader et al., 2011), OLLIE (Mausam et al., 2012), KrakeN (Akbik and Löser, 2012) and ClausIE (Del Corro and Gemulla, 2013).

Two recent systems take a semantically-oriented approach. Open IE-4[2] uses semantic role labeling to extract tuples, while Stanford Open Information Extraction (Angeli et al., 2015) uses natural logic inference to arrive at shorter, more salient, arguments.

Recently, Stanovsky et al. (2016b) presented PropS, a proposition oriented representation, obtained via conversion rules from dependency trees. Performing Open IE extraction over PropS structures is straightforward – follow the clearly marked predicated nodes to their direct arguments.

Contrary to the vast interest in Open IE, its task formulation has been largely overlooked. There are currently no common guidelines defining a valid extraction, which consequently hinders the creation of an evaluation benchmark for the task. Most Open IE extractors[3] evaluate performance by manually examining a small sample of their output. Table 1 summarizes the evaluations taken by the most prominent Open IE systems.

2.2 QA-SRL

Semantic Role Labeling (SRL) (Carreras and Màrquez, 2005) is typically perceived as answering **argument role questions**, such as *who, what, to whom, when*, or *where*, regarding a target predicate. For instance, PropBank's ARG0 for the predicate **say** answers the question "*who* **said** *something?*".

QA-SRL (He et al., 2015) suggests that answering explicit role questions is an intuitive means to solicit predicate-argument structures from non-expert annotators. Annotators are presented with a sentence in which a target predicate[4] was marked, and are requested to annotate argument role questions and corresponding answers.

Consider the sentence "*Giles Pearman, Microsoft's director of marketing, left his job*" and the target predicate **left**. The QA-SRL annotation consists of the following pairs: (1) *Who left something?* {**Giles Pearman**; **Microsoft's director of marketing**} and (2) *what did someone leave?* **his job**.[5]

He et al. assessed the validity of QA-SRL by annotating 3200 sentences from PropBank and Wikipedia, showing high agreement with the PropBank annotations. In the following section we automatically derive an Open IE benchmark from this QA-SRL annotation.

3 Creating an Open IE Benchmark

3.1 Open IE Guidelines

Before creating a generic benchmark for evaluating Open IE systems, it is first needed to obtain a clearer specification of the common task that they address. Despite some nuances, we identified the following core aspects of the Open IE task as consensual across all systems mentioned in Section 2:

[2] https://github.com/knowitall/openie

[3] Except for (Wu and Weld, 2010) who evaluated recall.

[4] Currently consisting of automatically annotated verbs.

[5] Three cases give rise to multiple answers for the same question: appositives (as illustrated in this example), co-reference ("***Jimmy Hendrix*** *played the guitar,* ***he*** *was really good at it*"), and distributive coordinations ("***Bob*** *and* ***Mary*** *were born in America*").

System	#Sentences	Genre	Metric	#Annot.	Agreement
TextRunner	400	Web	% Correct	3	-
WOE	300	Web, Wiki, News	Precision / Recall	5	-
ReVerb	500	Web	Precision / AUC	2	86%, .68 k
KrakeN	500	Web	% Correct	2	87%
Ollie	300	News, Wiki, Biology	Precision/Yield AUC	2	96%
ClauseIE	300	Web, Wiki, News	Precision/Yield	2	57% / 68% / 63%

Table 1: The post-hoc evaluation metrics taken by the different systems described in Section 2. In contrast, Stanford Open IE and PropS took an extrinsic evaluation approach.

Assertedness Extracted propositions should be asserted by the original sentence. For example, given the sentence "*Sam succeeded in convincing John*", ReVerb and ClausIE produce the extraction: *(Sam;* **succeeded in convincing***; John)*. Most Open IE systems do not attempt to recover implied embedded propositions (e.g., *(Sam;* **convinced***; John)*), but rather include matrix verbs (e.g., **succeeded**) in the predicate slot. Other elements that affect assertedness, like negations and modals, are typically included in the predicate slot as well (e.g. *(John;* **could not join***; the band)*).

Minimal propositions Open IE systems aim to "break down" a sentence into a set of small isolated propositions. Accordingly, the span of each individual proposition, and hence the span of each of its predicate and argument slots, should be as minimal as possible, as long as the original information (truth conditions) is preserved. For example, this leads to splitting distributive coordination in the sentence "*Bell distributes electronic and building products*", for which ClausIE produces: *(Bell,* **distributes***, electronic products)* and *(Bell,* **distributes***, building products)*. Having shorter entities as Open IE arguments was further found to be useful in several semantic tasks (Angeli et al., 2015; Stanovsky et al., 2015).

Completeness and open lexicon Open IE systems aim to extract all asserted propositions from a sentence. In practice, most current Open IE systems limit their scope to extracting verbal predicates, but consider all possible verbs without being bound to a pre-specified lexicon.

3.2 From QA-SRL to Open IE

SRL and Open IE have been defined with different objectives. Particularly, SRL identifies argument role labels, which is not addressed in Open IE. Yet, the two tasks overlap as they both need to recover predicate-argument structures in sentences. We now examine the above Open IE requirements and suggest that while they are only partly embedded within SRL structures, they can be fully recovered from QA-SRL.

Asserted (matrix) propositions appear in SRL as non-embedded predicates (e.g., **succeeded** in the "*Sam succeeded to convince John*"). However, SRL's predicates are grounded to a lexicon such as PropBank (Palmer et al., 2005) or FrameNet (Baker et al., 1998), which violates the *completeness and open lexicon* principle. Further, in contrast to the *minimal propositions* principle, arguments in SRL annotations are inclusive, each marked as full subtrees in a syntactic parse.

Yet, QA-SRL seems to bridge this gap between traditional SRL structures and Open IE requirements. Its predicate vocabulary is open, and its question-answer format solicits *minimal propositions*, as was found in a recent study by (Stanovsky et al., 2016a). This correlation suggests that the QA-SRL methodology is in fact also an attractive means for soliciting Open IE extractions from non-experts annotators. Evidently, it enables automatically deriving high quality Open IE annotations from (current or future) QA-SRL gold annotations, as described in the following section

3.3 Generating Open-IE Extractions

Formally, we extract an Open-IE dataset from the QA-SRL dataset by the following algorithm, which is illustrated in more detail further below:

1. Given:
   - s - a sentence from the QA-SRL dataset.
   - p - a predicate in s.
   - $\{q_1, ..., q_n\}$ - a list of questions over p.
   - $\{\{a_{1,1}, ..., a_{1,l_1}\}, ...\{a_{n,1}, ..., a_{n,l_n}\}\}$ - a list of sets of corresponding answers, where question q_i has l_i answers.
2. If p is a non-embedded (matrix) verb:
   (a) Remove answers which are composed only of pronouns, as these are not expected to be extracted by Open-IE (and accordingly adjust the l_i's).
   (b) Return extractions composed of p and every combination of answers in $\{\{a_{1,1}, ..., a_{1,l_1}\} \times ... \times \{a_{n,1}, ..., a_{n,l_n}\}\}$ (the Cartesian product of the answers). This process results in a list of $l_1 \cdot l_2 \cdot ... \cdot l_n$ Open IE extractions.

For example, consider the sentence: "*Barack Obama, the U.S. president, was* **determined** *to win the majority vote in Washington and Arizona*". The questions corresponding to the predicate **determine** are: {*who was determined?*, *what was someone determined to do?*}, and the corresponding answer sets are: {{"Barack Obama", "the U.S president"}, {"win the majority vote in Washington", "win the majority vote in Arizona"}}.

Following, our algorithm will produce these Open IE extractions: *(Barack Obama;* **was determined***; to win the majority vote in Washington)*, *(the U.S. president;* **was determined***; to win the majority vote in Washington)*, *(Barack Obama;* **was determined***; to win the majority vote in Arizona)*, and *(the U.S. president;* **was determined***; to win the majority vote in Arizona)*.

Note that we do not produce extractions for embedded predicates (e.g., **win**) to conform with the *assertedness* principle, as discussed earlier.

With respect to pronoun removal (step 2(a)), we would remove the pronoun "he" as the answer to the question *who was tired?* in "*John went home,* ***he*** *was tired*". Notice that in this sentence "John" would be a second answer for the above question, yielding the extraction *(John;* ***was tired****)*. When the only answer to a question is a pronoun this question will be ignored in the extraction process, since the QA-SRL corpus does not address cross-sentence co-references. This issue may be addressed in future work.

Corpus	WSJ	WIKI	ALL
#Sentences	1241	1959	3200
#Predicates	2020	5690	7710
#Questions	8112	10798	18910
#Extractions	**4481**	**5878**	**10359**

Table 2: Corpus statistics.

System	#Extractions		
	WSJ	WIKI	ALL
Stanford	6423	14104	20527
ClausIE	5295	8265	13560
Open IE4	3634	5113	8747
OLLIE	2976	5250	8226
PropS	2852	4990	7842
ReVerb	1624	2552	4716

Table 3: The yield of the different Open IE systems.

Applying this process to the QA-SRL corpus yielded a total of 10,359 Open IE extractions over 3200 sentences from 2 domains (see Table 2). This corpus is about 13 times larger than the previous largest annotated Open IE corpus (Fader et al., 2011). The corpus is available at: `http://www.cs.biu.ac.il/nlp/resources/downloads`.

Corpus validation We assess the validity of our dataset by performing expert annotation[6] of Open IE extractions, following the principles discussed in Section 3.1, for 100 random sentences. We find that our benchmark extractions, derived automatically from QA-SRL, highly agree with the expert annotation, reaching 95.8 F1 by the head-agreement criterion defined in the next section.

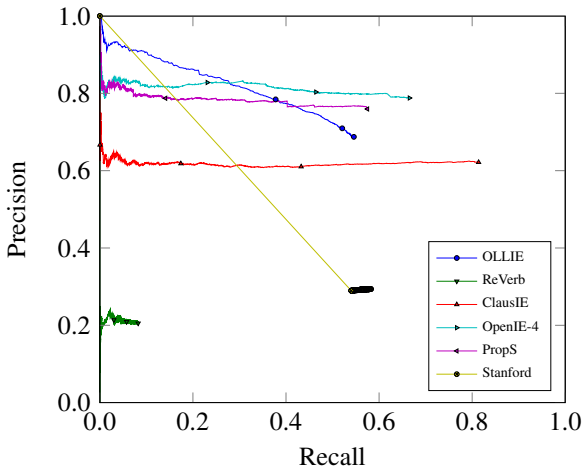

Figure 1: Precision-recall curve for the different Open IE systems on our corpus (see discussion in Section 4).

4 Comparative Evaluation

In this section, we illustrate the utility of our new corpus by testing the performance of 6 prominent Open IE systems: OpenIE-4, ClausIE, OLLIE, PropS, Stanford, and ReVerb (see Section 2).[7]

In order to evaluate these systems in terms of precision and recall, we need to match between their automated extractions and the benchmark extractions. To allow some flexibility (e.g., omissions of prepositions or auxiliaries), we follow (He et al., 2015) and match an automated extraction with a gold proposition if both agree on the grammatical head of all of their elements (predicate and arguments). We then analyze the recall and precision of Open IE systems on different confidence thresholds (Figure 1). Furthermore, we calculate the area under the PR curve for each of the different corpora (Figure 2) and the explicit yield per system (Table 3).

To the best of our knowledge, this is the first objective comparative evaluation of prominent Open-IE systems, over a large and independently created dataset. This comparison gives rise to several observations; which can be useful for future research and for choosing a preferred system for a particular application setting, such as:

[6]Carried by the first author.

[7]Currently, we test only the common case of verbal predicates.

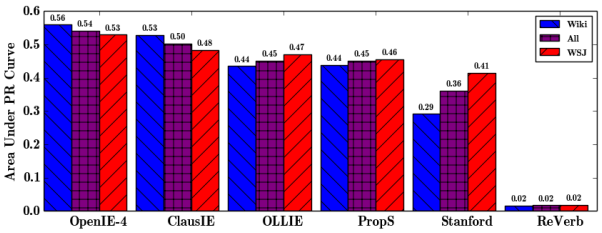

Figure 2: Area Under the PR Curve (AUC) measure for the evaluated systems.

1. *Open IE-4* achieves best precision above 3% recall ($\geqslant$ 78.67) and best AUC score (54.02),
2. *ClausIE* is best at recall (81.38), and
3. *Stanford Open IE* assigns confidence of 1 to 94% of its extractions, explaining its low precision.

5 Conclusions

We presented the first independent and large scale Open IE benchmark annotation, and tested the most prominent systems against it. We hope that future Open IE systems can make use of this new resource to easily and objectively measure and compare their performance.

Acknowledgments

We would like to thank Mausam for fruitful discussions, and the anonymous reviewers for their helpful comments.

Abstract

To alleviate the shortage of labeled data, we propose to use bilingually-constrained synthetic implicit data for implicit discourse relation recognition. These data are extracted from a bilingual sentence-aligned corpus according to the implicit/explicit mismatch between different languages. Incorporating these data via a multi-task neural network model achieves significant improvements over baselines, on both the English PDTB and Chinese CDTB data sets.

1 Introduction

Discovering the discourse relation between two sentences is crucial to understanding the meaning of a coherent text, and also beneficial to many downstream NLP applications, such as question answering and machine translation. Implicit discourse relation recognition (DRR_{imp}) remains a challenging task due to the absence of strong surface clues like discourse connectives (e.g. but). Most work resorts to large amounts of manually designed features (Soricut and Marcu, 2003; Pitler et al., 2009; Lin et al., 2009; Louis et al., 2010; Rutherford and Xue, 2014), or distributed features learned via neural network models (Braud and Denis, 2015; Zhang et al., 2015; Ji and Eisenstein, 2015). The above methods usually suffer from limited labeled data.

Marcu and Echihabi (2002) attempt to create labeled implicit data automatically by removing connectives from explicit instances, as additional training data. These data are usually called as *synthetic implicit data* (hereafter $SynData$). However, Sporleder and Lascarides (2008) argue that $SynData$ has two drawbacks: 1) meaning shifts in some cases when removing connectives, and 2) a different word distribution with the *real implicit data*. They also show that using $SynData$ directly degrades the performance. Recent work seeks to derive valuable information from $SynData$ while filtering noise, via domain adaptation (Braud and Denis, 2014; Ji et al., 2015), classifying connectives (Rutherford and Xue, 2015) or multi-task learning (Lan et al., 2013; Liu et al., 2016), and shows promising results.

but [many young people do not think there is anything wrong with them.]$_{Arg2}$

Figure 1: An example illustrating the implicit/explicit mismatch between Chinese (ch) and English (en). A Chinese implicit instance is translated into an English explicit one. In the PDTB, a discourse instance is defined as a connective (e.g. but) taking two arguments ($Arg1$ and $Arg2$).

Different from previous work, we propose to construct *bilingually-constrained synthetic implicit data* (called $BiSynData$) for DRR_{imp}, which can alleviate the drawbacks of $SynData$. Our method is inspired by the findings that a discourse instance expressed implicitly in one language may be expressed explicitly in another. For example, Zhou and Xue

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2306–2312,
Austin, Texas, November 1-5, 2016.

(2012) show that the connectives in Chinese omit much more frequently than those in English with about 82.0% vs. 54.5%. Li et al. (2014a) further argue that there are about 23.3% implicit/explicit mismatchs between Chinese/English instances. As illustrated in Figure 1, a Chinese implicit instance where the connective 但是 is absent, is translated into an English explicit one with the connective but. Intuitively, the Chinese instance is a *real* implicit one which can be signaled by but. Hence, it could potentially serve as additional training data for the Chinese DRR_{imp}, avoiding the different word distribution problem of $SynData$. Meanwhile, for the English explicit instance, it is very likely that removing but would not lose any information since its Chinese counterpart 但是 can be omitted. Therefore it could be used for the English DRR_{imp}, alleviating the meaning shift problem of $SynData$.

We extract our $BiSynData$ from a Chinese-English sentence-aligned corpus (Section 2). Then we design a multi-task neural network model to incorporate the $BiSynData$ (Section 3). Experimental results, on both the English PDTB (Prasad et al., 2008) and Chinese CDTB (Li et al., 2014b), show that $BiSynData$ is more effective than $SynData$ used in previous work (Section 4). Finally, we review the related work (Section 5) and draw conclusions (Section 6).

2 BiSynData

Formally, given a Chinese-English sentence pair (S_{ch}, S_{en}), we try to find an English explicit instance $(Arg1_{en}, Arg2_{en}, Conn_{en})$ in S_{en}[1], and a Chinese implicit instance $(Arg1_{ch}, Arg2_{ch})$ in S_{ch}, where $(Arg1_{en}, Arg2_{en}, Conn_{en})$ is the translation of $(Arg1_{ch}, Arg2_{ch})$. In most cases, discourse relations should be preserved during translating, so the connective $Conn_{en}$ is potentially a strong indicator of the discourse relation between not only $Arg1_{en}$ and $Arg2_{en}$, but also $Arg1_{ch}$ and $Arg2_{ch}$. Therefore, we can construct two synthetic implicit instances labeled by $Conn_{en}$, denoted as $\langle (Arg1_{en}, Arg2_{en}), Conn_{en} \rangle$ and $\langle (Arg1_{ch}, Arg2_{ch}), Conn_{en} \rangle$, respectively. We refer to these synthetic instances as $BiSynData$ because they are constructed according to the bilingual implicit/explicit mismatch.

Conn.	Freq.	Conn.	Freq.
and	14294	$while$	1031
if	2580	$before$	822
as	1951	$also$	552
$when$	1521	$since$	511
but	1122	$because$	503

Table 1: Top 10 most frequent connectives in our $BiSynData$.

In our experiments, we extract our $BiSynData$ from a combined corpus (FBIS and HongKong Law), with about 2.38 million Chinese-English sentence pairs. We generate 30,032 synthetic English instances and the same number of Chinese instances, with 80 connectives, as our $BiSynData$. Table 1 lists the top 10 most frequent connectives in our $BiSynData$, which are roughly consistent with the statistics of Chinese/English implicit/explicit mismatches in (Li et al., 2014a). According to connectives and their related relations in the PDTB, in most cases, and and $also$ indicate the $Expansion$ relation, if and $because$ the $Contigency$ relation, $before$ the $Temporal$ relation, and but the $Comparison$ relation. Connectives as, $when$, $while$ and $since$ are ambiguous. For example, $while$ can indicate the $Comparison$ or $Temporal$ relation. Overall, our constructed $BiSynData$ covers all four main discourse relations defined in the PDTB.

With our $BiSynData$, we define two connective classification tasks: 1) given $(Arg1_{en}, Arg2_{en})$ to predict the connective $Conn_{en}$, and 2) given $(Arg1_{ch}, Arg2_{ch})$ to predict $Conn_{en}$. We incorporate the first task to help the English DRR_{imp}, and the second for the Chinese DRR_{imp}. It is worthy to note that we use English connectives themselves as classification labels rather than mapping them to relations in both tasks.

3 Multi-Task Neural Network Model

We design a Multi-task Neural Network Model (denoted as MTN), which incorporates a connective classification task on $BiSynData$ (auxiliary task) to benefit DRR_{imp} (main task). In general, the more related two tasks are, the more powerful a multi-task learning method will be. In the current problem, the

[1]In our experiments, we use the pdtb-parser toolkit (Lin et al., 2014) to identify English explicit instances.

two tasks are essentially the same, just with different output labels. Therefore, as illustrated in Figure 2, MTN shares parameters in all feature layers (L_1-L_3) and uses two separate classifiers in the classifier layer (L_4). For each task, given an instance (Arg_1, Arg_2), MTN simply averages embeddings of words to represent arguments, as v_{Arg_1} and v_{Arg_2}. These two vectors are then concatenated and transformed through two non-linear hidden layers. Finally, the corresponding $softmax$ layer is used to perform classification.

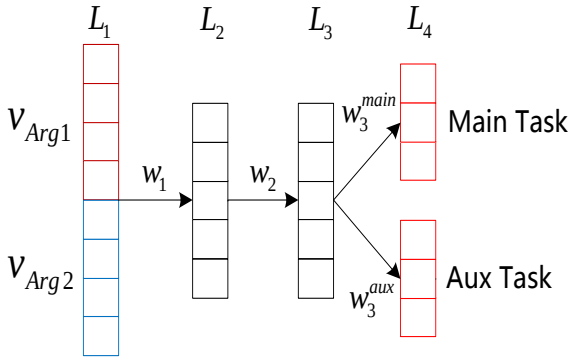

Figure 2: MTN with four layers L_1-L_4.

MTN ignores the word order in arguments and uses two hidden layers to capture the interactions between two arguments. The idea behind MTN is borrowed from (Iyyer et al., 2015), where a deep averaging network achieves close to the state-of-the-art performance on text classification. Though MTN is simple, it is easy to train and efficient on both memory and computational cost. In addition, the simplicity of MTN allows us to focus on measuring the quality of $BiSynData$.

We use the cross-entropy loss function and mini-batch AdaGrad (Duchi et al., 2011) to optimize parameters. Pre-trained word embeddings are fixed. We find that fine-tuning word embeddings during training leads to severe overfitting in our experiments. Following Liu et al. (2016), we alternately use two tasks to train the model, one task per epoch. For tasks on both the PDTB and CDTB, we use the same hyper-parameters. The dimension of word embedding is 100. We set the size of L_2 to 200, and L_3 to 100. $ReLU$ is used as the non-linear function. Different learning rates 0.005 and 0.001 are used in the main and auxiliary tasks, respectively. To avoid overfitting, we randomly drop out 20% words in each argument following Iyyer et al. (2015). All hyper-parameters are tuned on the development set.

4 Experiments

We evaluate our method on both the English PDTB and Chinese CDTB data sets. We tokenize English data and segment Chinese data using the Stanford CoreNLP toolkit (Manning et al., 2014). The English/Chinese Gigaword corpus (3rd edition) is used to train the English/Chinese word embeddings via $word2vec$ (Mikolov et al., 2013), respectively. Due to the skewed class distribution of test data (see Section 4.1), we use the macro-averaged F_1 for performance evaluation.

4.1 On the PDTB

Following Rutherford and Xue (2015), we perform a 4-way classification on the top-level discourse relations: $Temporal$ ($Temp$), $Comparison$ ($Comp$), $Contigency$ ($Cont$) and $Expansion$ ($Expa$). Sections 2-20 are used as training set, sections 0-1 as development set and sections 21-22 as test set. The training/test set contains 582/55 instances for $Temp$, 1855/145 for $Comp$, 3235/273 for $Cont$ and 6673/538 for $Expa$. The top 20 most frequent connectives in our $BiSynData$ are considered in the auxiliary task, with 28,013 synthetic English instances in total.

		STN	MTN_{bi}
$Temp$	P	33.33	**34.48**
	R	14.55	**18.18**
	F_1	20.25	**23.81**
$Comp$	P	38.54	**42.11**
	R	25.52	**33.10**
	F_1	30.71	**37.07**
$Cont$	P	38.36	**44.22**
	R	**41.03**	40.66
	F_1	39.65	**42.37**
$Expa$	P	59.60	**62.56**
	R	66.36	**71.75**
	F_1	62.80	**66.84**
$macro\ F_1$		38.35	**42.52**

Table 2: Results of 4-way classification on the PDTB.

Table 2 shows the results of MTN combining our $BiSynData$ (denoted as MTN_{bi}) on the PDTB.

STN means we train MTN with only the main task. On the $macro\ F_1$, MTN_{bi} gains an improvement of 4.17% over STN. The improvement is significant under one-tailed t-test (p<0.05). A closer look into the results shows that MTN_{bi} performs better across all relations, on the precision, recall and F_1 score, except a little drop on the recall of $Cont$. The reason for the recall drop of $Cont$ is not clear. The greatest improvement is observed on $Comp$, up to 6.36% F_1 score. The possible reason is that only $while$ is ambiguous about $Comp$ and $Temp$, while as, $when$ and $since$ are all ambiguous about $Temp$ and $Cont$, among top 10 connectives in our $BiSynData$. Meanwhile the amount of labeled data for $Comp$ is relatively small. Overall, using $BiSynData$ under our multi-task model achieves significant improvements on the English DRR_{imp}. We believe the reasons for the improvements are twofold: 1) the added synthetic English instances from our $BiSynData$ can alleviate the meaning shift problem, and 2) a multi-task learning method is helpful for addressing the different word distribution problem between implicit and explicit data.

Considering some of the English connectives (e.g., $while$) are highly ambiguous, we compare our method with ones that uses only unambiguous connectives. Specifically, we first discard as, $when$, $while$ and $since$ in top 20 connectives, and get 22,999 synthetic instances. Then, we leverage these instances in two different ways: 1) using them in our multi-task model as above, and 2) using them as additional training data directly after mapping unambiguous connectives into relations. Both methods using only unambiguous connectives do not achieve better performance. One possible reason is that these synthetic instances become more unbalanced after discarding ones with ambiguous connectives.

We also compare MTN_{bi} with recent systems using additional training data. Rutherford and Xue (2015) select explicit instances that are similar to the implicit ones via connective classification, to enrich the training data. Liu et al. (2016) use a multi-task model with three auxiliary tasks: 1) $conn$: connective classification on explicit instances, 2) exp: relation classification on the labeled explicit instances in the PDTB, and 3) rst: relation classification on the labeled RST corpus (William and Thompson, 1988), which defines different discourse relations with that in the PDTB. The results are shown in Table 3. Although Liu et al. (2016) achieve the state-of-the-art performance (Line 5), they use two additional labeled corpora. We can find that MTN_{bi} (Line 6) yields better results than those systems incorporating $SynData$ (Line 1, 2 and 3), or even the labeled RST (Line 4). These results confirm that $BiSynData$ can indeed alleviate the disadvantages of $SynData$ effectively.

	System	$macro\ F_1$
1	Rutherford and Xue (2015)	40.50
2	Liu et al. (2016) $_{conn}$	38.09

4	Liu et al. (2016) $_{rst}$	40.67
5	Liu et al. (2016) $_{conn+exp+rst}$	**44.98**
6	MTN_{bi}	42.52

Table 3: Comparison with recent systems on the PDTB. $conn+exp+rst$ means using three auxiliary tasks simultaneously.

4.2 On the CDTB

Four top-level relations are defined in the CDTB, including $Transition$ ($Tran$), $Causality$ ($Caus$), $Explanation$ ($Expl$) and $Coordination$ ($Coor$). We use instances in the first 50 documents as test set, second 50 documents as development set and remaining 400 documents as training set. We conduct a 3-way classification because of only 39 instances for $Tran$. The training/test set contains 682/95 instances for $Caus$, 1143/126 for $Expl$ and 2300/347 for $Coor$. The top 20 most frequent connectives (excluding and)[2] in our $BiSynData$ are considered in the auxiliary task, with 13,899 synthetic Chinese instances in total. The results are shown in Table 4. Compared with STN, MTN_{bi} raises the $macro\ F_1$ from 55.44% to 58.28%. The improvement is significant under one-tailed t-test (p<0.05). Therefore, $BiSynData$ is also helpful for the Chinese DRR_{imp}.

Because of no reported results on the CDTB, we use MTN with two different auxiliary tasks as baselines: 1) exp: relation classification on the labeled

[2]Including and degrades the performance slightly. A possible reason is that and can be related to both the $Expl$ and $Coor$ relations in the CDTB, and instances marked by and account for about half of our $BiSynData$.

		STN	MTN_{bi}
$Caus$	P	47.92	**52.94**
	R	24.21	**28.42**
	F_1	32.17	**36.99**
$Expl$	P	**54.62**	53.47
	R	56.35	**61.11**

5 Related Work

One line of research related to DRR_{imp} tries to take advantage of explicit discourse data. Zhou et al. (2010) predict the absent connectives based on a language model. Using these predicted connectives as features is proven to be helpful. Biran and McKeown (2013) aggregate word-pair features that are collected around the same connectives, which can effectively alleviate the feature sparsity problem. More recently, Braud and Denis (2014) and Ji et al. (2015) consider explicit data from a different domain, and use domain adaptation methods to explore the effect of them. Rutherford and Xue (2015) propose to gather weakly labeled data from explicit instances via connective classification, which are used as additional training data directly. Lan et al. (2013) and Liu et al. (2016) combine explicit and implicit data using multi-task learning models and gain improvements. Different from all the above work, we construct additional training data from a bilingual corpus.

Multi-task neural networks have been successfully used for many NLP tasks. For example, Collobert et al. (2011) jointly train models for the Part-of-Speech tagging, chunking, named entity recognition and semantic role labeling using convolutional network. Liu et al. (2015) successfully combine the tasks of query classification and ranking for web search using a deep multi-task neural network. Luong et al. (2016) explore multi-task sequence to sequence learning for constituency parsing, image caption generation and machine translation.

6 Conclusion

In this paper, we introduce bilingually-constrained synthetic implicit data ($BiSynData$), which are generated based on the bilingual implicit/explicit mismatch, into implicit discourse relation recognition for the first time. On both the PDTB and CDTB, using $BiSynData$ as the auxiliary task significantly improves the performance of the main task. We also show that $BiSynData$ is more beneficial than the synthetic implicit data typically used in previous work. Since the lack of labeled data is a major challenge for implicit discourse relation classification, our proposed $BiSynData$ can enrich the training data and then benefit future work.

Abstract

We introduce a novel approach to the decoding problem in transition-based parsing: heuristic backtracking. This algorithm uses a series of partial parses on the sentence to locate the best candidate parse, using confidence estimates of transition decisions as a heuristic to guide the starting points of the search. This allows us to achieve a parse accuracy comparable to beam search, despite using fewer transitions. When used to augment a Stack-LSTM transition-based parser, the parser shows an unlabeled attachment score of up to 93.30% for English and 87.61% for Chinese.

1 Introduction

Transition-based parsing, one of the most prominent dependency parsing techniques, constructs a dependency structure by reading words sequentially from the sentence, and making a series of local decisions (called transitions) which incrementally build the structure. Transition-based parsing has been shown to be both fast and accurate; the number of transitions required to fully parse the sentence is linear relative to the number of words in the sentence.

In recent years, the field has seen dramatic improvements in the ability to correctly predict transitions. Recent models include the greedy Stack-LSTM model of Dyer et al. (2015) and the globally normalized feed-forward networks of Andor et al. (2016). These models output a local decision at each transition point, so searching the space of possible paths to the predicted tree is an important component of high-accuracy parsers.

One common search technique is beam search. (Zhang and Clark, 2008; Zhang and Nivre, 2011; Bohnet and Nivre, 2012; Zhou et al., 2015; Weiss et al., 2015; Yazdani and Henderson, 2015) In beam-search, a fixed number of candidate transition sequences are generated, and the highest-scoring sequence is chosen as the answer. One downside to beam search is that it often results in a significant amount of wasted predictions. A constant number of beams are explored at all points throughout the sentence, leading to some unnecessary exploration towards the beginning of the sentence, and potentially insufficient exploration towards the end.

One way that this problem can be mitigated is by using a dynamically-sized beam (Mejia-Lavalle and Ramos, 2013). When using this technique, at each step, prune all beams whose scores are below some value s, where s is calculated based upon the distribution of scores of available beams. Common methods for pruning are removing all beams below some percentile, or any beams which scored below some constant percentage of the highest-scoring beam.

Another approach to solving this issue is given by Choi and McCallum (2013). They introduced selectional branching, which involves performing an initial greedy parse, and then using confidence estimates on each prediction to spawn additional beams. Relative to standard beam-search, this reduces the average number of predictions required to parse a sentence, resulting in a speed-up.

In this paper, we introduce heuristic backtracking, which expands on the ideas of selectional branching by integrating a search strategy based on a heuristic function (Pearl, 1984): a function which estimates

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2313–2318,
Austin, Texas, November 1-5, 2016.

the future cost of taking a particular decision. When paired with a good heuristic, heuristic backtracking maintains the property of reducing wasted predictions, but allows us to more fully explore the space of possible transition sequences (as compared to selectional branching). In this paper, we use a heuristic based on the confidence of transition predictions.

We also introduce a new optimization: heuristic backtracking with cutoff. Since heuristic backtracking produces results incrementally, it is possible to stop the search early if we have found an answer that we believe to be the gold parse, saving time proportional to the number of backtracks remaining.

We compare the performance of these various decoding algorithms with the Stack-LSTM parser (Dyer et al., 2015), and achieve slightly higher accuracy than beam search, in significantly less time.

2 Transition-Based Parsing With Stack-LSTM

Our starting point is the model described by Dyer et al. (2015).[1] The parser implements the arc-standard algorithm (Nivre, 2004) and it therefore makes use of a stack and a buffer. In (Dyer et al., 2015), the stack and the buffer are encoded with Stack-LSTMs, and a third sequence with the history of actions taken by the parser is encoded with another Stack-LSTM. The three encoded sequences form the parser state $\mathbf{p}_t$ defined as follows,

$$\mathbf{p}_t = \max\left\{\mathbf{0}, \mathbf{W}[\mathbf{s}_t; \mathbf{b}_t; \mathbf{a}_t] + \mathbf{d}\right\}, \quad (1)$$

where $\mathbf{W}$ is a learned parameter matrix, $\mathbf{b}_t$, $\mathbf{s}_t$ and $\mathbf{a}_t$ are the stack LSTM encoding of buffer, stack and the history of actions, and $\mathbf{d}$ is a bias term. The output $\mathbf{p}_t$ (after a component-wise rectified linear unit (ReLU) nonlinearity (Glorot et al., 2011)) is then used to compute the probability of the parser action at time t as:

$$p(z_t \mid \mathbf{p}_t) = \frac{\exp\left(\mathbf{g}_{z_t}^\top \mathbf{p}_t + q_{z_t}\right)}{\sum_{z' \in \mathcal{A}(S,B)} \exp\left(\mathbf{g}_{z'}^\top \mathbf{p}_t + q_{z'}\right)}, \quad (2)$$

where $\mathbf{g}_z$ is a column vector representing the (output) embedding of the parser action z, and q_z is a bias term for action z. The set $\mathcal{A}(S, B)$ represents the valid transition actions that may be taken in the current state. The objective function is:

$$\mathcal{L}_{\boldsymbol{\theta}}(\boldsymbol{w}, \boldsymbol{z}) = \sum_{t=1}^{|\boldsymbol{z}|} \log p(z_t \mid \mathbf{p}_t) \quad (3)$$

where $\boldsymbol{z}$ refers to parse transitions.

[1] We refer to the original work for details.

3 Heuristic Backtracking

Using the Stack-LSTM parsing model of Dyer et al. (2015) to predict each decision greedily yields very high accuracy; however, it can only explore one path, and it therefore can be improved by conducting a larger search over the space of possible parses. To do this, we introduce a new algorithm, heuristic backtracking. We also introduce a novel cutoff approach to further increase speed.

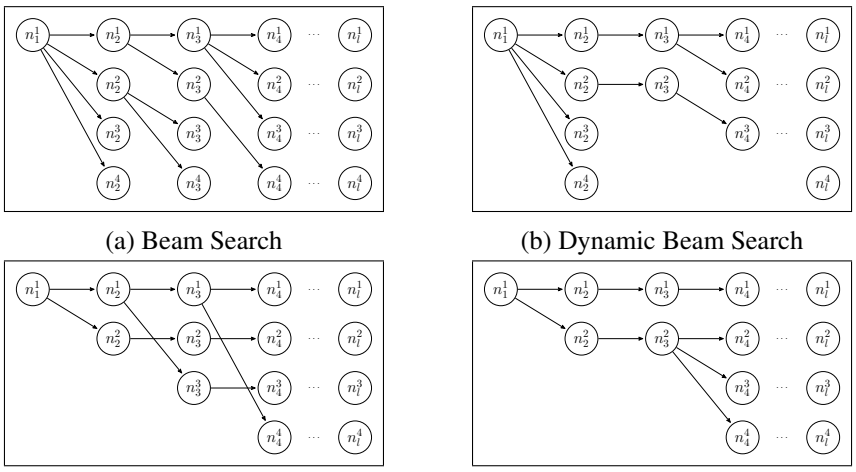
3.1 Decoding Strategy

We model the space of possible parses as a tree, where each node represents a certain parse state (with complete values for stack, buffer, and action history). Transitions connect nodes of the tree, and leaves of the tree represent final states.

During the first iteration, we start at the root of the tree, and greedily parse until we reach a leaf. That is, for each node, we use the Stack-LSTM model to calculate scores for each transition (as described in Section 2), and then execute the highest-scoring transition, generating a child node upon which we repeat the procedure. Additionally, we save an ordered list of the transition scores, and calculate the confidence of the node (as described in Section 3.2).

When we reach the leaf node, we backtrack to the location that is most likely to fix a mistake. To find this, we look at all explored nodes that still have at least one unexplored child, and choose the node with the lowest heuristic confidence (see Section 3.2). We rewind our stack, buffer, and action history to that state, and execute the highest-scoring transition from that node that has not yet been explored. At this point, we are again in a fully-unexplored node, and can greedily parse just as before until we reach another leaf.

Once we have generated b leaves, we score them all and return the transition sequence leading up to the highest-scoring leaf as the answer. Just as in previous studies (Collins and Roark, 2004), we use the



(a) Beam Search (b) Dynamic Beam Search

(c) Selectional Branching (d) Heuristic Backtracking

Figure 1: Visualization of various decoding algorithms

sum of the log probabilities of all individual transitions as the overall score for the parse.

3.2 Calculating Error Likelihood

Let n indicate a node, which consists of a state, a buffer, and an action history. We may refer to a specific node as n_i^j, which means it has i actions in its action history and it is part of the history of the jth leaf (and possibly subsequent leaves). Let the function $T(n)$ represent a sorted vector containing all possible transitions from n, and $S(n)$ represent a sorted vector containing the scores of all of these transitions, in terms of log probabilities of each score. We can index the scores in order of value, so $T_1(n)$ is the highest-scoring transition and $S_1(n)$ is its score, $T_2(n)$ is the second-highest-scoring transition, etc. Here, let u_n indicate the ranking of the transition leading to the first unexplored child of a node n. Also, let $V(n)$ represent the total score of all nodes in the history of n, i.e. the sum of all the scores of individual transitions that allowed us to get to n.

To calculate the confidence of an individual node, Choi and McCallum (2013) simply found the score margin, or difference in probability between the top-scoring transition and the second-highest scoring transition: $C(n) = S_1(n) - S_2(n)$. In selectional branching, the only states for which the confidence was relevant were the states in the first greedy parse, i.e. states n_i^1 for all i. For heuristic backtracking, we wish to generalize this to any state n_i^j for all i and j. We do this in the following way:

$$H(n_i^j) = (V(n_i^1) - V(n_i^j)) + (S_{(u_{n_i^j})-1}(n_i^j) + S_{(u_{n_i^j})}(n_i^j)) \quad (4)$$

Intuitively, this formula means that the node that will be explored first is the node that will yield a parse that scores as close to the greedy choice as possible. The first term ensures that it has a history of good choices, and the second term ensures that the new child node being explored will be nearly as good as the prior child.

3.3 Number of Predictions

As discussed earlier, we use number of predictions made by the model as a proxy for the speed; execution speed may vary based on system and algorithmic implementation, but prediction count gives a good estimate of the overall work done by the algorithm.

Consider a sentence of length l, which requires at most $2l$ transitions with the greedy decoder (Nivre, 2004). The number of predictions required for heuristic backtracking for b leaves is guaranteed to be less than or equal to a beam search with b beams.

When doing a beam search, the first transition will require 1 prediction, and then every subsequent transition will require 1 prediction per beam, or b predictions. This results in a total of $b(2l-1)+1$ predictions.

When doing heuristic backtracking, the first greedy search will require $2l$ predictions. Every

subsequent prediction will require a number of predictions dependent on the target of the backtrack: backtracking to n_i^j will require $2l - (i + 1)$ predictions. Note that $0 < i < 2l$. Thus, each backtrack will require at maximum $2l - 1$ predictions. Therefore, the maximum total amount of predictions is $2l + (b - 1)(2l - 1) = b(2l - 1) + 1$.

However, note that on average, there are significantly fewer. Assuming that all parts of a sentence have approximately equal score distributions, the average backtrack will be where $i = l$, and reduce predictions by 50%.

An intuitive understanding of this difference can be gained by viewing the graphs of various decoding methods in Figure 1. Beam search has many nodes which never yield children that reach an end-state; dynamic beam search has fewer, but still several. Selectional branching has none, but suffers from the restriction that every parse candidate can be no more than one decision away from the greedy parse. With heuristic backtracking, there is no such restriction, but yet every node explored is directly useful for generating a candidate parse.

3.4 Early Cutoff

Another inefficiency inherent to beam search is the fact that all b beams are always fully explored. Since the beams are calculated in parallel, this is inevitable. However, with heuristic backtracking, the beams are calculated incrementally; this gives us the opportunity to cut off our search at any point. In order to leverage this into more efficient parsing, we constructed a second Stack-LSTM model, which we call the cutoff model. The cutoff model uses a single Stack-LSTM[2] that takes as input the sequence of parser states (see Eq 1), and outputs a boolean variable predicting whether the entire parse is correct or incorrect.

To train the cutoff model, we used stochastic gradient descent over the training set. For each training example, we first parse it greedily using the Stack-LSTM parser. Then, for as long as the parse has at least one mistake, we pass it to the cutoff model as a negative training example. Once the parse is completely correct, we pass it to the cutoff model as a positive training example. The loss function that we use is:

$$\mathcal{L}_{\boldsymbol{\theta}} = -\log\ p(\mathbf{t} \mid \boldsymbol{s}) \tag{5}$$

where **s** is the LSTM encoded vector and **t** is the truth (parse correct/incorrect).

When decoding using early cutoff, we follow the exact same procedure as for normal heuristic backtracking, but after every candidate parse is generated, we use it as input to our cutoff model. When our cutoff model returns our selection as correct, we stop backtracking and return it as the answer. If we make b attempts without finding a correct parse, we follow the same procedure as before.

4 Experiments and Results

To test the effectiveness of heuristic backtracking, we compare it with other decoding techniques: greedy, beam search,[3], dynamic beam search (Mejia-Lavalle and Ramos, 2013), and selectional branching (Choi and McCallum, 2013). We then try heuristic backtracking (see Section 3.1), and heuristic backtracking with cutoff (see Section 3.4). Note that beam search was *not* used for early-update training (Collins and Roark, 2004). We use the same greedy training strategy for all models, and we only change the decoding strategy.

We tested the performance of these algorithms on the English SD and Chinese CTB.[4] A single model was trained using the techniques described in Section 2, and used as the transition model for all decoding algorithms. Each decoding technique was tested with varying numbers of beams; as b increased, both the predictions per sentence and accuracy trended upwards. The results are summarized in Table 1.[5] Note that we report results for only the highest-accuracy b (in the development set) for each.

We also report the results of the cutoff model in Table 2. The same greedily-trained model as above was used to generate candidate parses and confidence estimates for each transition, and then the cutoff model was trained to use these confidence esti-

[2] 2 layers and 300 dimensions.

mates to discriminate between correctly-parsed and incorrectly-parsed sentences.

5 Discussion

In Table 1 we see that in both English and Chinese, the best heuristic backtracking performs approximately as well as the best beam search, while making less than half the predictions. This supports our hypothesis that heuristic backtracking can perform at the same level as beam search, but with increased efficiency.

Dynamic beam search also performed as well as full beam search, despite demonstrating a reduction in predictions on par with that of heuristic backtracking. Since the implementation of dynamic beam search is very straightforward for systems which have already implemented beam search, we believe this will prove to be a useful finding.

Heuristic backtracking with cutoff outperformed greedy decoding, and reduced transitions by an additional 50%. However, it increased accuracy slightly less than full heuristic backtracking. We believe this difference could be mitigated with an improved cutoff model; as can be seen in Table 2, the cutoff model was only able to discriminate between correct and incorrect parses around 75% of the time. Also, note that while predictions per sentence were low, the overall runtime was increased due to running the cutoff LSTM multiple times per sentence.

Language	**Cutoff Accuracy**
English	72.43%
Chinese	75.18%

Table 2: Test-set accuracy of cutoff model on English and Chinese.

6 Related Work

Heuristic backtracking is most similar to the work of Choi and McCallum (2013), but is distinguished from theirs by allowing new beams to be initialized from any point in the parse, rather than only from points in the initial greedy parse. Heuristic backtracking also bears similarity to greedy-best-first-search (Pearl, 1984), but is unique in that it guarantees that b candidate solutions will be found within $b(2l-1)+1$ predictions. Our work also relates to beam-search parsers (Zhang and Clark, 2008, *inter alia*).

7 Conclusions

We have introduced a novel decoding algorithm, called heuristic backtracking, and presented evidence that it performs at the same level as beam search for decoding, while being significantly more efficient. We have demonstrated this for both English and Chinese, using a parser with strong results with a greedy decoder. We expect that heuristic backtracking could be applied to any other transition-based parser with similar benefits.

We plan on experimenting with various heuristics and cutoff models, such as adapting the attention-based models of Bahdanau et al. (2014) to act as a guide for both the heuristic search and cutoff.

Word Ordering Without Syntax

Allen Schmaltz and **Alexander M. Rush** and **Stuart M. Shieber**
Harvard University
{schmaltz@fas,srush@seas,shieber@seas}.harvard.edu

Abstract

Recent work on word ordering has argued that syntactic structure is important, or even required, for effectively recovering the order of a sentence. We find that, in fact, an n-gram language model with a simple heuristic gives strong results on this task. Furthermore, we show that a long short-term memory (LSTM) language model is even more effective at recovering order, with our basic model outperforming a state-of-the-art syntactic model by 11.5 BLEU points. Additional data and larger beams yield further gains, at the expense of training and search time.

1 Introduction

We address the task of recovering the original word order of a shuffled sentence, referred to as bag generation (Brown et al., 1990), shake-and-bake generation (Brew, 1992), or more recently, linearization, as standardized in a recent line of research as a method useful for isolating the performance of text-to-text generation models (Zhang and Clark, 2011; Liu et al., 2015; Liu and Zhang, 2015; Zhang and Clark, 2015). The predominant argument of the more recent works is that jointly recovering explicit syntactic structure is crucial for determining the correct word order of the original sentence. As such, these methods either generate or rely on given parse structure to reproduce the order.

Independently, Elman (1990) explored linearization in his seminal work on recurrent neural networks. Elman judged the capacity of early recurrent neural networks via, in part, the network's ability to predict word order in simple sentences. He notes,

> The order of words in sentences reflects a number of constraints... Syntactic structure, selective restrictions, subcategorization, and discourse considerations are among the many factors which join together to fix the order in which words occur... [T]here is an abstract structure which underlies the surface strings and it is this structure which provides a more insightful basis for understanding the constraints on word order.... It is, therefore, an interesting question to ask whether a network can learn any aspects of that underlying abstract structure (Elman, 1990).

Recently, recurrent neural networks have reemerged as a powerful tool for learning the latent structure of language. In particular, work on long short-term memory (LSTM) networks for language modeling has provided improvements in perplexity.

We revisit Elman's question by applying LSTMs to the word-ordering task, without any explicit syntactic modeling. We find that language models are in general effective for linearization relative to existing syntactic approaches, with LSTMs in particular outperforming the state-of-the-art by 11.5 BLEU points, with further gains observed when training with additional text and decoding with larger beams.

2 Background: Linearization

The task of linearization is to recover the original order of a shuffled sentence. We assume a vocabulary $\mathcal{V}$ and are given a sequence of out-of-order phrases $x_1, \ldots, x_N$, with $x_n \in \mathcal{V}^+$ for $1 \leq n \leq N$. Define M as the total number of tokens (i.e., the sum of the lengths of the phrases). We consider two varieties of the task: (1) WORDS, where each x_n consists of a single word and $M = N$, and (2) WORDS+BNPS,

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2319–2324,
Austin, Texas, November 1-5, 2016.

where base noun phrases (noun phrases not containing inner noun phrases) are also provided and $M \geq N$. The second has become a standard formulation in recent literature.

Given input x, we define the output set $\mathcal{Y}$ to be all possible permutations over the N elements of x, where $\hat{y} \in \mathcal{Y}$ is the permutation generating the true order. We aim to find $\hat{y}$, or a permutation close to it. We produce a linearization by (approximately) optimizing a learned scoring function f over the set of permutations, $y^* = \arg\max_{y \in \mathcal{Y}} f(x, y)$.

3 Related Work: Syntactic Linearization

Recent approaches to linearization have been based on reconstructing the syntactic structure to produce the word order. Let $\mathcal{Z}$ represent all projective dependency parse trees over M words. The objective is to find $y^*, z^* = \arg\max_{y \in \mathcal{Y}, z \in \mathcal{Z}} f(x, y, z)$ where f is now over both the syntactic structure and the linearization. The current state of the art on the Penn Treebank (PTB) (Marcus et al., 1993), without external data, of Liu et al. (2015) uses a transition-based parser with beam search to construct a sentence and a parse tree. The scoring function is a linear model $f(x, y) = \theta^\top \Phi(x, y, z)$ and is trained with an early update structured perceptron to match both a given order and syntactic tree. The feature function Φ includes features on the syntactic tree. This work improves upon past work which used best-first search over a similar objective (Zhang and Clark, 2011).

In follow-up work, Liu and Zhang (2015) argue that syntactic models yield improvements over pure surface n-gram models for the WORDS+BNPS case. This result holds particularly on longer sentences and even when the syntactic trees used in training are of low quality. The n-gram decoder of this work utilizes a single beam, discarding the probabilities of internal, non-boundary words in the BNPs when comparing hypotheses. We revisit this comparison between syntactic models and surface-level models, utilizing a surface-level decoder with heuristic future costs and an alternative approach for scoring partial hypotheses for the WORDS+BNPS case.

Additional previous work has also explored n-gram models for the word ordering task. The work of de Gispert et al. (2014) demonstrates improvements over the earlier syntactic model of Zhang et al. (2012) by applying an n-gram language model over the space of word permutations restricted to concatenations of phrases seen in a large corpus. Horvat and Byrne (2014) models the search for the highest probability permutation of words under an n-gram model as a Travelling Salesman Problem; however, direct comparisons to existing works are not provided.

4 LM-Based Linearization

In contrast to the recent syntax-based approaches, we use an LM directly for word ordering. We consider two types of language models: an n-gram model and a long short-term memory network (Hochreiter and Schmidhuber, 1997). For the purpose of this work, we define a common abstraction for both models. Let $\boldsymbol{h} \in \mathcal{H}$ be the current state of the model, with $\boldsymbol{h}_0$ as the initial state. Upon seeing a word $w_i \in \mathcal{V}$, the LM advances to a new state $\boldsymbol{h}_i = \delta(w_i, \boldsymbol{h}_{i-1})$. At any time, the LM can be queried to produce an estimate of the probability of the next word $q(w_i, \boldsymbol{h}_{i-1}) \approx p(w_i \mid w_1, \ldots, w_{i-1})$. For n-gram language models, $\mathcal{H}$, δ, and q can naturally be defined respectively as the state space, transition model, and edge costs of a finite-state machine.

LSTMs are a type of recurrent neural network (RNN) that are conducive to learning long-distance dependencies through the use of an internal memory cell. Existing work with LSTMs has generated state-of-the-art results in language modeling (Zaremba et al., 2014), along with a variety of other NLP tasks.

In our notation we define $\mathcal{H}$ as the hidden states and cell states of a multi-layer LSTM, δ as the LSTM update function, and q as a final affine transformation and softmax given as $q(*, \boldsymbol{h}_{i-1}; \theta_q) = \mathrm{softmax}(\boldsymbol{W}\boldsymbol{h}_{i-1}^{(L)} + \boldsymbol{b})$ where $\boldsymbol{h}_{i-1}^{(L)}$ is the top hidden layer and $\theta_q = (\boldsymbol{W}, \boldsymbol{b})$ are parameters. We direct readers to the work of Graves (2013) for a full description of the LSTM update.

For both models, we simply define the scoring function as

$$f(x, y) = \sum_{n=1}^{N} \log p(x_{y(n)} \mid x_{y(1)}, \ldots, x_{y(n-1)})$$

where the phrase probabilities are calculated word-by-word by our language model.

Algorithm 1 LM beam-search word ordering

procedure ORDER($x_1 \dots x_N, K, g$)
  $B_0 \leftarrow \langle(\langle\rangle, \{1, \dots, N\}, 0, \boldsymbol{h}_0)\rangle$
  for $m = 0, \dots, M-1$ **do**
    for $k = 1, \dots, |B_m|$ **do**
      $(y, \mathcal{R}, s, \boldsymbol{h}) \leftarrow B_m^{(k)}$
      for $i \in \mathcal{R}$ **do**
        $(s', \boldsymbol{h}') \leftarrow (s, \boldsymbol{h})$
        for word w in phrase x_i **do**
          $s' \leftarrow s' + \log q(w, \boldsymbol{h}')$
          $\boldsymbol{h}' \leftarrow \delta(w, \boldsymbol{h}')$
        $j \leftarrow m + |x_i|$
        $B_j \leftarrow B_j + (y + x_i, \mathcal{R} - i, s', \boldsymbol{h}')$
        keep top-K of B_j by $f(x, y) + g(\mathcal{R})$
  return B_M

Searching over all permutations $\mathcal{Y}$ is intractable, so we instead follow past work on linearization (Liu et al., 2015) and LSTM generation (Sutskever et al., 2014) in adapting beam search for our generation step. Our work differs from the beam search approach for the WORDS+BNPS case of previous work in that we maintain multiple beams, as in stack decoding for phrase-based machine translation (Koehn, 2010), allowing us to incorporate the probabilities of internal, non-boundary words in the BNPs. Additionally, for both WORDS and WORDS+BNPS, we also include an estimate of future cost in order to improve search accuracy.

Beam search maintains $M + 1$ beams, $B_0, \dots, B_M$, each containing at most the top-K partial hypotheses of that length. A partial hypothesis is a 4-tuple $(y, \mathcal{R}, s, \boldsymbol{h})$, where y is a partial ordering, $\mathcal{R}$ is the set of remaining indices to be ordered, s is the score of the partial linearization $f(x, y)$, and $\boldsymbol{h}$ is the current LM state. Each step consists of expanding all next possible phrases and adding the next hypothesis to a later beam. The full beam search is given in Algorithm 1.

As part of the beam search scoring function we also include a future cost g, an estimate of the score contribution of the remaining elements in $\mathcal{R}$. Together, $f(x, y) + g(\mathcal{R})$ gives a noisy estimate of the total score, which is used to determine the K best elements in the beam. In our experiments we use a very simple unigram future cost estimate, $g(\mathcal{R}) = \sum_{i \in \mathcal{R}} \sum_{w \in x_i} \log p(w)$.

LSTM-512+GW	44.5	65.8

Table 1: BLEU score comparison on the PTB test set. Results from previous works (for ZGEN) are those provided by the respective authors, except for the WORDS task. The final number in the model identifier is the beam size, +GW indicates additional Gigaword data. Models marked with +POS are provided with a POS dictionary derived from the PTB training set.

5 Experiments

Setup Experiments are on PTB with sections 2-21 as training, 22 as validation, and 23 as test[1]. We utilize two UNK types, one for initial uppercase tokens and one for all other low-frequency tokens; end sentence tokens; and start/end tokens, which are treated as words, to mark BNPs for the WORDS+BNPS task. We also use a special symbol to replace tokens that contain at least one numeric character. We otherwise train with punctuation and the original case of each token, resulting in a vocabulary containing around 16K types from around 1M training tokens.

For experiments marked GW we augment the PTB with a subset of the Annotated Gigaword corpus (Napoles et al., 2012). We follow Liu and Zhang (2015) and train on a sample of 900k Agence France-Presse sentences combined with the full PTB training set. The GW models benefit from both additional data and a larger vocabulary of around 25K types, which reduces unknowns in the validation and test sets.

We compare the models of Liu et al. (2015)

[1]In practice, the results in Liu et al. (2015) and Liu and Zhang (2015) use section 0 instead of 22 for validation (author correspondence).

BNP	g	GW	1	10	64	128	256	512

	•		27.1	34.6	37.5	38.1	38.4	38.7

Table 2: BLEU results on the validation set for the LSTM and NGRAM model with varying beam sizes, future costs, additional data, and use of base noun phrases.

(known as ZGEN), a 5-gram LM using Kneser-Ney smoothing (NGRAM)[2], and an LSTM. We experiment on the WORDS and WORDS+BNPS tasks, and we also experiment with including future costs (g), the Gigaword data (GW), and varying beam size. We retrain ZGEN using publicly available code[3] to replicate published results.

The LSTM model is similar in size and architecture to the medium LSTM setup of Zaremba et al. (2014)[4]. Our implementation uses the Torch[5] framework and is publicly available[6].

We compare the performance of the models using the BLEU metric (Papineni et al., 2002). In generation if there are multiple tokens of identical UNK type, we randomly replace each with possible unused tokens in the original source before calculating BLEU. For comparison purposes, we use the BLEU script distributed with the publicly available ZGEN code.

Results Our main results are shown in Table 1. On the WORDS+BNPS task the NGRAM-64 model scores nearly 5 points higher than the syntax-based model ZGEN-64. The LSTM-64 then surpasses

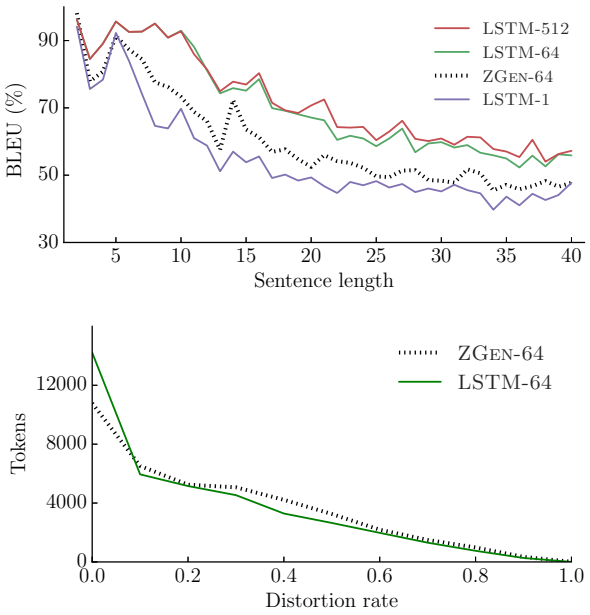

Figure 1: Experiments on the PTB validation on the WORDS+BNPS models: (a) Performance on the set by length on sentences from length 2 to length 40. (b) The distribution of token distortion, binned at 0.1 intervals.

NGRAM-64 by more than 5 BLEU points. Differences on the WORDS task are smaller, but show a similar pattern. Incorporating Gigaword further increases the result another 2 points. Notably, the NGRAM model outperforms the combined result of ZGEN-64+LM+GW+POS from Liu and Zhang (2015), which uses a 4-gram model trained on Gigaword. We believe this is because the combined ZGEN model incorporates the n-gram scores as discretized indicator features instead of using the probability directly.[7] A beam of 512 yields a further improvement at the cost of search time.

To further explore the impact of search accuracy, Table 2 shows the results of various models with beam widths ranging from 1 (greedy search) to 512, and also with and without future costs g. We see that for the better models there is a steady increase in accuracy even with large beams, indicating that search errors are made even with relatively large beams.

[2]We use the KenLM Language Model Toolkit (`https://kheafield.com/code/kenlm/`).

[3]`https://github.com/SUTDNLP/ZGen`

[4]We hypothesize that additional gains are possible via a larger model and model averaging, ceteris paribus.

[5]`http://torch.ch`

[6]`https://github.com/allenschmaltz/word_ordering`

[7]In work of Liu and Zhang (2015), with the given decoder, N-grams only yielded a small further improvement over the syntactic models when discretized versions of the LM probabilities were incorporated as indicator features in the syntactic models.

Model	WORDS	WORDS+BNPS
ZGEN-64(z^*)	39.7	64.9
ZGEN-64	40.8	65.2
NGRAM-64	46.1	67.0
NGRAM-512	47.2	67.8
LSTM-64	51.3	71.9
LSTM-512	52.8	73.1

Table 3: Unlabeled attachment scores (UAS) on the PTB validation set after parsing and aligning the output. For ZGEN we also include a result using the tree z^* produced directly by the system. For WORDS+BNPS, internal BNP arcs are always counted as correct.

One proposed advantage of syntax in linearization models is that it can better capture long-distance relationships. Figure 1 shows results by sentence length and distortion, which is defined as the absolute difference between a token's index position in y^* and $\hat{y}$, normalized by M. The LSTM model exhibits consistently better performance than existing syntax models across sentence lengths and generates fewer long-range distortions than the ZGEN model.

Finally, Table 3 compares the syntactic fluency of the output. As a lightweight test, we parse the output with the Yara Parser (Rasooli and Tetreault, 2015) and compare the unlabeled attachment scores (UAS) to the trees produced by the syntactic system. We first align the gold head to each output token. (In cases where the alignment is not one-to-one, we randomly sample among the possibilities.) The models with no knowledge of syntax are able to recover a higher proportion of gold arcs.

6 Conclusion

Strong surface-level language models recover word order more accurately than the models trained with explicit syntactic annotations appearing in a recent series of papers. This has implications for the utility of costly syntactic annotations in generation models, for both high- and low- resource languages and domains.

Acknowledgments

We thank Yue Zhang and Jiangming Liu for assistance in using ZGen, as well as verification of the task setup for a valid comparison. Jiangming Liu also assisted in pointing out a discrepancy in the implementation of an earlier version of our NGRAM decoder, the resolution of which improved BLEU performance.

Abstract

Morphological segmentation has traditionally been modeled with non-hierarchical models, which yield flat segmentations as output. In many cases, however, proper morphological analysis requires hierarchical structure—especially in the case of derivational morphology. In this work, we introduce a discriminative joint model of morphological segmentation along with the orthographic changes that occur during word formation. To the best of our knowledge, this is the first attempt to approach discriminative segmentation with a context-free model. Additionally, we release an annotated treebank of 7454 English words with constituency parses, encouraging future research in this area.

1 Introduction

In NLP, supervised morphological segmentation has typically been viewed as either a sequence labeling or a segmentation task (Ruokolainen et al., 2016). In contrast, we consider a hierarchical approach, employing a context-free grammar (CFG). CFGs provide a richer model of morphology: they capture (i) the intuition that words themselves have internal constituents, which belong to different categories, as well as (ii) the order in which affixes are attached. Moreover, many morphological processes, e.g., compounding and reduplication, are best modeled as hierarchical; thus, context-free models are expressively more appropriate.

The purpose of morphological segmentation is to decompose words into smaller units, known as morphemes, which are typically taken to be the smallest meaning bearing units in language. This work concerns itself with modeling hierarchical structure over these morphemes. Note a simple flat morphological segmentation can also be straightforwardly derived from the CFG parse tree. Segmentations have found use in a diverse set of NLP applications, e.g., automatic speech recognition (Afify et al., 2006), keyword spotting (Narasimhan et al., 2014), machine translation (Clifton and Sarkar, 2011) and parsing (Seeker and Çetinoğlu, 2015). In contrast to prior work, we focus on **canonical segmentation**, i.e., we seek to jointly model orthographic changes and segmentation. For instance, the canonical segmentation of *untestably* is *un*+*test*+*able*+*ly*, where we map *ably* to *able*+*ly*, restoring the letters *le*.

We make two contributions: (i) We introduce a joint model for canonical segmentation with a CFG backbone. We experimentally show that this model outperforms a semi-Markov model on flat segmentation. (ii) We release the first morphology treebank, consisting of 7454 English word types, each annotated with a full constituency parse.

2 The Case For Hierarchical Structure

Why should we analyze morphology hierarchically? It is true that we can model much of morphology with finite-state machinery (Beesley and Karttunen, 2003), but there are, nevertheless, many cases where hierarchical structure appears requisite. For instance, the flat segmentation of the word *untestably*↦*un*+*test*+*able*+*ly* is missing important information about how the word was derived. The correct *parse* [[*un*[[*test*]*able*]]*ly*], on the other hand, does tell us that this is the order in which the com-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2325–2330,
Austin, Texas, November 1-5, 2016.

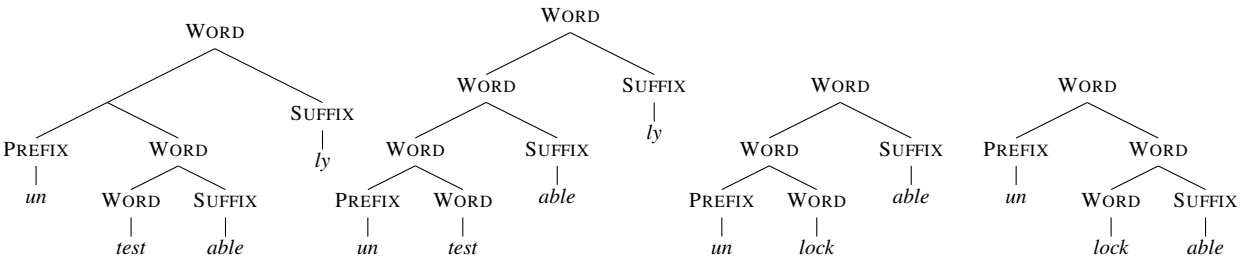

Figure 1: Canonical segmentation parse trees for *untestably* and *unlockable*. For both words, the scope of *un* is ambiguous. Arguably, (a) is the only correct parse tree for *untestably*; the reading associated with (b) is hard to get. On the other hand, *unlockable* is truly ambiguous between "able to be unlocked" (c) and "unable to be locked" (d).

plex form was derived:

$$\textit{test} \xmapsto{\text{able}} \textit{testable} \xmapsto{\text{un}} \textit{untestable} \xmapsto{\text{ly}} \textit{untestably}.$$

This gives us clear insight into the structure of the lexicon—we should expect that the segment *testable* exists as an independent word, but *ably* does not.

Moreover, a flat segmentation is often semantically ambiguous. There are two potentially valid readings of *untestably* depending on how the negative prefix *un* scopes. The correct tree (see Figure 1) yields the reading "in the manner of not able to be tested". A second—likely infelicitous reading—where the segment *untest* forms a constituent yields the reading "in a manner of being able to untest". Recovering the hierarchical structure allows us to select the correct reading; note there are even cases of true ambiguity; e.g., *unlockable* has two readings: "unable to be locked" and "able to be unlocked".

Theoretical linguists often implicitly assume a context-free treatment of word formation, e.g., by employing brackets to indicate different levels of affixation. Others have explicitly modeled word-internal structure with grammars (Selkirk, 1982; Marvin, 2002).

3 Parsing the Lexicon

A novel component of this work is the development of a discriminative parser (Finkel et al., 2008; Hall et al., 2014) for morphology. The goal is to define a probability distribution over all trees that could arise from the input word, after reversal of orthographic and phonological processes. We employ the simple grammar shown in Table 1. Despite its simplicity, it models the *order in which morphemes are attached*.

More formally, our goal is to map a surface form w (e.g., w=*untestably*) into its underlying canonical form u (e.g., u=*untestablely*) and then into a parse tree t over its morphemes. We assume $u, w \in \Sigma^*$, for some discrete alphabet Σ.[1] Note that a parse tree over the string implicitly defines a flat segmentation given our grammar—one can simply extract the characters spanned by all preterminals in the resulting tree. Before describing the joint model in detail, we first consider its pieces individually.

3.1 Restoring Orthographic Changes

To extract a *canonical segmentation* (Naradowsky and Goldwater, 2009; Cotterell et al., 2016), we restore orthographic changes that occur during word formation. To this end, we define the score function,

$$\text{score}_{\boldsymbol{\eta}}(u, w) = \sum_{a \in A(u,w)} \exp\left(\boldsymbol{g}(u, a, w)^\top \boldsymbol{\eta}\right), \quad (1)$$

where $A(u, w)$ is the set of all monotonic alignments between the strings u and w. The goal is for $\text{score}_{\boldsymbol{\eta}}$ to assign higher values to better matched pairs, e.g., (w=*untestably*, u=*untestablely*).

We have left these out of the equation for simplicity, but we refer to the reader Dreyer et al. (2008) for a more thorough exposition. To ensure that the partition function $Z_{\boldsymbol{\eta}}(w)$ is finite, we cap the maximum string length u, which yields

$$Z_{\boldsymbol{\eta}}(w) = \sum_{u' \in \Sigma^{|w|+k}} \exp\left(\boldsymbol{g}(u', w)^\top \boldsymbol{\eta}\right), \quad (2)$$

[1] For efficiency, we assume $u \in \Sigma^{|w|+k}$, $k = 5$.

ROOT	$\rightarrow$	WORD
WORD	$\rightarrow$	PREFIX WORD
WORD	$\rightarrow$	WORD SUFFIX
WORD	$\rightarrow$	Σ^+
PREFIX	$\rightarrow$	Σ^+
SUFFIX	$\rightarrow$	Σ^+

Table 1: The context-free grammar used in this work to model word formation. The productions closely resemble those of Johnson et al. (2006)'s Adaptor Grammar.

where $|w| + k$ is the maximum length for u.

For ease of computation, we can encode this function as a weighted finite-state machine (WFST) (Mohri et al., 2002). This requires, however, that the feature function $\boldsymbol{g}$ factors over the topology of the finite-state encoding. Since our model conditions on the word w, the feature function $\boldsymbol{g}$ can extract features from *any* part of this string. Features on the output string, u, however, are more restricted. In this work, we employ a bigram model over output characters. This implies that each state remembers exactly one character, the previous one. See Cotterell et al. (2014) for details. We can compute the score for two strings u and w using a weighted generalization of the Levenshtein algorithm. Computing the partition function requires a different dynamic program, which runs in $\mathcal{O}(|w|^2 \cdot |\Sigma|^2)$ time. Note that since $|\Sigma| \approx 26$ (lower case English letters), it takes roughly $26^2 = 676$ times longer to compute the partition function than to score a pair of strings.

Our model includes several simple feature templates, including features that fire on individual edit actions as well as conjunctions of edit actions and characters in the surrounding context. See Cotterell et al. (2016) for details.

3.2 Morphological Analysis as Parsing

Next, we need to score an underlying canonical form (e.g., u=*untestablely*) together with a parse tree (e.g., t=[[*un*[[*test*]*able*]]*ly*]). Thus, we define the parser score

$$\text{score}_{\boldsymbol{\omega}}(t, u) = \exp\left(\sum_{\pi \in \Pi(t)} \boldsymbol{f}(\pi, u)^\top \boldsymbol{\omega}\right), \quad (3)$$

where $\Pi(t)$ is the set of *anchored productions* in the tree t. An anchored production π is a grammar rule in Chomsky normal form attached to a span, e.g., $A_{i,k} \rightarrow B_{i,j} C_{j+1,k}$. Each π is then assigned a weight by the linear function $\boldsymbol{f}(\pi, u)^\top \boldsymbol{\omega}$, where the function $\boldsymbol{f}$ extracts relevant features from the anchored production as well as the corresponding span of the underlying form u. This model is typically referred to as a weighted CFG (WCFG) (Smith and Johnson, 2007) or a CRF parser.

Luckily, we can exploit the structure of the problem to efficiently compute the partition function,

$$Z_{\boldsymbol{\omega}}(u) = \sum_{t \in \mathcal{T}(u)} \exp\left(\sum_{\pi \in \Pi(t)} \boldsymbol{f}(\pi, u)^\top \boldsymbol{\omega}\right), \quad (4)$$

where $\mathcal{T}(u)$ is the set of all trees under the grammar that have yield u. Specifically, we make use of the inside algorithm, which is just CKY (Aho and Ullman, 1979) in the $(+, \times)$ semiring (Goodman, 1998), which runs in $\mathcal{O}(|\mathcal{G}| \cdot |u|^3)$ time, where $|\mathcal{G}|$ is the size of the grammar.

For $\boldsymbol{f}$, we define three span features: (i) indicator features on the span's segment, (ii) an indicator feature that fires if the segment appears in an external corpus[2] and (iii) the conjunction of the segment with the label (e.g., PREFIX) of the subtree root. Following Hall et al. (2014), we employ an indicator feature for each production as well as production backoff features.

4 A Joint Model

Our complete model is a joint CRF (Koller and Friedman, 2009) where each of the above scores are factors. We define the likelihood as

$$p_{\boldsymbol{\theta}}(t, u \mid w) = \frac{1}{Z_{\boldsymbol{\theta}}} \text{score}_{\boldsymbol{\omega}}(t, u) \cdot \text{score}_{\boldsymbol{\eta}}(u, w), \quad (5)$$

where $\boldsymbol{\theta} = \{\boldsymbol{\omega}, \boldsymbol{\eta}\}$ is the parameter vector and

$$Z_{\boldsymbol{\theta}} = \sum_{u' \in \Sigma^*} \sum_{t' \in \mathcal{T}_{u'}} \text{score}_{\boldsymbol{\omega}}(t', u') \cdot \text{score}_{\boldsymbol{\eta}}(u', w) \quad (6)$$

is the partition function and $\mathcal{T}_{u'}$ is set of all parse trees for the string u'. We see now that both WFST and WCFG are just structured factors in the model.

[2] We use the Wikipedia dump from 2016-05-01.

The joint approach has the advantage that it allows both factors to work together to influence the choice of the underlying form u. This is useful as the parser now has access to which words are attested in the language; this helps guide the relatively weak transduction model. On the downside, the partition function $Z_{\boldsymbol{\theta}}$ now involves a sum over *both* all strings in $\Sigma^{|w|+k}$ *and* all possible parses of each string! Inference in this joint model is intractable, so we resort to approximate methods.

4.1 Learning and Inference

We use stochastic gradient descent to optimize the log-probability of the training data $\sum_{i=1}^{N} \log p_{\boldsymbol{\theta}}(t^{(i)}, u^{(i)} \mid w^{(i)})$; this requires the computation of the gradient of the partition function $\nabla_{\boldsymbol{\theta}} \log Z_{\boldsymbol{\theta}}$, which is intractable. As in all CRFs, this gradient is in fact an expectation:

$$\nabla_{\boldsymbol{\theta}} \log Z_{\boldsymbol{\theta}} = \mathbb{E}_{(u,t)\sim p_{\boldsymbol{\theta}}} \left[\log \left(\text{score}_{\boldsymbol{\omega}}(t,u) \cdot \text{score}_{\boldsymbol{\eta}}(u,w)\right)\right]. \quad (7)$$

To approximate this expectation, we use an importance sampling routine. Roughly speaking, we approximate the hard-to-sample-from distribution $p_{\boldsymbol{\theta}}$ by taking samples from an easy-to-sample-from proposal distribution q. We then *reweight* the samples using the *unnormalized* score from $p_{\boldsymbol{\theta}}$. Due to a lack of space, we omit the derivation of the approximate gradient.

4.2 Decoding

We also decode by importance sampling. Given w, we sample canonical forms u and then run the CKY algorithm to get the highest scoring tree.

5 Related Work

We believe our attempt to train discriminative grammars for morphology is novel. Nevertheless, other researchers have described parsers for morphology. Most of this work is unsupervised: Johnson et al. (2007) applied a Bayesian PCFG to unsupervised morphological segmentation. Similarly, Adaptor Grammars (Johnson et al., 2006), a non-parametric Bayesian generalization of PCFGs, have been applied to the unsupervised version of the task (Botha and Blunsom, 2013; Sirts and Goldwater, 2013). Relatedly, Schmid (2005) performed unsupervised disambiguation of a German morphological analyzer (Schmid et al., 2004) using a PCFG, using the inside-outside algorithm (Baker, 1979). Also, discriminative parsing approaches have been applied to the related problem of Chinese word segmentation (Zhang et al., 2014).

6 Morphological Treebank

Supervised morphological segmentation has historically been treated as a segmentation problem, devoid of hierarchical structure. A core reason behind this is that—to the best of our knowledge—there are no hierarchically annotated corpora for the task. To remedy this, we provide tree annotations for a subset of the English portion of CELEX (Baayen et al., 1993). We reannotated 7454 English types with a full constituency parse.[3] The resource will be freely available for future research.

6.1 Annotation Guidelines

The annotation of the morphology treebank was guided by three core principles. The first principle concerns **productivity**: we exclusively annotate *productive* morphology. In the context of morphology, productivity refers to the degree that native speakers actively employ the affix to create new words (Aronoff, 1976). We believe that for NLP applications, we should focus on productive affixation. Indeed, this sets our corpus apart from many existing morphologically annotated corpora such as CELEX. For example, CELEX contains *warmth*↦*warm*+*th*, but *th* is not a productive suffix and cannot be used to create new words. Thus, we *do not* want to analyze *hearth*↦*hear*+*th* or, in general, allow *wug*↦*wug*+*th*. Second, we annotate for **semantic coherence**. When there are several candidate parses, we choose the one that is best compatible with the compositional semantics of the derived form.

Interestingly, multiple trees can be considered valid depending on the linguistic tier of interest. Consider the word *unhappier*. From a semantic perspective, we have the parse [[*un* [*happy*]] *er*] which gives us the correct meaning "not happy to a greater degree". However, since the suffix *er* only attaches to mono- and bisyllabic words, we get [*un*[[*happy*] *er*]] from a phonological perspective. In the linguis-

[3] In many cases, we corrected the flat segmentation as well.

	Segmentation			Tree
	Morph. F_1	*Edit*	*Acc.*	*Const.* F_1
Flat	78.89 (0.9)	0.72 (0.04)	72.88 (1.21)	N/A
Hier	**85.55** (0.6)	**0.55** (0.03)	**73.19** (1.09)	79.01 (0.5)

Table 2: Results for the 10 splits of the treebank. Segmentation quality is measured by morpheme F_1, edit distance and accuracy; tree quality by constituent F_1.

tics literature, this problem is known as the bracketing paradox (Pesetsky, 1985; Embick, 2015). We annotate exclusively at the syntactic-semantic tier.

Thirdly, in the context of derivational morphology, we *force spans to be words* themselves. Since derivational morphology—by definition—forms new words from existing words (Lieber and Štekauer, 2014), it follows that each span rooted with WORD or ROOT in the correct parse corresponds to a word in the lexicon. For example, consider *unlickable*. The correct parse, under our scheme, is [*un* [[*lick*] *able*]]. Each of the spans (*lick*, *lickable* and *unlickable*) exists as a word. By contrast, the parse [[*un* [*lick*]] *able*] contains the span *unlick*, which is not a word in the lexicon. The span in the segmented form may involve changes, e.g., [*un* [[*achieve*] *able*]], where *achieveable* is not a word, but *achievable* (after deleting *e*) is.

7 Experiments

We run a simple experiment to show the empirical utility of parsing words—we compare a WCFG-based canonical segmenter with the semi-Markov segmenter introduced in Cotterell et al. (2016). We divide the corpus into 10 distinct train/dev/test splits with 5454 words for train and 1000 for each of dev and test. We report three evaluation metrics: full form accuracy, morpheme F_1 (Van den Bosch and Daelemans, 1999) and average edit distance to the gold segmentation with boundaries marked by a distinguished symbol. For the WCFG model, we also report constituent F_1—typical for sentential constituency parsing— as a baseline for future systems. This F_1 measures how well we predict the whole tree (not just a segmentation). For all models, we use L_2 regularization and run 100 epochs of ADAGRAD (Duchi et al., 2011) with early stopping. We tune the regularization coefficient by grid search considering $\lambda \in \{0.0, 0.1, 0.2, 0.3, 0.4, 0.5\}$.

7.1 Results and Discussion

Table 2 shows the results. The hierarchical WCFG model outperforms the flat semi-Markov model on all metrics on the segmentation task. This shows that modeling structure among the morphemes, indeed, does help segmentation. The largest improvements are found under the morpheme F_1 metric (≈ 6.5 points). In contrast, accuracy improves by $< 1\%$. Edit distance is in between with an improvement of 0.2 characters. Accuracy, in general, is an all or nothing metric since it requires getting every canonical segment correct. Morpheme F_1, on the other hand, gives us partial credit. Thus, what this shows us is that the WCFG gets a lot more of the morphemes in the held-out set correct, even if it only gets a few complete forms correct. We provide additional results evaluating the entire tree with constituency F_1 as a future baseline.

8 Conclusion

We presented a discriminative CFG-based model for canonical morphological segmentation and showed empirical improvements on its ability to segment words under three metrics. We argue that our hierarchical approach to modeling morphemes is more often appropriate than the traditional flat segmentation. Additionally, we have annotated 7454 words with a morphological constituency parse. The corpus is available online at `http://ryancotterell.github.io/data/morphological-treebank` to allow for exact comparison and to spark future research.

Parsing as Language Modeling

Do Kook Choe

Abstract

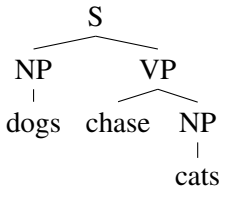
We recast syntactic parsing as a language modeling problem and use recent advances in neural network language modeling to achieve a new state of the art for constituency Penn Treebank parsing — 93.8 F_1 on section 23, using 2-21 as training, 24 as development, plus tri-training. When trees are converted to Stanford dependencies, UAS and LAS are 95.9% and 94.1%.

1 Introduction

Recent work on deep learning syntactic parsing models has achieved notably good results, e.g., Dyer et al. (2016) with 92.4 F_1 on Penn Treebank constituency parsing and Vinyals et al. (2015) with 92.8 F_1. In this paper we borrow from the approaches of both of these works and present a neural-net parse reranker that achieves very good results, 93.8 F_1, with a comparatively simple architecture.

In the remainder of this section we outline the major difference between this and previous work — viewing parsing as a language modeling problem. Section 2 looks more closely at three of the most relevant previous papers. We then describe our exact model (Section 3), followed by the experimental setup and results (Sections 4 and 5).

(a)



(b)

(S (NP dogs)$_{\mathrm{NP}}$ (VP chase (NP cats)$_{\mathrm{NP}}$)$_{\mathrm{VP}}$)$_{\mathrm{S}}$

Figure 1: A tree (a) and its sequential form (b). There is a one-to-one mapping between a tree and its sequential form. (Part-of-speech tags are not used.)

1.1 Language Modeling

Formally, a language model (LM) is a probability distribution over strings of a language:

$$P(\boldsymbol{x}) = P(x_1, \cdots, x_n) = \prod_{t=1}^{n} P(x_t | x_1, \cdots, x_{t-1}), \quad (1)$$

where $\boldsymbol{x}$ is a sentence and t indicates a word position. The efforts in language modeling go into computing $P(x_t|x_1, \cdots, x_{t-1})$, which as described next is useful for parsing as well.

1.2 Parsing as Language Modeling

A generative parsing model parses a sentence $(\boldsymbol{x})$ into its phrasal structure $(\boldsymbol{y})$ according to

$$\operatorname*{argmax}_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x})} P(\boldsymbol{x}, \boldsymbol{y}'),$$

where $\mathcal{Y}(\boldsymbol{x})$ lists all possible structures of $\boldsymbol{x}$. If we think of a tree $(\boldsymbol{x}, \boldsymbol{y})$ as a sequence $(\boldsymbol{z})$ (Vinyals et

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2331–2336,
Austin, Texas, November 1-5, 2016.

al., 2015) as illustrated in Figure 1, we can define a probability distribution over $(\boldsymbol{x}, \boldsymbol{y})$ as follows:

$$P(\boldsymbol{x}, \boldsymbol{y}) = P(\boldsymbol{z}) = P(z_1, \cdots, z_m) = \prod_{t=1}^{m} P(z_t | z_1, \cdots, z_{t-1}), \quad (2)$$

which is equivalent to Equation (1). We have reduced parsing to language modeling and can use language modeling techniques of estimating $P(z_t | z_1, \cdots, z_{t-1})$ for parsing.

2 Previous Work

We look here at three neural net (NN) models closest to our research along various dimensions. The first (Zaremba et al., 2014) gives the basic language modeling architecture that we have adopted, while the other two (Vinyals et al., 2015; Dyer et al., 2016) are parsing models that have the current best results in NN parsing.

2.1 LSTM-LM

The LSTM-LM of Zaremba et al. (2014) turns $(x_1, \cdots, x_{t-1})$ into h_t, a hidden state of an LSTM (Hochreiter and Schmidhuber, 1997; Gers et al., 2003; Graves, 2013), and uses h_t to guess x_t:

$$P(x_t | x_1, \cdots, x_{t-1}) = P(x_t | h_t) = \mathrm{softmax}(W h_t)[x_t],$$

where W is a parameter matrix and $[i]$ indexes ith element of a vector. The simplicity of the model makes it easily extendable and scalable, which has inspired a character-based LSTM-LM that works well for many languages (Kim et al., 2016) and an ensemble of large LSTM-LMs for English with astonishing perplexity of 23.7 (Jozefowicz et al., 2016). In this paper, we build a parsing model based on the LSTM-LM of Zaremba et al. (2014).

2.2 MTP

Vinyals et al. (2015) observe that a phrasal structure $(\boldsymbol{y})$ can be expressed as a sequence and build a machine translation parser (MTP), a sequence-to-sequence model, which translates $\boldsymbol{x}$ into $\boldsymbol{y}$ using a conditional probability:

$$P(\boldsymbol{y} | \boldsymbol{x}) = P(y_1, \cdots, y_l | \boldsymbol{x}) = \prod_{t=1}^{l} P(y_t | \boldsymbol{x}, y_1, \cdots, y_{t-1}),$$

where the conditioning event $(\boldsymbol{x}, y_1, \cdots, y_{t-1})$ is modeled by an LSTM encoder and an LSTM decoder. The encoder maps $\boldsymbol{x}$ into $\boldsymbol{h}^e$, a set of vectors that represents $\boldsymbol{x}$, and the decoder obtains a summary vector (h'_t) which is concatenation of the decoder's hidden state (h^d_t) and weighted sum of word representations $(\sum_{i=1}^{n} \alpha_i h^e_i)$ with an alignment vector $(\boldsymbol{\alpha})$. Finally the decoder predicts y_t given h'_t. Inspired by MTP, our model processes sequential trees.

2.3 RNNG

Recurrent Neural Network Grammars (RNNG), a generative parsing model, defines a joint distribution over a tree in terms of actions the model takes to generate the tree (Dyer et al., 2016):

$$P(\boldsymbol{x}, \boldsymbol{y}) = P(\boldsymbol{a}) = \prod_{t=1}^{m} P(a_t | a_1, \cdots, a_{t-1}), \quad (3)$$

where $\boldsymbol{a}$ is a sequence of actions whose output precisely matches the sequence of symbols in $\boldsymbol{z}$, which implies Equation (3) is the same as Equation (2). RNNG and our model differ in how they compute the conditioning event $(z_1, \cdots, z_{t-1})$: RNNG combines hidden states of three LSTMs that keep track of actions the model has taken, an incomplete tree the model has generated and words the model has generated whereas our model uses one LSTM's hidden state as shown in the next section.

3 Model

Our model, the model of Zaremba et al. (2014) applied to sequential trees and we call LSTM-LM from now on, is a joint distribution over trees:

$$P(\boldsymbol{x}, \boldsymbol{y}) = P(\boldsymbol{z}) = \prod_{t=1}^{m} P(z_t | z_1, \cdots, z_{t-1}) = \prod_{t=1}^{m} P(z_t | h_t) = \prod_{t=1}^{m} \mathrm{softmax}(W h_t)[z_t],$$

where h_t is a hidden state of an LSTM. Due to lack of an algorithm that searches through an exponentially large phrase-structure space, we use an n-best parser to reduce $\mathcal{Y}(\boldsymbol{x})$ to $\mathcal{Y}'(\boldsymbol{x})$, whose size is polynomial, and use LSTM-LM to find $\boldsymbol{y}$ that satisfies

$$\underset{\boldsymbol{y}' \in \mathcal{Y}'(\boldsymbol{x})}{\operatorname{argmax}} P(\boldsymbol{x}, \boldsymbol{y}'). \quad (4)$$

3.1 Hyper-parameters

The model has three LSTM layers with 1,500 units and gets trained with truncated backpropagation through time with mini-batch size 20 and step size 50. We initialize starting states with previous mini-batch's last hidden states (Sutskever, 2013). The forget gate bias is initialized to be one (Jozefowicz et al., 2015) and the rest of model parameters are sampled from $\mathcal{U}(-0.05, 0.05)$. Dropout is applied to non-recurrent connections (Pham et al., 2014) and gradients are clipped when their norm is bigger than 20 (Pascanu et al., 2013). The learning rate is $0.25 \cdot 0.85^{\max(\epsilon - 15,\, 0)}$ where ϵ is an epoch number. For simplicity, we use vanilla softmax over an entire vocabulary as opposed to hierarchical softmax (Morin and Bengio, 2005) or noise contrastive estimation (Gutmann and Hyvärinen, 2012).

4 Experiments

We describe datasets we use for evaluation, detail training and development processes.[1]

4.1 Data

We use the Wall Street Journal (WSJ) of the Penn Treebank (Marcus et al., 1993) for training (2-21), development (24) and testing (23) and millions of auto-parsed "silver" trees (McClosky et al., 2006; Huang et al., 2010; Vinyals et al., 2015) for tri-training. To obtain silver trees, we parse the entire section of the New York Times (NYT) of the fifth Gigaword (Parker et al., 2011) with a product of eight Berkeley parsers (Petrov, 2010)[2] and ZPar (Zhu et al., 2013) and select 24 million trees on which both parsers agree (Li et al., 2014). We do not resample trees to match the sentence length distribution of the NYT to that of the WSJ (Vinyals et al., 2015) because in preliminary experiments Charniak parser (Charniak, 2000) performed better when trained on all of 24 million trees than when trained on resampled two million trees.

Given $\boldsymbol{x}$, we produce $\mathcal{Y}'(\boldsymbol{x})$, 50-best trees, with Charniak parser and find $\boldsymbol{y}$ with LSTM-LM as Dyer et al. (2016) do with their discriminative and generative models.[3]

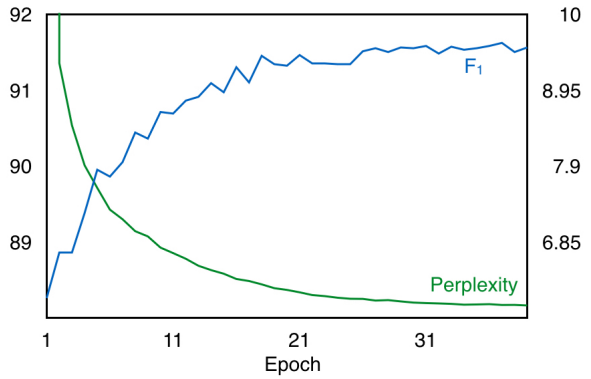


Figure 2: Perplexity and F_1 on the development set at each epoch during training.

n	Oracle	Final	Exact
10	94.0	91.2	39.8
50	96.7	91.7	40.0
51^o	100	93.9	49.7
100	96.3	91.7	39.9
500	97.0	91.8	40.0

Table 1: The performance of LSTM-LM (G) with varying n-best parses on the dev set. Oracle refers to Charniak parser's oracle F_1. Final and Exact report LSTM-LM (G)'s F_1 and exact match percentage respectively. To simulate an optimal scenario, we include gold trees to 50-best trees and rerank them with LSTM-LM (G) (51^o).

4.2 Training and Development

4.2.1 Supervision

We unk words that appear fewer than 10 times in the WSJ training (6,922 types) and drop activations with probability 0.7. At the beginning of each epoch, we shuffle the order of trees in the training data. Both perplexity and F_1 of LSTM-LM (G) improve and then plateau (Figure 2). Perplexity, the

[1] The code and trained models used for experiments are available at github.com/cdg720/emnlp2016.

[2] We use the reimplementation by Huang et al. (2010).

[3] Dyer et al. (2016)'s discriminative model performs comparably to Charniak (89.8 vs. 89.7).

	Base	Final
Vinyals et al. (2015)	88.3	90.5
Dyer et al. (2016)	89.8	92.4
LSTM-LM (G)	89.7	**92.6**

Table 2: F_1 of models trained on WSJ. Base refers to performance of a single base parser and Final that of a final parser.

model's training objective, nicely correlates with F_1, what we care about. Training takes 12 hours (37 epochs) on a Titan X. We also evaluate our model with varying n-best trees including optimal 51-best trees that contain gold trees (51^o). As shown in Table 1, the LSTM-LM (G) is robust given sufficiently large n, i.e. 50, but does not exhibit its full capacity because of search errors in Charniak parser. We address this problem in Section 5.3.

4.2.2 Semi-supervision

We unk words that appear at most once in the training (21,755 types). We drop activations with probability 0.45, smaller than 0.7, thanks to many silver trees, which help regularization. We train LSTM-LM (GS) on the WSJ and a different set of 400,000 NYT trees for each epoch except for the last one during which we use the WSJ only. Training takes 26 epochs and 68 hours on a Titan X. LSTM-LM (GS) achieves 92.5 F_1 on the development.

5 Results

5.1 Supervision

As shown in Table 2, with 92.6 F_1 LSTM-LM (G) outperforms an ensemble of five MTPs (Vinyals et al., 2015) and RNNG (Dyer et al., 2016), both of which are trained on the WSJ only.

5.2 Semi-supervision

We compare LSTM-LM (GS) to two very strong semi-supervised NN parsers: an ensemble of five MTPs trained on 11 million trees of the high-confidence corpus[4] (HC) (Vinyals et al., 2015); and an ensemble of six one-to-many sequence models trained on the HC and 4.5 millions of English-German translation sentence pairs (Luong et al., 2016). We also compare LSTM-LM (GS) to best performing non-NN parsers in the literature. Parsers' parsing performance along with their training data is reported in Table 3. LSTM-LM (GS) outperforms all the other parsers with 93.1 F_1.

5.3 Improved Semi-supervision

Due to search errors – good trees are missing in 50-best trees – in Charniak (G), our supervised and semi-supervised models do not exhibit their full potentials when Charniak (G) provides $\mathcal{Y}'(\boldsymbol{x})$. To mitigate the search problem, we tri-train Charniak (GS) on all of 24 million NYT trees in addition to the WSJ, to yield $\mathcal{Y}'(\boldsymbol{x})$. As shown in Table 3, both LSTM-LM (G) and LSTM-LM (GS) are affected by the quality of $\mathcal{Y}'(\boldsymbol{x})$. A single LSTM-LM (GS) together with Charniak (GS) reaches 93.6 and an ensemble of eight LSTM-LMs (GS) with Charniak (GS) achieves a new state of the art, 93.8 F_1. When trees are converted to Stanford dependencies,[5] UAS and LAS are 95.9% and 94.1%,[6] more than 1% higher than those of the state of the art dependency parser (Andor et al., 2016). Why an indirect method (converting trees to dependencies) is more accurate than a direct one (dependency parsing) remains unanswered (Kong and Smith, 2014).

6 Conclusion

The generative parsing model we presented in this paper is very powerful. In fact, we see that a generative parsing model, LSTM-LM, is more effective than discriminative parsing models (Dyer et al., 2016). We suspect building large models with character embeddings would lead to further improvement as in language modeling (Kim et al., 2016; Jozefowicz et al., 2016). We also wish to develop a complete parsing model using the LSTM-LM framework.

Acknowledgments

We thank the NVIDIA corporation for its donation of a Titan X GPU, Tstaff of Computer Science

[4]The HC consists of 90,000 gold trees, from the WSJ, English Web Treebank and Question Treebank, and 11 million silver trees, whose sentence length distribution matches that of the WSJ, parsed and agreed on by Berkeley parser and ZPar.

Human-in-the-Loop Parsing

Luheng He **Julian Michael** **Mike Lewis** **Luke Zettlemoyer**

{luheng,julianjm,mlewis,lsz}@cs.washington.edu

Abstract

This paper demonstrates that it is possible for a parser to improve its performance with a human in the loop, by posing simple questions to non-experts. For example, given the first sentence of this abstract, if the parser is uncertain about the subject of the verb "pose," it could generate the question *What would pose something?* with candidate answers *this paper* and *a parser*. Any fluent speaker can answer this question, and the correct answer resolves the original uncertainty. We apply the approach to a CCG parser, converting uncertain attachment decisions into natural language questions about the arguments of verbs. Experiments show that crowd workers can answer these questions quickly, accurately and cheaply. Our human-in-the-loop parser improves on the state of the art with less than 2 questions per sentence on average, with a gain of 1.7 F1 on the 10% of sentences whose parses are changed.

1 Introduction

The size of labelled datasets has long been recognized as a bottleneck in the performance of natural language processing systems (Marcus et al., 1993; Petrov and McDonald, 2012). Such datasets are expensive to create, requiring expert linguists and extensive annotation guidelines. Even relatively large datasets, such as the Penn Treebank, are much smaller than required—as demonstrated by improvements from semi-supervised learning (Søgaard and Rishøj, 2010; Weiss et al., 2015).

We take a step towards cheap, reliable annotations by introducing human-in-the-loop parsing, where non-experts improve parsing accuracy by answering questions automatically generated from the parser's output. We develop the approach for CCG parsing, leveraging the link between CCG syntax and semantics to convert uncertain attachment decisions into natural language questions. The answers are used as soft constraints when re-parsing the sentence.

Temple also said Sea Containers' plan raises numerous legal, regulatory, financial and fairness issues, but didn't ***elaborate***.	
Q:	What didn't ***elaborate***?
[1] ****	Temple
[2] *	Sea Containers' plan
[3]	None of the above.

Table 1: An automatically generated query from CCGbank. 4 out of 5 annotators correctly answered *Temple*, providing a signal that can be used to improve parse predictions.

Previous work used crowdsourcing for less structured tasks such as named entity recognition (Werling et al., 2015) and prepositional phrase attachment (Jha et al., 2010). Our work is most related to that of Duan et al. (2016), which automatically generates paraphrases from n-best parses and gained significant improvement by re-training from crowdsourced judgments on two out-of-domain datasets. Choe and McClosky (2015) improve a parser by creating paraphrases of sentences, and then parsing the sentence and its paraphrase jointly. Instead of using paraphrases, we build on the approach of QA-SRL (He et al., 2015), which shows that untrained crowd workers can annotate predicate–argument structures by writing question–answer pairs.

Our experiments for newswire and biomedical

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2337–2342,
Austin, Texas, November 1-5, 2016.

text demonstrate improvements to parsing accuracy of 1.7 F1 on the sentences changed by re-parsing, while asking only less than 2 questions per sentence. The annotations we collected[1] are a representation-independent resource that could be used to develop new models or human-in-the-loop algorithms for related tasks, including semantic role labeling and syntactic parsing with other formalisms.

2 Mapping CCG Parses to Queries

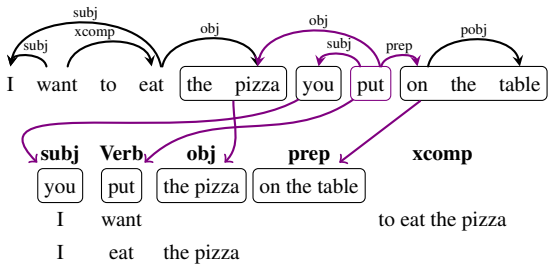
Our annotation task consists of multiple-choice *what*-questions that admit multiple answers. To generate them, we produce question–answer (QA) pairs from each parse in the 100-best scored output of a CCG parser and aggregate the results together.

We designed the approach to generate queries with high **question confidence**—questions should be simple and grammatical, so annotators are more likely to answer them correctly—and high **answer uncertainty**—the parser should be uncertain about the answers, so there is potential for improvement.

Our questions only apply to core arguments of verbs where the argument phrase is an NP, which account for many of the parser's mistakes. Prepositional phrase attachment mistakes are also a large source of errors—we tried several approaches to generate questions for these, but the greater ambiguity and inconsistency among both annotators and the gold parses made it difficult to extract meaningful signal from the crowd.

Generating Question–Answer Pairs Figure 1 shows how we generate QA pairs. Each QA pair corresponds to a dependency such that if the answer is correct, it indicates that the dependency is in the correct parse. We determine a verb's set of arguments by the CCG supertag assigned to it in the parse (see Steedman (2000) for an introduction to CCG). For example, in Figure 1 the word *put* takes the category ((S\NP)/PP)/NP (not shown), indicating that it has a subject, a prepositional phrase argument, and an object. CCG parsing assigns dependencies to each argument position, even when the arguments are reordered (as with *put* → *pizza*) or span long distances (as with *eat* → *I*).

[1]Our code and data are available at `https://github.com/luheng/hitl_parsing`.



Dependency	Question	Answer
want → I	What wants to eat something?	I
eat → I	What would eat something?	I
eat → pizza	What would something eat?	the pizza
put → you	What put something?	you
put → pizza	What did something put?	the pizza
on → table	What did something put something on?	the table

Figure 1: From a labeled dependency graph, we extract phrases corresponding to every argument of every verb using simple heuristics. We then create questions about dependencies, adding a *would* modal to untensed verbs and placing arguments to the left or right of the verb based on its CCG category. We only generate QA pairs for *subj*, *obj*, and *pobj* dependencies. To identify multiple answer options, we create QA pairs from all parses in the 100-best list and pool equivalent questions with different answers. See Table 2 for example queries.

To reduce the chance of parse errors causing nonsensical questions (for example, *What did the pizza put something on?*), we replace all noun phrases with *something* and delete unnecessary prepositional phrases. The exception to this is with copular predicates, where we include the span of the argument in the question (see Example 4 in Table 2).

Grouping QA Pairs into Queries After generating QA pairs for every parse in the 100-best output of the parser, we pool the QA pairs by the head of the dependency used to generate them, its CCG category, and their question strings. We also compute marginalized scores for each question and answer phrase by summing over the scores of all the parses that generated them. Each pool becomes a query, and for each unique dependency used to generate QA pairs in that pool, we add a candidate answer to the query by choosing the answer phrase that has the highest marginalized score for that dependency. For example, if some parses generated the answer phrase *pizza* for the dependency *eat* → *pizza*, but most of the high-scoring parses generated the answer phrase *the pizza*, then only *the pizza* appears as an answer.

		2	None of the above

Table 2: Example annotations from the CCGbank development set. Answers that agree with the gold parse are in bold. The answer choice *None of the above* was present for all examples, but we only show it when it was chosen by annotators.

From the resulting queries, we filter out questions and answers whose marginalized scores are below a certain threshold and queries that only have one answer choice. This way we only ask confident questions with uncertain answer lists.

3 Crowdsourcing

We collected data on the crowdsourcing platform CrowdFlower.[2] Annotators were shown a sentence, a question, and a list of answer choices. Annotators could choose multiple answers, which was useful in case of coordination (see Example 3 in Table 2). There was also a *None of the above* option for when no answer was applicable or the question was nonsensical.

We instructed annotators to only choose options that *explicitly* and *directly* answer the question, to encourage their answers to closely mirror syntax. We also instructed them to ignore *who*/*what* and *someone*/*something* distinctions and overlook mistakes where the question was missing a negation. The instructions included 6 example queries with answers and explanations. We used CrowdFlower's quality control mechanism, displaying pre-annotated queries 20% of the time and requiring annotators to maintain high accuracy.

Dataset Statistics Table 3 shows how many sentences we asked questions for and the total number of queries annotated. We collected annotations for the development and test set for CCGbank (Hockenmaier and Steedman, 2007) as in-domain data and the test set of the Bioinfer corpus (Pyysalo et al., 2007) as out-of-domain. The CCGbank development set was used for building question generation heuristics and setting hyperparameters for reparsing.

5 annotators answered each query; on CCGbank we required 85% accuracy on test questions and on Bioinfer we set the threshold at 80% because of the difficulty of the sentences. Table 4 shows inter-annotator agreement. Annotators unanimously chose the same set of answers for over 40% of the queries; an absolute majority is achieved for over 90% of the queries.

[2] www.crowdflower.com

Dataset	Sentences	Covered	Queries	Q/S
CCG-Dev	1913	1155	1904	1.7
CCG-Test	2407	1460	2511	1.7
Bioinfer	500	360	680	1.9

Table 3: Sentence coverage, number of queries annotated, and average number of queries per sentence (Q/S).

k-Agreed	CCG-Dev	CCG-Test	Bioinfer
5	48.0%	40.2%	47.7%
$\geq$ **4**	76.6%	68.0%	75.0%
$\geq$ **3**	94.9%	91.5%	94.0%

Table 4: The percentage of queries with at least k annotators agreeing on the exact same set of answers.

Qualitative Analysis Table 2 shows example queries from the CCGbank development set. Examples 1 and 2 show that workers could annotate long-range dependencies and scoping decisions, which are challenging for existing parsers.

However, there are some cases where annotators disagree with the gold syntax, mostly involving semantic phenomena which are not reflected in the syntactic structure. Many cases involve co-reference, where annotators often prefer a proper noun referent over a pronoun or indefinite (see Examples 4 and 5), even if it is not the syntactic argument of the verb. Example 6 shows a complex control structure, where the gold CCGbank syntax does not recover the true agent of *build*. CCGbank also does not distinguish between subject and object control. For these cases, our method could be used to extend existing treebanks. Another common error case involved partitives and related constructions, where the correct attachment is subtle—as reflected by the annotators' split decision in Example 7.

Question Quality Table 5 shows the percentage of questions that are answered with *None of the above* (written *N/A* below) by at most k annotators. On all domains, about 80% of the queries are considered answerable by all 5 annotators. To have a better understanding of the quality of automatically generated questions, we did a manual analysis on 50 questions for sentences from the CCGbank development set that are marked *N/A* by more than one annotator. Among the 50 questions, 31 of them are either generated from an incorrect supertag or unanswerable given the candidates. So the *N/A* answer

k-N/A	CCG-Dev	CCG-Test	Bioinfer
0	77.6%	81.6%	79.3%
$\leq$ **1**	89.6%	92.6%	89.1%
$\leq$ **2**	93.8%	96.1%	92.8%

Table 5: The percentage of queries with at most k annotators choosing the *None of the above* (N/A) option.

can provide useful signal that the parses that generated the question are likely incorrect. Common mistakes in question generation include: bad argument span in a copula question (4 questions), bad modality/negation (3 questions), and missing argument or particle (5 questions). Example 8 in Table 2 shows an example of a nonsensical question. While the parses agreed with the gold category $\mathsf{S\backslash NP}$, the question they generated omitted the negation and the verb phrase that was elided in the original sentence. In this case, 3 out of 5 annotators were able to answer with the correct dependency, but such mistakes can make re-parsing more challenging.

Cost and Speed We paid 6 cents for each answer. With 5 judgments per query, 20% test questions, and CrowdFlower's 20% service fee, the average cost per query was about 46 cents. On average, we collected about 1000 judgments per hour, so we were able to annotate all the queries generated from the CCGbank test set within 15 hours.

4 Re-Parsing with QA Annotation

To improve the output of the parser, we re-parse each sentence with an augmented scoring function that penalizes parses for disagreeing with annotators' choices. If q is a question, a is an answer to q, d is the dependency that produced the QA pair $\langle q, a \rangle$, and $v(a)$ annotators chose a, we add re-parsing constraints as follows:

- If $v(\textit{None of the above}) \geq T^+$, penalize parses that agree with q's supertag on the verb by w^t
- If $v(a) \leq T^-$, penalize parses containing d by w^-
- If $v(a) \geq T^+$, penalize parses that do not contain d by w^+

where T^+, T^-, w^t, w^-, and w^+ are hyperparameters. We incorporate these penalties into the parsing model during decoding. By using soft constraints, we mitigate the risk of incorrect annotations worsening a high-confidence parse.

Data	L16	HITL
CCG-Dev	87.9	88.4
CCG-Test	88.1	88.3
Bioinfer	82.2	82.8

Table 6: CCG parsing accuracy with human in the loop (HITL) versus the state-of-the-art baseline (L16) in terms of labeled F1 score. For both in-domain and out-domain, we have a modest gain over the entire corpus.

Data	L16	HITL	Pct.
CCG-Dev	83.9	87.1	12%
CCG-Test	84.2	85.9	10%

Table 7: Improvements of CCG parsing accuracy on changed sentences for in-domain data. We achieved significant improvement over the 10%–12% (Pct.) sentences that were changed by re-parsing.

Some errors are predictable: for example, if a is a non-possessive pronoun and is closer to the verb than its referent a', annotators often choose a' when a is correct (See Example 4 in Table 2). If a is a subspan of another answer a' and their votes differ by at most one (See Example 7 in Table 2), it is unlikely that both a and a' are correct. In these cases we use disjunctive constraints, where the parse needs to have at least one of the desired dependencies.

Experimental Setup We use Lewis et al. (2016)'s state-of-the-art CCG parser for our baseline. We chose the following set of hyperparameters based on performance on development data (CCG-Dev): $w^+ = 2.0$, $w^- = 1.5$, $w^t = 1.0$, $T^+ = 3$, $T^- = 0$. In the Bioinfer dataset, we found during development that the pronoun/subspan heuristics were not as useful, so we did not use them in re-parsing.

Results Table 6 shows our end-to-end parsing results. The larger improvement on out-of-domain sentences shows the potential for using our method for domain adaptation. There is a much smaller improvement on test data than development data, which may be related to the lower annotator agreement reported in Table 4.

There was much larger improvement (1.7 F1) on the subset of sentences that are changed after re-parsing, as shown in Table 7. This suggests that our method could be effective for semi-supervised learning or re-training parsers. Overall improvements on CCGbank are modest, due to only modifying 10% of sentences.

5 Discussion and Future Work

We introduced a human-in-the-loop framework for automatically correcting certain parsing mistakes. Our method identifies attachment uncertainty for core arguments of verbs and automatically generates questions that can be answered by untrained annotators. These annotations improve performance, particularly on out-of-domain data, demonstrating for the first time that untrained annotators can improve state-of-the-art parsers.

Sentences modified by our framework show substantial improvements in accuracy, but only 10% of sentences are changed, limiting the effect on overall accuracy. This work is a first step towards a complete approach to human-in-the-loop parsing.

Future work will explore the possibility of asking questions about other types of parsing uncertainties, such as nominal and adjectival argument structure, and a more thorough treatment of prepositional-phrase attachment, including distinctions between arguments and adjuncts. We hope to scale these methods to large unlabelled corpora or other languages, to provide data for re-training parsers.

Unsupervised Timeline Generation for Wikipedia History Articles

Sandro Bauer and **Simone Teufel**
Computer Laboratory
University of Cambridge
Cambridge, United Kingdom
{sandro.bauer, simone.teufel}@cl.cam.ac.uk

Abstract

This paper presents a generic approach to content selection for creating timelines from individual history articles for which no external information about the same topic is available. This scenario is in contrast to existing works on timeline generation, which require the presence of a large corpus of news articles. To identify salient events in a given history article, we exploit lexical cues about the article's subject area, as well as time expressions that are syntactically attached to an event word. We also test different methods of ensuring timeline coverage of the entire historical time span described. Our best-performing method outperforms a new unsupervised baseline and an improved version of an existing supervised approach. We see our work as a step towards more semantically motivated approaches to single-document summarisation.

1 Introduction

While there has been much work on generating history timelines automatically, these approaches are commonly evaluated on events that took place in recent decades, as they depend on the availability of large numbers of articles describing the same historical period. If such a rich data source is available, it is possible to exploit document creation times, redundancy across documents, as well as back-references to earlier events in order to identify salient events. For instance, the start of the Iraq War in 2003 is mentioned frequently in a general news corpus, including in articles published years after the event took place. The high number of mentions suggests that the beginning of the Iraq War was an important historical event.

However, for most historical periods covered in history articles (e.g., Antiquity or the Middle Ages), such cues are not commonly available, as no news articles from these eras exist. Generating event timelines for arbitrary historical periods is therefore a much harder problem, which requires methods that rely less heavily on the types of rich, parallel and dense information contained in news clusters.

To investigate this problem, we approach timeline generation as a special single-document summarisation task. In other words, we assume that the information to be summarised is contained in a single history article, and that no further mentions of specific events exist externally. This is a realistic scenario, for instance, for a specialist article describing the history of music in Ancient China.

We introduce a method for selecting salient content in history articles of any subject area, as long as the events in the text are roughly ordered chronologically. The hypothesis is that knowledge of an text's subject area can help decide which content should be selected. Another intuition is that certain combinations of events should be avoided in a timeline. We therefore investigate ways of encouraging a balanced selection of content from all parts of the text.

2 Related work

Timeline extraction has mostly been explored in a multi-document summarisation setting using corpora of news articles (Tran et al., 2015; Swan and Allan, 2000; Yan et al., 2011; Chieu and Lee, 2004;

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2343–2349,
Austin, Texas, November 1-5, 2016.

Allan et al., 2001). This task definition allows the exploitation of features such as document creation times and headlines. The most important feature is redundancy between articles, which facilitates the identification of salient events.

A second important strand of work focuses on extracting *all* events from a single input text and anchoring them in time. The creation of the TimeML specification language (Pustejovsky et al., 2003) laid the foundations for the TempEval series of shared tasks (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013), in which systems had to identify TimeML events and temporal expressions in free-form text. Further subtasks included the normalisation of temporal expressions and the creation of links between events and temporal expressions. A further shared task investigated the use of TimeML annotation for the downstream task of question answering (Llorens et al., 2015). Kolomiyets et al. (2012) created a connected timeline for a text based on TimeML annotations; a dependency parser infers dependency structures between events. Finally, a recent SemEval task (Minard et al., 2015) explored the related problem of cross-document event ordering. Here, relevant events and temporal expressions concerning a single target entity of interest have to be identified in more than one input document.

Chasin et al. (2014) try to identify important events in single texts, but their approach is limited to articles on wars and battles, and the problem is not approached as a summarisation task. Their method is lightly supervised, using features such as the presence of negation or past tense verbs in the sentence, and TextRank (Mihalcea and Tarau, 2004) for identifying salient sentences. We use an improved version of this system as a baseline.

3 Overall approach

Our problem is that of finding an optimal sequence of events (of a given maximum length) in a given input article. We follow the literature on event extraction and use TimeML events (Pustejovsky et al., 2003). Most TimeML events are verbs, but some are nominalisations such as "invasion" or other event-like words such as "war". The use of TimeML events, aside from the practical advantage that commonly-available event extraction algorithms exist, allows us to evaluate content selection at the event rather than at the sentence level.

We assume that there are both local and global factors that determine which events should be contained in the timeline. Local factors reflect how important an event is in its own right. Global factors represent intuitions about which combinations of events should or should not be selected. Our approach, which is unsupervised, takes into account the factors described in what follows.

3.1 Date presence

Intuitively, we expect that many important events have a date attached to them, as authors tend to give the reader this information if it is available. This is true for all historical periods from prehistory onwards, since for most events at least an approximate date is known. We considered two alternatives: The simplest approach is to only use sentences that contain a date, regardless of where in the sentence the date is located. A more sophisticated alternative verifies that the date is syntactically attached to the event, such as in "Richelieu died in 1642". To identify such cases, we constructed a parse tree using the C&C dependency parser (Clark and Curran, 2007) and only considered a TimeML event to be "dated" if it is at most two outgoing dependencies away from a temporal expression. We used HeidelTime (Strötgen and Gertz, 2013), a the state-of-the-art temporal expression software package, to identify such temporal expressions.

3.2 Lexical cues

The key component we use to judge the importance of any event are lexical cues about the input text's subject area. Examples of such subject areas include `INVENTION` and `FOOD/DRINK`. The subject area of a text should give us prior knowledge about which types of events are likely to be important. For instance, we would expect that a timeline describing the history of a country should contain information about revolutions, invasions, elections and similar events, whereas a timeline about science will instead focus on discoveries, publications, and Nobel prizes.

To mine knowledge about such subject-area-specific preferences, we make use of Wikipedia as a background corpus. Only history-specific articles whose title starts with "History of" are considered.

We start by generating sets of all Wikipedia history articles belonging to a given subject area, e.g. $A_{\texttt{GPE}}$ or $A_{\texttt{INVENTION}}$. To do this, we make use of the Wikipedia category system. For instance, for constructing a set of articles for the subject area `FIELD OF SCIENCE`, we collected all history articles that belong to the Wikipedia category "History of science by discipline". For each subject area g, we then calculate a *preference score* for each word lemma l found in any of the articles in the corresponding list A_g, using the following formula:

$$sc(g,l) = \frac{\frac{freq(A_g,l)}{freq(A_g,*)}}{\frac{freq(*,l)}{freq(*,*)}}$$

where $freq(A_g, l)$ is the summed frequency of word lemma l in all documents belonging to subject area g, and "*" stands for any. The numerator denotes how often lemma l appears in the subject-area-specific set of articles A_g, normalised by the total number of tokens found in this set. The denominator is invariant across all subject areas. If the ratio is high, lemma l is more likely to appear in articles of subject area g than in Wikipedia overall, suggesting that it is typical for the given subject area.

For each event e in the input text, a *local importance score* $imp(e)$ is calculated as

$$imp(e) = \frac{\sum_{w \in R(e)} \frac{sc(g,l)}{1+dist(w_e,w)}}{N}$$

where $R(e)$ is a window of words around the word representing the event (including the event word w_e itself), and $dist(w_1, w_2)$ refers to the absolute distance in words between two words w_1 and w_2. $imp(e)$ is a weighted average of the preference scores of all words in a window. The intuition is that context words of the event word can also be expected to be indicative of the subject area (consider "publish a paper") in many cases. $1 + dist(w_e, w)$ is used as a distance penalty in order to give more importance to words that are closer to the event word w_e. N is a constant which normalises the score by the sum of all distance penalties, to account for cases where the event word occurs at the beginning or end of a sentence. Table 1 shows examples of words with high and low preference scores.

3.3 Temporal coverage

We would like to avoid cases where too many events are selected from a small portion of the document, even if all these events are relevant. For instance, an article might list all a country's elections of the past few years, while mentioning only very important elections in earlier time periods. In this case, knowing that elections are important in the history of a country is not helpful, since this would lead to insufficient coverage of the remaining events in the article. We therefore take into account global factors as well. We experiment with two different methods:

GPE	INVENTION	FOOD/DRINK
absolutism	gas-works	yerba
protectorate	reverse-angle	hamburger
serfdom	flashback	saffron
club	season	play
game	team	member
season	school	bear

Table 1: Words with high (top) and low (bottom) preference scores for three subject areas

Exploiting document structure. We select salient events from each section of the Wikipedia article in a round-robin fashion. The algorithm operates in a greedy fashion by selecting the most locally important remaining event for each section, until the desired timeline length has been reached.

Integer linear program. We use an integer linear program to encode the intuition that no two timeline entries should have the same year. The ILP maximises the following objective function for each article (E refers to the set of all dated events):

$$\sum_{e_i \in E} x_i \cdot imp(e_i) - \sum_{e_i \in E} \sum_{e_j \in E} b_{ij} \cdot pen(e_i, e_j)$$

subject to the constraints:

$$b_{ij} \leq x_i \; \forall i, j \in E$$
$$x_i + x_j - b_{ij} \leq 1 \; \forall i, j \in E$$
$$x_i \in \{0,1\} \; \forall i \in E \qquad b_{ij} \in \{0,1\} \; \forall i, j \in E$$
$$\sum_{e_i \in E} x_i = L_{max}$$

This is similar to the model used by McDonald (2007) for multi-document summarisation. The model tries to find a set of locally important events while discouraging the selection of events that have the same date. x_i is a variable denoting whether the corresponding event e_i has been selected. b_{ij} is a variable which is 1 if and only if both events i and j have been selected. $pen(e_i, e_j)$ is a penalty function that is 1 if the two events e_i and e_j have

the same date, otherwise 0. Each event was linked to the preceding temporal expression identified by HeidelTime; this heuristic was found to work well. The last constraint ensures that not more than L_{max} events are chosen, where L_{max} is the desired timeline length for the article considered.

4 Evaluation

For evaluating our algorithms, the methodology we introduced in (Bauer and Teufel, 2015) is used, along with the accompanying Cambridge Single-Document Timeline Corpus (CSDTC, version 2.0), which has been made publicly available[1].

4.1 Cambridge Single-Document Timeline Corpus

The CSDTC contains 10 articles from 3 subject areas: `GPE` (geo-political entities such as countries and cities), `FIELD OF SCIENCE` and `INVENTION`. To tune our algorithms, we constructed a development set of a further 30 annotated history articles from the subject areas in the CSDTC and one additional subject area (`FOOD/DRINK`). Due to the high annotation cost, only a single timeline creator was used. Important events were directly marked up in the source text (as opposed to the CSDTC, where timeline entries were written by hand), and exactly one HCU[2] was created per event. Using this development corpus, the window size of words considered for calculating local importance scores (cf. Section 3.2) was set to 3. We report the performance of all algorithms on both the development set and the test set (the CSDTC).

Although the number of subject areas in the two corpora is rather small owing to the considerable annotation effort, we believe that the resulting system would generalise rather well to other subject areas, were they added, as the subject areas in the corpus are very different in nature from each other. Care was taken when constructing the CSDTC to use a set of subject areas that is representative for human-written timelines on the Web.

[1]The corpus is available on the first author's website: `http://www.cl.cam.ac.uk/~smb89/form.html`

[2]As opposed to the CSDTC, HCUs in the development set always have a weight of 1, as only timeline writer was used.

4.2 Evaluation based on Historical Content Units

The evaluation is based on abstract ("deep") meaning units called *Historical Content Units* (HCUs). HCUs were derived on the basis of human-created timelines. Between 32 and 80 HCUs per article were annotated for the articles in the CSDTC.

Each HCU is weighted by the number of timeline creators who expressed its semantic content in their timelines. Because HCUs are linked to TimeML events in the surface text, it is possible to perform automatic deep evaluation without requiring any manual annotation of system summaries.

Algorithms are evaluated on a given input article using an adapted version of the pyramid score (Nenkova and Passonneau, 2004), which is calculated as the ratio between the sum of all rewards for HCUs chosen by the algorithm normalised by the maximum possible score $score_{max}$:

$$score = \frac{\sum_{h \in HCUs} w_h \cdot Cov(h,E,T)}{score_{max}}$$

where w_h is the weight of HCU h (a number between 1 and the number of annotators), E is the set of events in the article, T are the events in the system timeline, and the *coverage score* $Cov(h, E, T)$ is a number between 0 and 1 that indicates to what extent the events chosen by the algorithm jointly express the semantic content of HCU h. The basic version of $Cov(h, E, T)$ is defined as follows:

$$Cov(h, E, T) = min(1.0, \sum_{e_j \in E} v_{h,e_j} \cdot s(T, e_j))$$

where v_{h,e_j} is an *anchor weight* between 0 and 1 which denotes to what extent event e_j expresses the semantic content of HCU h, and $s(T, e)$ is a helper function that returns 1 if the set of selected events T includes event e, and 0 otherwise.

The coverage score for each HCU is calculated by summing up the anchor weights of those events that the algorithm has selected. A coverage score of 0 means that the events mentioned in the timeline do not express the HCU's semantic content at all, while a score of 1 occurs where the HCU's content is fully expressed by the timeline. Scores between 0 and 1 occur in a large number of cases. For instance, an HCU may express the fact that a country was invaded and destroyed. If the system timeline merely contains a TimeML event that refers to the invasion, it is assigned a coverage score of 0.5 for this HCU,

as it expresses only half of the HCU's semantic content. Where the sum exceeds 1, the coverage score is set to a hard upper limit of 1. This ensures that algorithms are not doubly rewarded for selecting multiple TimeML events expressing the same semantic content. The final formula we used to calculate coverage scores is slightly more complex, as some TimeML events in the CSDTC have been grouped together into *event groups*. A detailed description is given in the documentation of the corpus.

Pyramid scores are recall-based: The evaluation assumes a maximum number of timeline entries n, and the maximum possible score is the sum of the HCU weights of the n most highly weighted HCUs. The values for n are given in the CSDTC.

4.3 System and baselines

We report the performance of two systems. Both systems first remove all events that do not have a date, or whose date is too far away, as described in Section 3.1. Our first system ("ILP-based") selects events based on the integer linear program described, while the second system ("Round-robin") selects locally important events per section.

We have speculated above that dates are important for our task. We therefore compare against a date baseline which selects events randomly from the list of all dated events. We also compare against several modified versions of our method: To investigate the influence of the parser in identifying suitable dated events, we report the results for a simpler method which considers all events that have a date in the same sentence ("Round-robin, simple date criterion"). Two alternative systems select locally important events from all (not only dated) events ("Round-robin, without date criterion") or salient dated events from the entire article without considering document structure ("Local importance + date criterion").

The supervised baseline ("Chasin et al. (2014)") was re-implemented using LibSVM (Chang and Lin, 2011), and SVM parameters were tuned using grid search. 25 of the 30 articles were used for training and 5 for development. We improved their system by defining some of their sentence-level features at the event level. Probability estimates as described by Platt (2000) were used as importance scores.

System	Dev	Test
ILP-based	**0.22**▲	**0.30**▲
Round-robin	0.20▲	0.30▲
Round-robin w/o local importance	0.18	0.26
Local importance + date criterion	0.21▲	0.29
Round-robin, simple date criterion	0.19	0.25
Round-robin without date criterion	0.14	0.18
Date baseline	0.18	0.25
Chasin et al. (2014) (improved)	–	0.12
Random baseline	0.08	0.10

Table 2: Average pyramid scores across all articles (▲ = significantly better than the date baseline)

4.4 Results

The results in Table 2 show that only a combination of all three factors (date presence, local importance, coverage) results in a statistically significant improvement over the date baseline at $\alpha = 0.05$ according to Wilcoxon's signed-rank test on the test set. Both our systems perform comparably on the test set; removing any of the three components results in lower performance. Using a parser to identify dated events has a strong positive effect (see "Round-robin, simple date criterion"). Our system also outperforms the improved supervised baseline by a large margin. The fact that a completely unsupervised system performs best is encouraging, as training data for this task is very expensive to obtain. Our results suggest that it might be worth investigating other types of prior knowledge about the semantics of an input text in further research. The crucial advantage of such generic methods is that no texts on exactly the same topic are needed, which is a requirement with texts about niche topics.

5 Conclusion

We have introduced an unsupervised method for the challenging problem of timeline generation from single history articles, a scenario where parallel texts cannot be assumed to exist. Our method results in a significant improvement over a novel unsupervised baseline as well as an existing supervised approach.

Abstract

Most existing knowledge base (KB) embedding methods solely learn from time-unknown fact triples but neglect the temporal information in the knowledge base. In this paper, we propose a novel time-aware KB embedding approach taking advantage of the happening time of facts. Specifically, we use temporal order constraints to model transformation between time-sensitive relations and enforce the embeddings to be temporally consistent and more accurate. We empirically evaluate our approach in two tasks of link prediction and triple classification. Experimental results show that our method outperforms other baselines on the two tasks consistently.

1 Introduction

Knowledge bases (KBs) such as Freebase (Bollacker et al., 2008) and YAGO (Fabian et al., 2007) play a pivotal role in many NLP related applications. KBs consist of facts in the form of triplets (e_i, r, e_j), indicating that head entity e_i and tail entity e_j is linked by relation r. Although KBs are large, they are far from complete. Link prediction is to predict relations between entities based on existing triplets, which can alleviate the incompleteness of current KBs. Recently a promising approach for this task called knowledge base embedding (Nickel et al., 2011; Bordes et al., 2011; Socher et al., 2013) aims to embed entities and relations into a continuous vector space while preserving certain information of the KB graph. TransE (Bordes et al., 2013) is a typical model considering relation vector as translating operations between head and tail vector, i.e., $\mathbf{e}_i + \mathbf{r} \approx \mathbf{e}_j$ when (e_i, r, e_j) holds.

Most existing KB embedding methods solely learn from time-unknown facts but ignore the useful temporal information in the KB. In fact, there are many temporal facts (or events) in the KB, e.g., (*Obama, wasBornIn, Hawaii*) happened at August 4, 1961. (*Obama, presidentOf, USA*) is true since 2009. Current KBs such as YAGO and Freebase store such temporal information either directly or indirectly. The happening time of time-sensitive facts may indicate special temporal order of facts and time-sensitive relations. For example, *(Einstein, wasBornIn, Ulm)* happened in 1879, *(Einstein, wonPrize, Nobel Prize)* happened in 1922, *(Einstein, diedIn, Princeton)* occurred in 1955. We can infer the temporal order of time-sensitive relations from all such kinds of facts: *wasBornIn* $\rightarrow$ *wonPrize* $\rightarrow$ *diedIn*. Traditional KB embedding models such as TransE often confuse relations such as *wasBornIn* and *diedIn* when predicting *(person,?,location)* because TransE learns only from time-unknown facts and cannot distinguish relations with similar semantic meaning. To make more accurate predictions, it is non-trivial for existing KB embedding methods to incorporate temporal order information.

This paper mainly focuses on incorporating the temporal order information and proposes a time-aware link prediction model. A new temporal dimension is added to fact triples, denoted as a quadruple: (e_i, r, e_j, t_r), indicating the fact happened at time t_r[1]. To make the embedding space compati-

[1] t_r is the absolute beginning time when the fact is true, e.g., "1961-08-04" for (*Obama, wasBornIn, Hawaii*).

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2350–2354,
Austin, Texas, November 1-5, 2016.

ble with the observed triple in the fact dimension, relation vectors behave as translations between entity vectors similarly as TransE models. To incorporate temporal order information between pair-wise temporal facts, we assume that prior time-sensitive relation vector can evolve into a subsequent time-sensitive relation vector through a temporal transition. For example, we have two temporal facts sharing the same *head entity*: (e_i, r_i, e_j, t_1) and (e_i, r_j, e_k, t_2) and the temporal order constraint $t_1 < t_2$, i.e., r_i happens before r_j, then we propose the assumption that prior relation $\mathbf{r}_i$ after temporal transition should lie close to subsequent relation $\mathbf{r}_j$, i.e., $\mathbf{r}_i\mathbf{M} \approx \mathbf{r}_j$, here matrix $\mathbf{M}$ captures the temporal order information between relations. In this way, both semantic and temporal information are embedded into a continuous vector space during learning. To the best of our knowledge, we are the first to consider such temporal information for KB embedding.

We evaluate our approach on public available datasets and our method outperforms state-of-the-art methods in the time-aware link prediction and triple classification tasks.

2 Time-Aware KB Embedding

Traditional KB embedding methods encode only observed fact triples but neglect temporal constraints between time-sensitive entities and facts. To deal with this limitation, we introduce *Time-Aware KB Embedding* which constrains the task by incorporating temporal constraints.

To consider the happening time of facts, we formulate a temporal order constraint as an optimization problem based on a manifold regularization term. Specially, temporal order of relations in time-sensitive facts should affect KB representation. If r_i and r_j share the same head entity e_i, and r_i occurs before r_j, then prior relation's vector r_i could evolve into subsequent relation's vector r_j in the temporal dimension.

To encode the transition between time-sensitive relations, we define a transition matrix $\mathbf{M} \in \mathbb{R}^{n\times n}$ between pair-wise temporal ordering relation pair (r_i, r_j). Our optimization requires that positive temporal ordering relation pairs should have lower scores (energies) than negative pairs, so we define a **temporal order** score function as

$$g(r_i, r_j) = \|\mathbf{r}_i\mathbf{M} - \mathbf{r}_j\|_1, \tag{1}$$

which is expected to be a low score when the relation pair is in chronological order, and high otherwise.

To make the embedding space compatible with the observed triples, we make use of the triple set Δ and follow the same strategy adopted in previous methods such as TransE.

$$f(e_i, r, e_j) = \|\mathbf{e}_i + \mathbf{r} - \mathbf{e}_j\|_1. \tag{2}$$

For each candidate triple, it requires positive triples to have lower scores than negative triples.

The optimization is to minimize the **joint** score function,

$$\begin{aligned} L = \sum_{x^+\in\Delta} \Big[\sum_{x^-\in\Delta'} [\gamma_1 + f(x^+) - f(x^-)]_+ \\ +\lambda \sum_{y^+\in\Omega_{e_i}, y^-\in\Omega'_{e_i}} [\gamma_2 + g(y^+) - g(y^-)]_+ \Big] \end{aligned} \tag{3}$$

where $x^+ = (e_i, r_i, e_j) \in \Delta$ is the positive triple (quad), $x^- = (e'_i, r_i, e'_j) \in \Delta'$ is corresponding the negative triple. $y^+ = (r_i, r_j) \in \Omega_{e_i}$ is the positive relation ordering pair with respect to (e_i, r_i, e_j, t_x). It's defined as

$$\begin{aligned} \Omega_{e_i} = \{(r_i, r_j) | (e_i, r_i, e_j, t_x) \in \Delta_\tau, \\ (e_i, r_j, e_k, t_y) \in \Delta_\tau, t_x < t_y\}, \end{aligned} \tag{4}$$

where r_i and r_j share the same head entity e_i, and $y^- = (r_j, r_i) \in \Omega'_{e_i}$ are the corresponding negative relation order pairs by inverse. In experiments, we enforce constrains as $\|\mathbf{e}_i\|_2 \leq 1$, $\|\mathbf{r}_i\|_2 \leq 1$, $\|\mathbf{r}_j\| \leq 1$ and $\|\mathbf{r}_i\mathbf{M}\|_2 \leq 1$.

The first term in Equation (3) enforces the resultant embedding space compatible with all the observed triples, and the second term further requires the space to be temporally consistent and more accurate. Hyperparameter λ makes a trade-off between the two cases. Stochastic gradient descent (in mini-batch mode) is adopted to solve the minimization problem.

3 Experiments

We adopt the same evaluation metrics for time-aware KB embedding in two tasks: link prediction (Bordes et al., 2013) and triple classification (Socher et al., 2013).

Dataset	#Rel	#Ent	#Train/#Valid/#Test	#Trip.	#Quad
YG15k	10	9513	13345/1320/1249	15914	15914
YG36k	10	9513	29757/3252/3058	36067	15914

Table 1: Statistics of data sets.

3.1 Datasets

We create two temporal datasets from YAGO2 (Hoffart et al., 2013), consisting of time-sensitive facts. In YAGO2, *MetaFacts* contains all happening time for facts. *DateFacts* contains all creation time for entities. First, to make a pure time-sensitive dataset where all facts have time annotations, we selected the subset of entities that have at least 2 mentions in *MetaFacts* and *DateFacts*. This resulted in 15,914 triples (quadruples) which were randomly split with the ratio shown in Table 1. This dataset is denoted *YG15k*. Second, to make a mixed dataset, we created *YG36k* where 50% facts have time annotations and 50% do not. We will release the data upon request.

3.2 Link Prediction

Link prediction is to complete the triple (h, r, t) when h, r or t is missing.

3.2.1 Entity Prediction

Evaluation protocol. For each test triple with missing head or tail entity, various methods are used to compute the scores for all candidate entities and rank them in descending order. We use two metrics for our evaluation as in (Bordes et al., 2013): the mean of correct entity ranks (Mean Rank) and the proportion of valid entities ranked in top-10 (Hits@10). As mentioned in (Bordes et al., 2013), the metrics are desirable but flawed when a corrupted triple exists in the KB. As a countermeasure, we filter out all these valid triples in the KB before ranking. We name the first evaluation set as *Raw* and the second as *Filter*.

Baseline methods. For comparison, we select translating methods such as TransE (Bordes et al., 2013), TransH (Wang et al., 2014b) and TransR (Lin et al., 2015b) as our baselines. We then use time-aware embedding based on these methods to obtain the corresponding time-aware embedding models. A model with time-aware embedding is denoted as "tTransE" for example.

Implementation details. For all methods, we create 100 mini-batches on each data set. The dimension of the embedding n is set in the range of $\{20,50,100\}$, the margin γ_1 and γ_2 are set in the range $\{1,2,4,10\}$. The learning rate is set in the range $\{0.1,\ 0.01,\ 0.001\}$. The regularization hyperparameter λ is tuned in $\{10^{-1},10^{-2},10^{-3},10^{-4}\}$. The best configuration is determined according to the mean rank in validation set. The optimal configurations are n=100,γ_1=γ_2=4,λ=10^{-2}, learning rate is 0.001 and taking ℓ_1-norm.

	Mean Rank		Hits@1 (%)	
Metric	Raw	Filter	Raw	Filter
TransE	1.53	1.48	69.4	73.0
tTransE	**1.42**	**1.35**	**71.1**	**75.7**
TransH	1.51	1.37	70.5	72.2
tTransH	**1.38**	**1.30**	**74.6**	**76.9**
TransR	1.40	1.28	71.1	74.3
tTransR	**1.27**	**1.12**	**74.5**	**78.9**

Table 3: Evaluation results on relation prediction.

Results. Table 2 reports the results on the test set. From the results, we can see that time-aware embedding methods outperform all the baselines on all the data sets and with all the metrics. The improvements are usually quite significant. The Mean Rank drops by about 75%, and Hits@10 rises about 19% to 30%. This demonstrates the superiority and generality of our method. When dealing with sparse data YG15k, all the temporal information is utilized to model temporal associations and make the embeddings more accurate, so it obtains better improvement than mixing the time-unknown triples in YG36k.

3.2.2 Relation Prediction

Relation prediction aims to predict relations given two entities. Evaluation results are shown in Table 3 on only YG15K due to limited space, where we report Hits@1 instead of Hits@10. Example prediction results for TransE and tTransE are compared in Table 4. For example, when testing *(Billy_Hughes,?,London,1862)*, it's easy for TransE to mix relations *wasBornIn* and *diedIn* because they act similarly for a person and a place. But known that *(Billy_Hughes, isAffiliatedTo, National_Labor_Party)* happened in 1916, and tTransE have learnt temporal order that *wasBornIn*→*isAffiliatedTo*→*diedIn*, so the regularization term $|\mathbf{r}_{born}\mathbf{T} - \mathbf{r}_{affiliated}|$ is smaller than $|\mathbf{r}_{died}\mathbf{T} - \mathbf{r}_{affiliated}|$, so correct answer *wasBornIn* ranks higher than *diedIn*.

Dataset	YG15k				YG36k			
Metric	MeanRank		Hits@10(%)		MeanRank		Hits@10(%)

3.3 Triple Classification

Triple classification aims to judge whether an unseen triple is correct or not.

Evaluation protocol. We follow the same evaluation protocol used in Socher et al. (2013). To create labeled data for classification, for each triple in the test and validation sets, we construct a corresponding negative triple by randomly corrupting the entities. To corrupt a position (head or tail), only entities that have appeared in that position are allowed. During triple classification, a triple is predicted as positive if the score is below a relation-specific threshold δ_r; otherwise as negative. We report averaged accuracy on the test sets.

Implementation details. We use the same hyperparameter settings as in the link prediction task. The relation-specific threshold δ_r is determined by maximizing averaged accuracy on the validation sets.

Results. Table 5 reports the results on the test sets. The results indicate that time-aware embedding outperforms all the baselines consistently. Temporal order information may help to distinguish positive and negative triples as different head entities may have different temporally associated relations. If the temporal order is the same with most facts, the regularization term helps it get lower energies and vice versa.

4 Related Work

Many models have been proposed for KB embedding (Nickel et al., 2011; Bordes et al., 2013; Socher et al., 2013). External information is employed to improve KB embedding such as text (Riedel et al., 2013; Wang et al., 2014a; Zhao et al., 2015), entity type and relationship domain (Guo et al., 2015; Chang et al., 2014), and relation path (Lin et al., 2015a; Gu et al., 2015). However, these methods solely rely on triple facts but neglect temporal order constraints between facts. Temporal information such as relation ordering in text has been explored (Talukdar et al., 2012; Chambers et al., 2014; Bethard, 2013; Cassidy et al., 2014; Chambers et al., 2007; Chambers and Jurafsky, 2008). This paper proposes a time-aware embedding approach that employs temporal order constraints to improve KB embedding.

5 Conclusion and Future Work

In this paper, we propose a general time-aware KB embedding, which incorporates creation time of entities and imposes temporal order constraints on the geometric structure of the embedding space and enforce it to be temporally consistent and accurate. As future work: (1) We will incorporate the valid time of facts. (2) Some time-sensitive facts lack temporal information in YAGO2, we will mine such temporal information from texts.

Abstract

Most successful information extraction systems operate with access to a large collection of documents. In this work, we explore the task of acquiring and incorporating external evidence to improve extraction accuracy in domains where the amount of training data is scarce. This process entails issuing search queries, extraction from new sources and reconciliation of extracted values, which are repeated until sufficient evidence is collected. We approach the problem using a reinforcement learning framework where our model learns to select optimal actions based on contextual information. We employ a deep Q-network, trained to optimize a reward function that reflects extraction accuracy while penalizing extra effort. Our experiments on two databases – of shooting incidents, and food adulteration cases – demonstrate that our system significantly outperforms traditional extractors and a competitive meta-classifier baseline.[1]

1 Introduction

In many realistic domains, information extraction (IE) systems require exceedingly large amounts of annotated data to deliver high performance. Increases in training data size enable models to handle robustly the multitude of linguistic expressions that convey the same semantic relation. Consider, for instance, an IE system that aims to identify entities such as the perpetrator and the number of victims in a shooting incident (Figure 1). The document does not explicitly mention the shooter (*Scott Westerhuis*), but instead refers to him as a suicide victim. Extraction of the number of fatally shot victims is similarly difficult, as the system needs to infer that *"A couple and four children"* means *six people*. Even a large annotated training set may not provide sufficient coverage to capture such challenging cases.

ShooterName: Scott Westerhuis
NumKilled: 6

A couple and four children found dead in their burning South Dakota home had been shot in an apparent murder-suicide, officials said Monday.
...
Scott Westerhuis's cause of death was "shotgun wound with manner of death as suspected suicide," it added in a statement.

Figure 1: Sample news article on a shooting case. Note how the article contains both the name of the shooter and the number of people killed but both pieces of information require complex extraction schemes.

In this paper, we explore an alternative approach for boosting extraction accuracy, when a large training corpus is not available. Instead, the proposed method utilizes external information sources to resolve ambiguities inherent in text interpretation. Specifically, our strategy is to find other documents that contain the information sought, expressed in a form that a basic extractor can "understand". For instance, Figure 2 shows two other articles describing the same event, wherein the entities of interest

[1]Code is available at http://people.csail.mit.edu/karthikn/rl-ie/

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2355–2365,
Austin, Texas, November 1-5, 2016.

The **six** members of a South Dakota family found dead in the ruins of their burned home were fatally shot, with one death believed to be a suicide, authorities said Monday.

AG Jackley says all evidence supports the story he told based on preliminary findings back in September: **Scott Westerhuis** shot his wife and children with a shotgun, lit his house on fire with an accelerant, then shot himself with his shotgun.

Figure 2: Two other articles on the same shooting case. The first article clearly mentions that six people were killed. The second one portrays the shooter in an easily extractable form.

– the number of people killed and the name of the shooter – are expressed explicitly. Processing such stereotypical phrasing is easier for most extraction systems, compared to analyzing the original source document. This approach is particularly suitable for extracting information from news where a typical event is covered by multiple news outlets.

The challenges, however, lie in (1) performing *event coreference* (i.e. retrieving suitable articles describing the same incident) and (2) reconciling the entities extracted from these different documents. Querying the web (using the source article's title for instance) often retrieves documents about other incidents with a tangential relation to the original story. For example, the query "*4 adults, 1 teenager shot in west Baltimore 3 april 2015*" yields only two relevant articles among the top twenty results on Bing search, while returning other shooting events at the same location. Moreover, the values extracted from these different sources require resolution since some of them might be inaccurate.

One solution to this problem would be to perform a single search to retrieve articles on the same event and then reconcile values extracted from them (say, using a *meta-classifier*). However, if the confidence of the new set of values is still low, we might wish to perform further queries. Thus, the problem is inherently sequential, requiring alternating phases of querying to retrieve articles and integrating the extracted values.

We address these challenges using a Reinforcement Learning (RL) approach that combines query formulation, extraction from new sources, and value reconciliation. To effectively select among possible actions, our state representation encodes information about the current and new entity values along with the similarity between the source article and the newly retrieved document. The model learns to select good actions for both article retrieval and value reconciliation in order to optimize the reward function, which reflects extraction accuracy and includes penalties for extra moves. We train the RL agent using a Deep Q-Network (DQN) (Mnih et al., 2015) that is used to predict both querying and reconciliation choices simultaneously. While we use a maximum entropy model as the base extractor, this framework can be inherently applied to other extraction algorithms.

We evaluate our system on two datasets where available training data is inherently limited. The first dataset is constructed from a publicly available database of mass shootings in the United States. The database is populated by volunteers and includes the source articles. The second dataset is derived from a FoodShield database of illegal food adulterations. Our experiments demonstrate that the final RL model outperforms basic extractors as well as a meta-classifier baseline in both domains. For instance, in the *Shootings* domain, the average accuracy improvement over the meta-classifier is 7%.

2 Related Work

Open Information Extraction Existing work in open IE has used external sources from the web to improve extraction accuracy and coverage (Agichtein and Gravano, 2000; Etzioni et al., 2011; Fader et al., 2011; Wu and Weld, 2010). Such research has focused on identifying multiple instances of the same relation, independent of the context in which this information appears. In contrast, our goal is to extract information from additional sources about a specific event described in a source article. Therefore, the novel challenge of our task resides in performing event coreference (Lee et al., 2012; Bejan and Harabagiu, 2014) (i.e identifying other sources describing the same event) while simultaneously reconciling extracted information. Moreover, relations typically considered by open IE systems have significantly higher coverage in online documents than a specific incident described in

a few news sources. Hence, we require a different mechanism for finding and reconciling online information.

Entity linking, multi-document extraction and event coreference Our work also relates to the task of multi-document information extraction, where the goal is to connect different mentions of the same entity across input documents (Mann and Yarowsky, 2005; Han et al., 2011; Durrett and Klein, 2014). Since this setup already includes multiple input documents, the model is not required to look for additional sources or decide on their relevance. Also, while the set of input documents overlap in terms of entities mentioned, they do not necessarily describe the same event. Given these differences in setup, the challenges and opportunities of the two tasks are distinct.

Knowledge Base Completion and Online Search Recent work has explored several techniques to perform Knowledge Base Completion (KBC) such as vector space models and graph traversal (Socher et al., 2013; Yang et al., 2014; Gardner et al., 2014; Neelakantan et al., 2015; Guu et al., 2015). Though our work also aims at increasing extraction recall for a database, traditional KBC approaches do not require searching for additional sources of information. West et al. (2014) explore query reformulation in the context of KBC. Using existing search logs, they learn how to formulate effective queries for different types of database entries. Once query learning is completed, the model employs several selected queries, and then aggregates the results based on retrieval ranking. This approach is complementary to the proposed method, and can be combined with our approach if search logs are available.

Kanani and McCallum (2012) also combine search and information extraction. In their task of faculty directory completion, the system has to find documents from which to extract desired information. They employ reinforcement learning to address computational bottlenecks, by minimizing the number of queries, document downloads and extraction action. The extraction accuracy is not part of this optimization, since the baseline IE system achieves high performance on the relations of interest. Hence, given different design goals, the two RL formulations are very different. Our approach is also close in spirit to the AskMSR system (Banko et al., 2002) which aims at using information redundancy on the web to better answer questions. Though our goal is similar, we learn to query and consolidate the different sources of information instead of using predefined rules. Several slot-filling methods have experimented with query formulation over web-based corpora to populate knowledge bases (Surdeanu et al., 2010; Ji and Grishman, 2011).

3 Framework

We model the information extraction task as a markov decision process (MDP), where the model learns to utilize external sources to improve upon extractions from a source article (see Figure 3). The MDP framework allows us to dynamically incorporate entity predictions while also providing flexibility to choose the type of articles to extract from. At each step, the system has to reconcile extracted values from a related article (e_{new}) with the current set of values (e_{cur}), and decide on the next query for retrieving more articles.

We represent the MDP as a tuple $\langle S, A, T, R \rangle$, where $S = \{s\}$ is the space of all possible states, $A = \{a = (d, q)\}$ is the set of all actions, $R(s, a)$ is the reward function, and $T(s'|s, a)$ is the transition function. We describe these in detail below.

States The state s in our MDP consists of the extractor's confidence in predicted entity values, the context from which the values are extracted and the similarity between the new document and the original one. We represent the state as a continuous real-valued vector (Figure 3) incorporating these pieces of information:

1. Confidence scores of current and newly extracted entity values.
2. One-hot encoding of matches between current and new values.
3. Unigram/tf-idf counts[2] of context words. These are words that occur in the neighborhood of the entity values in a document (e.g. the words *which*, *left*, *people* and *wounded* in the phrase "*which left 5 people wounded*").
4. *tf-idf* similarity between the original article and the new article.

[2]Counts are computed on the documents used to train the basic extraction system.

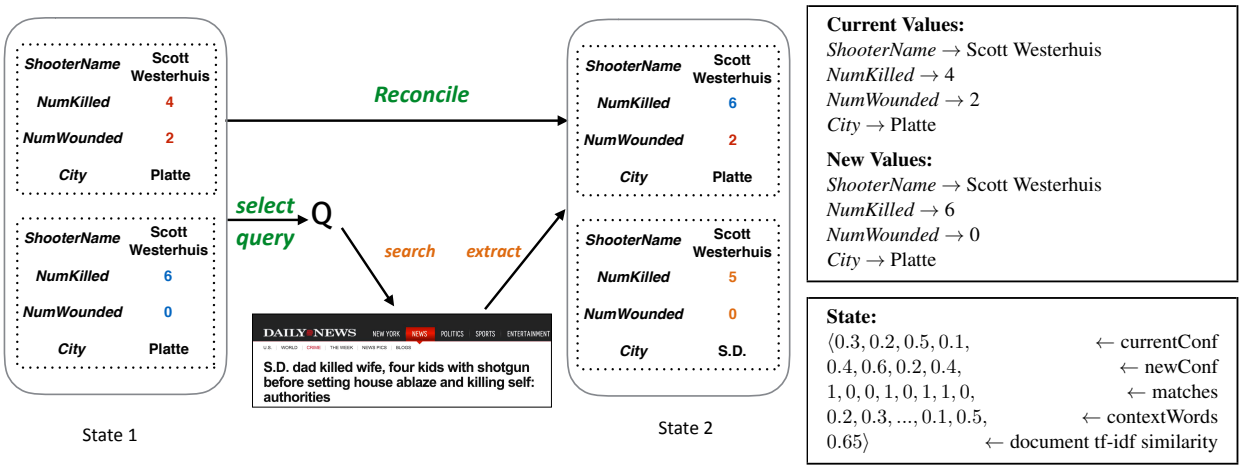

Figure 3: Left: Illustration of a transition in the MDP – the top box in each state shows the current entities and the bottom one consists of the new entities extracted from a downloaded article on the same event. **Right:** Sample state representation (bottom) in the MDP based on current and new values of entities (top). *currentConf*: confidence scores of current entities, *newConf*: confidence scores of new entities, *contextWords*: tf-idf counts of context words.

Actions At each step, the agent is required to take two actions - a reconciliation decision d and a query choice q. The decision d on the newly extracted values can be one of the following types: (1) accept a specific entity's value (one action per entity)[3], (2) accept all entity values, (3) reject all values or (4) stop. In cases 1-3, the agent continues to inspect more articles, while the episode ends if a stop action (4) is chosen. The current values and confidence scores are simply updated with the accepted values and the corresponding confidences.[4] The choice q is used to choose the next query from a set of automatically generated alternatives (details below) in order to retrieve the next article.

Rewards The reward function is chosen to maximize the final *extraction accuracy* while minimizing the number of queries. The accuracy component is calculated using the difference between the accuracy of the current and the previous set of entity values:

$$R(s,a) = \sum_{\text{entity } j} \text{Acc}(e^j_{cur}) - \text{Acc}(e^j_{prev})$$

There is a negative reward per step to penalize the agent for longer episodes.

[3]No entity-specific features are used for action selection.

[4]We also experiment with other forms of value reconciliation. See Section 5 for details.

Queries The queries are based on automatically generated templates, created using the title of an article along with words[5] most likely to co-occur with each entity type in the training data. Table 1 provides some examples – for instance, the second template contains words such as *arrested* and *identified* which often appear around the name of the shooter.

⟨*title*⟩
⟨*title*⟩ + (police | identified | arrested | charged)
⟨*title*⟩ + (killed | shooting | injured | dead | people)
⟨*title*⟩ + (injured | wounded | victim)
⟨*title*⟩ + (city | county | area)

Table 1: Examples of different query templates for web search for articles on mass shootings. The \| symbol represents logical OR. The last 4 queries contain context words around values for entity types ShooterName, NumKilled, NumWounded and City, respectively. At query time, ⟨*title*⟩ is replaced by the source article's title.

We use a search engine to query the web for articles on the same event as the source article and retrieve the top k links per query.[6] Documents that are more than a month older than the original article are filtered out of the search results.

Transitions Each episode starts off with a single source article x_i from which an initial set of entity

[5]Stop words, numeric terms and proper nouns are filtered.

[6]We use k=20 in our experiments.

values are extracted. The subsequent steps in the episode involve the extra articles, downloaded using different types of query formulations based on the source article. A single transition in the episode consists of the agent being given the state s containing information about the current and new set of values (extracted from a single article) using which the next action $a = (d, q)$ is chosen. The transition function $T(s'|s, a)$ incorporates the reconciliation decision d from the agent in state s along with the values from the next article retrieved using query q and produces the next state s'. The episode stops whenever d is a stop decision.

Algorithm 1 details the entire MDP framework for the training phase. During the test phase, each source article is handled only once in a single episode (lines 8-23).

Algorithm 1 MDP framework for Information Extraction (Training Phase)

1: Initialize set of original articles X
2: **for** $x_i \in X$ **do**
3: **for** each query template T^q **do**
4: Download articles with query $T^q(x_i)$
5: Queue retrieved articles in Y_i^q
6: **for** $epoch = 1, M$ **do**
7: **for** $i = 1, |X|$ **do** //episode
8: Extract entities e_0 from x_i
9: $e_{cur} \leftarrow e_0$
10: q $\leftarrow 0$, r $\leftarrow 0$ //query type, reward
11: **while** Y_i^q not empty **do**
12: Pop next article y from Y_i^q
13: Extract entities e_{new} from y
14: Compute tf-idf similarity $\mathcal{Z}(x_i, y)$
15: Compute context vector $\mathcal{C}(y)$
16: Form state s using e_{cur}, e_{new}, $\mathcal{Z}(x_i, y)$ and $\mathcal{C}(y)$
17: Send (s, r) to agent
18: Get decision d, query q from agent
19: **if** q == "end_episode" **then break**
20: $e_{prev} \leftarrow e_{cur}$
21: $e_{cur} \leftarrow$ *Reconcile*(e_{cur}, e_{new}, d)
22: $r \leftarrow \sum_{\text{entity } j} \text{Acc}(e_{cur}^j) - \text{Acc}(e_{prev}^j)$
23: Send (s_{end}, r) to agent

4 Reinforcement Learning for Information Extraction

In order to learn a good policy for an agent, we utilize the paradigm of reinforcement learning (RL). The MDP described in the previous section can be viewed in terms of a sequence of transitions (s, a, r, s'). The agent typically utilizes a state-action value function $Q(s, a)$ to determine which action a to perform in state s. A commonly used technique for learning an optimal value function is Q-learning (Watkins and Dayan, 1992), in which the agent iteratively updates $Q(s, a)$ using the rewards obtained from episodes. The updates are derived from the recursive Bellman equation (Sutton and Barto, 1998) for the optimal Q:

$$Q_{i+1}(s, a) = \mathrm{E}[r + \gamma \max_{a'} Q_i(s', a') \mid s, a]$$

Here, $r = R(s, a)$ is the reward and γ is a factor discounting the value of future rewards and the expectation is taken over all transitions involving state s and action a.

Since our problem involves a continuous state space S, we use a deep Q-network (DQN) (Mnih et al., 2015) as a function approximator $Q(s, a) \approx Q(s, a; \theta)$. The DQN, in which the Q-function is approximated using a deep neural network, has been shown to learn better value functions than linear approximators (Narasimhan et al., 2015; He et al., 2015) and can capture non-linear interactions between the different pieces of information in our state.

We use a DQN consisting of two linear layers (20 hidden units each) followed by rectified linear units (ReLU), along with two separate output layers.[7] The network takes the continuous state vector s as input and predicts $Q(s, d)$ and $Q(s, q)$ for reconciliation decisions d and query choices q simultaneously using the different output layers (see Supplementary material for the model architecture).

Parameter Learning The parameters θ of the DQN are learnt using stochastic gradient descent with RMSprop (Tieleman and Hinton, 2012). Each parameter update aims to close the gap between the $Q(s_t, a_t; \theta)$ predicted by the DQN and the expected Q-value from the Bellman equation, $r_t + \gamma \max_a Q(s_{t+1}, a; \theta)$. Following Mnih et al. (2015), we make use of a (separate) target Q-network to calculate the expected Q-value, in order

[7] We did not observe significant differences with additional linear layers or the choice of non-linearity (Sigmoid/ReLU).

Algorithm 2 Training Procedure for DQN agent with ϵ-greedy exploration

Initialize experience memory $\mathcal{D}$
Initialize parameters θ randomly
for $episode = 1, M$ **do**
  Initialize environment and get start state s_1
  for $t = 1, N$ **do**
    if $random() < \epsilon$ **then**
      Select a random action a_t
    else
      Compute $Q(s_t, a)$ for all actions a
      Select $a_t = \text{argmax}\ Q(s_t, a)$
    Execute action a_t and observe reward r_t and new state s_{t+1}
    Store transition (s_t, a_t, r_t, s_{t+1}) in $\mathcal{D}$
    Sample random mini batch of transitions (s_j, a_j, r_j, s_{j+1}) from $\mathcal{D}$
    $y_j = \begin{cases} r_j, & \text{if } s_{j+1} \text{ is terminal} \\ r_j + \gamma \max_{a'} Q(s_{j+1}, a'; \theta_t), & \text{else} \end{cases}$
    Perform gradient descent step on the loss $\mathcal{L}(\theta) = (y_j - Q(s_j, a_j; \theta))^2$
    if $s_{t+1} == s_{end}$ **then break**

to have 'stable updates'. The target Q-network is periodically updated with the current parameters θ. We also make use of an experience replay memory $\mathcal{D}$ to store transitions. To perform updates, we sample a batch of transitions $(\hat{s}, \hat{a}, \hat{s}', r)$ at random from $\mathcal{D}$ and minimize the loss function[8]:

$$\mathcal{L}(\theta) = \mathrm{E}_{\hat{s},\hat{a}}[(y - Q(\hat{s}, \hat{a}; \theta))^2]$$

where $y = r + \gamma \max_{a'} Q(\hat{s}', a'; \theta_t)$ is the target Q-value. The learning updates are made every training step using the following gradients:

$$\nabla_\theta \mathcal{L}(\theta) = \mathrm{E}_{\hat{s},\hat{a}}[2(y - Q(\hat{s}, \hat{a}; \theta)) \nabla_\theta Q(\hat{s}, \hat{a}; \theta)]$$

Algorithm 2 details the DQN training procedure.

5 Experimental Setup

Data We perform experiments on two different datasets. For the first set, we collected data from the Gun Violence archive,[9] a website tracking shootings in the United States. The data contains a news article on each shooting and annotations for (1) the name of the shooter, (2) the number of people killed, (3) the number of people wounded, and (4) the city where the incident took place. We consider these as the entities of interest, to be extracted from the articles. The second dataset we use is the Foodshield EMA database[10] documenting adulteration incidents since 1980. This data contains annotations for (1) the affected food product, (2) the adulterant and (3) the location of the incident. Both datasets are classic examples where the number of recorded incidents is insufficient for large-scale IE systems to leverage.

Number	Shootings			Adulteration		
	Train	**Test**	**Dev**	**Train**	**Test**	**Dev**
Source articles	306	292	66	292	148	42
Downloaded articles	8201	7904	1628	7686	5333	1537

Table 2: Stats for *Shootings* and *Adulteration* datasets

For each source article in the above databases, we download extra articles (top 20 links) using the Bing Search API[11] with different automatically generated queries. We use only the source articles from the *train* portion to learn the parameters of the base extractor. The entire *train* set with downloaded articles is used to train the DQN agent and the meta-classifier baseline (described below). All parameters are tuned on the *dev* set. For the final results, we train the models on the combined train and dev sets and use the entire *test* set (source + downloaded articles) to evaluate. Table 2 provides data statistics.

Extraction model We use a maximum entropy classifier as the base extraction system, since it provides flexibility to capture various local context features and has been shown to perform well for information extraction (Chieu and Ng, 2002). The classifier is used to tag each word in a document as one of the entity types or not (e.g. {*ShooterName, NumKilled, NumWounded, City, Other*} in the *Shootings* domain). Then, for each tag except *Other*, we choose the mode of the values to obtain the set of entity extractions from the article.[12] Features used in the classifier are provided in the Supplementary material.

The features and context window $c = 4$ of neighboring words are tuned to maximize performance on a dev set. We also experimented with a conditional random field (CRF) (with the same features) for the sequence tagging (Culotta and McCallum, 2004)

[8] The expectation is over the transitions sampled uniformly at random from $\mathcal{D}$.

[10] www.foodshield.org/member/login/

[11] www.bing.com/toolbox/bingsearchapi

[12] We normalize numerical words (e.g. "one" to "1") before taking the mode.

but obtained worse empirical performance (see Section 6). The parameters of the base extraction model are not changed during training of the RL model.

Evaluation We evaluate the extracted entity values against the gold annotations and report the corpus-level average accuracy on each entity type. For entities like ShooterName, the annotations (and the news articles) often contain multiple names (first and last) in various combinations, so we consider retrieving either name as a successful extraction. For all other entities, we look for exact matches.

Baselines We explore 4 types of baselines:

Basic extractors: We use the CRF and the Maxent classifier mentioned previously.

Aggregation systems: We examine two systems that perform different types of value reconciliation. The first model (*Confidence*) chooses entity values with the highest confidence score assigned by the base extractor. The second system (*Majority*) takes a majority vote over all values extracted from these articles. Both methods filter new entity values using a threshold τ on the cosine similarity over the tf-idf representations of the source and new articles.

Meta-classifer: To demonstrate the importance of modeling the problem in the RL framework, we consider a meta-classifier baseline. The classifier operates over the same input state space and produces the same set of reconciliation decisions $\{d\}$ as the DQN. For training, we use the original source article for each event along with a related downloaded article to compute the state. If the downloaded article has the correct value and the original one does not, we label it as a positive example for that entity class. If multiple such entity classes exist, we create several training instances with appropriate labels, and if none exist, we use the label corresponding to the *reject all* action. For each *test* event, the classifier is used to provide decisions for all the downloaded articles and the final extraction is performed by aggregating the value predictions using the *Confidence*-based scheme described above.

Oracle: Finally, we also have an ORACLE score which is computed assuming perfect reconciliation and querying decisions on top of the Maxent base extractor. This helps us analyze the contribution of the RL system in isolation of the inherent limitations of the base extractor.

RL models We perform experiments using three variants of RL agents – (1) *RL-Basic*, which performs only reconciliation decisions[13], (2) *RL-Query*, which takes only query decisions with the reconciliation strategy fixed (similar to Kanani and McCallum (2012)), and (3) *RL-Extract*, our full system incorporating both reconciliation and query decisions.

We train the models for 10000 steps every epoch using the Maxent classifier as the base extractor, and evaluate on the entire *test* set every epoch. The final accuracies reported are averaged over 3 independent runs; each run's score is averaged over 20 epochs after 100 epochs of training. The penalty per step is set to -0.001. For the DQN, we use the dev set to tune all parameters. We used a replay memory $\mathcal{D}$ of size 500k, and a discount (γ) of 0.8. We set the learning rate to 2.5E^{-5}. The ϵ in ϵ-greedy exploration is annealed from 1 to 0.1 over 500k transitions. The target-Q network is updated every 5k steps.

6 Results

Performance Table 3 demonstrates that our system (RL-Extract) obtains a substantial gain in accuracy over the basic extractors on all entity types over both domains. For instance, RL-Extract is 11.4% more accurate than the basic Maxent extractor on City and 7.1% better on NumKilled, while also achieving gains of more than 5% on the other entities on the *Shootings* domain. The gains on the *Adulteration* dataset are also significant, up to a 11.5% increase on the Location entity.

We can also observe that simple aggregation schemes like the *Confidence* and *Majority* baselines don't handle the complexity of the task well. RL-Extract outperforms these by 7.2% on *Shootings* and 5% on *Adulteration* averaged over all entities. Further, the importance of sequential decision-making is established by RL-Extract performing significantly better than the meta-classifier (7.0% on *Shootings* over all entities). This is also due to the fact that the meta-classifier aggregates over the entire set of extra documents, including the long tail of noisy, irrelevant documents. Finally, we see the advantage of enabling the RL system to select queries as our full model RL-Extract obtains significant im-

[13] Articles are presented to the agent in a round-robin fashion from the different query lists.

System	Shootings				Adulteration		
	ShooterName	**NumKilled**	**NumWounded**	**City**	**Food**	**Adulterant**	**Location**
CRF extractor	9.5	65.4	64.5	47.9	41.2	28.3	51.7
Maxent extractor	45.2	69.7	68.6	53.7	56.0	52.7	67.8
Confidence Agg. (τ)	45.2 (0.6)	70.3 (0.6)	72.3 (0.6)	55.8 (0.6)	56.0 (0.8)	54.0 (0.8)	69.2 (0.6)
Majority Agg. (τ)	47.6 (0.6)	69.1 (0.9)	68.6 (0.9)	54.7 (0.7)	56.7 (0.5)	50.6 (0.95)	72.0 (0.4)
Meta-classifier	45.2	70.7	68.4	55.3	55.4	52.7	72.0
RL-Basic	45.2	71.2	70.1	54.0	57.0	55.1	76.1
RL-Query (conf)	39.6	66.6	69.4	44.4	39.4	35.9	66.4
RL-Extract	**50.0**	**77.6***	**74.6***	**65.6***	**59.6***	**58.9***	**79.3***
ORACLE	57.1	86.4	83.3	71.8	64.8	60.8	83.9

Table 3: Accuracy of various baselines (italics), our system (DQN) and the Oracle on *Shootings* and *Adulteration* datasets. **Agg.** refers to aggregation baselines. Bold indicates best system scores. *statistical significance of $p < 0.0005$ vs basic Maxent extractor using the Student-t test. Numbers in parentheses indicate the optimal threshold (τ) for the aggregation baselines. Confidence-based reconciliation was used for RL-Query.

Entity	System: Value	Example
ShooterName	**Basic**: Stewart	A source tells Channel 2 Action News that Thomas Lee has been arrested in Mississippi ... Sgt . Stewart Smith, with the Troup County Sheriff's office, said.
	RL-Extract: Lee	Lee is accused of killing his wife, Christie; ...
NumKilled	**Basic**: 0	Shooting leaves 25 year old Pittsfield man dead , 4 injured
	RL-Extract: 1	One man is dead after a shooting Saturday night at the intersection of Dewey Avenue and Linden Street.
NumWounded	**Basic**: 0	Three people are dead and a fourth is in the hospital after a murder suicide
	RL-Extract: 1	3 dead, 1 injured in possible Fla. murder-suicide
City	**Basic**: Englewood	A 2 year old girl and four other people were wounded in a shooting in West Englewood Thursday night, police said
	RL-Extract: Chicago	At least 14 people were shot across Chicago between noon and 10:30 p.m. Thursday. The last shooting left five people wounded.

Table 4: Sample outputs (along with corresponding article snippets) on the *Shootings* domain showing correct predictions from RL-Extract where the basic extractor (Maxent) fails.

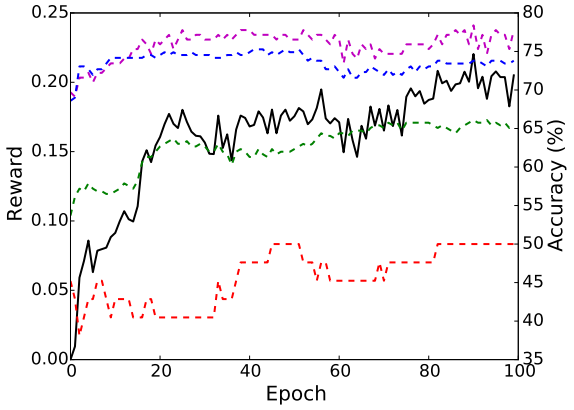

Figure 4: Evolution of average reward (solid black) and accuracy on various entities (dashed lines; red=*ShooterName*, magenta=*NumKilled*, blue=*NumWounded*, green=*City*) on the *test* set of the *Shootings* domain.

provements over RL-Basic on both domains. The full model also outperforms RL-Query, demonstrating the importance of performing both query selection and reconciliation in a joint fashion.

Figure 4 shows the learning curve of the agent by measuring reward on the test set after each training epoch. The reward improves gradually and the accuracy on each entity increases simultaneously. Table 4 provides some examples where our model is able to extract the right values when the baseline fails. One can see that in most cases this is due to the model making use of articles with prototypical language or articles containing the entities in readily extractable form.

Analysis We also analyze the importance of different reconciliation schemes, rewards and context-vectors in RL-Extract on the Shootings domain (Table 5). In addition to simple replacement (Re-

Reconciliation (RL-Extract)	Context	Reward	Accuracy				Steps
			S	K	W	C	
Confidence	tf-idf	Step	47.5	71.5	70.4	60.1	8.4
Majority	tf-idf	Step	43.6	71.8	69.0	59.2	9.9
Replace	*No context*	Step	44.4	77.1	72.5	63.4	8.0
Replace	*Unigram*	Step	48.9	76.8	74.0	63.2	10.0
Replace	tf-idf	*Episode*	42.6	62.3	68.9	52.7	6.8
Replace	tf-idf	Step	**50.0**	**77.6**	**74.6**	**65.6**	9.4

Table 5: Effect of using different reconciliation schemes, context-vectors, and rewards in our RL framework (*Shootings* domain). The last row is the overall best scheme (deviations from this are in *italics*). Context refers to the type of word counts used in the state vector to represent entity context. Rewards are either per step or per episode. (**S**: ShooterName, **K**: NumKilled, **W**: NumWounded, **C**: City, **Steps**: Average number of steps per episode)

place), we also experiment with using Confidence and Majority-based reconciliation schemes for RL-Extract. We observe that the Replace scheme performs much better than the others (2-6% on all entities) and believe this is because it provides the agent with more flexibility in choosing the final values.

From the same table, we see that using the tf-idf counts of context words as part of the state provides better performance than using no context or using simple unigram counts. In terms of reward structure, providing rewards after each step is empirically found to be significantly better (>10% on average) compared to a single delayed reward per episode. The last column shows the average number of steps per episode – the values range from 6.8 to 10.0 steps for the different schemes. The best system (RL-Extract with Replace, tf-idf and step-based rewards) uses 9.4 steps per episode.

7 Conclusions

In this paper, we explore the task of acquiring and incorporating external evidence to improve information extraction accuracy for domains with limited access to training data. This process comprises issuing search queries, extraction from new sources and reconciliation of extracted values, repeated until sufficient evidence is obtained. We use a reinforcement learning framework and learn optimal action sequences to maximize extraction accuracy while penalizing extra effort. We show that our model, trained as a deep Q-network, outperforms traditional extractors by 7.2% and 5% on average on two different domains, respectively. We also demonstrate the importance of sequential decision-making by comparing our model to a meta-classifier operating on the same space, obtaining up to a 7% gain.

Global Neural CCG Parsing with Optimality Guarantees

Kenton Lee **Mike Lewis** **Luke Zettlemoyer**

Abstract

We introduce the first global recursive neural parsing model with optimality guarantees during decoding. To support global features, we give up dynamic programs and instead search directly in the space of all possible subtrees. Although this space is exponentially large in the sentence length, we show it is possible to learn an efficient A* parser. We augment existing parsing models, which have informative bounds on the outside score, with a global model that has loose bounds but only needs to model non-local phenomena. The global model is trained with a novel objective that encourages the parser to search both efficiently and accurately. The approach is applied to CCG parsing, improving state-of-the-art accuracy by 0.4 F1. The parser finds the optimal parse for 99.9% of held-out sentences, exploring on average only 190 subtrees.

1 Introduction

Recursive neural models perform well for many structured prediction problems, in part due to their ability to learn representations that depend globally on all parts of the output structures. However, global models of this sort are incompatible with existing exact inference algorithms, since they do not decompose over substructures in a way that allows effective dynamic programming. Existing work has therefore used greedy inference techniques such as beam search (Vinyals et al., 2015; Dyer et al., 2015) or reranking (Socher et al., 2013). We introduce the first global recursive neural parsing approach with optimality guarantees for decoding and use it to build a state-of-the-art CCG parser.

To enable learning of global representations, we modify the parser to search directly in the space of all possible parse trees with no dynamic programming. Optimality guarantees come from A* search, which provides a certificate of optimality if run to completion with a heuristic that is a bound on the future cost. Generalizing A* to global models is challenging; these models also break the locality assumptions used to efficiently compute existing A* heuristics (Klein and Manning, 2003; Lewis and Steedman, 2014). Rather than directly replacing local models, we show that they can simply be augmented by adding a score from a global model that is constrained to be non-positive and has a trivial upper bound of zero. The global model, in effect, only needs to model the remaining non-local phenomena. In our experiments, we use a recent factored A* CCG parser (Lewis et al., 2016) for the local model, and we train a Tree-LSTM (Tai et al., 2015) to model global structure.

Finding a model that achieves these A* guarantees in practice is a challenging learning problem. Traditional structured prediction objectives focus on ensuring that the gold parse has the highest score (Collins, 2002; Huang et al., 2012). This condition is insufficient in our case, since it does not guarantee that the search will terminate in subexponential time. We instead introduce a new objective that optimizes efficiency as well as accuracy. Our loss function is defined over states of the A* search agenda, and it penalizes the model whenever the top agenda item is not a part of the gold parse.

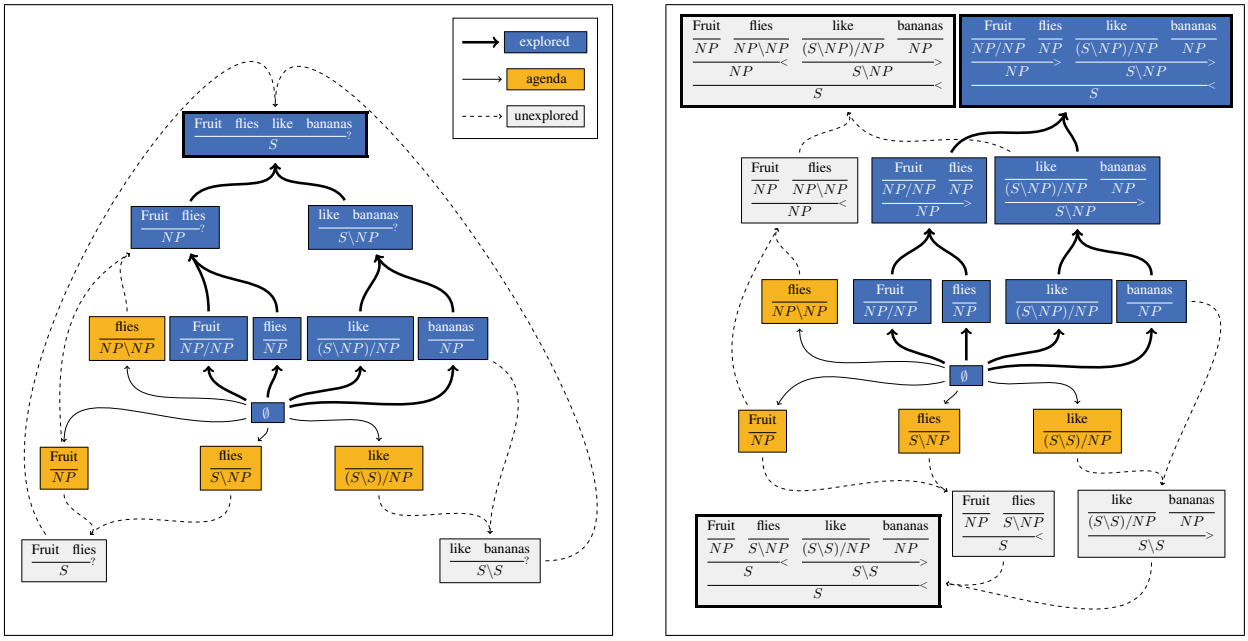
Austin, Texas, November 1-5, 2016.



(a) The search space in chart parsing, with one node for each labeling of a span.

(b) The search space in this work, with one node for each partial parse.

Figure 1: Illustrations of CCG parsing as hypergraph search, showing partial views of the search space. Weighted hyperedges from child nodes to a parent node represent rule productions scored by a parsing model. A path starting at ∅, for example the set of bolded hyperedges, represents the derivation of a parse. During decoding, we find the highest scoring path to a complete parse. Both figures show an ideal exploration that efficiently finds the optimal path. Figure 1a depicts the traditional search space, and Figure 1b depicts the search space in this work. Hyperedge scores can only depend on neighboring nodes, so our model can condition on the entire parse structure, at the price of an exponentially larger search space.

Minimizing this loss encourages the model to return the correct parse as quickly as possible.

The combination of global representations and optimal decoding enables our parser to achieve state-of-the-art accuracy for Combinatory Categorial Grammar (CCG) parsing. Despite being intractable in the worst case, the parser in practice is highly efficient. It finds optimal parses for 99.9% of held out sentences while exploring just 190 subtrees on average—allowing it to outperform beam search in both speed and accuracy.

2 Overview

Parsing as hypergraph search Many parsing algorithms can be viewed as a search problem, where parses are specified by paths through a hypergraph.

A node y in this hypergraph is a labeled span, representing structures within a parse tree, as shown in Figure 1. Each hyperedge e in the hypergraph represents a rule production in a parse. The head node of the hyperedge HEAD(e) is the parent of the rule production, and the tail nodes of the hyperedge are the children of the rule production. For example, consider the hyperedge in Figure 1b whose head is *like bananas*. This hyperedge represents a forward application rule applied to its tails, *like* and *bananas*.

To define a path in the hypergraph, we first include a special start node ∅ that represents an empty parse. ∅ has outgoing hyperedges that reach every leaf node, representing assignments of labels to words (supertag assignments in Figure 1). We then define a path to be a set of hyperedges E starting at ∅ and ending at a single destination node. A path therefore specifies the derivation of the parse constructed from the labeled spans at each node. For example, in Figure 1, the set of bolded hyperedges form a path deriving a complete parse.

Each hyperedge e is weighted by a score $s(e)$ from a parsing model. The score of a path E is the

sum of its hyperedge scores:

$$g(E) = \sum_{e \in E} s(e)$$

Viterbi decoding is equivalent to finding the highest scoring path that forms a complete parse.

Search on parse forests Traditionally, the hypergraph represents a packed parse chart. In this work, our hypergraph instead represents a *forest* of parses. Figure 1 contrasts the two representations.

In the parse chart, labels on the nodes represent local properties of a parse, such as the category of a span in Figure 1a. As a result, multiple parses that contain the same property include the same node in their path, (e.g. the node spanning the phrase *Fruit flies* with category NP). The number of nodes in this hypergraph is polynomial in the sentence length, permitting exhaustive exploration (e.g. CKY parsing). However, the model scores can only depend on local properties of a parse. We refer to these models as *locally factored* models.

In contrast, nodes in the parse forest are labeled with entire subtrees, as shown in Figure 1b. For example, there are two nodes spanning the phrase *Fruit flies* with the same category NP but different internal substructures. While the parse forest requires an exponential number of nodes in the hypergraph, the model scores can depend on entire subtrees.

A* parsing A* parsing has been successfully applied in locally factored models (Klein and Manning, 2003; Lewis and Steedman, 2014; Lewis et al., 2015; Lewis et al., 2016). We present a special case of A* parsing that is conceptually simpler, since the parse forest constrains each node to be reachable via a unique path. During exploration, we maintain the unique (and therefore highest scoring) path to a hyperedge e, which we define as $\text{PATH}(e)$.

Similar to the standard A* search algorithm, we maintain an agenda $\mathcal{A}$ of hyperedges to explore and a forest $\mathcal{F}$ of explored nodes that initially contains only the start node $\emptyset$.

Each hyperedge e in the agenda is sorted by the sum of its inside score $g(\text{PATH}(e))$ and an admissible heuristic $h(e)$. A heuristic $h(e)$ is admissible if it is an upper bound of the sum of hyperedge scores leading to any complete parse reachable from e (the Viterbi outside score). The efficiency of the search improves when this bound is tighter.

At every step, the parser removes the top of the agenda, $e_{max} = \text{argmax}_{e \in \mathcal{A}}(g(\text{PATH}(e)) + h(e))$. e_{max} is expanded by combining $\text{HEAD}(e_{max})$ with previously explored parses from $\mathcal{F}$ to form new hyperedges. These new hyperedges are inserted into $\mathcal{A}$, and $\text{HEAD}(e_{max})$ is added it to $\mathcal{F}$. We repeat these steps until the first complete parse y^* is explored. The bounds provided by $h(e)$ guarantee that the path to y^* has the highest possible score. Figure 1b shows an example of the agenda and the explored forest at the end of perfectly efficient search, where only the optimal path is explored.

Approach The enormous search space described above presents a challenge for an A* parser, since computing a tight and admissible heuristic is difficult when the model does not decompose locally.

Our key insight in addressing this challenge is that existing locally factored models with an informative A* heuristic can be augmented with a global score (Section 3). By constraining the global score to be non-positive, the A* heuristic from the locally factored model is still admissible.

While the heuristic from the local model offers some estimate of the future cost, the efficiency of the parser requires learning a well-calibrated global score, since the heuristic becomes looser as the global score provides stronger penalties (Section 5).

As we explore the search graph, we incrementally construct a neural network, which computes representations of the parses and allows backpropagation of errors from bad search steps (Section 4).

In the following sections, we present our approach in detail, assuming an existing locally factored model $s_{local}(e)$ for which we can efficiently compute an admissible A* heuristic $h(e)$.

In the experiments, we apply our model to CCG parsing, using the locally factored model and A* heuristic from Lewis et al. (2016).

3 Model

Our model scores a hyperedge e by combining the score from the local model with a global score that conditions on the entire parse at the head node:

$$s(e) = s_{local}(e) + s_{global}(e)$$

In $s_{global}(e)$, we first compute a hidden representation encoding the parse structure of $y = \text{HEAD}(e)$. We use a variant of the Tree-LSTM (Tai et al., 2015) connected to a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) at the leaves. The combination of linear and tree LSTMs allows the hidden representation of partial parses to condition on both the partial structure and the full sentence. Figure 2 depicts the neural network that computes the hidden representation for a parse.

Formally, given a sentence $\langle w_1, w_2, \ldots, w_n \rangle$, we compute hidden states h_t and cell states c_t in the forward LSTM for $1 < t \leq n$:

$$\begin{aligned} i_t &= \sigma(W_i[c_{t-1}, h_{t-1}, x_t] + b_i) \\ o_t &= \sigma(W_o[\tilde{c}_t, h_{t-1}, x_t] + b_o) \\ \tilde{c}_t &= \tanh(W_c[h_{t-1}, x_t] + b_c) \\ c_t &= i_t \circ \tilde{c}_t + (\mathbf{1} - i_t) \circ c_{t-1} \\ h_t &= o_t \circ \tanh(c_t) \end{aligned}$$

where σ is the logistic sigmoid, $\circ$ is the componentwise product, and x_t denotes a learned word embedding for w_t. We also construct a backward LSTM, which produces the analogous hidden and cell states starting at the end of the sentence, which we denote as c'_t and h'_t respectively. The start and end latent states, c_{-1}, h_{-1}, c'_{n+1}, and h'_{n+1}, are learned embeddings. This variant of the LSTM includes peephole connections and couples the input and forget gates.

The bidirectional LSTM over the words serves as a base case when we recursively compute a hidden representation for the parse y using the tree-structured generalization of the LSTM:

$$\begin{aligned} i_y &= \sigma(W_i^R[c_l, h_l, c_r, h_r, x_y] + b_i^R) \\ f_y &= \sigma(W_f^R[c_l, h_l, c_r, h_r, x_y] + b_f^R) \\ o_y &= \sigma(W_o^R[\widetilde{c}_y, h_l, h_r, x_y] + b_o^R) \\ c_{lr} &= f_y \circ c_l + (\mathbf{1} - f_y) \circ c_r \\ \widetilde{c}_y &= \tanh(W_c^R[h_l, h_r, x_y] + b_c^R) \\ c_y &= i_y \circ \widetilde{c}_y + (\mathbf{1} - i_y) \circ c_{lr} \\ h_y &= o_y \circ \tanh(c_y) \end{aligned}$$

where the weights and biases are parametrized by the rule R that produces y from its children, and x_y denotes a learned embedding for the category at the root of y. For example, in CCG, the rule would correspond to the CCG combinator, and the label would correspond to the CCG category.

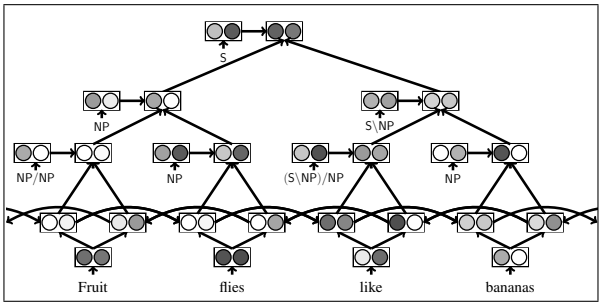


Figure 2: Visualization of the Tree-LSTM which computes vector embeddings for each parse node. The leaves of the Tree-LSTM are connected to a bidirectional LSTM over words, encoding lexical information within and outside of the parse.

We assume that nodes are binary, unary, or leaves. Their left and right latent states, c_l, h_l, c_r, and h_r are defined as follows:

- In a binary node, c_l and h_l are the cell and hidden states of the left child, and c_r and h_r are the cell and hidden states of the right child.
- In a unary node, c_l and h_l are learned embeddings, and c_r and h_r are the cell and hidden states of the singleton child.
- In a leaf node, let w denote the index of the corresponding word. Then c_l and h_l are c_w and h_w from the forward LSTM, and c_r and h_r are c'_w and h'_w from the backward LSTM.

The cell state of the recursive unit is a linear combination of the intermediate cell state $\widetilde{c}_y$, the left cell state c_l, and the right cell state c_r. To preserve the normalizing property of coupled gates, we perform coupling in a hierarchical manner: the input gate i_y decides the weights for $\widetilde{c}_y$, and the forget gate f_y shares the remaining weights between c_l and c_r.

Given the hidden representation h_y at the root, we score the global component as follows:

$$s_{global}(e) = \log(\sigma(W \cdot h_y))$$

This definition of the global score ensures that it is non-positive—an important property for inference.

4 Inference

Using the hyperedge scoring model $s(e)$ described in Section 3, we can find the highest scoring path that derives a complete parse tree by using the A* parsing algorithm described in Section 2.

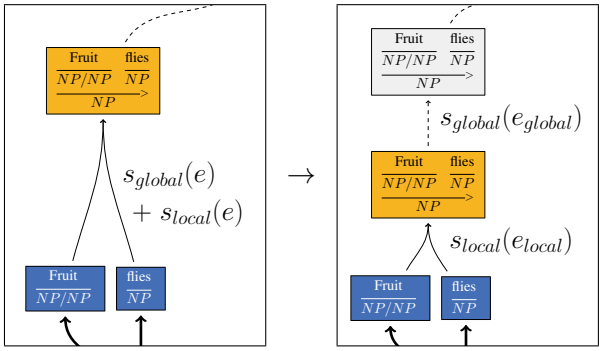

Figure 3: The hyperedge on the left requires computing both the local and global score when placed on the agenda. Splitting the hyperedge, as shown on the right, saves expensive computation of the global score if the local score alone indicates that the parse is not worth exploring.

Admissible A* heuristic Since our full model adds non-positive global scores to the existing local scores, path scores under the full model cannot be greater than path scores under the local model. Upper bounds for path scores under the local model also hold for path scores under the full model, and we simply reuse the A* heuristic from the local model to guide the full model during parsing without sacrificing optimality guarantees.

Incremental neural network construction The recursive hidden representations used in $s_{global}(e)$ can be computed in constant time during parsing. When scoring a new hyperedge, its children must have been previously scored. Instead of computing the full recursion, we reuse the existing latent states of the children and compute $s_{global}(e)$ with an incremental forward pass over a single recursive unit in the neural network. By maintain the latent states of each parse, we incrementally build a single DAG-structured LSTM mirroring the explored subset of the hypergraph. This not only enables quick forward passes during decoding, but also allows back-propagation through the search space after decoding, which is crucial for efficient learning (see Section 5).

Lazy global scoring The global score is expensive to compute. We introduce an optimization to avoid computing it when provably unnecessary. We split each hyperedge e into two successive hyperedges, e_{local} and e_{global}, as shown in Figure 3. The score for e, previously $s(e) = s_{local}(e) + s_{global}(e)$, is also split between the two new hyperedges:

$$s(e_{local}) = s_{local}(e_{local})$$
$$s(e_{global}) = s_{global}(e_{global})$$

Intuitively, this transformation requires A* to verify that the local score is good enough before computing the global score, which requires an incremental forward pass over a recursive unit in the neural network. In the example, this involves first summing the supertag scores of *Fruit* and *flies* and inserting the result back into the agenda. The score for applying the forward application rule to the recursive representations is only computed if that item appears again at the head of the agenda. In practice, the lazy global scoring reduces the number of recursive units by over 91%, providing a 2.4X speed up.

5 Learning

During training (Algorithm 1), we assume access to sentences labeled with gold parse trees $\hat{y}$ and gold derivations $\hat{E}$. The gold derivation $\hat{E}$ is a path from $\emptyset$ to $\hat{y}$ in the parse forest.

A* search with our global model is not guaranteed to terminate in sub-exponential time. This creates challenges for learning—for example, it is not possible in practice to use the standard structured perceptron update (Collins, 2002), because the search procedure rarely terminates early in training. Other common loss functions assume inexact search (Huang et al., 2012), and do not optimize efficiency.

Instead, we optimize a new objective that is tightly coupled with the search procedure. During parsing, we would like hyperedges from the gold derivation to appear at the top of the agenda $\mathcal{A}$. When this condition does not hold, A* is searching inefficiently, and we refer to this as a *violation* of the agenda, which we formally define as:

$$v(\hat{E}, \mathcal{A}) = \max_{e \in \mathcal{A}} (g(\text{PATH}(e)) + h(e)) - \max_{e \in \mathcal{A} \cap \hat{E}} (g(\text{PATH}(e)) + h(e))$$

where $g(\text{PATH}(e))$ is the score of the unique path to e, and $h(e)$ is the A* heuristic. If all violations are zero, we find the gold parse without exploring any incorrect partial parses—maximizing both accuracy and efficiency. Figure 1b shows such a case—if any other nodes were explored, they would be violations.

Update	Loss($\mathcal{V}$)
Greedy	$\mathcal{V}_1$
Max violation	$\max_{t=1}^{T} \mathcal{V}_t$
All violations	$\sum_{t=1}^{T} \mathcal{V}_t$

Table 1: Loss functions optimized by the different update methods. The updates depend on the list of T non-zero violations, $\mathcal{V} = \langle \mathcal{V}_1, \mathcal{V}_2, \ldots, \mathcal{V}_T \rangle$, as defined in Section 5.

In existing work on violation-based updates, comparisons are only made between derivations with the same number of steps (Huang et al., 2012; Clark et al., 2015)—whereas our definition allows subtrees of arbitrary spans to compete with each other, because hyperedges are not explored in a fixed order. Our violations also differ from Huang et al.'s in that we optimize efficiency as well as accuracy.

We define loss functions over these violations, which are minimized to encourage correct and efficient search. During training, we parse each sentence until either the gold parse is found or we reach computation limits. We record $\mathcal{V}$, the list of non-zero violations of the agenda $\mathcal{A}$ observed:

$$\mathcal{V} = \langle v(\hat{E}, \mathcal{A}) \mid v(\hat{E}, \mathcal{A}) > 0 \rangle$$

We can optimize several loss functions over $\mathcal{V}$, as defined in Table 1. The greedy and max-violation updates are roughly analogous to the violation-fixing updates proposed by Huang et al. (2012), but adapted to exact agenda-based parsing. We also introduce a new *all-violations* update, which minimizes the sum of all observed violations. The all-violations update encourages correct parses to be explored early (similar to the greedy update) while being robust to parses with multiple deviations from the gold parse (similar to the max-violation update).

The violation losses are optimized with subgradient descent and backpropagation. For our experiments, $s_{local}(e)$ and $h(e)$ are kept constant. Only the parameters θ of $s_{global}(e)$ are updated. Therefore, a subgradient of a violation $v(\hat{E}, \mathcal{A})$ can be computed by summing subgradients of the global scores.

$$\frac{\partial v(\hat{E}, \mathcal{A})}{\partial \theta} = \sum_{e \in \text{PATH}(e_{max})} \frac{\partial s_{global}(e)}{\partial \theta} - \sum_{e \in \text{PATH}(\hat{e}_{max})} \frac{\partial s_{global}(e)}{\partial \theta}$$

where e_{max} denotes the hyperedge at the top of the agenda $\mathcal{A}$ and $\hat{e}_{max}$ denotes the hyperedge in the gold derivation $\hat{E}$ that is closest to the top of $\mathcal{A}$.

Algorithm 1 Violation-based learning algorithm

Definitions D is the training data containing input sentences x and gold derivations $\hat{E}$. e variables denote scored hyperedges. TAG(x) returns a set of scored pre-terminals for every word. ADD($\mathcal{F}$, y) adds partial parse y to forest $\mathcal{F}$. RULES($\mathcal{F}$, y) returns the set of scored hyperedges that can be created by combining y with entries in F. SIZE_OK($\mathcal{F}$, $\mathcal{A}$) returns whether the sizes of the forest and agenda are within predefined limits.

```

    return θ
```

6 Experiments

6.1 Data

We trained our parser on Sections 02-21 of CCGbank (Hockenmaier and Steedman, 2007), using Section 00 for development and Section 23 for test. To recover a single gold derivation for each sentence to use during training, we find the right-most branching parse that satisfies the gold dependencies.

6.2 Experimental Setup

For the local model, we use the *supertag-factored* model of Lewis et al. (2016). Here, $s_{local}(e)$ corresponds to a supertag score if a HEAD(e) is a leaf and zero otherwise. The outside score heuristic is computed by summing the maximum supertag score for every word outside of each span. In the reported results, we back off to the supertag-factored model after the forest size exceeds 500,000, the agenda size exceeds 2 million, or we build more than 200,000 recursive units in the neural network.

Model	Dev F1	Test F1
C & C	83.8	85.2
C & C + RNN	86.3	87.0
Xu (2016)	87.5	87.8
Vaswani et al. (2016)	87.8	88.3
Supertag-factored	87.5	88.1
Global A*	**88.4**	**88.7**

Table 2: Labeled F1 for CCGbank dependencies on the CCGbank development and test set for our system **Global A*** and the baselines.

Model	Dev F1	Optimal	Explored
Supertag-factored	87.5	100.0%	402.5
− dynamic program	87.5	97.1%	17119.6
Span-factored	87.9	99.9%	176.5
− dynamic program	87.8	99.5%	578.5
Global A*	**88.4**	99.8%	309.6
− lexical inputs	87.8	99.6%	538.5
− lexical context	88.1	99.4%	610.5

Table 3: Ablations of our full model (**Global A***) on the development set. *Explored* refers to the size of the parse forest. Results show the importance of global features and lexical information in context.

Our full system is trained with all-violations updates. During training, we lower the forest size limit to 2000 to reduce training times. The model is trained for 30 epochs using ADAM (Kingma and Ba, 2014), and we use early stopping based on development F1. The LSTM cells and hidden states have 64 dimensions. We initialize word representations with pre-trained 50-dimensional embeddings from Turian et al. (2010). Embeddings for categories have 16 dimensions and are randomly initialized. We also apply dropout with a probability of 0.4 at the word embedding layer during training. Since the structure of the neural network is dynamically determined, we do not use mini-batches. The neural networks are implemented using the CNN library,[1] and the CCG parser is implemented using the EasySRL library.[2] The code is available online.[3]

6.3 Baselines

We compare our parser to several baseline CCG parsers: the C&C parser (Clark and Curran, 2007); C&C + RNN (Xu et al., 2015), which is the C&C parser with an RNN supertagger; Xu (2016), a LSTM shift-reduce parser; Vaswani et al. (2016) who combine a bidirectional LSTM supertagger with a beam search parser using global features (Clark et al., 2015); and *supertag-factored* (Lewis et al., 2016), which uses deterministic A* decoding and an LSTM supertagging model.

6.4 Parsing Results

Table 2 shows parsing results on the test set. Our global features let us improve over the supertag-factored model by 0.6 F1. Vaswani et al. (2016) also use global features, but our optimal decoding leads to an improvement of 0.4 F1.

Although we observed an overall improvement in parsing performance, the supertag accuracy was not significantly different after applying the parser.

On the test data, the parser finds the optimal parse for 99.9% sentences before reaching our computational limits. On average, we parse 27.1 sentences per second,[4] while exploring only 190.2 subtrees.

6.5 Model Ablations

We ablate various parts of the model to determine how they contribute to the accuracy and efficiency of the parser, as shown in Table 3. For each model, the comparisons include the average number of parses explored and the percentage of sentences for which an optimal parse can be found without backing off.

Structure ablation We first ablate the global score, $s_{global}(y)$, from our model, thus relying entirely on the local supertag-factors that do not explicitly model the parse structure. This ablation allows dynamic programming and is equivalent to the backoff model (*supertag-factored* in Table 3). Surprisingly, even in the exponentially larger search space, the global model explores *fewer* nodes than the supertag-factored model—showing that the global model efficiently prune large parts of the search space. This effect is even larger when not using dynamic programming in the supertag-factored model.

Global structure ablation To examine the importance of global features, we ablate the recursive hidden representation (*span-factored* in Table 3). The model in this ablation decomposes over labels for

[1] https://github.com/clab/cnn

[2] https://github.com/mikelewis0/EasySRL

[3] https://github.com/kentonl/neuralccg

[4] We use a single 3.5GHz CPU core.

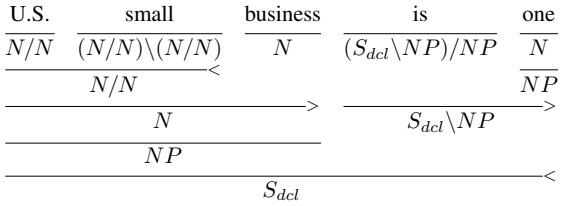

Figure 4: Example of an incorrect partial parse that appears syntactically plausible in isolation. The full sentence is *'Indeed, for many Japanese trading companies, the favorite **U.S. small business is one** whose research and development can be milked for future Japanese use.'* The global model heavily penalizes this garden path, thereby avoiding regions that lead to dead ends and allowing the global model to explore fewer nodes.

spans, as in Durrett and Klein (2015). In this model, the recursive unit uses, instead of latent states from its children, the latent states of the backward LSTM at the start of the span and the latent states of the forward LSTM at the end of the span. Therefore, this model encodes the lexical information available in the full model but does not encode the parse structure beyond the local rule production. While the dynamic program allows this model to find the optimal parse with fewer explorations, the lack of global features significantly hurts its parsing accuracy.

Lexical ablation We also show lexical ablations instead of structural ablations. We remove the bidirectional LSTM at the leaves, thus delexicalizing the global model. This ablation degrades both accuracy and efficiency, showing that the model uses lexical information to discriminate between parses.

To understand the importance of contextual information, we also perform a partial lexical ablation by using word embeddings at the leaves instead of the bidirectional LSTM, thus propagating only lexical information from within the span of each parse. The degradation in F1 is about half of the degradation from the full lexical ablation, suggesting that a significant portion of the lexical cues comes from the context of a parse. Figure 4 illustrates the importance of context with an incorrect partial parse that appears syntactically plausible in isolation. These bottom-up garden paths are typically problematic for parsers, since their incompatibility with the remaining sentence is difficult to recognize until later stages of decoding. However, our global model learns to heavily penalize these garden paths by using the context provided by the bidirectional LSTM and avoid paths that lead to dead ends or bad regions of the search space.

Update	Dev F1	Optimal	Explored
Greedy	87.9	99.2%	2313.8
Max-violation	88.1	99.9%	217.3
All-violations	**88.4**	99.8%	309.6

Table 4: Parsing results trained with different update methods. Our system uses **all-violations** updates and is the most accurate.

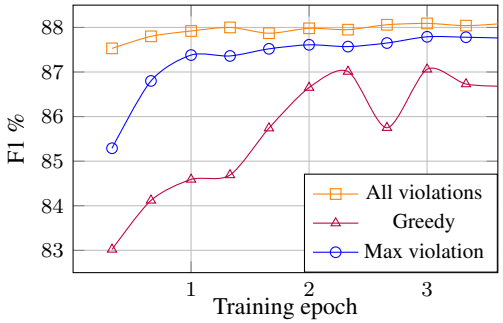

Figure 5: Learning curves for the first 3 training epochs on the development set when training with different updates strategies. The all-violations update shows the fastest convergence.

6.6 Update Comparisons

Table 4 compares the different violation-based learning objectives, as discussed in Section 5. Our novel *all-violation* updates outperform the alternatives. We attribute this improvement to the robustness over poor search spaces, which the greedy update lacks, and the incentive to explore good parses early, which the max-violation update lacks. Learning curves in Figure 5 show that the all-violations update also converges more quickly.

6.7 Decoder Comparisons

Lastly, to show that our parser is both more accurate and efficient than other decoding methods, we decode our full model using best-first search, reranking, and beam search. Table 5 shows the F1 scores with and without the backoff model, the portion of the sentences that each decoder is able to parse, and the time spent decoding relative to the A* parser.

In the best-first search comparison, we do not include the informative A* heuristic, and the parser completes very few parses before reaching computational limits—showing the importance of heuristics in large search spaces. In the reranking comparison,

Decoder	Dev F1	Dev F1 − backoff	Relative Time
Global A*	**88.4**	88.4 (99.8%)	1X
Best-first	87.5	2.8 (6.7%)	293.4X
10-best reranking	87.9	87.9 (99.7%)	8.5X
100-best reranking	88.2	88.0 (99.4%)	72.3X
2-best beam search	88.2	85.7 (94.0%)	2.0X
4-best beam search	88.3	88.1 (99.2%)	6.7X
8-best beam search	88.2	86.8 (98.1%)	26.3X

Table 5: Comparison of various decoders using the same model from our full system (**Global A***). We report F1 with and without the backoff model, the percentage of sentences that the decoder can parse, and the time spent decoding relative to A*.

we obtain n-best lists from the backoff model and rerank each result with the full model. In the beam search comparison, we use the approach from Clark et al. (2015) which greedily finds the top-n parses for each span in a bottom-up manner. Results indicate that both approximate methods are less accurate and slower than A*.

7 Related Work

Many structured prediction problems are based around dynamic programs, which are incompatible with recursive neural networks because of their real-valued latent variables. Some recent models have neural factors (Durrett and Klein, 2015), but these cannot condition on global parse structure, making them less expressive. Our search explores fewer nodes than dynamic programs, despite an exponentially larger search space, by allowing the recursive neural network to guide the search.

Previous work on structured prediction with recursive or recurrent neural models has used beam search–e.g. in shift reduce parsing (Dyer et al., 2015), string-to-tree transduction (Vinyals et al., 2015), or reranking (Socher et al., 2013)–at the cost of potentially recovering suboptimal solutions. For our model, beam search is both less efficient and less accurate than optimal A* decoding. In the non-neural setting, Zhang et al. (2014) showed that global features with greedy inference can improve dependency parsing. The CCG beam search parser of Clark et al. (2015), most related to this work, also uses global features. By using neural representations and exact search, we improve over their results.

A* parsing has been previously proposed for locally factored models (Klein and Manning, 2003; Pauls and Klein, 2009; Auli and Lopez, 2011; Lewis and Steedman, 2014). We generalize these methods to enable global features. Vaswani and Sagae (2016) apply best-first search to an unlabeled shift-reduce parser. Their use of error states is related to our global model that penalizes local scores. We demonstrated that best-first search is infeasible in our setting, due to the larger search space.

A close integration of learning and decoding has been shown to be beneficial for structured prediction. SEARN (Daumé III et al., 2009) and DAGGER (Ross et al., 2011) learn greedy policies to predict structure by sampling classification examples over actions from single states. We similarly generate classification examples over hyperedges in the agenda, but actions from multiple states compete against each other. Other learning objectives that update parameters based on a beam or agenda of partial structures have also been proposed (Collins and Roark, 2004; Daumé III and Marcu, 2005; Huang et al., 2012; Andor et al., 2016; Wiseman and Rush, 2016), but the impact of search errors is unclear.

8 Conclusion

We have shown for the first time that a parsing model with global features can be decoded with optimality guarantees. This enables the use of powerful recursive neural networks for parsing without resorting to approximate decoding methods. Experiments show that this approach is effective for CCG parsing, resulting in a new state-of-the-art parser. In future work, we will apply our approach to other structured prediction tasks, where neural networks—and greedy beam search—have become ubiquitous.

Abstract

Language documentation begins by gathering speech. Manual or automatic transcription at the word level is typically not possible because of the absence of an orthography or prior lexicon, and though manual phonemic transcription is possible, it is prohibitively slow. On the other hand, translations of the minority language into a major language are more easily acquired. We propose a method to harness such translations to improve automatic phoneme recognition. The method assumes no prior lexicon or translation model, instead learning them from phoneme lattices and translations of the speech being transcribed. Experiments demonstrate phoneme error rate improvements against two baselines and the model's ability to learn useful bilingual lexical entries.

1 Introduction

Most of the world's languages are dying out and have little recorded data or linguistic documentation (Austin and Sallabank, 2011). It is important to adequately document languages while they are alive so that they may be investigated in the future. Language documentation traditionally involves one-on-one elicitation of speech from native speakers in order to produce lexicons and grammars that describe the language. However, this does not scale: linguists must first transcribe the speech phonemically as most of these languages have no standardized orthography. This is a critical bottleneck since it takes a trained linguist about 1 hour to transcribe the phonemes of 1 minute of speech (Do et al., 2014).

Smartphone apps for rapid collection of bilingual data have been increasingly investigated (De Vries et al., 2011; De Vries et al., 2014; Reiman, 2010; Bird et al., 2014; Blachon et al., 2016). It is common for these apps to collect speech segments paired with spoken translations in another language, making spoken translations quicker to obtain than phonemic transcriptions.

We present a method to improve automatic phoneme transcription by harnessing such bilingual data to learn a lexicon and translation model directly from source phoneme lattices and their written target translations, assuming that the target side is a major language that can be efficiently transcribed.[1] A Bayesian non-parametric model expressed with a weighted finite-state transducer (WFST) framework represents the joint distribution of source acoustic features, phonemes and latent source words given the target words. Sampling of alignments is used to learn source words and their target translations, which are then used to improve transcription of the source audio they were learnt from. Importantly, the model assumes no prior lexicon or translation model.

This method builds on work on phoneme translation modeling (Besacier et al., 2006; Stüker et al., 2009; Stahlberg et al., 2012; Stahlberg et al., 2014; Adams et al., 2015; Duong et al., 2016), speech translation (Casacuberta et al., 2004; Matusov et al., 2005), computer-aided translation, (Brown et al., 1994; Vidal et al., 2006; Khadivi and Ney, 2008; Reddy and Rose, 2010; Pelemans et al., 2015), translation modeling from automatically transcribed

Austin, Texas, November 1-5, 2016.

speech (Paulik and Waibel, 2013), word segmentation and translation modeling (Chang et al., 2008; Dyer, 2009; Nguyen et al., 2010; Chen and Xu, 2015), Bayesian word alignment (Mermer et al., 2013; Zezhong et al., 2013) and language model learning from lattices (Neubig et al., 2012). While we previously explored learning a translation model from word lattices (Adams et al., 2016), in this paper we extend the model to perform unsupervised word segmentation over phoneme lattices in order to improve phoneme recognition.

Experiments demonstrate that our method significantly reduces the phoneme error rate (PER) of transcriptions compared with a baseline recogniser and a similar model that harnesses only monolingual information, by up to 17% and 5% respectively. We also find that the model learns meaningful bilingual lexical items.

2 Model description

Our model extends the standard automatic speech recognition (ASR) problem by seeking the best phoneme transcription $\hat{\boldsymbol{\phi}}$ of an utterance in a joint probability distribution that incorporates acoustic features $\boldsymbol{x}$, phonemes $\boldsymbol{\phi}$, latent source words $\boldsymbol{f}$ and observed target transcriptions $\boldsymbol{e}$:

$$\hat{\boldsymbol{\phi}} = \underset{\boldsymbol{\phi},\boldsymbol{f}}{\operatorname{argmax}} P(\boldsymbol{x}|\boldsymbol{\phi})P(\boldsymbol{\phi}|\boldsymbol{f})P(\boldsymbol{f}|\boldsymbol{e})\,, \qquad (1)$$

assuming a Markov chain of conditional independence relationships (bold symbols denote utterances as opposed to tokens). Deviating from standard ASR, we replace language model probabilities with those of a translation model, and search for phonemes instead of words. Also, no lexicon or translation model are given in training.

2.1 Expression of the distribution using finite-state transducers

We use a WFST framework to express the factors of (1) since it offers computational tractability and simple inference in a clear, modular framework. Figure 1 uses a toy German–English error resolution example to illustrate the components of the framework: a phoneme lattice representing phoneme uncertainty according to $P(\boldsymbol{x}|\boldsymbol{\phi})$; a lexicon that transduces phoneme substrings $\boldsymbol{\phi}_s$ of $\boldsymbol{\phi}$ to source tokens f according to $P(\boldsymbol{\phi}_s|f)$; and a lexical translation model representing $P(f|e)$ for each e in the written translation. The composition of these components is also shown at the bottom of Figure 1, illustrating how would-be transcription errors can be resolved. This framework is reminiscent of the WFST framework used by Neubig et al. (2012) for lexicon and language model learning from monolingual data.

2.2 Learning the lexicon and translation model

Because we do not have knowledge of the source language, we must learn the lexicon and translation model from the phoneme lattices and their written translation. We model lexical translation probabilities using a Dirichlet process. Let A be both the transcription of each source utterance $\mathbf{f}$ and its word alignments to the translation $\mathbf{e}$ that generated them. The conditional posterior can be expressed as:

$$P(f|e;A) = \frac{c_A(f,e) + \alpha P_0(f)}{c_A(e) + \alpha}\,, \qquad (2)$$

where $c_A(f,e)$ is a count of how many times f has aligned to e in A and $c_A(e)$ is a count of how many times e has been aligned to; P_0 is a base distribution that influences how phonemes are clustered; and α determines the emphasis on the base distribution.

In order to express the Dirichlet process using the WFST components, we take the union of the lexicon with a *spelling model* base distribution that consumes phonemes $\phi_i \ldots \phi_j$ and produces a special $\langle\text{unk}\rangle$ token with probability $P_0(\phi_i \ldots \phi_j)$. This $\langle\text{unk}\rangle$ token is consumed by a designated arc in the translation model WFST with probability $\frac{\alpha}{c_A(e)+\alpha}$, yielding a composed probability of $\frac{\alpha P_0(f)}{c_A(e)+\alpha}$. Other arcs in the translation model express the probability $\frac{c_A(f,e)}{c_A(e)+\alpha}$ of entries already in the lexicon. The sum of these two probabilities equates to (2).

As for the spelling model P_0, we consider three distributions and implement WFSTs to represent them: a geometric distribution, *Geometric(γ)*, a Poisson distribution, *Poisson(λ)*,[2] and a 'shifted' geometric distribution, *Shifted(α, γ)*. The shifted geometric distribution mitigates a shortcoming of the geometric distribution whereby words of length 1 have the highest probability. It does so by having

[2]While the geometric distribution can be expressed recursively, we cap the number of states in the Poisson WFST to 100.

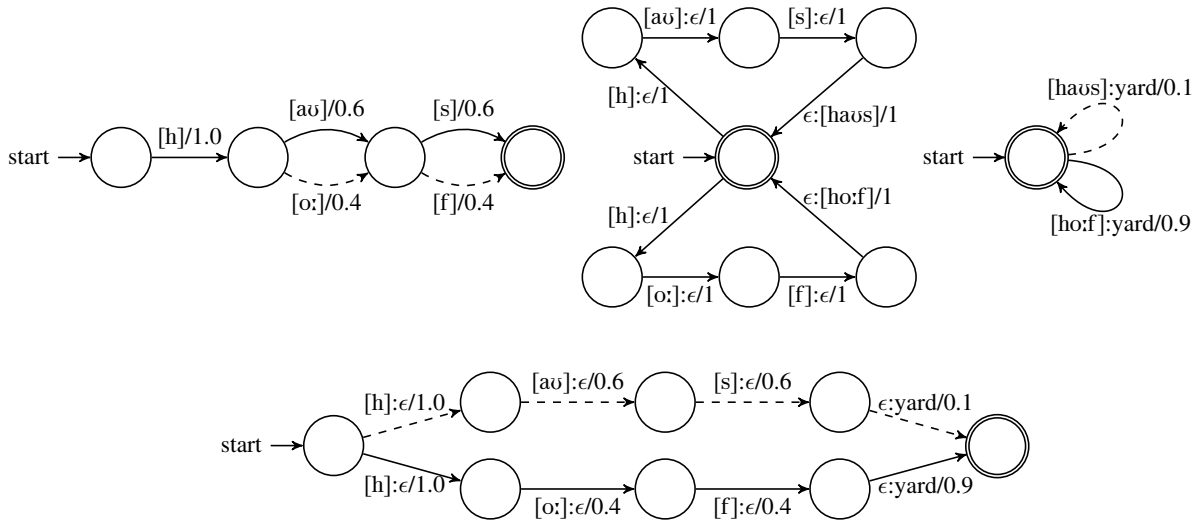

Figure 1: Top left to right: the phoneme lattice, the lexicon, and the translation model. Bottom: the resulting composed WFST. Given an English translation *'yard'*, the most likely transcription is corrected to [hoːf] (*'Hof'*) in the composed WFST, while in the original phoneme lattice it is [haʊs] (*'Haus'*). Solid edges represent most likely paths.

another parameter α that specifies the probability of a word of length 1, with the remaining probability mass distributed geometrically. All phonemes types are treated the same in these distributions, with uniform probability.

2.3 Inference

In order to determine the translation model parameters as described above, we require the alignments A. We sample these proportionally to their probability given the data and our prior, in effect integrating over all parameter configurations T:

$$P(A|\mathcal{X};\alpha,P_0) = \int_T P(A|\mathcal{X},T)P(T;\alpha,P_0)dT\,, \tag{3}$$

where $\mathcal{X}$ is our dataset of source phoneme lattices paired with target sentences.

This is achieved using blocked Gibbs sampling, with each utterance constituting one block. To sample from WFSTs, we use *forward-filtering/backward-sampling* (Scott, 2002; Neubig et al., 2012), creating forward probabilities using the forward algorithm for hidden Markov models before *backward-sampling* edges proportionally to the product of the forward probability and the edge weight.[3]

[3]No Metropolis-Hastings rejection step was used.

3 Experimental evaluation

We evaluate the lexicon and translation model by their ability to improve phoneme recognition, measuring phoneme error rate (PER).

3.1 Experimental setup

We used less than 10 hours of English–Japanese data from the BTEC corpus (Takezawa et al., 2002), comprised of spoken utterances paired with textual translations. This allows us to assess the approach assuming quality acoustic models. We used acoustic models similar to Heck et al. (2015) to obtain source phoneme lattices. Gold phoneme transcriptions were obtained by transforming the text with pronunciation lexicons and, in the Japanese case, first segmenting the text into tokens using KyTea (Neubig et al., 2011).

We run experiments in both directions: English–Japanese and Japanese–English (*en–ja* and *ja–en*), while comparing against three settings: the ASR 1-best path uninformed by the model (*ASR*); a monolingual version of our model that is identical except without conditioning on the target side (*Mono*); and the model applied using the source language sentence as the target (*Oracle*).

We tuned on the first 1,000 utterences (about 1 hour) of speech and trained on up to 9 hours of the

	English (en)			Japanese (ja)		
	Mono	–ja	Oracle	Mono	–en	Oracle
ASR		22.1			24.3	
Vague	17.7	18.5	17.2	21.5	20.8	21.6
Shifted	17.4	16.9	16.6	21.2	20.1	20.2
Poisson	17.3	17.2	16.8	21.3	20.1	20.8

Table 1: Phoneme error rates (percent) when training on 9 hours of speech, averaged over 4 runs.

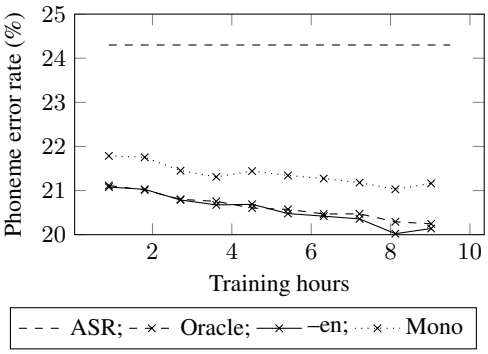

Figure 2: Japanese phoneme error rates using the *shifted* geometric prior when training data is scaled up from 1–9 hours, averaged over 3 runs.

remaining data.[4] Only the oracle setup was used for tuning, with Geometric(0.01) (taking the form of a *vague* prior), Shifted(10^{-5}, 0.25) and Poisson(7) performing best.

3.2 Results and Discussion

Table 1 shows en–ja and ja–en results for all methods with the full training data. Figure 2 shows improvements of ja–en over both the ASR baseline and the Mono method as the training data increases, with translation modeling gaining an increasing advantage with more training data.

Notably, English recognition gains less from using Japanese as the target side (en–ja) than the other way around, while the 'oracle' approach for Japanese recognition, which also uses Japanese as the target, underperforms ja–en. These observations suggest that using the Japanese target is less helpful, likely explained by the fine-grained morphological segmentation we used, making it harder for the model to relate source phonemes to target tokens.

The vague geometric prior significantly underperforms the other priors. In the en–ja/vague case, the model actually underperforms its monolingual counterpart. The vague prior biases slightly towards fine-grained English source segmentation, with words of length 1 most common. In this case, fine-grained Japanese is also used as the target which results in most lexical entries arising from uninformative alignments between single English phonemes and Japanese syllables, such as *[t]*⇔す. For similar reasons, the shifted geometric prior gains an advantage over Poisson, likely because of its ability to even further penalize single-phoneme lexical items, which regularly end up in all lexicons anyway due to their combinatorical advantage when sampling.

While many bilingual lexical entries are correct, such as *[wʌn]*⇔一 (*'one'*), most are not. Some have segmentation errors *[liːz]*⇔ください (*'please'*); some are correctly segmented but misaligned to commonly co-occurring words *[wʌt]*⇔時 (*'what'* aligned to *'time'*); others do not constitute individual words, but morphemes aligned to common Japanese syllables *[iːŋ]*⇔く (*'-ing'*); others still align multi-word units correctly *[haʊmʌtʃ]*⇔いくら (*'how much'*). Note though that entries such as those listed above capture information that may nevertheless help to reduce phoneme transcription errors.

4 Conclusion and Future Work

We have demonstrated that a translation model and lexicon can be learnt directly from phoneme lattices in order to improve phoneme transcription of those very lattices.

One of the appealing aspects of this modular framework is that there is much room for extension and improvement. For example, by using adaptor grammars to encourage syllable segmentation (Johnson, 2008), or incorporating language model probabilities in addition to our translation model probabilities (Neubig et al., 2012).

We assume a good acoustic model with phoneme error rates between 20 and 25%. In a language documentation scenario, acoustic models for the low-resource source language won't exist. Future work should use a universal phoneme recognizer or acoustic model of a similar language, thus making a step towards true generalizability.

[4] A 1 hour subset was used for PER evaluation.

SQuAD: 100,000+ Questions for Machine Comprehension of Text

Pranav Rajpurkar and **Jian Zhang** and **Konstantin Lopyrev** and **Percy Liang**
{pranavsr,zjian,klopyrev,pliang}@cs.stanford.edu
Computer Science Department
Stanford University

Abstract

We present the Stanford Question Answering Dataset (SQuAD), a new reading comprehension dataset consisting of 100,000+ questions posed by crowdworkers on a set of Wikipedia articles, where the answer to each question is a segment of text from the corresponding reading passage. We analyze the dataset to understand the types of reasoning required to answer the questions, leaning heavily on dependency and constituency trees. We build a strong logistic regression model, which achieves an F1 score of 51.0%, a significant improvement over a simple baseline (20%). However, human performance (86.8%) is much higher, indicating that the dataset presents a good challenge problem for future research. The dataset is freely available at https://stanford-qa.com.

1 Introduction

Reading Comprehension (RC), or the ability to read text and then answer questions about it, is a challenging task for machines, requiring both understanding of natural language and knowledge about the world. Consider the question "*what causes precipitation to fall?*" posed on the passage in Figure 1. In order to answer the question, one might first locate the relevant part of the passage "*precipitation ... falls under gravity*", then reason that "*under*" refers to a cause (not location), and thus determine the correct answer: "*gravity*".

How can we get a machine to make progress on the challenging task of reading comprehension? Historically, large, realistic datasets have played a critical role for driving fields forward—famous examples include ImageNet for object recognition (Deng et al., 2009) and the Penn Treebank for syntactic parsing (Marcus et al., 1993). Existing datasets for RC have one of two shortcomings: (i) those that are high in quality (Richardson et al., 2013; Berant et al., 2014) are too small for training modern data-intensive models, while (ii) those that are large (Hermann et al., 2015; Hill et al., 2015) are semi-synthetic and do not share the same characteristics as explicit reading comprehension questions.

To address the need for a large and high-quality reading comprehension dataset, we present the Stan-

In meteorology, precipitation is any product of the condensation of atmospheric water vapor that falls under **gravity**. The main forms of precipitation include drizzle, rain, sleet, snow, **graupel** and hail... Precipitation forms as smaller droplets coalesce via collision with other rain drops or ice crystals **within a cloud**. Short, intense periods of rain in scattered locations are called "showers".

What causes precipitation to fall?
gravity

What is another main form of precipitation besides drizzle, rain, snow, sleet and hail?
graupel

Where do water droplets collide with ice crystals to form precipitation?
within a cloud

Figure 1: Question-answer pairs for a sample passage in the SQuAD dataset. Each of the answers is a segment of text from the passage.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 2383–2392,
Austin, Texas, November 1-5, 2016.

ford Question Answering Dataset v1.0 (SQuAD), freely available at https://stanford-qa.com, consisting of questions posed by crowdworkers on a set of Wikipedia articles, where the answer to every question is a segment of text, or *span*, from the corresponding reading passage. SQuAD contains 107,785 question-answer pairs on 536 articles, and is almost two orders of magnitude larger than previous manually labeled RC datasets such as MCTest (Richardson et al., 2013).

In contrast to prior datasets, SQuAD does not provide a list of answer choices for each question. Rather, systems must select the answer from all possible spans in the passage, thus needing to cope with a fairly large number of candidates. While questions with span-based answers are more constrained than the more interpretative questions found in more advanced standardized tests, we still find a rich diversity of questions and answer types in SQuAD. We develop automatic techniques based on distances in dependency trees to quantify this diversity and stratify the questions by difficulty. The span constraint also comes with the important benefit that span-based answers are easier to evaluate than free-form answers.

To assess the difficulty of SQuAD, we implemented a logistic regression model with a range of features. We find that lexicalized and dependency tree path features are important to the performance of the model. We also find that the model performance worsens with increasing complexity of (i) answer types and (ii) syntactic divergence between the question and the sentence containing the answer; interestingly, there is no such degradation for humans. Our best model achieves an F1 score of 51.0%,[1] which is much better than the sliding window baseline (20%). Over the last four months (since June 2016), we have witnessed significant improvements from more sophisticated neural network-based models. For example, Wang and Jiang (2016) obtained 70.3% F1 on SQuAD v1.1 (results on v1.0 are similar). These results are still well behind human performance, which is 86.8% F1 based on inter-annotator agreement. This suggests that there is plenty of room for advancement in modeling and learning on the SQuAD dataset.

[1] All experimental results in this paper are on SQuAD v1.0.

Dataset	Question source	Formulation	Size
SQuAD	**crowdsourced**	**RC, spans in passage**	**100K**
MCTest (Richardson et al., 2013)	crowdsourced	RC, multiple choice	2640
Algebra (Kushman et al., 2014)	standardized tests	computation	514
Science (Clark and Etzioni, 2016)	standardized tests	reasoning, multiple choice	855
WikiQA (Yang et al., 2015)	query logs	IR, sentence selection	3047
TREC-QA (Voorhees and Tice, 2000)	query logs + human editor	IR, free form	1479
CNN/Daily Mail (Hermann et al., 2015)	summary + cloze	RC, fill in single entity	1.4M
CBT (Hill et al., 2015)	cloze	RC, fill in single word	688K

Table 1: A survey of several reading comprehension and question answering datasets. SQuAD is much larger than all datasets except the semi-synthetic cloze-style datasets, and it is similar to TREC-QA in the open-endedness of the answers.

2 Existing Datasets

We begin with a survey of existing reading comprehension and question answering (QA) datasets, highlighting a variety of task formulation and creation strategies (see Table 1 for an overview).

Reading comprehension. A data-driven approach to reading comprehension goes back to Hirschman et al. (1999), who curated a dataset of 600 real 3rd–6th grade reading comprehension questions. Their pattern matching baseline was subsequently improved by a rule-based system (Riloff and Thelen, 2000) and a logistic regression model (Ng et al., 2000). More recently, Richardson et al. (2013) curated MCTest, which contains 660 stories created by crowdworkers, with 4 questions per story and 4 answer choices per question. Because many of the questions require commonsense reasoning and reasoning across multiple sentences, the dataset remains quite challenging, though there has been noticeable progress (Narasimhan and Barzilay, 2015; Sachan et al., 2015; Wang et al., 2015). Both curated datasets, although real and difficult, are too small to support very expressive statistical models.

Some datasets focus on deeper reasoning abilities. Algebra word problems require understanding a story well enough to turn it into a system of equa-

tions, which can be easily solved to produce the answer (Kushman et al., 2014; Hosseini et al., 2014). BAbI (Weston et al., 2015), a fully synthetic RC dataset, is stratified by different types of reasoning required to solve each task. Clark and Etzioni (2016) describe the task of solving 4th grade science exams, and stress the need to reason with world knowledge.

Open-domain question answering. The goal of open-domain QA is to answer a question from a large collection of documents. The annual evaluations at the Text REtreival Conference (TREC) (Voorhees and Tice, 2000) led to many advances in open-domain QA, many of which were used in IBM Watson for Jeopardy! (Ferrucci et al., 2013). Recently, Yang et al. (2015) created the WikiQA dataset, which, like SQuAD, use Wikipedia passages as a source of answers, but their task is sentence selection, while ours requires selecting a specific span in the sentence.

Selecting the span of text that answers a question is similar to *answer extraction*, the final step in the open-domain QA pipeline, methods for which include bootstrapping surface patterns (Ravichandran and Hovy, 2002), using dependency trees (Shen and Klakow, 2006), and using a factor graph over multiple sentences (Sun et al., 2013). One key difference between our RC setting and answer extraction is that answer extraction typically exploits the fact that the answer occurs in multiple documents (Brill et al., 2002), which is more lenient than in our setting, where a system only has access to a single reading passage.

Cloze datasets. Recently, researchers have constructed cloze datasets, in which the goal is to predict the missing word (often a named entity) in a passage. Since these datasets can be automatically generated from naturally occurring data, they can be extremely large. The Children's Book Test (CBT) (Hill et al., 2015), for example, involves predicting a blanked-out word of a sentence given the 20 previous sentences. Hermann et al. (2015) constructed a corpus of cloze style questions by blanking out entities in abstractive summaries of CNN / Daily News articles; the goal is to fill in the entity based on the original article. While the size of this dataset is impressive, Chen et al. (2016) showed that the dataset requires less reasoning than previously thought, and concluded that performance is almost saturated.

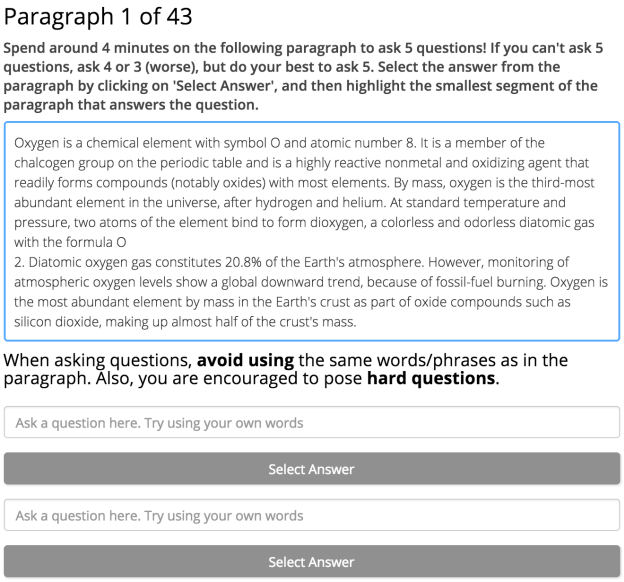

Figure 2: The crowd-facing web interface used to collect the dataset encourages crowdworkers to use their own words while asking questions.

One difference between SQuAD questions and cloze-style queries is that answers to cloze queries are single words or entities, while answers in SQuAD often include non-entities and can be much longer phrases. Another difference is that SQuAD focuses on questions whose answers are entailed by the passage, whereas the answers to cloze-style queries are merely suggested by the passage.

3 Dataset Collection

We collect our dataset in three stages: curating passages, crowdsourcing question-answers on those passages, and obtaining additional answers.

Passage curation. To retrieve high-quality articles, we used Project Nayuki's Wikipedia's internal PageRanks to obtain the top 10000 articles of English Wikipedia, from which we sampled 536 articles uniformly at random. From each of these articles, we extracted individual paragraphs, stripping away images, figures, tables, and discarding paragraphs shorter than 500 characters. The result was 23,215 paragraphs for the 536 articles covering a wide range of topics, from musical celebrities to abstract concepts. We partitioned the articles randomly into a training set (80%), a development set (10%),

and a test set (10%).

Question-answer collection. Next, we employed crowdworkers to create questions. We used the Daemo platform (Gaikwad et al., 2015), with Amazon Mechanical Turk as its backend. Crowdworkers were required to have a 97% HIT acceptance rate, a minimum of 1000 HITs, and be located in the United States or Canada. Workers were asked to spend 4 minutes on every paragraph, and paid $9 per hour for the number of hours required to complete the article. The task was reviewed favorably by crowdworkers, receiving positive comments on Turkopticon.

On each paragraph, crowdworkers were tasked with asking and answering up to 5 questions on the content of that paragraph. The questions had to be entered in a text field, and the answers had to be highlighted in the paragraph. To guide the workers, tasks contained a sample paragraph, and examples of good and bad questions and answers on that paragraph along with the reasons they were categorized as such. Additionally, crowdworkers were encouraged to ask questions in their own words, without copying word phrases from the paragraph. On the interface, this was reinforced by a reminder prompt at the beginning of every paragraph, and by disabling copy-paste functionality on the paragraph text.

Additional answers collection. To get an indication of human performance on SQuAD and to make our evaluation more robust, we obtained at least 2 additional answers for each question in the development and test sets. In the secondary answer generation task, each crowdworker was shown only the questions along with the paragraphs of an article, and asked to select the shortest span in the paragraph that answered the question. If a question was not answerable by a span in the paragraph, workers were asked to submit the question without marking an answer. Workers were recommended a speed of 5 questions for 2 minutes, and paid at the same rate of $9 per hour for the number of hours required for the entire article. Over the development and test sets, 2.6% of questions were marked unanswerable by at least one of the additional crowdworkers.

Answer type	Percentage	Example
Date	8.9%	19 October 1512
Other Numeric	10.9%	12
Person	12.9%	Thomas Coke
Location	4.4%	Germany
Other Entity	15.3%	ABC Sports
Common Noun Phrase	31.8%	property damage
Adjective Phrase	3.9%	second-largest
Verb Phrase	5.5%	returned to Earth
Clause	3.7%	to avoid trivialization
Other	2.7%	quietly

Table 2: We automatically partition our answers into the following categories. Our dataset consists of large number of answers beyond proper noun entities.

4 Dataset Analysis

To understand the properties of SQuAD, we analyze the questions and answers in the development set. Specifically, we explore the (i) diversity of answer types, (ii) the difficulty of questions in terms of type of reasoning required to answer them, and (iii) the degree of syntactic divergence between the question and answer sentences.

Diversity in answers. We automatically categorize the answers as follows: We first separate the numerical and non-numerical answers. The non-numerical answers are categorized using constituency parses and POS tags generated by Stanford CoreNLP. The proper noun phrases are further split into person, location and other entities using NER tags. In Table 2, we can see dates and other numbers make up 19.8% of the data; 32.6% of the answers are proper nouns of three different types; 31.8% are common noun phrases answers; and the remaining 15.8% are made up of adjective phrases, verb phrases, clauses and other types.

Reasoning required to answer questions. To get a better understanding of the reasoning required to answer the questions, we sampled 4 questions from each of the 48 articles in the development set, and then manually labeled the examples with the categories shown in Table 3. The results show that all examples have some sort of lexical or syntactic divergence between the question and the answer in the passage. Note that some examples fall into more than one category.

Reasoning	Description	Example	Percentage
Lexical variation (synonymy)	Major correspondences between the question and the answer sentence are synonyms.	Q: What is the Rankine cycle sometimes **called**? Sentence: The Rankine cycle is sometimes **referred** to as a practical Carnot cycle.	33.3%
Lexical variation (world knowledge)	Major correspondences between the question and the answer sentence require world knowledge to resolve.	Q: Which **governing bodies** have veto power? Sen.: **The European Parliament and the Council of the European Union** have powers of amendment and veto during the legislative process.	9.1%
Syntactic variation	After the question is paraphrased into declarative form, its syntactic dependency structure does not match that of the answer sentence even after local modifications.	Q: What Shakespeare scholar **is currently on the faculty**? Sen.: **Current faculty include** the anthropologist Marshall Sahlins, ..., Shakespeare scholar David Bevington.	64.1%
Multiple sentence reasoning	There is anaphora, or higher-level fusion of multiple sentences is required.	Q: What collection does **the V&A Theatre & Performance galleries** hold? Sen.: **The V&A Theatre & Performance galleries** opened in March 2009. ... **They** hold the UK's biggest national collection of material about live performance.	13.6%
Ambiguous	We don't agree with the crowdworkers' answer, or the question does not have a unique answer.	Q: What is the main goal of criminal punishment? Sen.: **Achieving crime control via incapacitation and deterrence** is a major goal of criminal punishment.	6.1%

Table 3: We manually labeled 192 examples into one or more of the above categories. Words relevant to the corresponding reasoning type are bolded, and the crowdsourced answer is underlined.

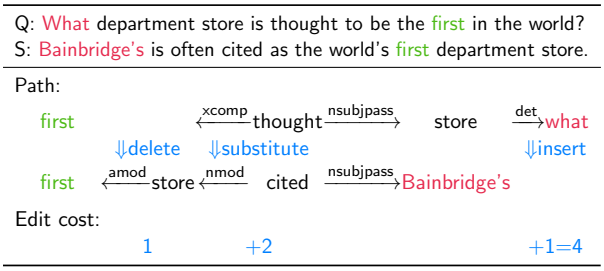

Figure 3: An example walking through the computation of the syntactic divergence between the question Q and answer sentence S.

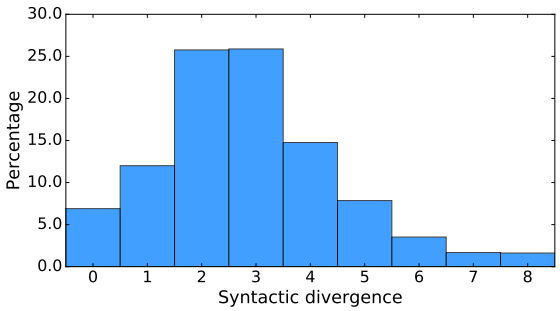
Stratification by syntactic divergence. We also develop an automatic method to quantify the syntactic divergence between a question and the sentence containing the answer. This provides another way to measure the difficulty of a question and to stratify the dataset, which we return to in Section 6.3.

We illustrate how we measure the divergence with the example in Figure 3. We first detect anchors (word-lemma pairs common to both the question and answer sentences); in the example, the anchor is "*first*". The two unlexicalized paths, one from the anchor "*first*" in the question to the wh-word "*what*", and the other from the anchor in the answer sentence and to the answer span "*Bainbridge's*", are then extracted from the dependency parse trees. We measure the edit distance between these two paths, which we define as the minimum number of deletions or insertions to transform one path into the other. The syntactic divergence is then defined as the minimum edit distance over all possible anchors. The histogram in Figure 4a shows that there is a wide range of syntactic divergence in our dataset. We also show a concrete example where the edit distance is 0 and another where it is 6. Note that our syntactic divergence ignores lexical variation. Also, small divergence does not mean that a question is easy since there could be other candidates with similarly small divergence.

5 Methods

We developed a logistic regression model and compare its accuracy with that of three baseline methods.



(a) Histogram of syntactic divergence.

Q: Who went to Wittenberg to hear Luther speak?
S: Students thronged to Wittenberg to hear Luther speak.
Path:

Wittenberg $\xleftarrow{\text{nmod}}$ went $\xrightarrow{\text{nsubj}}$ Who
Wittenberg $\xleftarrow{\text{nmod}}$ thronged $\xrightarrow{\text{nsubj}}$ Students

(b) An example of a question-answer pair with edit distance 0 between the dependency paths (note that lexical variation is ignored in the computation of edit distance).

Q: What impact did the high school education movement have on the presence of skilled workers?
S: During the mass high school education movement from 1910 – 1940 , there was an increase in skilled workers.
Path:

school $\xleftarrow{\text{compound}}$ movement $\xleftarrow{\text{nsubj}}$ have $\xrightarrow{\text{dobj}}$ impact $\xrightarrow{\text{det}}$ What
school $\xleftarrow{\text{compound}}$ movement $\xrightarrow{\text{nmod}}$ 1910 $\xrightarrow{\text{acl}}$ was $\xrightarrow{\text{nsubj}}$ increase

(c) An example of a question-answer pair with edit distance 6.

Figure 4: We use the edit distance between the unlexicalized dependency paths in the question and the sentence containing the answer to measure *syntactic divergence*.

Candidate answer generation. For all four methods, rather than considering all $O(L^2)$ spans as candidate answers, where L is the number of words in the sentence, we only use spans which are constituents in the constituency parse generated by Stanford CoreNLP. Ignoring punctuation and articles, we find that 77.3% of the correct answers in the development set are constituents. This places an effective ceiling on the accuracy of our methods. During training, when the correct answer of an example is not a constituent, we use the shortest constituent containing the correct answer as the target.

5.1 Sliding Window Baseline

For each candidate answer, we compute the unigram/bigram overlap between the sentence containing it (excluding the candidate itself) and the question. We keep all the candidates that have the maximal overlap. Among these, we select the best one using the sliding-window approach proposed in Richardson et al. (2013).

In addition to the basic sliding window approach, we also implemented the distance-based extension (Richardson et al., 2013). Whereas Richardson et al. (2013) used the entire passage as the context of an answer, we used only the sentence containing the candidate answer for efficiency.

5.2 Logistic Regression

In our logistic regression model, we extract several types of features for each candidate answer. We discretize each continuous feature into 10 equally-sized buckets, building a total of 180 million features, most of which are lexicalized features or dependency tree path features. The descriptions and examples of the features are summarized in Table 4.

The matching word and bigram frequencies as well as the root match features help the model pick the correct sentences. Length features bias the model towards picking common lengths and positions for answer spans, while span word frequencies bias the model against uninformative words. Constituent label and span POS tag features guide the model towards the correct answer types. In addition to these basic features, we resolve lexical variation using lexicalized features, and syntactic variation using dependency tree path features.

The multiclass log-likelihood loss is optimized using AdaGrad with an initial learning rate of 0.1. Each update is performed on the batch of all questions in a paragraph for efficiency, since they share the same candidates. L_2 regularization is used, with a coefficient of 0.1 divided by the number of batches. The model is trained with three passes over the train-

Feature Groups	Description	Examples
Matching Word Frequencies	Sum of the TF-IDF of the words that occur in both the question and the sentence containing the candidate answer. Separate features are used for the words to the left, to the right, inside the span, and in the whole sentence.	Span: $[0 \leq \text{sum} < 0.01]$ Left: $[7.9 \leq \text{sum} < 10.7]$
Matching Bigram Frequencies	Same as above, but using bigrams. We use the generalization of the TF-IDF described in Shirakawa et al. (2015).	Span: $[0 \leq \text{sum} < 2.4]$ Left: $[0 \leq \text{sum} < 2.7]$
Root Match	Whether the dependency parse tree roots of the question and sentence match, whether the sentence contains the root of the dependency parse tree of the question, and whether the question contains the root of the dependency parse tree of the sentence.	Root Match = False
Lengths	Number of words to the left, to the right, inside the span, and in the whole sentence.	Span: $[1 <= \text{num} < 2]$ Left: $[15 \leq \text{num} < 19]$
Span Word Frequencies	Sum of the TF-IDF of the words in the span, regardless of whether they appear in the question.	Span: $[5.2 \leq \text{sum} < 6.9]$
Constituent Label	Constituency parse tree label of the span, optionally combined with the wh-word in the question.	Span: NP Span: NP, wh-word: "*what*"
Span POS Tags	Sequence of the part-of-speech tags in the span, optionally combined with the wh-word in the question.	Span: [NN] Span: [NN], wh-word: "*what*"
Lexicalized	Lemmas of question words combined with the lemmas of words within distance 2 to the span in the sentence based on the dependency parse trees. Separately, question word lemmas combined with answer word lemmas.	Q: "*cause*", S: "*under*" $\xleftarrow{\text{case}}$ Q: "*fall*", A: "*gravity*"
Dependency Tree Paths	For each word that occurs in both the question and sentence, the path in the dependency parse tree from that word in the sentence to the span, optionally combined with the path from the wh-word to the word in the question. POS tags are included in the paths.	VBZ $\xrightarrow{\text{nmod}}$ NN what $\xleftarrow{\text{nsubj}}$ VBZ $\xrightarrow{\text{advcl}}$ + VBZ$\xrightarrow{\text{nmod}}$NN

Table 4: Features used in the logistic regression model with examples for the question "*What causes precipitation to fall?*", sentence "*In meteorology, precipitation is any product of the condensation of atmospheric water vapor that falls under gravity.*" and answer "*gravity*". Q denotes question, A denotes candidate answer, and S denotes sentence containing the candidate answer.

ing data.

6 Experiments

6.1 Model Evaluation

We use two different metrics to evaluate model accuracy. Both metrics ignore punctuations and articles (a, an, the).

Exact match. This metric measures the percentage of predictions that match any one of the ground truth answers exactly.

(Macro-averaged) F1 score. This metric measures the average overlap between the prediction and ground truth answer. We treat the prediction and ground truth as bags of tokens, and compute their F1. We take the maximum F1 over all of the ground truth answers for a given question, and then average over all of the questions.

6.2 Human Performance

We assess human performance on SQuAD's development and test sets. Recall that each of the questions in these sets has at least three answers. To evaluate human performance, we treat the second answer to each question as the human prediction, and keep the other answers as ground truth answers. The resulting human performance score on the test set is 77.0% for the exact match metric, and 86.8% for F1. Mismatch occurs mostly due to inclusion/exclusion of non-essential phrases (e.g., *monsoon trough* versus *movement of the monsoon trough*) rather than fundamental disagreements about the answer.

6.3 Model Performance

Table 5 shows the performance of our models alongside human performance on the v1.0 of development and test sets. The logistic regression model significantly outperforms the baselines, but underperforms

	Exact Match		F1	
	Dev	Test	Dev	Test
Random Guess	1.1%	1.3%	4.1%	4.3%
Sliding Window	13.2%	12.5%	20.2%	19.7%
Sliding Win. + Dist.	13.3%	13.0%	20.2%	20.0%
Logistic Regression	40.0%	40.4%	51.0%	51.0%
Human	80.3%	77.0%	90.5%	86.8%

Table 5: Performance of various methods and humans. Logistic regression outperforms the baselines, while there is still a significant gap between humans.

	F_1	
	Train	Dev
Logistic Regression	91.7%	51.0%
– Lex., – Dep. Paths	33.9%	35.8%
– Lexicalized	53.5%	45.4%
– Dep. Paths	91.4%	46.4%
– Match. Word Freq.	91.7%	48.1%
– Span POS Tags	91.7%	49.7%
– Match. Bigram Freq.	91.7%	50.3%
– Constituent Label	91.7%	50.4%
– Lengths	91.8%	50.5%
– Span Word Freq.	91.7%	50.5%
– Root Match	91.7%	50.6%

Table 6: Performance with feature ablations. We find that lexicalized and dependency tree path features are most important.

humans. We note that the model is able to select the sentence containing the answer correctly with 79.3% accuracy; hence, the bulk of the difficulty lies in finding the exact span within the sentence.

Feature ablations. In order to understand the features that are responsible for the performance of the logistic regression model, we perform a feature ablation where we remove one group of features from our model at a time. The results, shown in Table 6, indicate that lexicalized and dependency tree path features are most important. Comparing our analysis to the one in Chen et al. (2016), we note that the dependency tree path features play a much bigger role in our dataset. Additionally, we note that with lexicalized features, the model significantly overfits the training set; however, we found that increasing L_2 regularization hurts performance on the development set.

Performance stratified by answer type. To gain more insight into the performance of our logistic regression model, we report its performance across

	Logistic Regression Dev F1	Human Dev F1
Date	72.1%	93.9%
Other Numeric	62.5%	92.9%
Person	56.2%	95.4%
Location	55.4%	94.1%
Other Entity	52.2%	92.6%
Common Noun Phrase	46.5%	88.3%
Adjective Phrase	37.9%	86.8%
Verb Phrase	31.2%	82.4%
Clause	34.3%	84.5%
Other	34.8%	86.1%

Table 7: Performance stratified by answer types. Logistic regression performs better on certain types of answers, namely numbers and entities. On the other hand, human performance is more uniform.

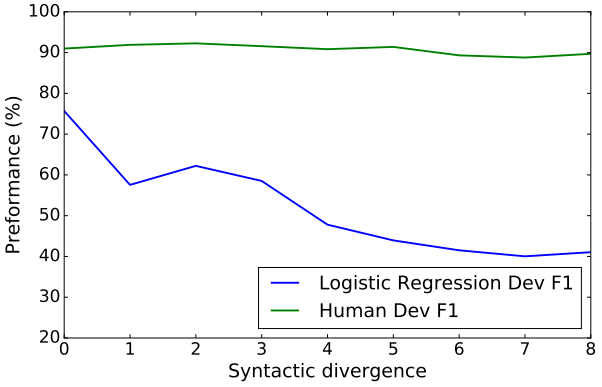


Figure 5: Performance stratified by syntactic divergence of questions and sentences. The performance of logistic regression degrades with increasing divergence. In contrast, human performance is stable across the full range of divergence.

the answer types explored in Table 2. The results (shown in Table 7) show that the model performs best on dates and other numbers, categories for which there are usually only a few plausible candidates, and most answers are single tokens. The model is challenged more on other named entities (i.e., location, person and other entities) because there are many more plausible candidates. However, named entities are still relatively easy to identify by their POS tag features. The model performs worst on other answer types, which together form 47.6% of the dataset. Humans have exceptional performance on dates, numbers and all named entities. Their performance on other answer types degrades only slightly.

Performance stratified by syntactic divergence. As discussed in Section 4, another challenging aspect of the dataset is the syntactic divergence between the question and answer sentence. Figure 5 shows that the more divergence there is, the lower the performance of the logistic regression model. Interestingly, humans do not seem to be sensitive to syntactic divergence, suggesting that deep understanding is not distracted by superficial differences. Measuring the degree of degradation could therefore be useful in determining the extent to which a model is generalizing in the right way.

7 Conclusion

Towards the end goal of natural language understanding, we introduce the Stanford Question Answering Dataset, a large reading comprehension dataset on Wikipedia articles with crowdsourced question-answer pairs. SQuAD features a diverse range of question and answer types. The performance of our logistic regression model, with 51.0% F1, against the human F1 of 86.8% suggests ample opportunity for improvement. We have made our dataset freely available to encourage exploration of more expressive models. Since the release of our dataset, we have already seen considerable interest in building models on this dataset, and the gap between our logistic regression model and human performance has more than halved (Wang and Jiang, 2016). We expect that the remaining gap will be harder to close, but that such efforts will result in significant advances in reading comprehension.

Reproducibility

All code, data, and experiments for this paper are available on the CodaLab platform: https://worksheets.codalab.org/worksheets/0xd53d03a48ef64b329c16b9baf0f99b0c/ .

Acknowledgments

We would like to thank Durim Morina and Professor Michael Bernstein for their help in crowdsourcing the collection of our dataset, both in terms of funding and technical support of the Daemo platform.
