Abstract

Transfer learning is aimed to make use of valuable knowledge in a *source* domain to help model performance in a *target* domain. It is particularly important to neural networks, which are very likely to be overfitting. In some fields like image processing, many studies have shown the effectiveness of neural network-based transfer learning. For neural NLP, however, existing studies have only casually applied transfer learning, and conclusions are inconsistent. In this paper, we conduct systematic case studies and provide an illuminating picture on the transferability of neural networks in NLP.[1]

1 Introduction

Transfer learning, or sometimes known as domain adaptation,[2] plays an important role in various natural language processing (NLP) applications, especially when we do not have large enough datasets for the task of interest (called the *target* task $\mathcal{T}$). In such scenarios, we would like to transfer or adapt knowledge from other domains (called the *source* domains/tasks $\mathcal{S}$) so as to mitigate the problem of overfitting and to improve model performance in $\mathcal{T}$. For traditional feature-rich or kernel-based models, researchers have developed a variety of elegant methods for domain adaptation; examples include EasyAdapt (Daumé III, 2007; Daumé III et al., 2010), instance weighting (Jiang and Zhai, 2007; Foster et al., 2010), and structural correspondence learning (Blitzer et al., 2006; Prettenhofer and Stein, 2010).

Recently, deep neural networks are emerging as the prevailing technical solution to almost every field in NLP. Although capable of learning highly nonlinear features, deep neural networks are very prone to overfitting, compared with traditional methods. Transfer learning therefore becomes even more important. Fortunately, neural networks can be trained in a transferable way by their incremental learning nature: we can directly use trained (tuned) parameters from a source task to initialize the network in the target task; alternatively, we may also train two tasks simultaneously with some parameters shared. But their performance should be verified by empirical experiments.

Existing studies have already shown some evidence of the transferability of neural features. For example, in image processing, low-level neural layers closely resemble Gabor filters or color blobs (Zeiler and Fergus, 2014; Krizhevsky et al., 2012); they can be transferred well to different tasks. Donahue et al. (2014) suggest that high-level layers are also transferable in general visual recognition; Yosinski et al. (2014) further investigate the transferability of neural layers in different levels of abstraction.

Although transfer learning is promising in image processing, conclusions appear to be less clear in NLP applications. Image pixels are low-level signals, which are generally continuous and less related to semantics. By contrast, natural language tokens

[2]In this paper, we do not distinguish the conceptual difference between *transfer learning* and *domain adaptation*. *Domain*—in the sense we use throughout this paper—is defined by datasets.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 479–489,
Austin, Texas, November 1-5, 2016.

are discrete: each word well reflects the thought of humans, but neighboring words do not share as much information as pixels in images do. Previous neural NLP studies have casually applied transfer techniques, but their results are not consistent. Collobert and Weston (2008) apply multi-task learning to SRL, NER, POS, and CHK,[3] but obtain only 0.04–0.21% error reduction[4] (out of a base error rate of 16–18%). Bowman et al. (2015), on the contrary, improve a natural language inference task from an accuracy of 71.3% to 80.8% by initializing parameters with an additional dataset of 550,000 samples. Therefore, more systematic studies are needed to shed light on transferring neural networks in the field of NLP.

Our Contributions

In this paper, we investigate the question "*How transferable are neural networks in NLP applications?*"

We distinguish two scenarios of transfer: (1) transferring knowledge to a semantically similar/equivalent task but with a different dataset; (2) transferring knowledge to a task that is semantically different but shares the same neural topology/architecture so that neural parameters can indeed be transferred. We further distinguish two transfer methods: (1) using the parameters trained on $\mathcal{S}$ to initialize $\mathcal{T}$ (INIT), and (2) multi-task learning (MULT), i.e., training $\mathcal{S}$ and $\mathcal{T}$ simultaneously. (Please see Sections 2 and 4). Our study mainly focuses on the following research questions:

RQ1: How transferable are neural networks between two tasks with similar or different semantics in NLP applications?

RQ2: How transferable are different layers of NLP neural models?

RQ3: How transferable are INIT and MULT, respectively? What is the effect of combining these two methods?

[3]The acronyms refer to *semantic role labeling*, *named entity recognition*, *part-of-speech tagging*, and *chunking*, respectively.

[4]Here, we quote the accuracies obtained by using unsupervised pretraining of word embeddings. This is the highest performance in that paper; using pretrained word embeddings is also a common practice in the literature.

We conducted extensive experiments over six datasets on classifying sentences and sentence pairs. We leveraged the widely-used convolutional neural network (CNN) and long short term memory (LSTM)-based recurrent neural network (RNN) as our models.

Based on our experimental results, we have the following main observations, some of which are unexpected.

- Whether a neural network is transferable in NLP depends largely on how semantically similar the tasks are, which is different from the consensus in image processing.
- The output layer is mainly specific to the dataset and not transferable. Word embeddings are likely to be transferable to semantically different tasks.
- MULT and INIT appear to be generally comparable to each other; combining these two methods does not result in further gain in our study.

The rest of this paper is organized as follows. Section 2 introduces the datasets that neural models are transferred across; Section 3 details the neural architectures and experimental settings. We describe two approaches (INIT and MULT) to transfer learning in Section 4. We present experimental results in Sections 5–6 and have concluding remarks in Section 7.

2 Datasets

In our study, we conducted two series of experiments using six open datasets as follows.

- **Experiment I**: Sentence classification
  - `IMDB`. A large dataset for binary sentiment classification (`positive` vs. `negative`).[5]
  - `MR`. A small dataset for binary sentiment classification.[6]
  - `QC`. A (small) dataset for 6-way question classification (e.g., `location`, `time`, and `number`).[7]

Statistics (# of Samples)						
	Experiment I			Experiment II		
	IMDB	MR	QC	SNLI	SICK	MSRP
#Train	550,000	8,500	4,800	550,152	4,439	3,575
#Val	50,000	1,100	600	10,000	495	501
#Test	2,000	1,100	500	10,000	4,906	1,725

Examples in Experiment I	
Sentiment Analysis (IMDB and MR)	
An idealistic love story that brings out the latent 15-year-old romantic in everyone.	+
Its mysteries are transparently obvious, and its too slowly paced to be a thriller.	−
Question Classification (QC)	
What is the temperature at the center of the earth?	number
What state did the Battle of Bighorn take place in?	location

Examples in Experiment II		
Natural Language Inference (SNLI and SICK)		
Premise	Two men on bicycles competing in a race.	
Hypothesis	People are riding bikes.	E
	Men are riding bicycles on the streets.	C
	A few people are catching fish.	N
Paraphrase Detection (MSRP)		
The DVD-CCA then appealed to the state Supreme Court.		Paraphrase
The DVD CCA appealed that decision to the U.S. Supreme Court.		
Earnings per share from recurring operations will be 13 cents to 14 cents.		Non-Paraphrase
That beat the company's April earnings forecast of 8 to 9 cents a share.		

Table 1: Statistics and examples of the datasets.

- **Experiment II**: Sentence-pair classification
  - SNLI. A large dataset for sentence entailment recognition. The classification objectives are entailment, contradiction, and neutral.[8]
  - SICK. A small dataset with exactly the same classification objective as SNLI.[9]
  - MSRP. A (small) dataset for paraphrase detection. The objective is binary classification: judging whether two sentences have the same meaning.[10]

In each experiment, the large dataset serves as the source domain and small ones are the target domains. Table 1 presents statistics of the above datasets.

We distinguish two scenarios of transfer regarding semantic similarity: (1) semantically equivalent transfer (IMDB→MR, SNLI→SICK), that is, the tasks of $\mathcal{S}$ and $\mathcal{T}$ are defined by the same meaning, and (2) semantically different transfer (IMDB→QC, SNLI→MSRP). Examples are also illustrated in Table 1 to demonstrate semantic relatedness.

It should be noticed that in image or speech processing (Yosinski et al., 2014; Wang and Zheng, 2015), the input of neural networks pretty much consists of raw signals; hence, low-level feature detectors are almost always transferable, even if Yosinski et al. (2014) manually distinguish artificial objects and natural ones in an image classification task.

Distinguishing semantic relatedness—which emerges from very low layers of either word embeddings or the successive hidden layer—is specific to NLP and also a new insight of our paper. As we shall see in Sections 5 and 6, the transferability of neural networks in NLP is more sensitive to semantics than in image processing.

3 Neural Models and Settings

In each group, we used a single neural model to solve three problems in a unified manner. That is to say, the neural architecture is the same among the three datasets, which makes it possible to investigate transfer learning regardless of whether the tasks are semantically equivalent. Concretely, the neural models are as follows.

- **Experiment I: LSTM-RNN**. To classify a sentence according to its sentiment or question type, we use a recurrent neural network (RNN, Figure 1a) with long short term memory (LSTM) units (Hochreiter and Schmidhuber, 1997). A softmax layer is added to the last word's hidden state for classification.

- **Experiment II: CNN-pair**. In this group, we use a "Siamese" architecture (Bromley et al., 1993) to classify the relation of two sentences. We first apply a convolutional neural network (CNN, Figure 1b) with a window size of 5 to model local context, and a max pooling layer gathers information to a fixed-size vector. Then the sentence vectors are concatenated and fed to a hidden layer before the softmax output.

In our experiments, embeddings were pretrained by word2vec (Mikolov et al., 2013); all embeddings and hidden layers were 100 dimensional. We

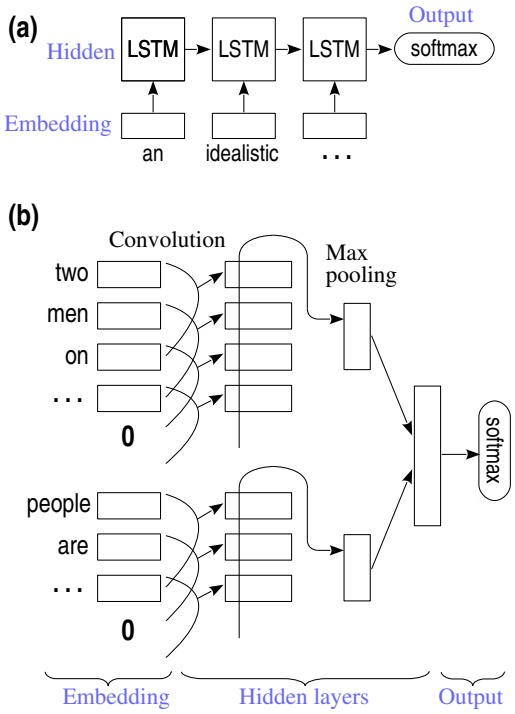

Figure 1: The models in our study. (a) Experiment I: RNNs with LSTM units for sentence classification. (b) Experiment II: CNN for sentence pair modeling.

applied stochastic gradient descent with a mini-batch size of 50 for optimization. In each setting, we tuned the hyperparameters as follows: learning rate from $\{3, 1, 0.3, 0.1, 0.03\}$, power decay of learning rate from {fast, moderate, low} (defined by how much, after one epoch, the learning rate residual is: 0.1x, 0.3x, 0.9x, resp). We regularized our network by dropout with a rate from $\{0, 0.1, 0.2, 0.3\}$. Note that we might not run nonsensical settings, e.g., a larger dropout rate if the network has already been underfitting (i.e., accuracy has decreased when the dropout rate increases). We report the test performance associated with the highest validation accuracy.

To setup a baseline, we trained our models without transfer 5 times by different random parameter initializations (Table 2). We have achieved reasonable performance that is comparable to similar models reported in the literature with all six datasets. Therefore, our implementation is fair and suitable for further study of transfer learning.

It should be mentioned that the goal of this paper is not to outperform state-of-the-art results; instead, we would like to conduct a fair comparison of different methods and settings for transfer learning in NLP.

	Dataset	Avg acc.±std.	Related model
Exp. I	IMDB	87.0	89.3 (Non-NN, Dong$^+$,2015)
	MR	75.1 ± 0.6	77.7 (RAE, Socher$^+$, 2013)
	QC	90.8 ± 0.9	90.2 (RNN, Zhao$^+$,2015)
Exp. II	SNLI	76.3	77.6 (RNN, Bowman$^+$,2015)
	SICK	70.9 ± 1.3	71.3 (RNN, Bowman$^+$,2015)
	MSRP	69.0 ± 0.5	69.6 (Arc-I CNN, Hu$^+$,2014)

Table 2: Accuracy (%) without transfer. We also include related models for comparison (Dong et al., 2015; Socher et al., 2011; Zhao et al., 2015; Bowman et al., 2015; Hu et al., 2014), showing that we have achieved comparable results, and thus are ready to investigate transfer learning. The models were run one only once in source domains, because we could only transfer a particular model instead of an average of several models.

4 Transfer Methods

Transfer learning aims to use knowledge in a source domain to aid the target domain. As neural networks are usually trained incrementally with gradient descent (or variants), it is straightforward to use gradient information in both source and target domains for optimization so as to accomplish knowledge transfer. Depending on how samples in source and target domains are scheduled, there are two main approaches to neural network-based transfer learning:

- Parameter initialization (INIT). The INIT approach first trains the network on $\mathcal{S}$, and then directly uses the tuned parameters to initialize the network for $\mathcal{T}$. After transfer, we may fix (🔒) the parameters in the target domain (Glorot et al., 2011), i.e., no training is performed on $\mathcal{T}$. But when labeled data are available in $\mathcal{T}$, it would be better to fine-tune (🔓) the parameters.

  INIT is also related to unsupervised pretraining such as word embedding learning (Mikolov et al., 2013) and autoencoders (Bengio et al., 2006). In these approaches, parameters that are (pre)trained in an unsupervised way are transferred to initialize the model for a supervised task (Plank and Moschitti, 2013). However, our paper focuses on "supervised pretraining," which means we transfer knowledge from a labeled source domain.

- Multi-task learning (MULT). MULT, on the other hand, simultaneously trains samples in both domains (Collobert and Weston, 2008; Liu et al., 2016). The overall cost function is given by

$$J = \lambda J_{\mathcal{T}} + (1 - \lambda) J_{\mathcal{S}} \quad (1)$$

  where $J_{\mathcal{T}}$ and $J_{\mathcal{S}}$ are the individual cost function of each domain. (Both $J_{\mathcal{T}}$ and $J_{\mathcal{S}}$ are normalized by the number of training samples.) $\lambda \in (0, 1)$ is a hyperparameter balancing the two domains.

  It is nontrivial to optimize Equation 1 in practice by gradient-based methods. One may take the partial derivative of J and thus λ goes to the learning rate (Liu et al., 2016), but the model is then vulnerable because it is likely to blow up with large learning rates (multiplied by λ or $1 - \lambda$) and be stuck in local optima with small ones.

  Collobert and Weston (2008) alternatively choose a data sample from either domain with a certain probability (controlled by λ) and take the derivative for the particular data sample. In this way, domain transfer is independent of learning rates, but we may not be able to fully use the entire dataset of $\mathcal{S}$ if λ is large. We adopted the latter approach in our experiment for simplicity. (More in-depth analysis may be needed in future work.) Formally, our multi-task learning strategy is as follows.

  1 Switch to $\mathcal{T}$ with prob. λ, or to $\mathcal{S}$ with prob. $1 - \lambda$.
  2 Compute the gradient of the next data sample in the particular domain.

Further, INIT and MULT can be combined straightforwardly, and we obtain the third setting:

- Combination (MULT+INIT). We first pretrain on the source domain $\mathcal{S}$ for parameter initialization, and then train $\mathcal{S}$ and $\mathcal{T}$ simultaneously.

From a theoretical perspective, INIT and MULT work in different ways. In the MULT approach, the source domain regularizes the model by "aliasing" the error surface of the target domain; hence the neural network is less prone to overfitting. In INIT, $\mathcal{T}$'s error surface remains intact. Before training on the target dataset, the parameters are initialized in such a meaningful way that they contain additional knowledge in the source domain. However, in an extreme case where $\mathcal{T}$'s error surface is convex, INIT is ineffective because the parameters can reach the global optimum regardless of their initialization. In practice, deep neural networks usually have highly complicated, non-convex error surfaces. By properly initializing parameters with the knowledge of $\mathcal{S}$, we can reasonably expect that the parameters are in a better "catchment basin," and that the INIT approach can transfer knowledge from $\mathcal{S}$ to $\mathcal{T}$.

5 Results of Transferring by INIT

We first analyze how INIT behaves in NLP-based transfer learning. In addition to two different transfer scenarios regarding semantic relatedness as described in Section 2, we further evaluated two settings: (1) fine-tuning parameters 🔓, and (2) freezing parameters after transfer 🔒. Existing evidence shows that frozen parameters would generally hurt the performance (Peng et al., 2015), but this setting provides a more direct understanding on how transferable the features are (because the factor of target domain optimization is ruled out). Therefore, we included it in our experiments. Moreover, we transferred parameters layer by layer to answer our second research question.

Through Subsections 5.1–5.3, we initialized the parameters of $\mathcal{T}$ with the ones corresponding to the highest validation accuracy of $\mathcal{S}$. In Subsection 5.4, we further investigated when the parameters are ready to be transferred during the training on $\mathcal{S}$.

5.1 Overall Performance

Table 3 shows the main results of INIT. A quick observation is that, in both groups, transfer learning of semantically equivalent tasks (IMDB→MR, SNLI→SICK) appears to be successful with an improvement of ∼6%. The results are not surprising and also reported in Bowman et al. (2015).

For IMDB→QC and SNLI→MSRP, however, there is no improvement of transferring hidden layers (embeddings excluded), namely LSTM-RNN units and CNN feature maps. The E🔓H🔓O□ setting yields a slight degradation of 0.2–0.4%, ∼.5x std. The incapability of transferring is also proved by locking embeddings and hidden layers

(E🔒H🔒O□). We see in this setting, the test performance is very low in QC or even worse than majority-class guess in MSRP. By further examining its training accuracy, which is 48.2% and 65.5%, respectively, we conclude that extracted features by LSTM-RNN and CNN models in $\mathcal{S}$ are almost irrelevant to the ultimate tasks $\mathcal{T}$ (QC and MSRP).

Although in previous studies, researchers have mainly drawn positive conclusions about transfer learning, we find a negative result similar to ours upon careful examination of Collobert and Weston (2008), and unfortunately, their results may be somewhat misinterpreted. In that paper, the authors report transferring NER, POS, CHK, and pretrained word embeddings improves the SRL task by 1.91–3.90% accuracy (out of 16.54–18.40% error rate), but their gain is mainly due to word embeddings. In the settings that use pretrained word embeddings (which is common in NLP), NER, POS, and CHK together improve the SRL accuracy by only 0.04–0.21%.

The above results are rather frustrating, indicating for RQ1 that neural networks may not be transferable to NLP tasks of different semantics. Transfer learning for NLP is more prone to semantics than the image processing domain, where even high-level feature detectors are almost always transferable (Donahue et al., 2014; Yosinski et al., 2014).

Experiment I		
Setting	IMDB→MR	IMDB→QC
Majority	50.0	22.9
E⊠ H□ O□	75.1	90.8
E🔒 H□ O□	78.2	93.2
E🔒 H🔒 O□	78.8	55.6
E🔒 H🔒 O🔒	73.6	–
E🔓 H□ O□	78.3	92.6
E🔓 H🔓 O□	81.4	90.4
E🔓 H🔓 O🔓	80.9	–
Experiment II		
Setting	SNLI→SICK	SNLI→MSRP
Majority	56.9	66.5
E⊠ H□ O□	70.9	69.0
E🔒 H□ O□	69.3	68.1
E🔒 H🔒 O□	70.0	66.4
E🔒 H🔒 O🔒	43.1	–
E🔓 H□ O□	71.0	69.9
E🔓 H🔓 O□	76.3	68.8
E🔓 H🔓 O🔓	77.6	–

Table 3: Main results of neural transfer learning by INIT. We report test accuracies (%) in this table. E: embedding layer; H: hidden layers; O: output layer. ⊠: Word embeddings are pretrained by word2vec; □: Parameters are randomly initialized); 🔒: Parameters are transferred but frozen; 🔓: Parameters are transferred and fine-tuned. Notice that the E🔒H🔒O🔒 and E🔓H🔓O🔓 settings are inapplicable to IMDB→QC and SNLI→MSRP, because the output targets do not share same meanings and numbers of target classes.

5.2 Layer-by-Layer Analysis

To answer RQ2, we next analyze the transferability of each layer. First, we freeze both embeddings and hidden layers (E🔒H🔒). Even in semantically equivalent settings, if we further freeze the output layer (O🔒), the performance in both IMDB→MR and SNLI→SICK drops, but by randomly initializing the output layer's parameters (O□), we can obtain a similar or higher result compared with the baseline (E⊠H□O□). The finding suggests that the output layer is mainly specific to a dataset. Transferring the output layer's parameters yields little (if any) gain.

Regarding embeddings and hidden layers (in the settings E🔓H🔓O□/E🔓H□O□ vs. E⊠H□O□), the IMDB→MR experiment suggests both of embeddings and the hidden layer play an important role, each improving the accuracy by 3%. In SNLI→SICK, however, the main improvement lies in the hidden layer. A plausible explanation is that in sentiment classification tasks (IMDB and MR), information emerges from raw input, i.e., sentiment lexicons and thus their embeddings, but natural language inference tasks (SNLI and SICK) address more on semantic compositionality and thus hidden layers are more important.

Moreover, for semantically different tasks (IMDB→QC and SNLI→MSRP), the embeddings are the only parameters that have been observed to be transferable, slightly benefiting the target task by 2.7x and 1.8x std, respectively.

5.3 How does learning rate affect transfer?

Bowman et al. (2015) suggest that after transferring, a large learning rate may damage the knowledge stored in the parameters; in their paper, they transfer the learning rate information (AdaDelta) from $\mathcal{S}$ to $\mathcal{T}$ in addition to the parameters.

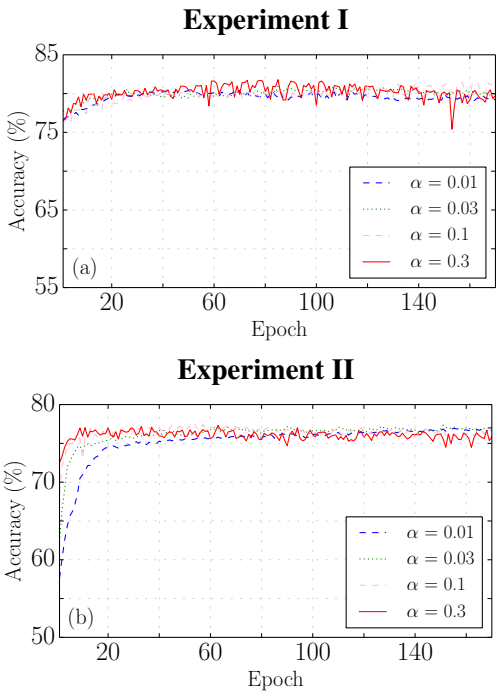

Figure 2: Learning curves of different learning rates (denoted as α). (a) Experiment I: IMDB→MR; (b) Experiment II: SNLI→SICK.

Although the rule of the thumb is to choose all hyperparameters—including the learning rate—by validation, we are curious whether the above conjecture holds. Estimating a rough range of sensible hyperparameters can ease the burden of model selection; it also provides evidence to better understand how transfer learning actually works.

We plot the learning curves of different learning rates α in Figure 2 (IMDB→MR and SNLI→SICK, E🔓H🔓O□). (In the figure, no learning rate decay is applied.) As we see, with a large learning rate like $\alpha = 0.3$, the accuracy increases fast and peaks at earlier epochs. Training with a small learning rate (e.g., $\alpha = 0.01$) is slow, but its peak performance is comparable to large learning rates when iterated by, say, 100 epochs. The learning curves in Figure 2 are similar to classic speed/variance trade-off, and we have the following additional discovery:

> In INIT, transferring learning rate information is not necessarily useful. A large learning rate does not damage the knowledge stored in the pretrained hyperparameters, but accelerates the training process to a large extent. In all, we may need to perform validation to choose the learning rate if computational resources are available.

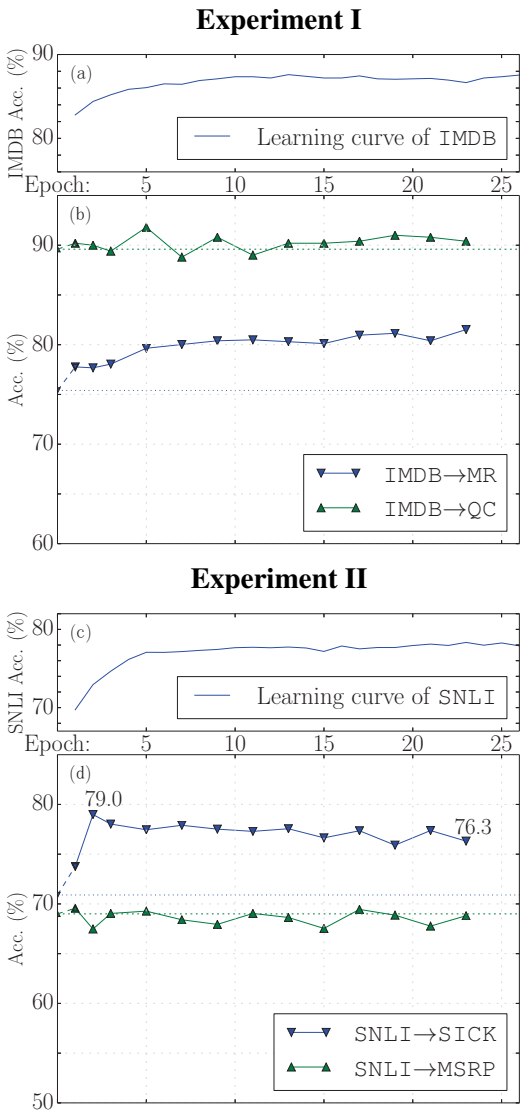

Figure 3: (a) and (c): Learning curves of $\mathcal{S}$. (b) and (d): Accuracies of $\mathcal{T}$ when parameters are transferred at a certain epoch during the training of $\mathcal{S}$. Dotted lines refer to non-transfer, which can be equivalently viewed as transferring before training on $\mathcal{S}$, i.e., epoch $= 0$. Note that the x-axis shares across different subplots.

5.4 When is it ready to transfer?

In the above experiments, we transfer the parameters when they achieve the highest validation performance on $\mathcal{S}$. This is a straightforward and intuitive practice.

However, we may imagine that the parameters well-tuned to the source dataset may be too specific to it, i.e., the model overfits $\mathcal{S}$ and thus may underfit $\mathcal{T}$. Another advantage of early transfer lies in com-

putational concerns. If we manage to transfer model parameters after one or a few epochs on $\mathcal{S}$, we can save much time especially when $\mathcal{S}$ is large.

We therefore made efforts in studying when the neural model is ready to be transferred. Figures 3a and 3c plot the learning curves of the source tasks. The accuracy increases sharply from epochs 1–5; later, it reaches a plateau but is still growing slowly.

We then transferred the parameters at different stages (epochs) of training to target tasks (also with the setting E🔓H🔓O□). Their accuracies are plotted in Figures 3b and 3d.

In IMDB→MR, the source performance and transferring performance align well. The SNLI→SICK experiment, however, produces interesting yet unexpected results. Using the second epoch of SNLI's training yields the highest transfer performance on SICK, i.e., 78.98%, when the SNLI performance itself is comparatively low (72.65% vs. 76.26% at epoch 23). Later, the transfer performance decreases gradually by ∼2.7%. The results in these two experiments are inconsistent and lack explanation.

6 MULT, and its Combination with INIT

To answer RQ3, we investigate how multi-task learning performs in transferring knowledge, as well as the effect of the combination of MULT and INIT. In this section, we applied the setting: sharing embeddings and hidden layers (denoted as E❤H❤O□), analogous to E🔓H🔓O□ in INIT. When combining MULT and INIT, we used the pretrained parameters of embeddings and hidden layers on $\mathcal{S}$ to initialize the multi-task training of $\mathcal{S}$ and $\mathcal{T}$, visually represented by E🔓❤H🔓❤O□.

In both MULT and MULT+INIT, we had a hyperparameter $\lambda \in (0, 1)$ balancing the source and target tasks (defined in Section 4). λ was tuned with a granularity of 0.1. As a friendly reminder, $\lambda = 1$ refers to using $\mathcal{T}$ only; $\lambda = 0$ refers to using $\mathcal{S}$ only. After finding that a small λ yields high performance of MULT in the IMDB+MR and SNLI+SICK experiments (thick blue lines in Figures 4a and 4c), we further tuned the λ from 0.01 to 0.09 with a fine-grained granularity of 0.02.

The results are shown in Figure 4. From the green curves in the 2nd and 4th subplots, we see MULT (with or without INIT) does not improve the accuracy of target tasks (QC and MSRP); the inability to transfer is cross-checked by the INIT method in Section 5. For MR and SICK, on the other hand, transferability of the neural model is also consistently positive (blue curves in Figures 4a and 4c), supporting our conclusion to RQ1 that neural trans-

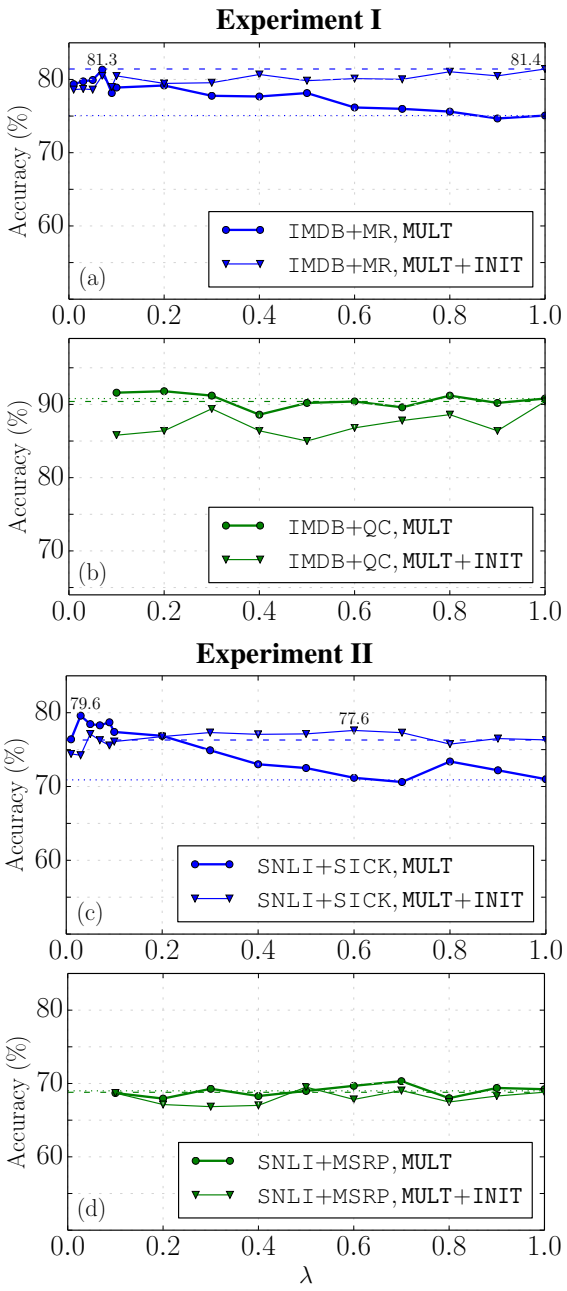

Figure 4: Results of MULT and MULT+INIT, where we share word embeddings and hidden layers. Dotted lines are the non-transfer setting; dashed lines are the INIT setting E🔓H🔓O□, transferred at the peak performance of IMDB and SNLI.

fer learning in NLP depends largely on how similar in semantics the source and target datasets are.

Moreover, we see that the peak performance of MULT is slightly lower than INIT in Experiment I (Figure 4a), but higher in Experiment II (Figure 4c); they are in the same ballpark.

In MULT+INIT (E❤H❤O□), the transfer performance of MULT+INIT remains high for different values of λ. Because the parameters given by INIT have already conveyed sufficient information about the source task, MULT+INIT consistently outperforms non-transferring by a large margin. Its peak performance, however, is not higher than MULT or INIT. In summary, we answer our RQ3 as follows: in our experiments, MULT and INIT are generally comparable; we do not obtain further gain by combining MULT and INIT.

7 Concluding Remarks

In this paper, we addressed the problem of transfer learning in neural network-based NLP applications. We conducted two series of experiments on six datasets, showing that the transferability of neural NLP models depends largely on the semantic relatedness of the source and target tasks, which is different from other domains like image processing. We analyzed the behavior of different neural layers. We also experimented with two transfer methods: parameter initialization (INIT) and multi-task learning (MULT). Besides, we reported two additional studies in Sections 5.3 and 5.4 (not repeated here). Our paper provides insight on the transferability of neural NLP models; the results also help to better understand neural features in general.

How transferable are the conclusions in this paper? We have to concede that empirical studies are subject to a variety of factors (e.g., models, tasks, datasets), and that conclusions may vary in different scenarios. In our paper, we have tested all results on two groups of experiments involving 6 datasets and 2 neural models (CNN and LSTM-RNN). Both models and tasks are widely studied in the literature, and not chosen deliberately. Results are mostly consistent (except Section 5.4). Along with analyzing our own experimental data, we have also collected related results in previous studies, serving as additional evidence in answering our research questions. Therefore, we think the generality of this work is fair and that the conclusions can be generalized to similar scenarios.

Future work. Our work also points out some future directions of research. For example, we would like to analyze the effect of different MULT strategies. More efforts are also needed in developing an effective yet robust method for multi-task learning.

Abstract

Word embeddings allow natural language processing systems to share statistical information across related words. These embeddings are typically based on distributional statistics, making it difficult for them to generalize to rare or unseen words. We propose to improve word embeddings by incorporating morphological information, capturing shared sub-word features. Unlike previous work that constructs word embeddings directly from morphemes, we combine morphological and distributional information in a unified probabilistic framework, in which the word embedding is a latent variable. The morphological information provides a prior distribution on the latent word embeddings, which in turn condition a likelihood function over an observed corpus. This approach yields improvements on intrinsic word similarity evaluations, and also in the downstream task of part-of-speech tagging.

1 Introduction

Word embeddings have been shown to improve many natural language processing applications, from language models (Mikolov et al., 2010) to information extraction (Collobert and Weston, 2008), and from parsing (Chen and Manning, 2014) to machine translation (Cho et al., 2014). Word embeddings leverage a classical idea in natural language processing: use distributional statistics from large amounts of unlabeled data to learn representations that allow sharing across related words (Brown et al., 1992). While this approach is undeniably effective, the long-tail nature of linguistic data ensures that there will always be words that are not observed in even the largest corpus (Zipf, 1949). There will be many other words which are observed only a handful of times, making the distributional statistics too sparse to accurately estimate the 100- or 1000-dimensional dense vectors that are typically used for word embeddings. These problems are particularly acute in morphologically rich languages like German and Turkish, where each word may have dozens of possible inflections.

Recent work has proposed to address this issue by replacing word-level embeddings with embeddings based on subword units: morphemes (Luong et al., 2013; Botha and Blunsom, 2014) or individual characters (Santos and Zadrozny, 2014; Ling et al., 2015; Kim et al., 2016). Such models leverage the fact that word meaning is often *compositional*, arising from subword components. By learning representations of subword units, it is possible to generalize to rare and unseen words.

But while morphology and orthography are sometimes a signal of semantics, there are also many cases similar spellings do *not* imply similar meanings: *better-batter*, *melon-felon*, *dessert-desert*, etc. If each word's embedding is constrained to be a deterministic function of its characters, as in prior work, then it will be difficult to learn appropriately distinct embeddings for such pairs. Automated morphological analysis may be incorrect: for example, *really* may be segmented into *re+ally*, incorrectly suggesting a similarity to *revise* and *review*. Even correct morphological segmentation may be misleading. Consider

that *incredible* and *inflammable* share a prefix *in-*, which exerts the opposite effect in these two cases.[1] Overall, a word's observed internal structure gives evidence about its meaning, but it must be possible to override this evidence when the distributional facts point in another direction.

We formalize this idea using the machinery of probabilistic graphical models. We treat word embeddings as *latent variables* (Vilnis and McCallum, 2014), which are conditioned on a prior distribution that is based on word morphology. We then maximize a variational approximation to the expected likelihood of an observed corpus of text, fitting variational parameters over latent binary word embeddings. For common words, the expected word embeddings are largely determined by the expected corpus likelihood, and thus, by the distributional statistics. For rare words, the prior plays a larger role. Since the prior distribution is a function of the morphology, it is possible to impute embeddings for unseen words after training the model.

We model word embeddings as latent binary vectors. This choice is based on linguistic theories of lexical semantics and morphology. Morphemes are viewed as adding morphosyntactic *features* to words: for example, in English, *un-* adds a negation feature (*unbelievable*), *-s* adds a plural feature, and *-ed* adds a past tense feature (Halle and Marantz, 1993). Similarly, the lexicon is often viewed as organized in terms of features: for example, the word *bachelor* carries the features HUMAN, MALE, and UNMARRIED (Katz and Fodor, 1963). Each word's semantic role within a sentence can also be characterized in terms of binary features (Dowty, 1991; Reisinger et al., 2015). Our approach is more amenable to such theoretical models than traditional distributed word embeddings. However, we can also work with the *expected word embeddings*, which are vectors of probabilities, and can therefore be expected to hold the advantages of dense distributed representations (Bengio et al., 2013).

[1]The confusion is resolved by morphologically analyzing the second example as *(in+flame)+able*, but this requires hierarchical morphological parsing, not just segmentation.

2 Model

The modeling framework is illustrated in Figure 1, focusing on the word *sesquipedalianism*. This word is rare, but its morphology indicates several of its properties: the *-ism* suffix suggests that the word is a noun, likely describing some abstract property; the *sesqui-* prefix refers to one and a half, and so on. If the word is unknown, we must lean heavily on these intuitions, but if the word is well attested then we can rely instead on its examples in use.

It is this reasoning that our modeling framework aims to formalize. We treat word embeddings as latent variables in a joint probabilistic model. The prior distribution over a word's embedding is conditioned on its morphological structure. The embedding itself then participates, as a latent variable, in a neural sequence model over a corpus, contributing to the overall corpus likelihood. If the word appears frequently, then the corpus likelihood dominates the prior — which is equivalent to relying on the word's distributional properties. If the word appears rarely, then the prior distribution steps in, and gives a best guess as to the word's meaning.

Before describing these component pieces in detail, we first introduce some notation. The representation of word w is a latent binary vector $\boldsymbol{b}_w \in \{0,1\}^k$, where k is the size of each word embedding. As noted in the introduction, this binary representation is motivated by feature-based theories of lexical semantics (Katz and Fodor, 1963). Each word w is constructed from a set of M_w observed morphemes, $\mathcal{M}_w = (m_{w,1}, m_{w,2}, \ldots, m_{w,M_w})$. Each morpheme is in turn drawn from a finite vocabulary of size v_m, so that $m_{w,i} \in \{1, 2, \ldots, v_m\}$. Morphemes are obtained from an unsupervised morphological segmenter, which is treated as a black box. Finally, we are given a corpus, which is a sequence of words, $\boldsymbol{x} = (x_1, x_2, \ldots, x_N)$, where each word $x_t \in \{1, 2, \ldots, v_w\}$, with v_w equal to the size of the vocabulary, including the token $\langle \text{UNK} \rangle$ for unknown words.

2.1 Prior distribution

The key differentiating property of this model is that rather than estimating word embeddings directly, we treat them as a latent variable, with a prior distribution reflecting the word's morphological proper-

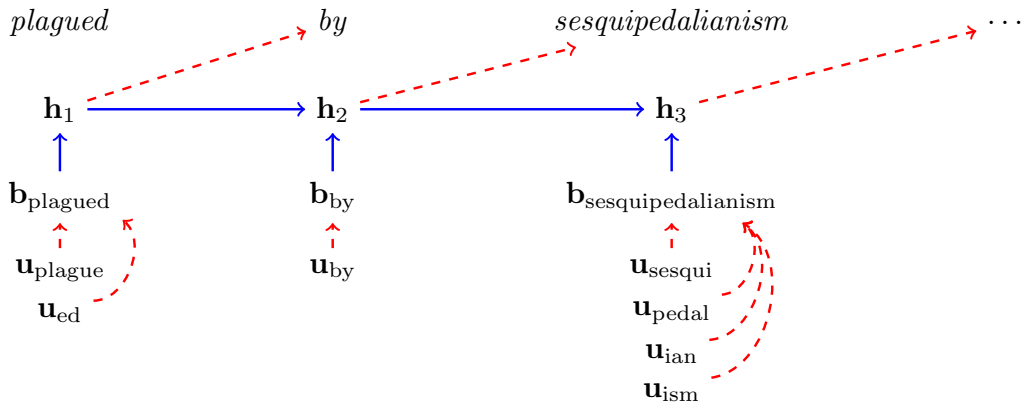

Figure 1: Model architecture, applied to the example sequence . . . *plagued by sesquipedalianism* . . . . Blue solid arrows indicate direct computation, red dashed arrows indicate probabilistic dependency. For simplicity, we present our models as recurrent neural networks rather than long short-term memories (LSTMs).

ties. To characterize this prior distribution, each morpheme m is associated with an embedding of its own, $\boldsymbol{u}_m \in \mathbb{R}^k$, where k is again the embedding size. Then for position i of the word embedding $\boldsymbol{b}_w$, we have the following prior,

$$b_{w,i} \sim \text{Bernoulli}\left(\sigma(\sum_{m \in \mathcal{M}_w} u_{m,i})\right), \quad (1)$$

where $\sigma(\cdot)$ indicates the sigmoid function. The prior log-likelihood for a set of word embeddings is,

$$\log P(\boldsymbol{b}; \mathcal{M}, \boldsymbol{u}) \quad (2)$$

$$= \sum_{w}^{V_w} \log P(\boldsymbol{b}_w; \mathcal{M}_w, \boldsymbol{u}) \quad (3)$$

$$= \sum_{w}^{V_w} \sum_{i}^{k} \log P(b_{w,i}; \mathcal{M}_w, \boldsymbol{u}) \quad (4)$$

$$= \sum_{w}^{V_w} \sum_{i}^{k} b_{w,i} \log \sigma\left(\sum_{m \in \mathcal{M}_w} u_{m,i}\right) \quad (5)$$

$$+ (1 - b_{w,i}) \log\left(1 - \sigma\left(\sum_{m \in \mathcal{M}_w} u_{m,i}\right)\right).$$

2.2 Expected likelihood

The corpus likelihood is computed via a recurrent neural network language model (Mikolov et al., 2010, RNNLM), which is a generative model of sequences of tokens. In the RNNLM, the probability of each word is conditioned on all preceding words through a recurrently updated state vector. This state vector in turn depends on the embeddings of the previous words, through the following update equations:

$$\boldsymbol{h}_t = f(\boldsymbol{b}_{x_t}, \boldsymbol{h}_{t-1}) \quad (6)$$

$$x_{t+1} \sim \text{Multinomial}\left(\text{Softmax}\left[\mathbf{V}\boldsymbol{h}_t\right]\right). \quad (7)$$

The function $f(\cdot)$ is a recurrent update equation; in the RNN, it corresponds to $\sigma(\Theta \boldsymbol{h}_{t-1} + \boldsymbol{b}_{x_t})$, where $\sigma(\cdot)$ is the elementwise sigmoid function. The matrix $\mathbf{V} \in \mathbb{R}^{v \times k}$ contains the "output embeddings" of each word in the vocabulary. We can then define the conditional log-likelihood of a corpus $\boldsymbol{x} = (x_1, x_2, \ldots x_N)$ as,

$$\log P(\boldsymbol{x} \mid \boldsymbol{b}) = \sum_{t}^{N} \log P(x_t \mid \boldsymbol{h}_{t-1}, \boldsymbol{b}). \quad (8)$$

Since $\boldsymbol{h}_{t-1}$ is deterministically computed from $\boldsymbol{x}_{1:t-1}$ (conditioned on $\boldsymbol{b}$), we can equivalently write the log-likelihood as,

$$\log P(\boldsymbol{x} \mid \boldsymbol{b}) = \sum_{t} \log P(x_t \mid \boldsymbol{x}_{1:t-1}, \boldsymbol{b}). \quad (9)$$

This same notation can be applied to compute the likelihood under a long-short term memory (LSTM) language model (Sundermeyer et al., 2012). The only difference is that the recurrence function $f(\cdot)$ from Equation 6 now becomes more complex, including the input, output, and forget gates, and the recurrent state $\boldsymbol{h}_t$ now includes the memory cell. As the LSTM

update equations are well known, we focus on the more concise RNN notation, but we employ LSTMs in all experiments due to their better ability to capture long-range dependencies.

2.3 Variational approximation

Inference on the marginal likelihood $P(\boldsymbol{x}_{1:N}) = \int P(\boldsymbol{x}_{1:N}, \boldsymbol{b}) d\boldsymbol{b}$ is intractable. We address this issue by making a variational approximation,

$$\log P(\boldsymbol{x}) = \log \sum_{\boldsymbol{b}} P(\boldsymbol{x} \mid \boldsymbol{b}) P(\boldsymbol{b}) \tag{10}$$

$$= \log \sum_{\boldsymbol{b}} \frac{Q(\boldsymbol{b})}{Q(\boldsymbol{b})} P(\boldsymbol{x} \mid \boldsymbol{b}) P(\boldsymbol{b}) \tag{11}$$

$$= \log E_q \left[P(\boldsymbol{x} \mid \boldsymbol{b}) \frac{P(\boldsymbol{b})}{Q(\boldsymbol{b})} \right] \tag{12}$$

$$\geq E_q[\log P(\boldsymbol{x} \mid \boldsymbol{b}) + \log P(\boldsymbol{b}) - \log Q(\boldsymbol{b})] \tag{13}$$

The variational distribution $Q(\boldsymbol{b})$ is defined using a fully factorized mean field approximation,

$$Q(\boldsymbol{b}; \boldsymbol{\gamma}) = \prod_{w}^{v_w} \prod_{i}^{k} q(b_{w,i}; \gamma_{w,i}). \tag{14}$$

The variational distribution is a product of Bernoullis, with parameters $\gamma_{w,j} \in [0, 1]$. In the evaluations that follow, we use the expected word embeddings $q(\boldsymbol{b}_w)$, which are dense vectors in $[0, 1]^k$. We can then use $Q(\cdot)$ to place a variational lower bound on the expected conditional likelihood,

Even with this variational approximation, the expected log-likelihood is still intractable to compute. In recurrent neural network language models, each word x_t is conditioned on the entire prior history, $\boldsymbol{x}_{1:t-1}$ — indeed, this is one of the key advantages over fixed-length n-gram models. However, this means that the individual expected log probabilities involve not just the word embedding of x_t and its immediate predecessor, but rather, the embeddings of *all* words in the sequence $\boldsymbol{x}_{1:t}$:

$$E_q \left[\log P(\boldsymbol{x} \mid \boldsymbol{b}) \right] \tag{15}$$

$$= \sum_{t}^{N} E_q \left[\log P(x_t \mid \boldsymbol{x}_{1:t-1}, \boldsymbol{b}) \right] \tag{16}$$

$$= \sum_{t}^{N} \sum_{\{\boldsymbol{b}_w : w \in \boldsymbol{x}_{1:t}\}} Q(\{\boldsymbol{b}_w : w \in \boldsymbol{x}_{1:t}\}) \times \log P(x_t \mid \boldsymbol{x}_{1:t-1}, \boldsymbol{b}). \tag{17}$$

We therefore make a further approximation by taking a local expectation over the recurrent state,

$$E_q \left[\boldsymbol{h}_t \right] \approx f(E_q \left[\boldsymbol{b}_{x_t} \right], E_q \left[\boldsymbol{h}_{t-1} \right]) \tag{18}$$

$$E_q \left[\log P(x_t \mid \boldsymbol{x}_{1:t-1}, \boldsymbol{b}) \right] \approx \log \text{Softmax} \left(\mathbf{V} E_q \left[\boldsymbol{h}_t \right] \right). \tag{19}$$

This approximation means that we do not propagate uncertainty about $\boldsymbol{h}_t$ through the recurrent update or through the likelihood function, but rather, we use local point estimates. Alternative methods such as variational autoencoders (Chung et al., 2015) or sequential Monte Carlo (de Freitas et al., 2000) might provide better and more principled approximations, but this direction is left for future work.

Variational bounds in the form of Equation 13 can generally be expressed as a difference between an expected log-likelihood term and a term for the Kullback-Leibler (KL) divergence between the prior distribution $P(\boldsymbol{b})$ and the variational distribution $Q(\boldsymbol{b})$ (Wainwright and Jordan, 2008). Incorporating the approximation in Equation 19, the resulting objective is,

$$\mathcal{L} = \sum_{t}^{N} \log P(x_t \mid \boldsymbol{x}_{1:t-1}; E_q[\boldsymbol{b}]) - D_{KL}(Q(\boldsymbol{b}) \parallel P(\boldsymbol{b})). \tag{20}$$

The KL divergence is equal to,

$$D_{KL}(Q(\boldsymbol{b}) \parallel P(\boldsymbol{b})) \tag{21}$$

$$= \sum_{w}^{v_w} \sum_{i}^{k} D_{KL}(q(b_{w,i}) \parallel P(b_{w,i})) \tag{22}$$

$$= \sum_{w}^{v_w} \sum_{i}^{k} \gamma_{w,i} \log \sigma(\sum_{m \in \mathcal{M}_w} u_{m,i}) + (1 - \gamma_{w,i}) \log(1 - \sigma(\sum_{m \in \mathcal{M}_w} u_{m,i})) - \gamma_{w,i} \log \gamma_{w,i} - (1 - \gamma_{w,i}) \log(1 - \gamma_{w,i}). \tag{23}$$

Each term in the variational bound can be easily constructed in a computation graph, enabling automatic differentiation and the application of standard stochastic optimization techniques.

3 Implementation

The objective function is given by the variational lower bound in Equation 20, using the approximation to the conditional likelihood described in Equation 19. This function is optimized in terms of several parameters:

- the morpheme embeddings, $\{\boldsymbol{u}_m\}_{m \in 1 \ldots v_m}$;
- the variational parameters on the word embeddings, $\{\boldsymbol{\gamma}\}_{w \in 1 \ldots v_w}$;
- the output word embeddings $\mathbf{V}$;
- the parameter of the recurrence function, Θ.

Each of these parameters is updated via the `RMSProp` online learning algorithm (Tieleman and Hinton, 2012). The model and baseline (described below) are implemented in `blocks` (van Merriënboer et al., 2015). In the remainder of the paper, we refer to our model as VAREMBED.

3.1 Data and preprocessing

All embeddings are trained on 22 million tokens from the the North American News Text (NANT) corpus (Graff, 1995). We use an initial vocabulary of 50,000 words, with a special ⟨UNK⟩ token for words that are not among the 50,000 most common. We then perform downcasing and convert all numeric tokens to a special ⟨NUM⟩ token. After these steps, the vocabulary size decreases to 48,986. Note that the method can impute word embeddings for out-of-vocabulary words under the prior distribution $P(\boldsymbol{b}; \mathcal{M}, \boldsymbol{u})$; however, it is still necessary to decide on a vocabulary size to determine the number of variational parameters $\boldsymbol{\gamma}$ and output embeddings to estimate.

Unsupervised morphological segmentation is performed using Morfessor (Creutz and Lagus, 2002), with a maximum of sixteen morphemes per word. This results in a total of 14,000 morphemes, which includes stems for monomorphemic words. We do not rely on any labeled information about morphological structure, although the incorporation of gold morphological analysis is a promising topic for future work.

3.2 Learning details

The LSTM parameters are initialized uniformly in the range $[-0.08, 0.08]$. The word embeddings are initialized using pre-trained `word2vec` embeddings. We train the model for 15 epochs, with an initial learning rate of 0.01, a decay of 0.97 per epoch, and minibatches of size 25. We clip the norm of the gradients (normalized by minibatch size) at 1, using the default settings in the `RMSprop` implementation in `blocks`. These choices are motivated by prior work (Zaremba et al., 2014). After each iteration, we compute the objective function on the development set; when the objective does not improve beyond a small threshold, we halve the learning rate.

Training takes roughly one hour per iteration using an NVIDIA 670 GTX, which is a commodity graphics processing unit (GPU) for gaming. This is nearly identical to the training time required for our reimplementation of the algorithm of Botha and Blunsom (2014), described below.

3.3 Baseline

The most comparable approach is that of Botha and Blunsom (2014). In their work, embeddings are estimated for each morpheme, as well as for each in-vocabulary word. The final embedding for a word is then the sum of these embeddings, e.g.,

$$\overline{\text{greenhouse}} = \overline{\textit{greenhouse}} + \overline{\textit{green}} + \overline{\textit{house}}, \tag{24}$$

where the italicized elements represent learned embeddings.

We build a baseline that is closely inspired by this approach, which we call SUMEMBED. The key difference is that while Botha and Blunsom (2014) build on the log-bilinear language model (Mnih and Hinton, 2007), we use the same LSTM-based architecture as in our own model implementation. This enables our evaluation to focus on the critical difference between the two approaches: the use of latent variables rather than summation to model the word embeddings. As with our method, we used pre-trained `word2vec` embeddings to initialize the model.

3.4 Number of parameters

The dominant terms in the overall number of parameters are the (expected) word embeddings themselves. The variational parameters of the input word embeddings, γ, are of size $k \times v_w$. The output word embeddings are of size $\#|\boldsymbol{h}| \times v_w$. The morpheme embeddings are of size $k \times v_m$, with $v_m \ll v_w$. In our main experiments, we set $v_w = 48,896$ (see above), $k = 128$, and $\#|\boldsymbol{h}| = 128$. After including the character embeddings and the parameters of the recurrent models, the total number of parameters is roughly 12.8 million. This is identical to number of parameters in the SUMEMBED baseline.

4 Evaluation

Our evaluation compares the following embeddings:

WORD2VEC We train the popular `word2vec` CBOW (continuous bag of words) model (Mikolov et al., 2013), using the `gensim` implementation.

SUMEMBED We compare against the baseline described in § 3.3, which can be viewed as a reimplementation of the compositional model of Botha and Blunsom (2014).

VAREMBED For our model, we take the *expected* embeddings $E_q[\boldsymbol{b}]$, and then pass them through an inverse sigmoid function to obtain values over the entire real line.

4.1 Word similarity

Our first evaluation is based on two classical word similarity datasets: Wordsim353 (Finkelstein et al., 2001) and the Stanford "rare words" (rw) dataset (Luong et al., 2013). We report Spearmann's ρ, a measure of rank correlation, evaluating on both the entire vocabulary as well as the subset of in-vocabulary words.

As shown in Table 1, VAREMBED consistently outperforms SUMEMBED on both datasets. On the subset of in-vocabulary words, WORD2VEC gives slightly better results on the wordsim words that are in the NANT vocabulary, but is not applicable to the complete dataset. On the rare words dataset, WORD2VEC performs considerably worse than both morphology-based models, matching the findings of Luong et al. (2013) and Botha and Blunsom (2014) regarding the importance of morphology for doing well on this dataset.

4.2 Alignment with lexical semantic features

Recent work questions whether these word similarity metrics are predictive of performance on downstream tasks (Faruqui et al., 2016). The QVEC statistic is another intrinsic evaluation method, which has been shown to be better correlated with downstream tasks (Tsvetkov et al., 2015). This metric measures the alignment between word embeddings and a set of lexical semantic features. Specifically, we use the semcor noun verb supersenses oracle provided at the qvec github repository.[2]

As shown in Table 2, VAREMBED outperforms SUMEMBED on the full lexicon, and gives similar performance to WORD2VEC on the set of in-vocabulary words. We also consider the morpheme embeddings alone. For SUMEMBED, this means that we construct the word embedding from the sum of the embeddings for its morphemes, *without* the additional embedding per word. For VAREMBED, we use the expected embedding under the prior distribution $E[\boldsymbol{b} \mid \boldsymbol{c}]$. The results for these representations are shown in the bottom half of Table 2, revealing that VAREMBED learns much more meaningful embeddings at the morpheme level, while much of the power of SUMEMBED seems to come from the word embeddings.

[2] `https://github.com/ytsvetko/qvec`

	WORD2VEC	SUMEMBED	VAREMBED
Wordsim353			
all words (353)	n/a	42.9	**48.8**
in-vocab (348)	**51.4**	45.9	51.3
rare words (rw)			
all words (2034)	n/a	23.0	**24.0**
in-vocab (715)	33.6	37.3	**44.1**

Table 1: Word similarity evaluation results, as measured by Spearmann's $\rho \times 100$. WORD2VEC cannot be evaluated on all words, because embeddings are not available for out-of-vocabulary words. The total number of words in each dataset is indicated in parentheses.

	all words (4199)	in vocab (3997)
WORD2VEC	n/a	**34.8**
SUMEMBED	32.8	33.5
VAREMBED	**33.6**	34.7
morphemes only		
SUMEMBED	24.7	25.1
VAREMBED	**30.2**	**31.0**

Table 2: Alignment with lexical semantic features, as measured by QVEC. Higher scores are better, with a maximum possible score of 100.

4.3 Part-of-speech tagging

Our final evaluation is on the downstream task of part-of-speech tagging, using the Penn Treebank. We build a simple classification-based tagger, using a feedforward neural network. (This is not intended as an alternative to state-of-the-art tagging algorithms, but as a comparison of the syntactic utility of the information encoded in the word embeddings.) The inputs to the network are the concatenated embeddings of the five word neighborhood $(x_{t-2}, x_{t-1}, x_t, x_{t+1}, x_{t+2})$; as in all evaluations, 128-dimensional embeddings are used, so the total size of the input is 640. This input is fed into a network with two hidden layers of size 625, and a softmax output layer over all tags. We train using RMSProp (Tieleman and Hinton, 2012).

Results are shown in Table 3. Both morphologically-informed embeddings are significantly better to WORD2VEC ($p < .01$, two-tailed binomial test), but the difference between SUMEMBED and VAREMBED is not significant

	dev	test
WORD2VEC	92.42	92.40
SUMEMBED	**93.26**	**93.26**
VAREMBED	93.05	93.09

Table 3: Part-of-speech tagging accuracies

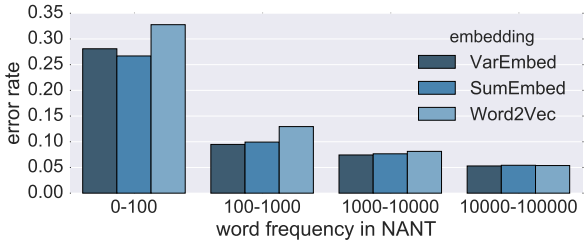

Figure 2: Error rates by word frequency.

at $p < .05$. Figure 2 breaks down the errors by word frequency. As shown in the figure, the tagger based on WORD2VEC performs poorly for rare words, which is expected because these embeddings are estimated from sparse distributional statistics. SUMEMBED is slightly better on the rarest words (the $0 - 100$ group accounts for roughly 10% of all tokens). In this case, it appears that this simple additive model is better, since the distributional statistics are too sparse to offer much improvement. The probabilistic VAREMBED embeddings are best for all other frequency groups, showing that it effectively combines morphology and distributional statistics.

5 Related work

Adding side information to word embeddings An alternative approach to incorporating additional

information into word embeddings is to constrain the embeddings of semantically-related words to be similar. Such work typically draws on existing lexical semantic resources such as WordNet. For example, Yu and Dredze (2014) define a joint training objective, in which the word embedding must predict not only neighboring word tokens in a corpus, but also related word *types* in a semantic resource; a similar approach is taken by Bian et al. (2014). Alternatively, Faruqui et al. (2015) propose to "retrofit" pre-trained word embeddings over a semantic network. Both retrofitting and our own approach treat the true word embeddings as latent variables, from which the pre-trained word embeddings are stochastically emitted. However, a key difference from our approach is that the underlying representation in these prior works is relational, and not generative. These methods can capture similarity between words in a relational lexicon such as WordNet, but they do not offer a generative account of how (approximate) meaning is constructed from orthography or morphology.

Word embeddings and morphology The SUMEMBED baseline is based on the work of Botha and Blunsom (2014), in which words are segmented into morphemes using MORFESSOR (Creutz and Lagus, 2002), and then word representations are computed through addition of morpheme representations. A key modeling difference from this prior work is that rather than computing word embeddings directly and deterministically from subcomponent embeddings (morphemes or characters, as in (Ling et al., 2015; Kim et al., 2016)), we use these subcomponents to define a prior distribution, which can be overridden by distributional statistics for common words. Other work exploits morphology by training word embeddings to optimize a joint objective over distributional statistics and rich, morphologically-augmented part of speech tags (Cotterell and Schütze, 2015). This can yield better word embeddings, but does not provide a way to compute embeddings for unseen words, as our approach does.

Recent work by Cotterell et al. (2016) extends the idea of retrofitting, which was based on semantic similarity, to a morphological framework. In this model, embeddings are learned for morphemes as well as for words, and each word embedding is conditioned on the sum of the morpheme embeddings, using a multivariate Gaussian. The covariance of this Gaussian prior is set to the inverse of the number of examples in the training corpus, which has the effect of letting the morphology play a larger role for rare or unseen words. Like all retrofitting approaches, this method is applied in a pipeline fashion after training word embeddings on a large corpus; in contrast, our approach is a joint model over the morphology and corpus. Another practical difference is that Cotterell et al. (2016) use gold morphological features, while we use an automated morphological segmentation.

Latent word embeddings Word embeddings are typically treated as a parameter, and are optimized through point estimation (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2010). Current models use word embeddings with hundreds or even thousands of parameters per word, yet many words are observed only a handful of times. It is therefore natural to consider whether it might be beneficial to model uncertainty over word embeddings. Vilnis and McCallum (2014) propose to model Gaussian densities over dense vector word embeddings. They estimate the parameters of the Gaussian directly, and, unlike our work, do not consider using orthographic information as a prior distribution. This is easy to do in the latent binary framework proposed here, which is also a better fit for some theoretical models of lexical semantics (Katz and Fodor, 1963; Reisinger et al., 2015). This view is shared by Kruszewski et al. (2015), who induce binary word representations using labeled data of lexical semantic entailment relations, and by Henderson and Popa (2016), who take a mean field approximation over binary representations of lexical semantic features to induce hyponymy relations.

More broadly, our work is inspired by recent efforts to combine directed graphical models with discriminatively trained "deep learning" architectures. The variational autoencoder (Kingma and Welling, 2014), neural variational inference (Mnih and Gregor, 2014; Miao et al., 2016), and black box variational inference (Ranganath et al., 2014) all propose to use a neural network to compute the variational approximation. These ideas are employed by Chung et al. (2015) in the variational recurrent neural network, which places a latent continuous variable at each time step. In contrast, we have a dictionary of latent vari-

ables — the word embeddings — which introduce uncertainty over the hidden state $\boldsymbol{h}_t$ in a standard recurrent neural network or LSTM. We train this model by employing a mean field approximation, but these more recent techniques for neural variational inference may also be applicable. We plan to explore this possibility in future work.

6 Conclusion and future work

We present a model that unifies compositional and distributional perspectives on lexical semantics, through the machinery of Bayesian latent variable models. In this framework, our prior expectations of word meaning are based on internal structure, but these expectations can be overridden by distributional statistics. The model is based on the very successful long-short term memory (LSTM) for sequence modeling, and while it employs a Bayesian justification, its inference and estimation are little more complicated than a standard LSTM. This demonstrates the advantages of reasoning about uncertainty even when working in a "neural" paradigm.

This work represents a first step, and we see many possibilities for improving performance by extending it. Clearly we would expect this model to be more effective in languages with richer morphological structure than English, and we plan to explore this possibility in future work. From a modeling perspective, our prior distribution merely sums the morpheme embeddings, but a more accurate model might account for sequential or combinatorial structure, through a recurrent (Ling et al., 2015), recursive (Luong et al., 2013), or convolutional architecture (Kim et al., 2016). There appears to be no technical obstacle to imposing such structure in the prior distribution. Furthermore, while we build the prior distribution from morphemes, it is natural to ask whether characters might be a better underlying representation: character-based models may generalize well to non-word tokens such as names and abbreviations, they do not require morphological segmentation, and they require a much smaller number of underlying embeddings. On the other hand, morphemes encode rich regularities across words, which may make a morphologically-informed prior easier to learn than a prior which works directly at the character level. It is possible that this tradeoff could be transcended by combining characters and morphemes in a single model.

Another advantage of latent variable models is that they admit partial supervision. If we follow Tsvetkov et al. (2015) in the argument that word embeddings should correspond to lexical semantic features, then an inventory of such features could be used as a source of partial supervision, thus locking dimensions of the word embeddings to specific semantic properties. This would complement the graph-based "retrofitting" supervision proposed by Faruqui et al. (2015), by instead placing supervision at the level of individual words.

Abstract

Structural isomorphism between languages benefits the performance of cross-lingual applications. We propose an automatic algorithm for cross-lingual similarization of dependency grammars, which automatically learns grammars with high cross-lingual similarity. The algorithm similarizes the annotation styles of the dependency grammars for two languages in the level of classification decisions, and gradually improves the cross-lingual similarity without losing linguistic knowledge resorting to iterative cross-lingual cooperative learning. The dependency grammars given by cross-lingual similarization have much higher cross-lingual similarity while maintaining non-triviality. As applications, the cross-lingually similarized grammars significantly improve the performance of dependency tree-based machine translation.

1 Introduction

Due to the inherent syntactic regularity of each language and the discrepancy between annotation guidelines of linguists, there is not necessarily structural isomorphism between grammars of different languages. For many cross-lingual scenarios such as information retrieval and machine translation, relationships between linguistic units are expected to be (at least roughly) consistent across languages (Hwa et al., 2002; Smith and Eisner, 2009). For cross-lingual applications, syntactic structures with high cross-lingual similarity facilitates knowledge extraction, feature representation and classification decision. The structural isomorphism between languages, therefore, is an important aspect for the performance of cross-lingual applications such as machine translation.

To achieve effective cross-lingual similarization for two grammars in different languages, an adequate algorithm should both improve the cross-lingual similarity between two grammars and maintain the non-triviality of each grammar, where non-triviality indicates that the resulted grammars should not give flat or single-branched outputs. Different from constituency structures, dependency structures are lexicalized without specialized hierarchical structures. Such concise structures depict the syntactic or semantic relationships between words, and thus have advantage on many cross-lingual scenarios. It is worth to perform cross-lingual similarization for dependency grammars, but the special property of dependency grammars makes it hard to directly adopt the conventional structure transformation methods resorting to hand-crafted rules or templates.

Both graph-based models (McDonald et al., 2005) and transition-based models (Nivre et al., 2006) factorize dependency parsing into fundamental classification decisions, that is, the relationships between words or the actions applied to current states. We assume that cross-lingual similarization can also be factorized into fundamental classification decisions, and propose an automatic cross-lingual similarization algorithm for dependency grammars according to this assumption. The algorithm conducts cross-lingual similarization on the level of classification decisions

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 501–510,
Austin, Texas, November 1-5, 2016.

with simple blending operations rather than on the level of syntactic structures with complicated hand-crafted rules or templates, and adopts iterative cross-lingual collaborative learning to gradually improve the cross-lingual similarity while maintaining the non-triviality of grammars.

We design an evaluation metric for the cross-lingual similarity of dependency grammars, which calculates the consistency degree of dependency relationships across languages. We also propose an effective method to measure the *real* performance of the cross-lingually similarized grammars based on the transfer learning methodology (Pan and Yang, 2010). We validate the method on the dependency grammar induction of Chinese and English, where significant increment of cross-lingual similarity is achieved without losing non-triviality of the grammars. As applications, the cross-lingually similarized grammars gain significant performance improvement for the dependency tree-based machine translation by simply replacing the parser of the translator.

2 Graph-based Dependency Parsing

Dependency parsing aims to link each word to its arguments so as to form a directed graph spanning the whole sentence. Normally the directed graph is restricted to a dependency tree where each word depends on exactly one parent, and all words find their parents. Given a sentence as a sequence n words:

$$x = x_1\ x_2\ ..\ x_n$$

dependency parsing finds a dependency tree y, where $(i, j) \in y$ is an edge from the head word x_i to the modifier word x_j. The root $r \in x$ in the tree y has no head word, and each of the other words, $j(j \in x \textbf{ and } j \neq r)$, depends on a head word $i(i \in x \textbf{ and } i \neq j)$.

Following the edge-based factorization method (Eisner, 1996), the score of a dependency tree can be factorized into the dependency edges in the tree. The graph-based method (McDonald et al., 2005) factorizes the score of the tree as the sum of the scores of all its edges, and the score of an edge is defined as the inner product of the feature vector and the weight vector. Given a sentence x, the parsing procedure searches for the candidate dependency tree with the maximum score:

$$\begin{aligned} y(x) &= \underset{y \in \mathbf{GEN}(x)}{\operatorname{argmax}} \mathbf{S}(y) \\ &= \underset{y \in \mathbf{GEN}(x)}{\operatorname{argmax}} \sum_{(i,j) \in y} \mathbf{S}(i, j) \end{aligned} \quad (1)$$

Here, the function $\mathbf{GEN}$ indicates the enumeration of candidate trees. The MIRA algorithm (Crammer et al., 2003) is used to train the parameter vector. A bottom-up dynamic programming algorithm is designed for projective parsing which gives projective parsing trees, and the Chu-Liu-Edmonds algorithm for non-projective parsing which gives non-projective parsing trees.

3 Cross-Lingual Similarization

Since structural analysis can be factorized into fundamental classification decisions, we assume that the adjustment of the analysis results can be factorized into the adjustment of the fundamental decisions. The classification decision for graph-based dependency parsing is to classify the dependency relationship between each pair of words, and we hope it works well to conduct cross-lingual similarization on the level of dependency relationship classification. In this work, we investigate the automatic cross-lingual similarization for dependency grammars on the level of fundamental classification decisions, to avoid the difficulty of using hand-crafted transformation rules or templates.

In this section, we first introduce the evaluation metric for cross-lingual similarity, then describe the automatic cross-lingual similarization algorithm, and finally give a method to measure the real performance of the cross-lingually similarized grammars.

3.1 Evaluation of Cross-Lingual Similarity

The cross-lingual similarity between two dependency structures can be automatically evaluated. Dependency parsing is conducted on sentences, so we take bilingual sentence pairs as the objects for evaluation. The calculation of cross-lingual similarity needs the lexical alignment information between two languages, which can be obtained by manual annotation or unsupervised algorithms.

Given a bilingual sentence pair x_α and x_β, their dependency structures y_α and y_β, and the word

alignment probabilities $\mathcal{A}$, the cross-lingual similarity can be calculated as below:

$$d(y_\alpha, y_\beta) = \frac{\sum_{(i,j)\in y_\alpha} \sum_{(i',j')\in y_\beta} \mathcal{A}_{i,i'}\mathcal{A}_{j,j'}}{\sum_{(i,j)\in y_\alpha} \sum_{i',j'\in x_\beta} \mathcal{A}_{i,i'}\mathcal{A}_{j,j'}} \quad (2)$$

The bracketed word pair indicates a dependency edge. The evaluation metric is a real number between 0 and 1, indicating the degree of cross-lingual consistency between two dependency structures. For the cross-lingual similarity between bilingual paragraphs, we simply define it as the average over the similarity between each sentence pairs.

3.2 Factorized Cooperative Similarization

The fundamental decisions for graph-based dependency parsing are to evaluate the candidate dependency edges. The cross-lingual similarization for fundamental decisions can be defined as some kinds of blending calculation on two evaluation scores, of which the one is directly given by the grammar of the current language (current grammar), and the other is bilingually projected from the grammar of the reference language (reference grammar).

For the words i and j in the sentence x_α in the current language, their evaluated score given by the current grammar is $\mathbf{S}_\alpha(i,j)$, which can be calculated according to formula 1. The score bilingually projected from the reference grammar, $\mathbf{S}^\beta(i,j)$, can be obtained according to the translation sentence x_β in the reference language and the word alignment between two sentences:

$$\mathbf{S}^\beta(i,j) = \sum_{i',j'\in x_\beta} \mathcal{A}_{i,i'}\mathcal{A}_{j,j'}\mathbf{S}_\beta(i',j') \quad (3)$$

where i' and j' are the corresponding words of i and j in the reference sentence x_β, $\mathcal{A}_{i,j}$ indicates the probability that i aligns to j, and $\mathbf{S}_\beta(i',j')$ is the evaluated score of the candidate edge (i',j') given by the reference grammar.

Given the two evaluated scores, we simply adopt the linear weighted summation:

$$\mathbf{S}^\beta_\alpha(i,j) = (1-\lambda)\mathbf{S}_\alpha(i,j) + \lambda\mathbf{S}^\beta(i,j) \quad (4)$$

where λ is the relative weight to control the degree of cross-lingual similarization, indicating to which degree we consider the decisions of the reference grammar when adjusting the decisions of the current grammar. We have to choose a value for λ to achieve an appropriate speed for effective cross-lingual similarization, in order to obtain similarized grammars with high cross-lingual similarity while maintaining the non-triviality of the grammars.

In the re-evaluated full-connected graph, the decoding algorithm searches for the cross-lingually similarized dependency structures, which are used to re-train the dependency grammars. Based on the cross-lingual similarization strategy, iterative cooperative learning simultaneously similarizes the sentences in the current and reference languages, and gradually improves the cross-lingual similarity between two grammars while maintaining the non-triviality of each monolingual grammar. The whole training algorithm is shown in Algorithm 1. To reduce the computation complexity, we choose the same λ for the cross-lingual similarization for both the current and the reference grammars. Another hyper-parameter for the iterative cooperative learning algorithm is the maximum training iteration, which can be determined according to the performance on the development sets.

3.3 Evaluation of Similarized Grammars

The *real* performance of a cross-lingually similarized grammar is hard to directly measured. The accuracy on the standard testing sets no longer reflects the actrual accuracy, since cross-lingual similarization leads to grammars with annotation styles different from those of the original treebanks. We adopt the transfer learning strategy to automatically adapt the divergence between different annotation styles, and design a *transfer classifier* to transform the dependency regularities from one annotation style to another.

The training procedure of the transfer classifier is analogous to the training of a normal classifier except for the features. The transfer classifier adopts guiding features where a guiding signal is attached to the tail of each normal feature. The guiding signal is the dependency path between the pair of words in the source annotations, as shown in Figure 2. Thus, the transfer classifier learns the statistical regularity of the transformation from the annotations of the cross-lingually similarized grammar to the annotations of the original treebank. Figure 1 shows

Algorithm 1 Cooperative cross-lingual similarization.

function BISIMILARIZE($\mathbf{G}_\alpha$, $\mathbf{G}_\beta$, λ, $\mathbf{C}$) ▷ $\mathbf{C}$ includes a set of sentence pairs (x_α, x_β)
  repeat
    $\mathbf{T}_\alpha, \mathbf{T}_\beta \leftarrow$ BIANNOTATE($\mathbf{G}_\alpha, \mathbf{G}_\beta, \lambda, \mathbf{C}$) ▷ it invokes BIPARSE to parse each (x_α, x_β)
    $\mathbf{G}_\alpha \leftarrow$ GRAMMARTRAIN($\mathbf{T}_\alpha$)
    $\mathbf{G}_\beta \leftarrow$ GRAMMARTRAIN($\mathbf{T}_\beta$)
  until SIMILARITY($\mathbf{G}_\alpha, \mathbf{G}_\beta$) converges ▷ according to formula 2, averaged across $\mathbf{C}$
  return $\mathbf{G}_\alpha$, $\mathbf{G}_\beta$
function BIPARSE($\mathbf{G}_\alpha$, $\mathbf{G}_\beta$, λ, x_α, x_β, $\mathcal{A}$)
  $y_\alpha \leftarrow \text{argmax}_y(1-\lambda)\mathbf{S}_\alpha(y) + \lambda\mathbf{S}^\beta(y)$ ▷ according to formula 4
  $y_\beta \leftarrow \text{argmax}_y(1-\lambda)\mathbf{S}_\beta(y) + \lambda\mathbf{S}^\alpha(y)$
  return y_α, y_β

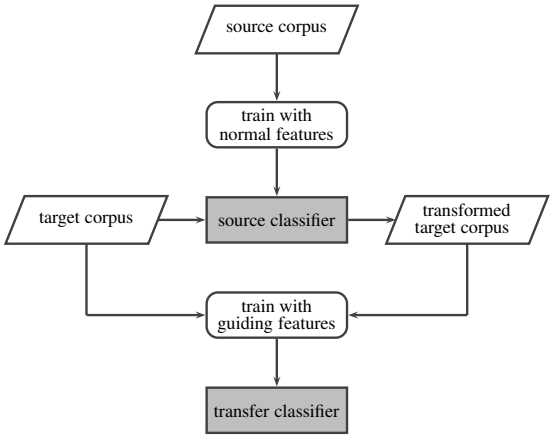

Figure 1: The training procedure of the transfer classifier.

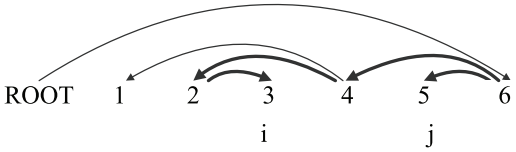
the training pipeline for the transfer classifier, where source corpus and target corpus indicate the cross-lingually similarized treebank and the manually annotated treebank, respectively.

In decoding, a sentence is first parsed by the cross-lingually similarized grammar, and then parsed by the transfer classifier with the result of the similarized grammar as guiding signals to obtain the final parsing results. The improvement achieved by the transfer classifier against a normal classifier trained only on the original treebank reflects the promotion effect of the cross-lingually similarized grammar. The accuracy of the transfer classifier, therefore, *roughly* indicates the real performance of the cross-lingually similarized grammar.



path(i =3, j = 5) = up-up-up-down

Figure 2: The guiding signal for dependency parsing, where $path(i, j)$ denotes the dependency path between i and j. In this example, j is a son of the great-grandfather of i.

4 Tree-based Machine Translation

Syntax-based machine translation investigates the hierarchical structures of natural languages, including formal structures (Chiang, 2005), constituency structures (Galley et al., 2006; Liu et al., 2006; Huang et al., 2006; Mi et al., 2008) and dependency structures (Lin, 2004; Quirk et al., 2005; Ding and Palmer, 2005; Xiong et al., 2007; Shen et al., 2008; Xie et al., 2011), so the performance is restricted to the quality and suitability of the parsers. Since the trees for training follow an annotation style not necessarily isomorphic to that of the target language, it would be not appropriate for syntax-based translation to directly use the parsers trained on the original treebanks. The cross-lingually similarized grammars, although performing poorly on a standard testing set, may be well suitable for syntax-based machine translation. In this work, we use the cross-lingually similarized dependency grammars in dependency tree-to-string machine translation (Xie et al., 2011), a state-of-the-art translation model resorting to dependency trees on the source side.

Treebank	Train	Develop	Test
CTB	1-270 400-931 1001-1151	301-325	271-300
WSJ	02-21	22	23

Table 1: Data partitioning for CTB and WSJ, in unit of section.

5 Experiments and Analysis

We first introduce the dependency parsing itself, then describe the cross-lingual similarization, and finally show the application of cross-lingually similarized grammars in tree-based machine translation. For convenience of description, a grammar trained by the conventional dependency model is named as *original grammar*, a grammar after cross-lingual similarization is named as *similarized grammar*, and the transferred version for a similarized grammar is named as *adapted grammar*.

5.1 Dependency Parsing

We take Chinese dependency parsing as a case study, and experiment on Penn Chinese Treebank (CTB) (Xue et al., 2005). The dependency structures are extracted from the original constituency trees according to the head-selection rules (Yamada and Matsumoto, 2003). The partitioning of the dataset is listed in the Table 1, where we also give the partitioning of Wall Street Journal (WSJ) (Marcus et al., 1993) used to train the English grammar. The evaluation metric for dependency parsing is unlabeled accuracy, indicating the proportion of the words correctly finding their parents. The MIRA algorithm is used to train the classifiers.

Figure 3 gives the performance curves on the development set with two searching modes, *projective* searching and *non-projective* searching. The curves show that the non-projective searching mode fall behind of the projective one, this is because the dependency structures extracted from constituency trees are projective, and the projective search mode implies appropriate constraints on the searching space. Therefore, we use the projective searching mode for the evaluation of the original grammar. Table 2 lists the performance of the original grammar on the CTB testing set.

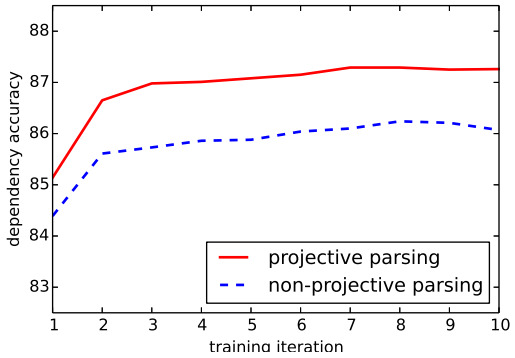


Figure 3: The developing curves of Chinese dependency parsing with both projective and non-projective searching modes.

5.2 Cross-Lingual Similarization

The experiments of cross-lingual similarization are conducted between Chinese and English, with FBIS Chinese-English dataset as bilingual corpus. The Chinese sentences are segmented into words with the character classification model (Ng and Low, 2004), which is trained by MIRA on CTB. The word sequences of both languages are labeled with part-of-speech tags with the maximum entropy hidden markov model (Ratnaparkhi and Adwait, 1996), which is reimplemented with MIRA and trained on CTB and WSJ. The word alignment information is obtained by summing and normalizing the 10 best candidate word alignment results of GIZA++ (Och and Ney, 2003).

The upmost configuration for cross-lingual similarization is the searching mode. On the Chinese side, both projective and non-projective modes can be adopted. For English, there is an additional *fixed* mode besides the previous two. In the fixed mode, the English dependency grammar remains unchanged during the whole learning procedure. The fixed mode on the English side means a degenerated version of cross-lingual similarization, where only the Chinese grammars are revolved during training. The combination of the searching modes for both languages results in a total of 6 kinds of searching configurations. For each configuration, the learning algorithm for cross-lingual similarization has two hyper-parameters, the coefficient λ and maximum iteration for iterative learning, which should be tuned first.

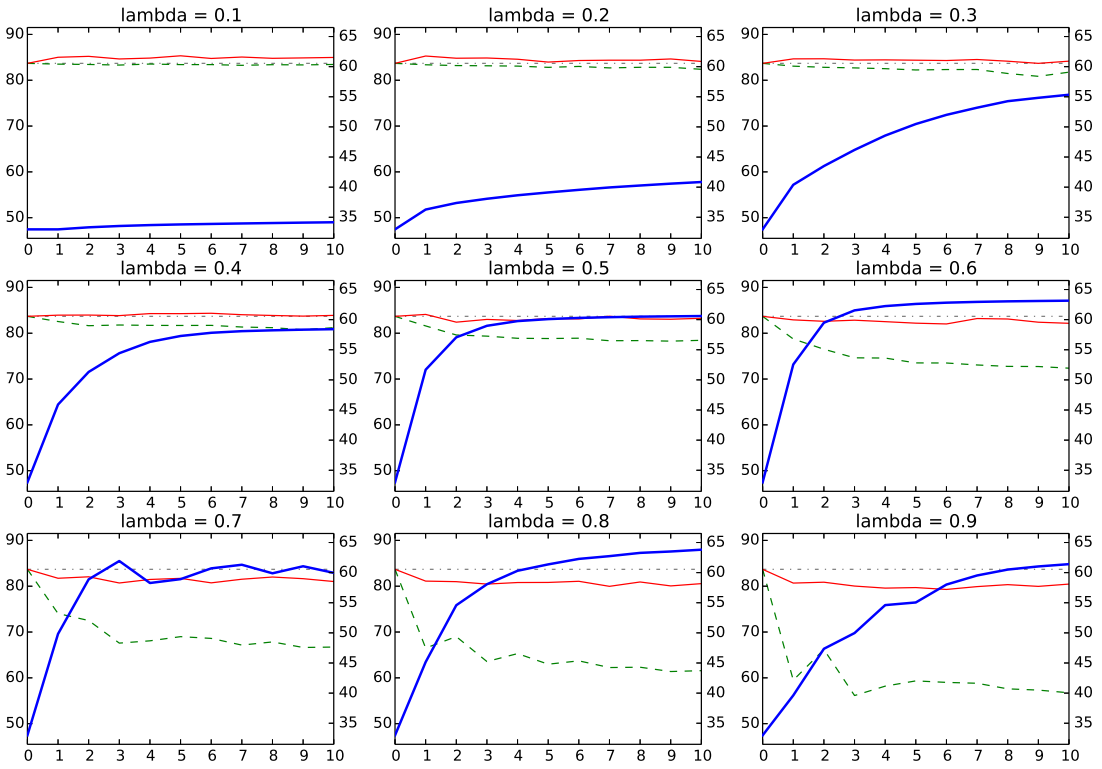

Figure 4: The developing curves of cross-lingual similarization with projective searching on both languages. X-axis: training iteration; Left Y-axis: parsing accuracy; Right Y-axis: cross-lingual similarity. Thin dash-dotted line (gray): accuracy of the baseline grammar; Thin dashed line (green): direct accuracy of cross-lingually similarized grammars; Thin solid line (red): adaptive accuracy of cross-lingually similarized grammars; Thick sold line (blue): the cross-lingual similarity of grammars.

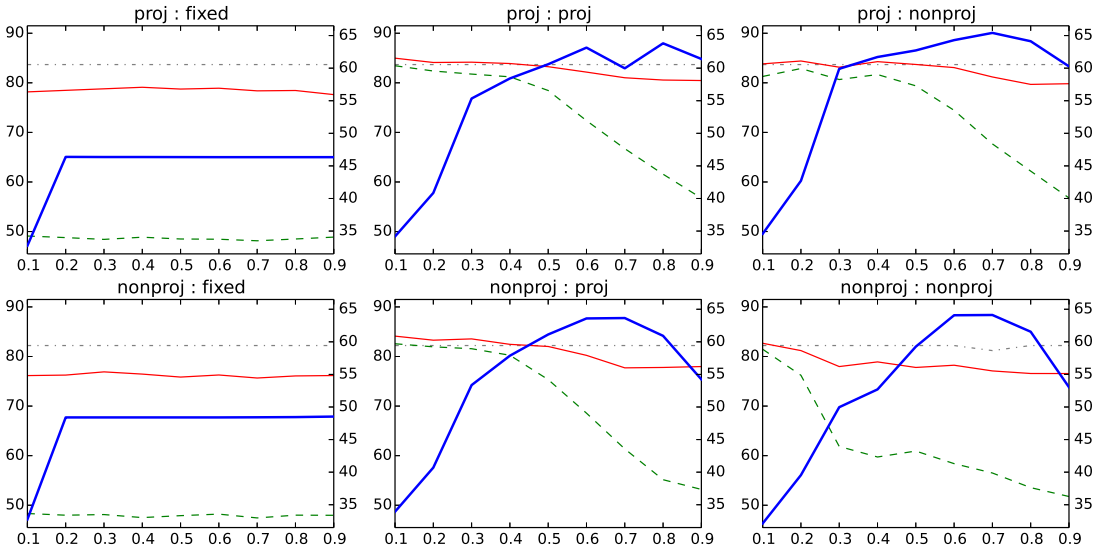

Figure 5: The developing curves of cross-lingual similarization with all searching configurations. X-axis: coefficient λ; Left Y-axis: parsing accuracy; Right Y-axis: cross-lingual similarity. The lines indicate the same as in Figure 4.

5.2.1 Determination of Hyper-Parameters

We select a subset of 40,000 sentence pairs out of the FBIS dataset, and use it as the smaller bilingual corpus to tune the hyper-parameters. For the coefficient λ we try from 0.1 to 0.9 with step 0.1; and for the iterative learning we simply set the maximum iteration as 10. The developing procedure results in a series of grammars. For the configuration with projective searching modes on both sides, a total of 90 pairs of Chinese and English grammars are generated. We use three indicators to validate each similarized grammar generated in the developing procedure, including the performance on the similarized grammar itself (direct accuracy), the performance of the corresponding adapted grammar (adaptive accuracy), and the cross-lingual similarity between the similarized grammar and its English counterpart. Figure 4 shows the developing curves for the configuration with projective searching on both sides. With the fixed maximum iteration 10, we draw the developing curves for the other searching configurations with respect to the weight coefficient, as shown in Figure 5.

We find that the optimal performance is also achieved at 0.6 in most situations. In all configurations, the training procedures increase the cross-lingual similarity of grammars. Along with the increment of cross-lingual similarity, the direct accuracy of the similarized grammars on the development set decreases, but the adaptive accuracy given by the corresponding adapted grammars approach to that of the original grammars. Note that the projective searching mode is adopted for the evaluation of the adapted grammar.

5.2.2 Selection of Searching Modes

With the hyper-parameters given by the developing procedures, cross-lingual similarization is conducted on the whole FBIS dataset. All the searching mode configurations are tried and 6 pairs of grammars are generated. For each of the 6 Chinese dependency grammars, we also give the three indicators as described before. Table 2 shows that, cross-lingual similarization results in grammars with much higher cross-lingual similarity, and the adaptive accuracies given by the adapted grammars approach to those of the original grammars. It indicates that the proposed algorithm improve the cross-lingual similarity without losing syntactic knowledge.

To determine the best searching mode for tree-based machine translation, we use the Chinese-English FBIS dataset as the small-scale bilingual corpus. A 4-gram language model is trained on the Xinhua portion of the Gigaword corpus with the SRILM toolkit (Stolcke and Andreas, 2002). For the analysis given by non-projective similarized grammars, The *projective transformation* should be conducted in order to produce projective dependency structures for rule extraction and translation decoding. In details, the projective transformation first traverses the non-projective dependency structures just as they are projective, then adjusts the order of the nodes according to the traversed word sequences. We take NIST MT Evaluation testing set 2002 (NIST 02) for developing , and use the case-sensitive BLEU (Papineni et al., 2002) to measure the translation accuracy.

The last column of Table 2 shows the performance of the grammars on machine translation. The cross-lingually similarized grammars corresponding to the configurations with projective searching for Chinese always improve the translation performance, while non-projective grammars always hurt the performance. It probably can be attributed to the low performance of non-projective parsing as well as the inappropriateness of the simple projective transformation method. In the final application in machine translation, we adopted the similarized grammar corresponding to the configuration with projective searching on the source side and non-projective searching on the target side.

5.3 Improving Tree-based Translation

Our large-scale bilingual corpus for machine translation consists of 1.5M sentence pairs from LDC data, including LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06. The source sentences are parsed by the original grammar and the selected cross-lingually similarized grammar. The alignments are obtained by running GIZA++ on the corpus in both directions and applying grow-diag-and refinement (Koehn et al., 2003). The English language model is trained on the Xinhua portion of the Gigaword corpus with the SRILM toolkit (Stol-

Grammar	Similarity (%)	Dep. P (%)	Ada. P (%)	BLEU-4 (%)
baseline	34.2	84.5	84.5	24.6
proj : fixed	46.3	54.1	82.3	25.8 $_{(+1.2)}$
proj : proj	63.2	72.2	84.6	26.1 $_{(+1.5)}$

(Liu et al., 2006)	34.55	31.94
(Chiang, 2007)	35.29	33.22
(Xie et al., 2011)	35.82	33.62
Original Grammar	35.44	33.08
Similarized Grammar	**36.78**	**35.12**

Table 3: The performance of the cross-lingually similarized grammar on dependency tree-based translation, compared with related work.

cke and Andreas, 2002). We use NIST 02 as the development set, and NIST 04 and NIST 05 as the testing sets. The quality of translations is evaluated by the case insensitive NIST BLEU-4 metric.

Table 3 shows the performance of the cross-lingually similarized grammar on dependency tree-based translation, compared with previous work (Xie et al., 2011). We also give the performance of constituency tree-based translation (Liu et al., 2006) and formal syntax-based translation (Chiang, 2007). The original grammar performs slightly worse than the previous work in dependency tree-based translation, this can ascribed to the difference between the implementation of the original grammar and the dependency parser used in the previous work. However, the similarized grammar achieves very significant improvement based on the original grammar, and also significant surpass the previous work. Note that there is no other modification on the translation model besides the replacement of the source parser.

From the perspective of performance improvement, tree-to-tree translation would be a better scenario to verify the effectiveness of cross-lingual similarization. This is because tree-to-tree translation suffers from more serious non-isomorphism between the source and the target syntax structures, and our method for cross-lingual similarization can simultaneously similarize both the source and the target grammars. For dependency-based translation, however, there are no available tree-to-tree models for us to verify this assumption. In the future, we want to propose a specific tree-to-tree translation method to better utilize the isomorphism between cross-lingually similarized grammars.

6 Related Work

There are some work devoted to adjusting the syntactic structures according to bilingual constraints to improve constituency tree-based translation (Huang and Knight, 2006; Ambati and Lavie, 2008; Wang et al., 2010; Burkett and Klein, 2012; Liu et al., 2012). These efforts concentrated on constituency structures, adopted hand-crafted transformation templates or rules, and learnt the operation sequences of structure transformation on the bilingual corpora. Such methods are hard to be directly applied to dependency structures due to the great discrepancy between constituency and dependency grammars. There are also work on automatically adjusting the syntactic structures for machine translation resorting to self-training (Morishita et al., 2015), where the parsed trees for self-training are selected according to translation performance. Our work focuses on the automatic cross-lingual similarization of dependency grammars, and learnt grammars with higher cross-lingual similarity while maintaining the non-triviality of the grammars.

There are substantial efforts that have been made in recent years towards harmonizing syntactic representations across languages. This includes the HamleDT project (Zeman et al., 2012; Zeman et al., 2014), as well as the Universal Dependencies initiative (Petrov et al., 2012; McDonald et al., 2013).

Our work aims to automatically harmonize the dependency representations resorting to bilingual correspondence, thus can be grouped into the building strategies for harmonized or universal dependencies. These existing annotated treebanks would also permit interesting control experiments, both for the measurement of similarity and for parsing.

7 Conclusion and Future Work

We propose an automatic cross-lingual similarization algorithm for dependency grammars, design an automatic evaluation metric to measure the cross-lingual similarity between grammars, and use the similarized grammars to improve dependency tree-based machine translation. Experiments show the efficacy of this method. The cross-lingual similarization in this paper is still *soft similarization*, it is worth to investigate the *hard similarization*, where the syntactic structures are totally isomorphic between two languages. Of course, in such syntactic structures, the syntactic nodes should be super-node, that is, a graph containing one or more basic syntactic nodes. Hard similarization could be more suitable for cross-lingual applications, and we leave this aspect for future research.

Abstract

Recent work on machine translation has used crowdsourcing to reduce costs of manual evaluations. However, crowdsourced judgments are often biased and inaccurate. In this paper, we present a statistical model that aggregates many manual pairwise comparisons to robustly measure a machine translation system's performance. Our method applies graded response model from item response theory (IRT), which was originally developed for academic tests. We conducted experiments on a public dataset from the Workshop on Statistical Machine Translation 2013, and found that our approach resulted in highly interpretable estimates and was less affected by noisy judges than previously proposed methods.

1 Introduction

Manual evaluation is a primary means of interpreting the performance of machine translation (MT) systems and evaluating the accuracy of automatic evaluation metrics. It is also essential for natural language processing tasks such as summarization and dialogue systems, where (1) the number of correct outputs is unlimited, and (2) naïve text matching cannot judge the correctness, that is, an evaluator must consider syntactic and semantic information.

Recent work has used crowdsourcing to reduce costs of manual evaluations. However, the judgments of crowd workers are often noisy and unreliable because they are not experts.

To maintain quality, evaluation tasks implemented using crowdsourcing should be simple. Thus, many previous studies focused on pairwise comparisons instead of absolute evaluations. The same task is given to multiple workers, and their responses are aggregated to obtain a reliable answer.

We must, therefore, develop methods that robustly estimate the MT performance based on many pairwise comparisons.

Some aggregation methods have been proposed for MT competitions hosted by the Workshop on Statistical Machine Translation (WMT) (Bojar et al., 2013; Hopkins and May, 2013; Sakaguchi et al., 2014), where a ranking of the submitted systems is produced by aggregating many manual judgments of pairwise comparisons of system outputs.

However, existing methods do not consider the following important issues.

Interpretability of the estimates: For the purpose of evaluation, their results must be interpretable so that we could use the results to improve MT systems and the next MT evaluation campaigns. Existing methods, however, only yield system-level scores.

Judge sensitivity: Some judges can examine the quality of translations with consistent standards, but others cannot (Graham et al., 2015). Sensitivities to the translation quality and judges' own standards are important factors.

Evaluation of a newly submitted system: Previous approaches considered all pairwise combinations of systems and must compare a newly submitted system with all the submitted systems. This made it difficult to allow participants to submit their systems after starting the evaluation step.

To address these issues, we use a model from

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 511–520,
Austin, Texas, November 1-5, 2016.

item response theory (IRT). This theory was originally developed for psychometrics, and has applications to academic tests. IRT models are highly interpretable and are supported by theoretical and empirical studies. For example, we can estimate the informativeness of a question in a test based on the responses of examinees.

We focused on aggregating many pairwise comparisons with a baseline translation so that we could use the analogy of standard academic tests. Figure 1 shows our problem setting. Each system of interest yields translations, and the translations are compared with a baseline translation by multiple human judges. Each judge produces a preference judgment.

The pairwise comparisons correspond to questions in academic tests, a judge's sensitivity to the translation quality is mapped to discrimination of questions, and the relative difficulty of winning the pairwise comparison is mapped to the difficulty of questions. MT systems correspond to students that take academic tests, and IRT models can be naturally applied to estimate the latent performance (ability) of MT systems (students).

Additionally, our approach, fixing baseline translations, can easily evaluate a newly submitted system. We only need to compare the new system with the baseline instead of testing all pairwise combinations of the submitted systems.

Our contributions are summarized as follows.[1]

1. We propose an IRT-based aggregation model of pairwise comparisons with highly interpretable parameters.
2. We simulated noisy judges on the WMT13 dataset and demonstrated that our model is less affected by the noisy judges than previously proposed methods.

2 Related Work

The WMT shared tasks have collected many manual judgments of segment-level pairwise comparisons and used them to produce system-level rankings for MT tasks. Various methods has been proposed to aggregate the judgments to produce reliable rankings.

[1]We also show that our method accurately replicated the WMT13 official system scores using a few comparisons. However, this is not the main focus of this paper.

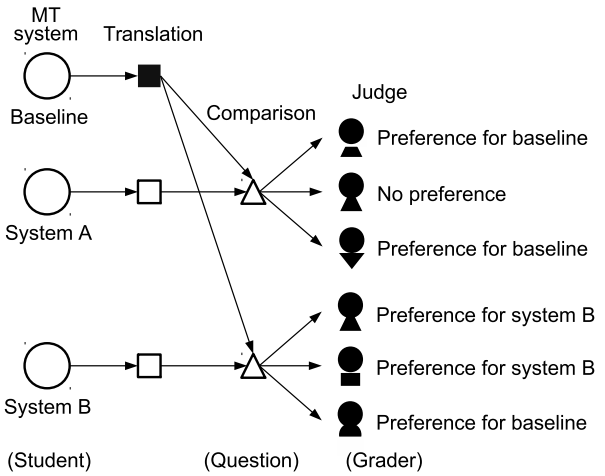

Figure 1: **Illustration of manual pairwise comparison.** Each system yields translations. Judges compare them with a baseline translation and report their preferences. Our goal is to aggregate the judgments to determine the performance of each system.

Frequency based approaches were used to produce the WMT13 official rankings (Bojar et al., 2013), considering statistical significance of the results (Koehn, 2012).

Hopkins and May (2013) noted that we should consider the relative matchup difficulty, and proposed a statistical aggregation model. Their model assumes that the quality of each system can be represented by a Gaussian distribution.

Sakaguchi et al. (2014) applied TrueSkill (Herbrich et al., 2006) to reduce the number of comparisons to reach the final estimate based on an active learning strategy. The same model was recently used for grammatical error correction (Grundkiewicz et al., 2015; Napoles et al., 2015).

These methods acquire the final system-level scores, whereas our model also estimates segment specific and judge specific parameters.

The Bradley–Terry (BT) model was the result of a seminal study on aggregating pairwise comparisons (Bradley and Terry, 1952; Chen et al., 2013; Dras, 2015). Recently, Chen et al. (2013) explicitly incorporated the quality of judges into the BT model, and applied it to quality control in crowdsourcing.

The previously mentioned methods focused on pairwise comparisons of all combination of the MT systems, and thus, the number of comparisons increases rapidly as the number of systems increases.

Our approach, however, only uses comparisons with a fixed baseline. This approach enables to apply IRT models for academic tests and makes it easy to evaluate a newly submitted system.

The work most relevant to our model is the IRT-based crowdsourcing model proposed by Baba and Kashima (2013). Their goal was to estimate the true quality of artifacts such as design works based on ratings assigned by reviewers. They also applied a graded response model to incorporate the authors' latent abilities and the reviewers' biases.

Yet their setting differs from ours in that they focused on the quality of the artifacts, whereas we are interested in the authors. Additionally, their model maps task difficulty and review bias to a difficulty parameter in IRT. However, we naturally extended the model so that standard analysis approaches can be applied to maintain interpretability.

Some studies have focused on absolute evaluations (Goto et al., 2014; Graham et al., 2015). Graham et al. (2015) gathered continuous scale evaluations in terms of adequacy and fluency for many segments, and filtered out noisy judgments based on their consistency. The proposed pipeline results in very accurate evaluations, but 40-50% of all the judgments were filtered out due to inconsistencies. This explains the difficulties of developing absolute evaluation methods in crowdsourcing.

3 Problem Setting

We first describe the problem setting, as shown in Figure 1.

Assume that there are a group of systems $\mathcal{I}$ indexed by i, a set of segments $\mathcal{J}$ indexed by j, and a set of judges $\mathcal{K}$ indexed by k.

Before a manual evaluation, we fix an arbitrary baseline system and use it to translate the segments $\mathcal{J}$. Then, each system $i \in \mathcal{I}$ produces a translation on segment $j \in \mathcal{J}$. One of the judges $k \in \mathcal{K}$ compares it with the baseline translation. The judge produces a preference judgment.

Let $u_{i,j,k}$ be the observed judgment that judge k assigns to a translation by system i on segment j, that is,

$$u_{i,j,k} = \begin{cases} 1 & \text{(preference for baseline)} \\ 2 & \text{(no preference)} \\ 3 & \text{(preference for system } i\text{)} \end{cases},$$

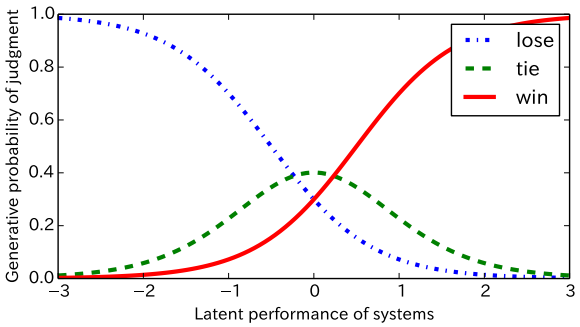

Figure 2: **ICC of graded response model for** $(b_1, b_2) = (-0.5, 0.5)$ **and** $a = 1.7$

and let $c \in \{1, 2, 3\}$ be the judgment label.

Each system i has its own latent performance $\theta_i \in \mathbb{R}$. Our goal is to estimate θ by using the observed judgments $U = \{u_{i,j,k}\}_{i \in \mathcal{I}, j \in \mathcal{J}, k \in \mathcal{K}}$.

4 Generative Judgment Model

We describe a statistical model for pairwise comparisons based on an IRT model.

4.1 Modified Graded Response Model

Based on the graded response model (GRM) proposed by Samejima (1968), we define a generative model of judgments. GRM deals with responses on ordered categories including ratings such as A+, A, B+ and B, and partial credits in tests. In our problem setting, judgments can be seen as partial credits. When a system beats a baseline translation, the system receives $c = 3$ credit. In the case of a tie, the system receives $c = 2$ credit. The system receives $c = 1$ credit when it lose to the baseline.

Let $\mathrm{P}^*_{jkc}(\theta_i)$ be the probability that judge k assigns judgment $\pi > c$ to a comparison on segment j between system i and a baseline.

$$\mathrm{P}^*_{jkc}(\theta_i) = \frac{1}{1 + \exp(-a_k(\theta_i - b_{jc}))},$$

where $\mathrm{P}^*_{jk0}(\theta_i) = 1, \mathrm{P}^*_{jk3}(\theta_i) = 0$. Parameters a and b are called *discrimination* and *difficulty* parameters, respectively. a represents the discriminablity or sensitivity of the judge, and b represents a segment-specific difficulty parameter. The discrimination parameter (a) is positive, and the difficulty parameter (b) satisfies $b_1 < b_2$, where b_1 corresponds to the difficulty of not losing to the baseline ($c > 1$), and b_2

corresponds to the difficulty of beating the baseline ($c > 2$).

The generative probability of judgment $u_{i,j,k}$ is defined as the difference in the probabilities defined above, that is,

$$\begin{aligned}\mathrm{P}_{jkc}(\theta_i) &= \mathrm{P}(u_{i,j,k} = c|\theta_i, b_j, a_k) \\ &= \mathrm{P}^*_{jkc-1}(\theta_i) - \mathrm{P}^*_{jkc}(\theta_i).\end{aligned}$$

This function is called *item characteristic curve* (ICC). Figure 2 illustrates the ICC in the GRM. The horizontal axis represents the latent performance of systems, and the vertical axis represents the generative probability of the judgments. This figure shows, for example, that the probability of the system with $\theta = 0$ beating the baseline is 0.3, whereas the system with $\theta = 1.0$ is much more likely to win. The discrimination parameter controls slope of the curves. If a is small, the probability drops a little when θ decreased.

The model described above is different from the original GRM, which assumed that the values of a are independent from question to question, and that each a belongs to exactly one question. However, in our problem setting, the judges evaluate multiple segments, and discrimination parameter a is independent from segment j. This modification means that the GRM can capture the judge's sensitivity.

4.2 Priors

We assign prior distributions to the parameters to obtain estimates stably. We assume Gaussian distributions on θ and b, that is, $\theta \sim \mathcal{N}(0, \tau^2)$ and $b_c \sim \mathcal{N}(\mu_{bc}, \sigma^2_{bc})$ $(c = 1, 2)$. The discrimination parameter is positive, so we assume a log Gaussian distribution on a, i.e., $\log(a) \sim \mathcal{N}(\mu_a, \sigma^2_a)$. Note that τ, μ, and σ are hyper parameters.

5 Parameter Estimation

We find the values of the parameters to maximize the log likelihood based on obtained judgments U:

$$\mathcal{L}(\theta, \xi) = \log\mathrm{P}(U, \theta, \xi).$$

We denote the parameters $a = \{a_k\}_{k\in\mathcal{K}}$ and $b = \{b_{j1}, b_{j2}\}_{j\in\mathcal{J}}$ to be ξ in this section.

5.1 Marginal Likelihood Maximization of Judge Sensitivity and Matchup Difficulty

Estimates are known to be inaccurate when all the parameters are optimized at once, so we first estimate the parameters ξ to maximize the marginal log likelihood w.r.t. the system performance θ.

$$\begin{aligned}m\mathcal{L}(\xi) &= \log\mathrm{P}(U, \xi) \\ &= \sum_{i\in\mathcal{I}} \log \int_{-\infty}^{\infty} \mathrm{P}(\theta)\mathrm{P}(U_i|\theta, \xi)d\theta + \log\mathrm{P}(\xi),\end{aligned}$$

where U_i is the set of judgments given to system i

The equation above can be approximated using Gauss-Hermite quadrature, i.e.,

$$\begin{aligned}m\mathcal{L}(\xi) &\approx \sum_{i\in\mathcal{I}} \log \sum_{t=1}^{T} \frac{1}{\sqrt{\pi}} w_t \mathrm{P}(U_i|\tau x_t, \xi) + \log\mathrm{P}(\xi) \\ w_t &= \frac{2^{T-1}T!\sqrt{\pi}}{T^2\left(H(x_t)\right)^2} \\ H(x_t) &= \left(2x_t - \frac{d}{dx_t}\right)^{T-1} \cdot 1,\end{aligned}$$

where a practically good approximation is obtained by taking $T \approx 20$.[2]

We solve the optimization problem using the gradient descent methods to maximize the approximated marginal likelihood. The inequality constraints on the parameters are handled by adding log barrier functions to the objective function.

5.2 Maximum A Posteriori (MAP) Estimation of System Performance

Given the estimates of ξ, we estimate the system performance $\theta = \{\theta_i\}_{i\in\mathcal{I}}$ by using MAP estimation.

We maximize the objective function,

$$\begin{aligned}\mathcal{L}(\theta) &= \log\mathrm{P}(U, \theta; \xi) \\ &= \sum_{i\in\mathcal{I}} \log\mathrm{P}(\theta_i) + \sum_{i\in\mathcal{I}} \log\mathrm{P}(U_i|\theta_i; \xi).\end{aligned}$$

The estimates of θ are obtained using the gradient descent method.

5.3 Discussion

So far we have assumed that the estimate is based on batch learning. However, it is known that active

[2] In this study, we set $T = 21$ to include $x = 0$.

learning can reduce the costs (i.e., the total number of comparisons) (Sakaguchi et al., 2014).

To extend our model to the active learning framework, one approach is to optimize the objective function online and actively select the next system to be compared based on criteria such as the uncertainty of the system's performance. We can apply stochastic gradient descent to the online optimization, which updates the estimates of the parameters using the gradients calculated based on a single comparison. This modification was left for future work.

6 Experiments

We conducted experiments on the WMT13 manual evaluation dataset for 10 language pairs.[3] For details of the evaluation data, see the overview of WMT13 (Bojar et al., 2013).

6.1 Setup

Models: Our method **(GRM)** was initialized using $a = 1.7, b = (-0.5, 0.5)$, and a θ value derived by summing up the judgments for each system and scaling θ to fit the prior distribution. For the hyper parameters, we set $\tau = \sqrt{2}, \mu_a = \log(1.7), \sigma_a = 1.0, \mu_b = (-0.5, 0.5), \sigma_b = 2.0$.

To compare with our method, we trained ExpectedWins **(EW)** (Bojar et al., 2013), the model by Hopkins and May (2013), **(HM)** and the two-stage crowdsourcing model proposed by Baba and Kashima (2013) **(TSt)**. We also trained TrueSkill **(TS)** (Sakaguchi et al., 2014), which was used to produce the gold score on this experiment.

We followed Sakaguchi et al. (2014), who also used the WMT13 datasets in their experiments, and initialized the HM and TS parameters. For TSt, we followed Baba and Kashima (2013).

Pairwise comparisons: The WMT dataset contains five-way partial rankings, so we converted the five-way partial rankings into pairwise comparisons. For example, given a five-way partial ranking A $>$ B $>$ C $>$ D $>$ E, we obtain ten pairwise comparisons A $>$ B, A $>$ C, A $>$ D, $\cdots$, and D $>$ E. We randomly sampled 800, 1,600, 3,200 and 6,400 pairwise comparisons from the whole dataset.

[3] http://statmt.org/wmt13/results.html

The training data differs between the models. For GRM and TSt, we first sampled five-way rankings that contained a baseline translation for each baseline system and obtained pairwise comparisons. For EW and HM, we first converted five-way rankings into pairwise comparisons and selected them at random.[4] TS first receives all the pairwise comparisons and selects the training data based on the active learning strategy, whereas we sampled the comparisons before running the other methods.

Gold scores: We followed the official evaluation procedure of the WMT14-15 (Bojar et al., 2014; Bojar et al., 2015) and made gold scores with TS. We produced 1,000 bootstrap-resampled datasets over all of the available comparisons. We then ran TS and collected the system scores. The gold score is the mean of the scores.

Evaluation metrics: We evaluated the models using the Pearson correlation coefficient and the normalized discounted cumulative gain (nDCG), comparing the estimated scores and gold scores. We used nDCG because we are often interested in ranks and scores, especially in MT competitions such as the WMT translation task.[5] These metrics were also used for experiments in Baba and Kashima (2013).

6.2 Results

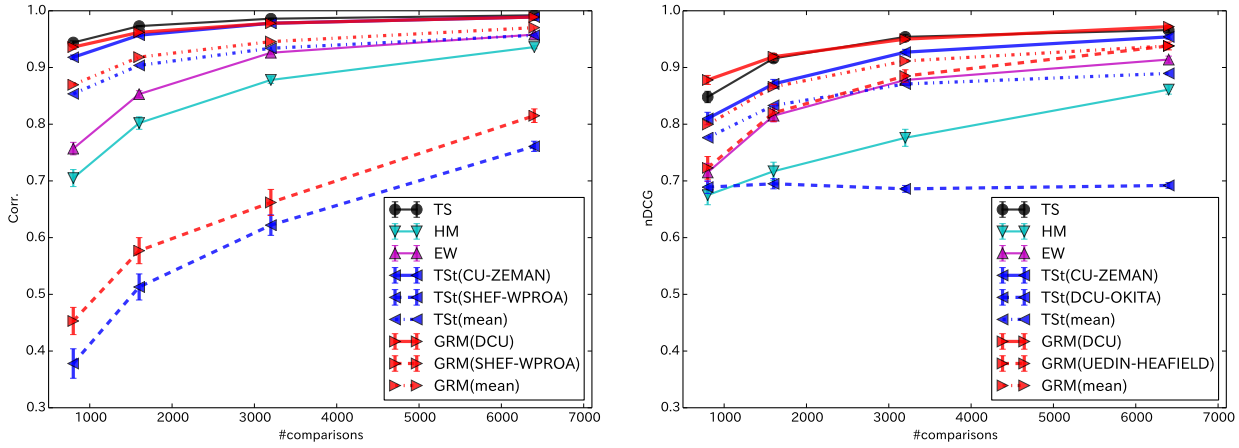
Figure 3 shows the correlation and nDCG between the estimated system performance and the gold scores for the WMT13 Spanish–English task. For the GRM and TSt, the baselines used in the evaluation are shown in parentheses in the labels. The other language pairs showed similar tendencies. The complete results for all language pairs can be found in the supplementary data files.

Note that the main contribution of our method is not to perform better than other methods in terms of correlation and nDCG to the gold scores, but to result in highly interpretable and robust estimates discussed later.

TS resulted in the highest correlation and nDCG. It is reasonable because the gold scores themselves were produced by TS, and because it estimates the

[4] We also applied the sampling procedure of GRM and TSt to EW and HM, but it made their estimation inaccurate.

[5] We did not use Spearman's rank correlation coefficient because it does not consider a margin between ranks.



(a) Correlation

(b) nDCG

Figure 3: **Correlation and nDCG comparing the estimated system performance and gold scores with the number of comparisons for the WMT13 Spanish–English task.** The baseline system is shown in parenthesis for TSt and GRM.

parameters using active learning, unlike the other models.

The GRM with the best baseline system (DCU) achieved almost the same scores as the TS, in terms of correlation and nDCG. Although the TSt with the best baseline resulted in accurate estimates in terms of correlation, it did not in terms of nDCG. With the worst baselines, the GRM and TSt both failed to replicate the gold scores, but the GRM was surprisingly accurate in terms of nDCG (even in the worst case). This implies that the GRM can effectively predict the top ranked systems.

6.3 Baseline Selection

It is likely that single pairwise comparisons do not work well if the baseline is very strong or weak. As shown in Figure 3, the baseline system influences the final result. When we used SHEF-WPROA as baseline, the estimated system performance was not accurate. This is because SHEF-WPROA loses 69.4% of the pairwise comparisons and fails to discriminate between the other systems. In contrast, DCU loses 34.5% and win 34.8% of the comparisons and discriminate the other systems successfully. Thus, when we used DCU as baseline, the best correlation and nDCG were achieved. Therefore, we must determine the appropriate baseline system before the comparisons.

One possible solution is to consider the system-level scores yielded by automatic evaluation metrics such as BLEU and METEOR. Figure 4 shows that we obtained relatively good results when we used a system whose system-level BLEU score and METEOR score[6] were close to the mean of all the systems. [7]

Noise(%)	0	10	20	30	40	50
Correlation						
GRM	.929	.917	.900	.879	.849	.807
HM	+.002	-.005	-.009	-.015	-.025	-.038
EW	-.025	-.028	-.035	-.038	-.040	-.046
nDCG						
GRM	.883	.867	.847	.822	.793	.752
HM	-.024	-.130	-.137	-.144	-.152	-.168
EW	-.035	-.054	-.064	-.060	-.060	-.069

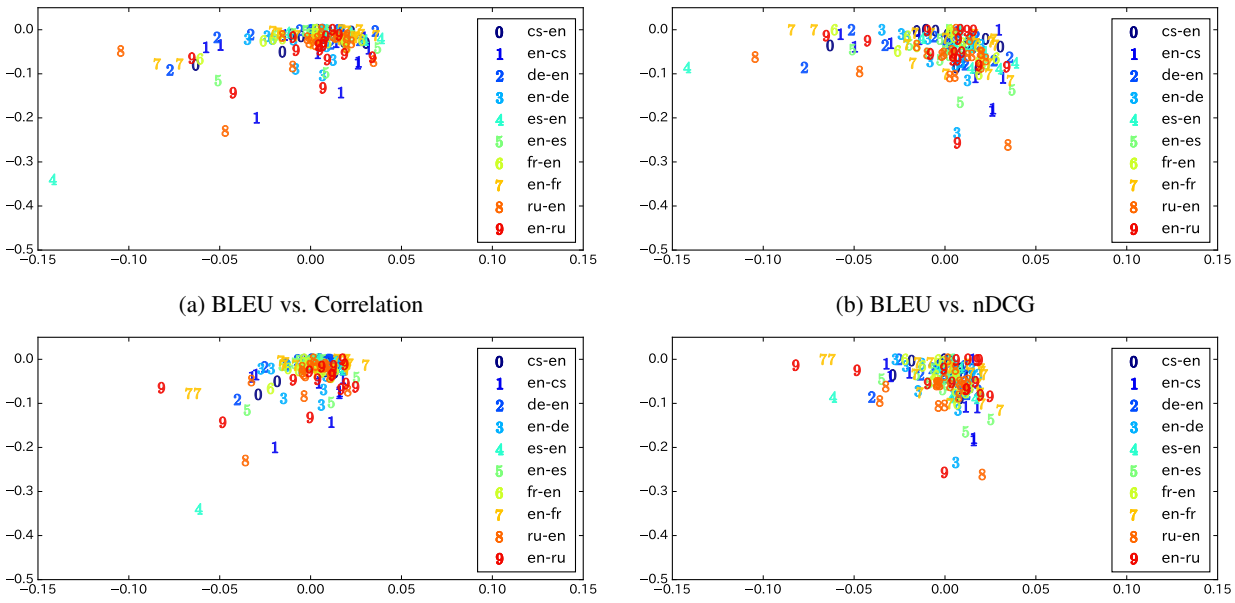
Table 1: **Correlation and nDCG between the estimated system performance and gold scores for the WMT13 Spanish–English task, based on noisy judges.** The values were averaged over all the datasets. The GRM scores were averaged over all baselines. The differences from the GRM are reported for the HM and EW.

6.4 Analysis of Judge Sensitivity

To investigate the robustness of the GRM, we simulated "noisy" judges. We selected a subset of

[6]BLEU and METEOR scores were given by the WMT13 organizers.

[7]The system-level scores can be found in the WMT13 Metrics Task dataset.



(a) BLEU vs. Correlation

(b) BLEU vs. nDCG

(c) METEOR vs. Correlation

(d) METEOR vs. nDCG

Figure 4: **Relationship between system-level BLEU/METEOR scores (horizontal) and correlation/nDCG scores (vertical).** The mean BLEU/METEOR was set to zero, and the best score was set to zero for each language pair.

judges and randomly changed their decisions based on a uniform distribution. The percentage of noisy judges varied between 10% and 50% (in increments of 10%).

We trained HM and EW on the simulated datasets. We excluded TS because it assumes that we can actively request more comparisons from judges when their decisions are ambiguous.

As shown in Table 1, the accuracy of the GRM was less affected by the noisy judges than HM and EW. This is because our model estimates judge-specific sensitivities and automatically reduces the influence of the noisy judges.

6.5 Analysis of the Interpretability of the Estimated Matchup Difficulty

Our model is a natural extension of the GRM Samejima (1968), so we can apply standard analyses for IRT models. Item information is one of the standard analysis methods and corresponds to sensitivity to a latent parameter of interest. Based on the item information, we can find which segment was difficult to be translated better than a baseline translation.

The item information is calculated using the esti-

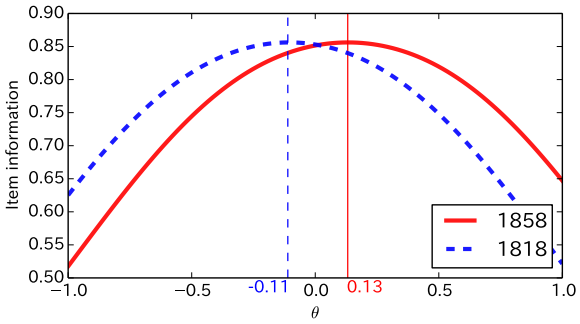


Figure 5: **Item information for the WMT13 Spanish–English task.** The DCU was used as a baseline. We used the averaged estimates of b on 100 sampled datasets with 6,400 comparisons to calculate the item information for all segments.

mated parameters ξ (Samejima, 1968), that is,

$$I_j(\theta) = -E\left[\frac{\partial^2 \mathcal{L}(\theta;\xi)}{\partial\theta^2}\right] = \sum_{c=1}^{3}\left[-\frac{\partial^2 \log \mathrm{P}_{jkc}(\theta)}{\partial\theta^2}\right]\mathrm{P}_{jkc} = \sum_{c=1}^{3}\frac{[\mathrm{P}^{*'}_{jkc-1}(\theta) - \mathrm{P}^{*'}_{jkc}(\theta)]^2}{\mathrm{P}^{*}_{jkc-1}(\theta) - \mathrm{P}^{*}_{jkc}(\theta)},$$

where $\mathrm{P}^{*'} = \partial \mathrm{P}^{*}/\partial\theta$.

Because the item information is only determined

Table 2: **Translation examples for the WMT13 Spanish–English task.** The reference is a correct translation given by the WMT organizers and was shown to human judges. Estimates of θ (averaged over 100 sampled datasets with 6,400 comparisons) are also reported in the table.

by segments and is independent of the judges, we set $a_k = 1$ $(k \in \mathcal{K})$.

Figure 5 gives two examples of the item information. The horizontal axis corresponds to the system performance θ, and the vertical axis represents the informativeness of a segment. This figure indicates that segment 1858 (red line) can effectively discriminate systems with $\theta \approx 0.13$, whereas segment 1818 (blue dashed line) is sensitive to those with $\theta \approx -0.11$. This means that systems with low θ tend to lose to a baseline translation on segment 1858, and the segment does not tell meaningful information on performance of the systems. However, they sometimes beat a baseline translation on segment 1818, and the segment can measure their performance accurately.

Table 2 shows translations for segments 1858 and 1818. We found that the baseline translation on segment 1818 was relatively good, whereas the baseline translation on segment 1858 contained wrong words such as "drink" and "galaxias". Consequently, systems with low θ tended to lose to the baseline on segment 1858 due to their wrong translation (see the translation of "hawaiano de Mauna Kea"). In contrast, some of the low-ranked systems beat the baseline on segment 1818, and the segment contributed to discriminate them.

The item information is used to design academic tests that can effectively capture students' abilities. It could analogously be used to preselect segments to be translated based on the item information in the MT evaluation.

7 Conclusion

We have addressed the task of manual judgment aggregation for MT evaluations. Our motivation was three folded: (1) to incorporate a judge's sensitivity to robustly measure a system's performance, (2) to maintain highly interpretable estimates, and (3) to handle with a newly submitted system.

To tackle these problems, we focused on pairwise comparisons with a fixed baseline translation so that we could apply the GRM model in IRT by using the analogy of standard academic tests. Unlike testing all pairwise combinations of systems, fixing baseline translations makes it easy to evaluate a newly submitted system. We demonstrated that our model gave robust and highly interpretable estimates on the WMT13 datasets.

In the future work, we will incorporate active learning to the proposed method so that we could reduce the total number of comparisons to obtain final results. Although we evaluated the correlation between the estimated system performance scores and the WMT official scores, other evaluation procedures might also be considered. For example, Hopkins and May (2013) considered model perplexity and Sakaguchi et al. (2014) compared accuracy. However, we cannot directly compare other methods to our method in terms of perplexity or accuracy because our method focuses on comparisons with a baseline translation, whereas they do not. It will be required to investigate correlation between the estimates and expert decisions.

Acknowledgments

We would like to thank Yukino Baba and Hisashi Kashima for providing an implementation of their method. We are also thankful for the useful comments from the anonymous reviewers.

Abstract

Models of neural machine translation are often from a discriminative family of encoder-decoders that learn a conditional distribution of a target sentence given a source sentence. In this paper, we propose a variational model to learn this conditional distribution for neural machine translation: a variational encoder-decoder model that can be trained end-to-end. Different from the vanilla encoder-decoder model that generates target translations from hidden representations of source sentences alone, the variational model introduces a *continuous latent variable* to explicitly model underlying semantics of source sentences and to guide the generation of target translations. In order to perform efficient posterior inference and large-scale training, we build a *neural posterior approximator* conditioned on both the source and the target sides, and equip it with a reparameterization technique to estimate the variational lower bound. Experiments on both Chinese-English and English-German translation tasks show that the proposed variational neural machine translation achieves significant improvements over the vanilla neural machine translation baselines.

1 Introduction

Neural machine translation (NMT) is an emerging translation paradigm that builds on a single and unified end-to-end neural network, instead of using a variety of sub-models tuned in a long training pipeline. It requires a much smaller memory than phrase- or syntax-based statistical machine translation (SMT) that typically has a huge phrase/rule table. Due to these advantages over traditional SMT system, NMT has recently attracted growing interests from both deep learning and machine translation community (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015a; Luong et al., 2015b; Shen et al., 2015; Meng et al., 2015; Tu et al., 2016).

Current NMT models mainly take a discriminative *encoder-decoder* framework, where a *neural encoder* transforms source sentence $\mathbf{x}$ into distributed representations, and a *neural decoder* generates the corresponding target sentence $\mathbf{y}$ according to these representations[1] (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2014). Typically, the underlying semantic representations of source and target sentences are learned in an implicit way in this framework, which heavily relies on the attention mechanism (Bahdanau et al., 2014) to identify semantic alignments between source and target words. Due to potential errors in these alignments, the attention-based context vector may be insufficient to capture the entire meaning of a source sentence, hence resulting in undesirable translation phenomena (Tu et al., 2016).

Unlike the vanilla encoder-decoder framework, we model underlying semantics of bilingual sentence pairs explicitly. We assume that there exists a continuous latent variable $\mathbf{z}$ from this underlying semantic space. And this variable, together with $\mathbf{x}$,

*Corresponding author

[1]In this paper, we use bold symbols to denote variables, and plain symbols to denote their values. Without specific statement, all variables are multivariate.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 521–530,
Austin, Texas, November 1-5, 2016.

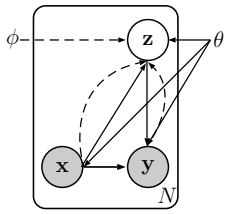

Figure 1: Illustration of VNMT as a directed graph. We use solid lines to denote the generative model $p_\theta(\mathbf{z}|\mathbf{x})p_\theta(\mathbf{y}|\mathbf{z},\mathbf{x})$, and dashed lines to denote the variational approximation $q_\phi(\mathbf{z}|\mathbf{x})$ to the intractable posterior $p(\mathbf{z}|\mathbf{x},\mathbf{y})$. Both variational parameters ϕ and generative model parameters θ are learned jointly.

guides the translation process, i.e. $p(\mathbf{y}|\mathbf{z},\mathbf{x})$. With this assumption, the original conditional probability evolves into the following formulation:

$$p(\mathbf{y}|\mathbf{x}) = \int_z p(\mathbf{y}, z|\mathbf{x})d_z = \int_z p(\mathbf{y}|z,\mathbf{x})p(z|\mathbf{x})d_z \quad (1)$$

This brings in the benefits that the latent variable $\mathbf{z}$ can serve as a global semantic signal that is complementary to the attention-based context vector for generating good translations when the model learns undesirable attentions. However, although this latent variable enables us to explicitly model underlying semantics of translation pairs, the incorporation of it into the above probabilistic model has two challenges: 1) the posterior inference in this model is intractable; 2) large-scale training, which lays the ground for the data-driven NMT, is accordingly problematic.

In order to address these issues, we propose a variational encoder-decoder model to neural machine translation (VNMT), motivated by the recent success of variational neural models (Rezende et al., 2014; Kingma and Welling, 2014). Figure 1 illustrates the graphic representation of VNMT. As deep neural networks are capable of learning highly non-linear functions, we employ them to fit the latent-variable-related distributions, i.e. the prior and posterior, to make the inference tractable. The former is modeled to be conditioned on the source side alone $p_\theta(\mathbf{z}|\mathbf{x})$, because the source and target part of a sentence pair usually share the same semantics so that the source sentence should contain the prior information for inducing the underlying semantics. The latter, instead, is approximated from all observed variables $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$, i.e. both the source and the target sides. In order to efficiently train parameters, we apply a reparameterization technique (Rezende et al., 2014; Kingma and Welling, 2014) on the variational lower bound. This enables us to use standard stochastic gradient optimization for training the proposed model. Specifically, there are three essential components in VNMT (The detailed architecture is illustrated in Figure 2):

- A *variational neural encoder* transforms source/target sentence into distributed representations, which is the same as the encoder of NMT (Bahdanau et al., 2014) (see section 3.1).
- A *variational neural inferer* infers the representation of $\mathbf{z}$ according to the learned source representations (i.e. $p_\theta(\mathbf{z}|\mathbf{x})$) together with the target ones (i.e. $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$), where the reparameterization technique is employed (see section 3.2).
- And a *variational neural decoder* integrates the latent representation of $\mathbf{z}$ to guide the generation of target sentence (i.e. $p(\mathbf{y}|\mathbf{z},\mathbf{x})$) together with the attention mechanism (see section 3.3).

Augmented with the posterior approximation and reparameterization, our VNMT can still be trained end-to-end. This makes our model not only efficient in translation, but also simple in implementation. To train our model, we employ the conventional maximum likelihood estimation. Experiments on both Chinese-English and English-German translation tasks show that VNMT achieves significant improvements over several strong baselines.

2 Background: Variational Autoencoder

This section briefly reviews the variational autoencoder (VAE) (Kingma and Welling, 2014; Rezende et al., 2014). Given an observed variable $\mathbf{x}$, VAE introduces a continuous latent variable $\mathbf{z}$, and assumes that $\mathbf{x}$ is generated from $\mathbf{z}$, i.e.,

$$p_\theta(\mathbf{x},\mathbf{z}) = p_\theta(\mathbf{x}|\mathbf{z})p_\theta(\mathbf{z}) \quad (2)$$

where θ denotes the parameters of the model. $p_\theta(\mathbf{z})$ is the prior, e.g, a simple Gaussian distribution. $p_\theta(\mathbf{x}|\mathbf{z})$ is the conditional distribution that models the generation procedure, typically estimated via a deep non-linear neural network.

Similar to our model, the integration of $\mathbf{z}$ in Eq. (2) imposes challenges on the posterior inference as

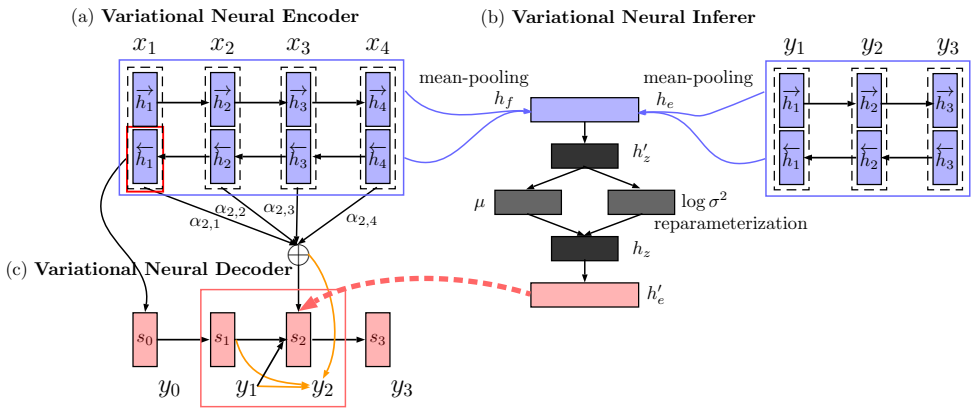

Figure 2: Neural architecture of VNMT. We use blue, gray and red color to indicate the encoder-related ($\mathbf{x}, \mathbf{y}$), underlying semantic ($\mathbf{z}$) and decoder-related ($\mathbf{y}$) representation respectively. The yellow lines show the flow of information employed for target word prediction. The dashed red line highlights the incorporation of latent variable $\mathbf{z}$ into target prediction. f and e represent the source and target language respectively.

well as large-scale learning. To tackle these problems, VAE adopts two techniques: *neural approximation* and *reparameterization*.

Neural Approximation employs deep neural networks to approximate the posterior inference model $q_\phi(\mathbf{z}|\mathbf{x})$, where ϕ denotes the variational parameters. For the posterior approximation, VAE regards $q_\phi(\mathbf{z}|\mathbf{x})$ as a diagonal Gaussian $\mathcal{N}(\mu, \text{diag}(\sigma^2))$, and parameterizes its mean μ and variance σ^2 with deep neural networks.

Reparameterization reparameterizes $\mathbf{z}$ as a function of μ and σ, rather than using the standard sampling method. In practice, VAE leverages the "location-scale" property of Gaussian distribution, and uses the following reparameterization:

$$\tilde{z} = \mu + \sigma \odot \epsilon \tag{3}$$

where ϵ is a standard Gaussian variable that plays a role of introducing noises, and $\odot$ denotes an element-wise product.

With these two techniques, VAE tightly incorporates both the generative model $p_\theta(\mathbf{x}|\mathbf{z})$ and the posterior inference model $q_\phi(\mathbf{z}|\mathbf{x})$ into an end-to-end neural network. This facilitates its optimization since we can apply the standard backpropagation to compute the gradient of the following variational lower bound:

$$\begin{aligned}\mathcal{L}_{\text{VAE}}(\theta, \phi; \mathbf{x}) = &- \text{KL}(q_\phi(\mathbf{z}|\mathbf{x})||p_\theta(\mathbf{z})) \\ &+\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] \leq \log p_\theta(\mathbf{x})\end{aligned} \tag{4}$$

$\text{KL}(Q||P)$ is the Kullback-Leibler divergence between Q and P. Intuitively, VAE can be considered as a regularized version of the standard autoencoder. It makes use of the latent variable $\mathbf{z}$ to capture the variations ϵ in the observed variable $\mathbf{x}$.

3 Variational Neural Machine Translation

Different from previous work, we introduce a latent variable $\mathbf{z}$ to model the underlying semantic space as a global signal for translation. Formally, given the definition in Eq. (1) and Eq. (4), the variational lower bound of VNMT can be formulated as follows:

$$\begin{aligned}\mathcal{L}_{\text{VNMT}}(\theta, \phi; \mathbf{x}, \mathbf{y}) = &-\text{KL}(q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})||p_\theta(\mathbf{z}|\mathbf{x})) \\ &+\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})}[\log p_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})]\end{aligned} \tag{5}$$

where $p_\theta(\mathbf{z}|\mathbf{x})$ is our prior model, $q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})$ is our posterior approximator, and $p_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})$ is the decoder with the guidance from $\mathbf{z}$. Based on this formulation, VNMT can be decomposed into three components, each of which is modeled by a neural network: a *variational neural inferer* that models $p_\theta(\mathbf{z}|\mathbf{x})$ and $q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})$ (see part (b) in Figure 2), a *variational neural decoder* that models $p_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})$ (see part (c) in Figure 2), and a *variational neural encoder* that provides distributed representations of a source/target sentence for the above two modules (see part (a) in Figure 2). Following the information flow illustrated in Figure 2, we describe part (a), (b) and (c) successively.

3.1 Variational Neural Encoder

As shown in Figure 2 (a), the variational neural encoder aims at encoding an input sequence $(w_1, w_2,$

$\ldots, w_T$) into continuous vectors. In this paper, we adopt the encoder architecture proposed by Bahdanau et al. (2014), which is a bidirectional RNN with a forward and backward RNN. The forward RNN reads the sequence from left to right while the backward RNN in the opposite direction (see the parallel arrows in Figure 2 (a)):

$$\begin{aligned} \overrightarrow{h}_i &= \text{RNN}(\overrightarrow{h}_{i-1}, E_{w_i}) \\ \overleftarrow{h}_i &= \text{RNN}(\overleftarrow{h}_{i+1}, E_{w_i}) \end{aligned} \tag{6}$$

where $E_{w_i} \in \mathbb{R}^{d_w}$ is the embedding for word w_i, and $\overrightarrow{h}_i$, $\overleftarrow{h}_i$ are hidden states generated in two directions. Following Bahdanau et al. (2014), we employ the Gated Recurrent Unit (GRU) as our RNN unit due to its capacity in capturing long-distance dependencies.

We further concatenate each pair of hidden states at each time step to build a set of *annotation* vectors ($\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_T$), $\mathbf{h}_i^T = \left[\overrightarrow{h}_i^T; \overleftarrow{h}_i^T\right]$. In this way, each annotation vector $\mathbf{h}_i$ encodes information about the i-th word with respect to all the other surrounding words in the sequence. Therefore, these annotation vectors are desirable for the following modeling.

We use this encoder to represent both the source sentence $\{x_i\}_{i=1}^{T_f}$ and the target sentence $\{y_i\}_{i=1}^{T_e}$ (see the blue color in Figure 2). Accordingly, our encoder generates both the source annotation vectors $\{\mathbf{h}_i\}_{i=1}^{T_f} \in \mathbb{R}^{2d_f}$ and the target annotation vectors $\{\mathbf{h}'_i\}_{i=1}^{T_e} \in \mathbb{R}^{2d_e}$. The source vectors flow into the inferer and decoder while the target vectors the posterior approximator.

3.2 Variational Neural Inferer

A major challenge of variational models is how to model the latent-variable-related distributions. In VNMT, we employ neural networks to model both the prior $p_\theta(\mathbf{z}|\mathbf{x})$ and the posterior $q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})$, and let them subject to a multivariate Gaussian distribution with a diagonal covariance structure.[2] As shown in Figure 1, these two distributions mainly differ in their conditions.

[2]The reasons of choosing Gaussian distribution are twofold: 1) it is a natural choice for modeling continuous variables; 2) it belongs to the family of "location-scale" distributions, which is required for the following reparameterization.

3.2.1 Neural Posterior Approximator

Exactly modeling the true posterior $p(\mathbf{z}|\mathbf{x}, \mathbf{y})$ exactly usually intractable. Therefore, we adopt an approximation method to simplify the posterior inference. Conventional models typically employ the *mean-field* approaches. However, a major limitation of this approach is its inability to capture the true posterior of $\mathbf{z}$ due to its oversimplification. Following the spirit of VAE, we use neural networks for better approximation in this paper, and assume the approximator has the following form:

$$q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y}) = \mathcal{N}(\mathbf{z}; \mu(\mathbf{x}, \mathbf{y}), \sigma(\mathbf{x}, \mathbf{y})^2\mathbf{I}) \tag{7}$$

The mean μ and s.d. σ of the approximate posterior are the outputs of neural networks based on the observed variables $\mathbf{x}$ and $\mathbf{y}$ as shown in Figure 2 (b).

Starting from the variational neural encoder, we first obtain the source- and target-side representation via a *mean-pooling* operation over the annotation vectors, i.e. $\mathbf{h}_f = \frac{1}{T_f}\sum_i^{T_f} \mathbf{h}_i, \mathbf{h}_e = \frac{1}{T_e}\sum_i^{T_e} \mathbf{h}'_i$. With these representations, we perform a non-linear transformation that projects them onto our concerned latent semantic space:

$$\mathbf{h}'_z = g(W_z^{(1)}[\mathbf{h}_f; \mathbf{h}_e] + b_z^{(1)}) \tag{8}$$

where $W_z^{(1)} \in \mathbb{R}^{d_z \times 2(d_f + d_e)}, b_z^{(1)} \in \mathbb{R}^{d_z}$ is the parameter matrix and bias term respectively, d_z is the dimensionality of the latent space, and $g(\cdot)$ is an element-wise activation function, which we set to be $\tanh(\cdot)$ throughout our experiments.

In this latent space, we obtain the abovementioned Gaussian parameters μ and $\log\sigma^2$ through linear regression:

$$\mu = W_\mu \mathbf{h}'_z + b_\mu, \;\; \log\sigma^2 = W_\sigma \mathbf{h}'_z + b_\sigma \tag{9}$$

where $\mu, \log\sigma^2$ are both d_z-dimension vectors.

3.2.2 Neural Prior Model

Different from the posterior, we model (rather than approximate) the prior as follows:

$$p_\theta(\mathbf{z}|\mathbf{x}) = \mathcal{N}(\mathbf{z}; \mu'(\mathbf{x}), \sigma'(\mathbf{x})^2\mathbf{I}) \tag{10}$$

We treat the mean μ' and s.d. σ' of the prior as neural functions of source sentence $\mathbf{x}$ alone. This is sound and reasonable because bilingual sentences are semantically equivalent, suggesting that either $\mathbf{y}$ or $\mathbf{x}$

is capable of inferring the underlying semantics of sentence pairs, i.e., the representation of latent variable $\mathbf{z}$.

The neural model for the prior $p_\theta(\mathbf{z}|\mathbf{x})$ is the same as that (i.e. Eq (8) and (9)) for the posterior $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$, except for the absence of $\mathbf{h}_e$. Besides, the parameters for the prior are independent of those for the posterior.

To obtain a representation for latent variable $\mathbf{z}$, we employ the same technique as the Eq. (3) and reparameterized it as $\mathbf{h}_z = \mu + \sigma \odot \epsilon, \epsilon \sim \mathcal{N}(0, \mathbf{I})$. During decoding, however, due to the absence of target sentence $\mathbf{y}$, we set $\mathbf{h}_z$ to be the mean of $p_\theta(\mathbf{z}|\mathbf{x})$, i.e., μ'. Intuitively, the reparameterization bridges the gap between the generation model $p_\theta(\mathbf{y}|\mathbf{z},\mathbf{x})$ and the inference model $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$. In other words, it connects these two neural networks. This is important since it enables the stochastic gradient optimization via standard backpropagation.

We further project the representation of latent variable $\mathbf{h}_z$ onto the target space for translation:

$$\mathbf{h}'_e = g(W_z^{(2)}\mathbf{h}_z + b_z^{(2)}) \tag{11}$$

where $\mathbf{h}'_e \in \mathbb{R}^{d'_e}$. The transformed $\mathbf{h}'_e$ is then integrated into our decoder. Notice that because of the noise from ϵ, the representation $\mathbf{h}'_e$ is not fixed for the same source sentence and model parameters. This is crucial for VNMT to learn to avoid overfitting.

3.3 Variational Neural Decoder

Given the source sentence $\mathbf{x}$ and the latent variable $\mathbf{z}$, our decoder defines the probability over translation $\mathbf{y}$ as a joint probability of ordered conditionals:

$$p(\mathbf{y}|\mathbf{z},\mathbf{x}) = \prod_{j=1}^{T_e} p(y_j|y_{<j},\mathbf{z},\mathbf{x}) \tag{12}$$

$$\text{where} \quad p(y_j|y_{<j},\mathbf{z},\mathbf{x}) = g'(y_{j-1}, s_{j-1}, c_j)$$

The feed forward model $g'(\cdot)$ (see the yellow arrows in Figure 2) and context vector $c_j = \sum_i \alpha_{ji}\mathbf{h}_i$ (see the "$\oplus$" in Figure 2) are the same as (Bahdanau et al., 2014). The difference between our decoder and Bahdanau et al.'s decoder (2014) lies in that in addition to the context vector, our decoder integrates the representation of the latent variable, i.e. $\mathbf{h}'_e$, into the computation of s_j, which is denoted by the bold dashed red arrow in Figure 2 (c).

Formally, the hidden state s_j in our decoder is calculated by[3]

$$\begin{aligned}
s_j &= (1-u_j)\odot s_{j-1} + u_j \odot \tilde{s}_j, \\
\tilde{s}_j &= \tanh(WE_{y_j} + U[r_j \odot s_{j-1}] + Cc_j + V\mathbf{h}'_e) \\
u_j &= \sigma(W_u E_{y_j} + U_u s_{j-1} + C_u c_j + V_u \mathbf{h}'_e) \\
r_j &= \sigma(W_r E_{y_j} + U_r s_{j-1} + C_r c_j + V_r \mathbf{h}'_e)
\end{aligned}$$

Here, r_j, u_j, $\tilde{s}_j$ denotes the reset gate, update gate and candidate activation in GRU respectively, and $E_{y_j} \in \mathbb{R}^{d_w}$ is the word embedding for target word. $W, W_u, W_r \in \mathbb{R}^{d_e \times d_w}$, $U, U_u, U_r \in \mathbb{R}^{d_e \times d_e}$, $C, C_u, C_r \in \mathbb{R}^{d_e \times 2d_f}$, and $V, V_u, V_r \in \mathbb{R}^{d_e \times d'_e}$ are parameter weights. The initial hidden state s_0 is initialized in the same way as Bahdanau et al. (2014) (see the arrow to s_0 in Figure 2).

In our model, the latent variable can affect the representation of hidden state s_j through the gate between r_j and u_j. This allows our model to access the semantic information of $\mathbf{z}$ indirectly since the prediction of y_{j+1} depends on s_j. In addition, when the model learns wrong attentions that lead to bad context vector c_j, the semantic representation $\mathbf{h_e}'$ can help to guide the translation process .

3.4 Model Training

We use the Monte Carlo method to approximate the expectation over the posterior in Eq. (5), i.e. $\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})}[\cdot] \simeq \frac{1}{L}\sum_{l=1}^{L} \log p_\theta(\mathbf{y}|\mathbf{x},\mathbf{h}_z^{(l)})$, where L is the number of samples. The joint training objective for a training instance $(\mathbf{x},\mathbf{y})$ is defined as follows:

$$\begin{aligned}
\mathcal{L}(\theta,\phi) \simeq & -\mathrm{KL}(q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})||p_\theta(\mathbf{z}|\mathbf{x})) \\
& + \frac{1}{L}\sum_{l=1}^{L}\sum_{j=1}^{T_e} \log p_\theta(y_j|y_{<j},\mathbf{x},\mathbf{h}_z^{(l)})
\end{aligned} \tag{13}$$

$$\text{where } \mathbf{h}_z^{(l)} = \mu + \sigma \odot \epsilon^{(l)} \text{ and } \epsilon^{(l)} \sim \mathcal{N}(0,\mathbf{I})$$

The first term is the KL divergence between two Gaussian distributions which can be computed and differentiated without estimation (see (Kingma and Welling, 2014) for details). And the second term is the approximate expectation, which is also differentiable. Suppose that L is 1 (which is used in our experiments), then our second term will be degenerated to the objective of conventional NMT. Intuitively, VNMT is exactly a regularized version of

[3] We omit the bias term for clarity.

System	MT05	MT02	MT03	MT04	MT06	MT08	AVG

Table 1: BLEU scores on the NIST Chinese-English translation task. **AVG** = average BLEU scores on test sets. We highlight the best results in bold for each test set. "↑/⇑": significantly better than *Moses* ($p < 0.05$/$p < 0.01$); "+/++": significantly better than *GroundHog* ($p < 0.05$/$p < 0.01$);

NMT, where the introduced noise ϵ increases its robustness, and reduces overfitting. We verify this point in our experiments.

Since the objective function in Eq. (13) is differentiable, we can optimize the model parameter θ and variational parameter ϕ jointly using standard gradient ascent techniques.

4 Experiments

4.1 Setup

To evaluate the effectiveness of the proposed VNMT, we conducted experiments on both Chinese-English and English-German translation tasks. Our Chinese-English training data[4] consists of 2.9M sentence pairs, with 80.9M Chinese words and 86.4M English words respectively. We used the NIST MT05 dataset as the development set, and the NIST MT02/03/04/06/08 datasets as the test sets for the Chinese-English task. Our English-German training data[5] consists of 4.5M sentence pairs with 116M English words and 110M German words[6]. We used the newstest2013 (3000 sentences) as the development set, and the newstest2014 (2737 sentences) as the test set for English-German translation. We employed the case-insensitive BLEU-4 (Papineni et al., 2002) metric to evaluate translation quality, and paired bootstrap sampling (Koehn, 2004) for significance test.

We compared our model against two state-of-the-art SMT and NMT systems:

- *Moses* (Koehn et al., 2007): a phrase-based SMT system.
- *GroundHog* (Bahdanau et al., 2014): an attention-based NMT system.

Additionally, we also compared with a variant of *VNMT*, which does not contain the KL part in the objective (*VNMT w/o KL*). This is achieved by setting $\mathbf{h}_z$ to μ'.

For *Moses*, we adopted all the default settings except for the language model. We trained a 4-gram language model on the Xinhua section of the English Gigaword corpus (306M words) using the SRILM[7] toolkit with modified Kneser-Ney smoothing. Importantly, we used all words in the vocabulary.

For *GroundHog*, we set the maximum length of training sentences to be 50 words, and preserved the most frequent 30K (Chinese-English) and 50K (English-German) words as both the source and target vocabulary , covering approximately 98.9%/99.2% and 97.3%/93.3% on the source and target side of the two parallel corpora respectively . All other words were represented by a specific token "UNK". Following Bahdanau et al. (2014), we set $d_w = 620$, $d_f = 1000$, $d_e = 1000$, and $M = 80$. All other settings are the same as the default configuration (for *RNNSearch*). During decoding, we used the beam-search algorithm, and set beam size to 10.

For *VNMT*, we initialized its parameters with the trained *RNNSearch* model. The settings of our model are the same as that of *GroundHog*, except for some parameters specific to VNMT. Following VAE, we set the sampling number $L = 1$. Additionally, we set $d'_e = d_z = 2d_f = 2000$ according to preliminary experiments. We used the Adadelta algorithm for model training with $\rho = 0.95$. With regard to the source and target encoders, we shared their recurrent parameters but not word embeddings.

We implemented our VNMT based on *GroundHog*[8]. Both NMT systems are trained on a Telsa K40

[4]This corpus consists of LDC2003E14, LDC2004T07, LDC2005T06, LDC2005T10 and LDC2004T08 (Hong Kong Hansards/Laws/News).

GPU. In one hour, *GroundHog* processes about 1100 batches, while our *VNMT* processes 630 batches.

4.2 Results on Chinese-English Translation

Table 1 summarizes the BLEU scores of different systems on the Chinese-English translation tasks. Clearly VNMT significantly improves translation quality in terms of BLEU on most cases, and obtains the best average results that gain 0.86 and 1.35 BLEU points over *Moses* and *GroundHog* respectively. Besides, without the KL objective, *VNMT w/o KL* obtains even worse results than GroundHog. These results indicate the following two points: 1) explicitly modeling underlying semantics by a latent variable indeed benefits neural machine translation, and 2) the improvements of our model are not from enlarging the network.

https://github.com/DeepLearnXMU/VNMT.

4.3 Results on Long Sentences

We further testify VNMT on long sentence translation where the vanilla NMT usually suffers from attention failures (Tu et al., 2016; Bentivogli et al., 2016). We believe that the global latent variable can play an important role on long sentence translation.

Our first experiment is carried out on 6 disjoint groups according to the length of source sentences in our test sets. Figure 3 shows the BLEU scores of two neural models. We find that the performance curve of our VNMT model always appears to be on top of that of *GroundHog* with a certain margin. Specifically, on the final group with the longest source sentences, our VNMT obtains the biggest improvement (3.55 BLEU points). Overall, these obvious improvements on all groups in terms of the length of source sentences indicate that the global guidance from the latent variable benefits our VNMT model.

Our second experiment is carried out on a synthetic dataset where each new source sentence is a concatenation of neighboring source sentences in the original test sets. As a result, the average length of source sentences in the new dataset (> 50) is almost twice longer than the original one. Translation results is summarized in Table 2, where our VNMT obtains significant improvements on all new test sets. This further demonstrates the advantage of introducing the latent variable.

4.4 Results on English-German Translation

Table 3 shows the results on English-German translation. We also provide several existing NMT sys-

Source	两 国 官员 确定 了 今后 会谈 的 日程 和 模式 , 建立 起 进行 持续 对话 的 机制 , 此举 标志 着 巴 印 对话 进程 在 中断 两 年 后 重新 启动 , 为 两 国 逐步 解决 包括 克什米 尔 争端 在内 的 所有 悬而未决 的 问题 奠定 了 基础 , 体现 了 双方 可贵 的 和平 诚意 。

Table 4: Translation examples of different systems. We highlight important parts in red color.

tems that use the same training, development and testing data. The results show that VNMT significantly outperforms GroundHog and achieves a significant gain of 0.73 BLEU points ($p < 0.01$). With unknown word replacement (Jean et al., 2015; Luong et al., 2015a), VNMT reaches the performance level that is comparable to the previous state-of-the-art NMT results.

4.5 Translation Analysis

Table 4 shows a translation example that helps understand the advantage of VNMT over NMT . As the source sentence in this example is long (more than 40 words), the translation generated by *Moses* is relatively messy and incomprehensible. In contrast, translations generated by neural models (both *GroundHog* and *VNMT*) are much more fluent and comprehensible. However, there are essential differences between *GroundHog* and our *VNMT*. Specifically, *GroundHog* does not translate the phrase "官员" at the beginning of the source sentence. The translation of the clause "体现 了 双方 可贵 的 和平 诚意 。" at the end of the source sentence is completely lost. In contrast, our VNMT model does not miss or mistake these fragments and can convey the meaning of entire source sentence to the target side.

From these examples, we can find that although attention networks can help NMT trace back to relevant parts of source sentences for predicting target translations, capturing the semantics of entire sentences still remains a big challenge for neural machine translation. Since NMT implicitly models variable-length source sentences with fixed-size hidden vectors, some details of source sentences (e.g., the red sequence of words in Table 4) may not be encoded in these vectors at all. VNMT seems to be able to capture these details through a latent variable that explicitly model underlying semantics of source sentences. The promising results suggest that VNMT provides a new mechanism to deal with sentence semantics.

5 Related Work

5.1 Neural Machine Translation

Neural machine translation starts from the sequence to sequence learning, where Sutskever et al. (2014) employ two multilayered Long Short-Term Memory (LSTM) models that first encode a source sentence into a single vector and then decode the translation word by word until a special end token is generated. In order to deal with issues caused by encoding all source-side information into a fixed-length vector, Bahdanau et al. (2014) introduce attention-based

NMT that aims at automatically concentrating on relevant source parts for predicting target words during decoding. The incorporation of attention mechanism allows NMT to cope better with long sentences, and makes it really comparable to or even superior to conventional SMT.

Following the success of attentional NMT, a number of approaches and models have been proposed for NMT recently, which can be grouped into different categories according to their motivations: dealing with rare words or large vocabulary (Jean et al., 2015; Luong et al., 2015b; Sennrich et al., 2015), learning better attentional structures (Luong et al., 2015a), integrating SMT techniques (Cheng et al., 2015; Shen et al., 2015; Feng et al., 2016; Tu et al., 2016), memory network (Meng et al., 2015), etc. All these models are designed within the discriminative encoder-decoder framework, leaving the explicit exploration of underlying semantics with a variational model an open problem.

5.2 Variational Neural Model

In order to perform efficient inference and learning in directed probabilistic models on large-scale dataset, Kingma and Welling (2014) as well as Rezende et al. (2014) introduce variational neural networks. Typically, these models utilize an neural inference model to approximate the intractable posterior, and optimize model parameters jointly with a reparameterized variational lower bound using the standard stochastic gradient technique. This approach is of growing interest due to its success in various tasks.

Kingma et al. (2014) revisit the approach to semi-supervised learning with generative models and further develop new models that allow effective generalization from a small labeled dataset to a large unlabeled dataset. Chung et al. (2015) incorporate latent variables into the hidden state of a recurrent neural network, while Gregor et al. (2015) combine a novel spatial attention mechanism that mimics the foveation of human eyes, with a sequential variational auto-encoding framework that allows the iterative construction of complex images. Very recently, Miao et al. (2015) propose a generic variational inference framework for generative and conditional models of text.

The most related work is that of Bowman et al. (2015), where they develop a variational autoencoder for unsupervised generative language modeling. The major difference is that they focus on the monolingual language model, while we adapt this technique to bilingual translation. Although variational neural models have been widely used in NLP tasks and the variational decoding has been investigated for SMT (Li et al., 2009), the adaptation and utilization of variational neural model to neural machine translation, to the best of our knowledge, has never been investigated before.

6 Conclusion and Future Work

In this paper, we have presented a variational model for neural machine translation that incorporates a continuous latent variable to model the underlying semantics of sentence pairs. We approximate the posterior distribution with neural networks and reparameterize the variational lower bound. This enables our model to be an end-to-end neural network that can be optimized through the stochastic gradient algorithms. Comparing with the conventional attention-based NMT, our model is better at translating long sentences. It also greatly benefits from a special regularization term brought with this latent variable. Experiments on Chinese-English and English-German translation tasks verified the effectiveness of our model.

In the future, since the latent variable in our model is at the sentence level, we want to explore more fine-grained latent variables for neural machine translation, such as the *Recurrent Latent Variable Model* (Chung et al., 2015). We are also interested in applying our model to other similar tasks.

Abstract

Among the alignment models used in statistical machine translation (SMT), the hidden Markov model (HMM) is arguably the most elegant: it performs consistently better than IBM Model 3 and is very close in performance to the much more complex IBM Model 4. In this paper we discuss a model which combines the structure of the HMM and IBM Model 2. Using this surrogate, our experiments show that we can attain a similar level of alignment quality as the HMM model implemented in GIZA++ (Och and Ney, 2003). For this model, we derive its convex relaxation and show that it too has strong performance despite not having the local optima problems of non-convex objectives. In particular, the word alignment quality of this new convex model is significantly above that of the standard IBM Models 2 and 3, as well as the popular (and still non-convex) IBM Model 2 variant of (Dyer et al., 2013).

1 Introduction

The IBM translation models are widely used in modern statistical translation systems. Typically, one seeds more complex models with simpler models, and the parameters of each model are estimated through an Expectation Maximization (EM) procedure. Among the IBM Models, perhaps the most elegant is the HMM model (Vogel et al., 1996). The HMM is the last model whose expectation step is both exact and simple, and it attains a level of accuracy that is very close to the results achieved by much more complex models. In particular, experiments have shown that IBM Models 1, 2, and 3 all perform worse than the HMM and Model 4 benefits greatly from being seeded by the HMM (Och and Ney, 2003).

In this paper we make the following contributions:

- We derive a new alignment model which combines the structure of the HMM and IBM Model 2 and show that its performance is very close to that of the HMM. There are several reasons why such a result would be of value (for more on this, see (Simion et al., 2013) and (Simion et al., 2015a), for example).
- *The main goal of this work is not to eliminate highly non-convex models such as the HMM entirely but, rather, to develop a new, powerful, convex alignment model and thus push the boundary of these theoretically justified techniques further.* Building on the work of (Simion et al., 2015a), we derive a convex relaxation for the new model and show that its performance is close to that of the HMM. Although it does not beat the HMM, the new convex model improves upon the standard IBM Model 2 significantly. Moreover, the convex relaxation also performs better than the strong IBM 2 variant FastAlign (Dyer et al., 2013), IBM Model 3, and the other available convex alignment models detailed in (Simion et al., 2015a) and (Simion et al., 2013).
- We derive a parameter estimation algorithm for

Austin, Texas, November 1-5, 2016.

new model and its convex relaxation based on the EM algorithm. Our model has both HMM emission probabilities and IBM Model 2's distortions, so we can use Model 2 to seed both the model's lexical and distortion parameters. For the convex model, we need not use any initialization heuristics since the EM algorithm we derive is guaranteed to converge to a local optima that is also global.

The goal of our work is to present a model which is convex and has state of the art empirical performance. Although one step of this task was achieved for IBM Model 2 (Simion et al., 2015a), our target goal deals with a much more local-optima-laden, non-convex objective. Finally, whereas IBM 2 in some ways leads to a clear method of attack, we will discuss why the HMM presents challenges that require the insertion of this new surrogate.

Notation. We adopt the notation introduced in (Och and Ney, 2003) of having $1^m 2^n$ denote the training scheme of m IBM Model 1 EM iterations followed by initializing Model 2 with these parameters and running n IBM Model 2 EM iterations. We denote by H the HMM and note that it too can be seeded by running Model 1 followed by Model 2. Additionally, we denote our model as 2_{H}, and note that it has distortion parameters like IBM Model 2 and emission parameters like that of the HMM. Under this notation, we let $1^m 2^n 2^o_{\text{H}}$ denote running Model 1 for m iterations, then Model 2 for n iteration, and then finally our Model for o iterations. As before, we are seeding from the more basic to the more complex model in turn. We denote the convex relaxation of 2_{H} by 2_{HC}. Throughout this paper, for any integer N, we use $[N]$ to denote $\{1 \dots N\}$ and $[N]_0$ to denote $\{0 \dots N\}$. Finally, in our presentation, "convex function" means a function for which a local maxima also global, for example, $f(x) = -x^2$.

2 IBM Models 1 and 2 and the HMM

In this section we give a brief review of IBM Models 1, 2, and the HMM, as well as the the optimization problems arising from these models. The standard approach for optimization within these latent variable models is the EM algorithm.

Throughout this section, and the remainder of the paper, we assume that our set of training examples is $(e^{(k)}, f^{(k)})$ for $k = 1 \dots n$, where $e^{(k)}$ is the k'th English sentence and $f^{(k)}$ is the k'th French sentence. Following standard convention, we assume the task is to translate from *French* (the "source" language) into *English* (the "target" language) [1]. We use E to denote the English vocabulary (set of possible English words), and F to denote the French vocabulary. The k'th English sentence is a sequence of words $e^{(k)}_1 \dots e^{(k)}_{l_k}$ where l_k is the length of the k'th English sentence, and each $e^{(k)}_i \in E$; similarly the k'th French sentence is a sequence $f^{(k)}_1 \dots f^{(k)}_{m_k}$, where m_k is the length of the k'th French sentence, and each $f^{(k)}_j \in F$. We define $e^{(k)}_0$ for $k = 1 \dots n$ to be a special NULL word (note that E contains the NULL word).

For each English word $e \in E$, we will assume that $D(e)$ is a *dictionary* specifying the set of possible French words that can be translations of e. The set $D(e)$ is a subset of F. In practice, $D(e)$ can be derived in various ways; in our experiments we simply define $D(e)$ to include all French words f such that e and f are seen in a translation pair.

Given these definitions, the IBM Model 2 optimization problem is presented in several sources, for example, (Simion et al., 2013). The parameters in this problem are $t(f|e)$ and $d(i|j,l,m)$. The objective function for IBM Model 2 is then the log-likelihood of the training data; we can simplify the log-likelihood (Koehn, 2008) as

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log p(f^{(k)}_j|e^{(k)}) \,,$$

where

$$p(f^{(k)}_j|e^{(k)}) = \sum_{i=0}^{l_k} t(f^{(k)}_j|e^{(k)}_i)d(i|j,l_k,m_k) \,.$$

[1] Technically, in most standard sources (Koehn, 2008), this goes as follows: when we want to translate from *French* to *English* we note that $p(e|f) \propto p(f|e)p(e)$ by Bayes's Theorem. When translating, the alignment models we consider are concerned with modeling $p(f|e)$ while the rest of the translation is handled by the language model $p(e)$. Therefore, in the context of the original task, we have that English is the target language while French is the source. However, for the sake of clarity, we emphasize that the alignment models we study are concerned with the development of $p(f|e)$.

This last simplification is crucial as it allows for a simple multinomial EM implementation, and can be done for IBM Model 1 as well (Koehn, 2008). Furthermore, the ability to write out the marginal likelihood per sentence in this manner has seen other applications: it was crucial, for example, in deriving a convex relaxation of IBM Model 2 and solving the new problem using subgradient methods (Simion et al., 2013).

An improvement on IBM Model 2, called the HMM alignment model, was introduced by Vogel et al (Vogel et al., 1996). For this model, the distortion parameters are replaced by *emission* parameters $d(a_j|a_{j-1}, l)$. These emission parameters specify the probability of the next alignment variable for the j^{th} target word is a_j, given that the previous source word was aligned to a target word whose position was a_{j-1} in a target sentence with length of l. The objective of the HMM is given by

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{a_1^{(k)}\ldots a_{m_k}^{(k)}}\log\prod_{j=1}^{m_k} t(f_j^{(k)}|e_{a_j^k}^{(k)})d(a_j^{(k)}|a_{j-1}^{(k)}, l_k)$$

and we present this in Fig 1. We note that unlike IBM Model 2, we cannot simplify the exponential sum within the log-likelihood of the HMM, and so EM training for this model requires the use of a special EM implementation knows as the Baum-Welch algorithm (Rabiner and Juang., 1986).

Once these models are trained, each model's highest probability (Viterbi) alignment is computed. For IBM Models 1 and 2, the Viterbi alignment splits easily (Koehn, 2008). For the HMM, dynamic programming is used (Vogel et al., 1996). Although it is non-convex and thus its initialization is important, the HMM is the last alignment model in the classical setting that has an exact EM procedure (Och and Ney, 2003): from IBM Model 3 onwards heuristics are used within the expectation and maximization steps of each model's associated EM procedure.

3 Distortion and emission parameter structure

The structure of IBM Model 2's distortion parameters and the HMM's emission parameters is important and is used in our model as well, so we detail this here. We are using the roughly same structure as (Liang et al., 2006) and (Dyer et al., 2013): the distortions and emissions of our model are parametrized by forcing the model to concentrate its alignments on the diagonal.

Input: Define E, F, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 2.

Parameters:

- A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.
- A parameter $d(i|i, l_k)$ for each $i \in [l_k]_0$, $i' \in [l_k]_0$.

Constraints:

$$\forall e \in E, f \in D(e), t(f|e) \geq 0 \quad (1)$$

$$\forall e \in E, \sum_{f \in D(e)} t(f|e) = 1 \quad (2)$$

$$\forall i, i' \in [l_k]_0, d(i'|i, l_k) \geq 0 \quad (3)$$

$$\forall i \in [l_k]_0, \sum_{i' \in [l_k]_0} d(i'|i, l_k) = 1 \quad (4)$$

Objective: Maximize

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{a_1^{(k)}\ldots a_{m_k}^{(k)}}\log\prod_{j=1}^{m_k} t(f_j^{(k)}|e_{a_j^k}^{(k)})d(a_j^{(k)}|a_{j-1}^{(k)}, l_k)$$

with respect to the $t(f|e)$ parameters $d(i'|i, l)$.

Figure 1: The HMM Optimization Problem

3.1 Distortion Parameters for IBM2

Let $\lambda > 0$. For the IBM Model 2 distortions we set the NULL word probability as $d(0|j, l, m) = p_0$, where $p_0 = \frac{1}{l+1}$ and note that this will generally depend on the target sentence length within a bitext training pair that we are considering. For $i \neq 0$ which satisfies we set

$$d(i|j, l, m) = \frac{(1 - p_0)e^{-\lambda|\frac{i}{l} - \frac{j}{m}|}}{Z_\lambda(j, l, m)},$$

where $Z_\lambda(j, l, m)$ is a normalization constant as in (Dyer et al., 2013).

3.2 Emission Parameters for HMM

Let $\theta > 0$. For the HMM emissions we first set the NULL word generation to $d(0|i, l) = p_0$, with

$p_0 = \frac{1}{l+1}$. For target word position $i, i' \neq 0$, we set

$$d(i'|i,l) = \frac{(1-p_0)e^{-\theta|\frac{i'}{l}-\frac{i}{l}|}}{Z_\theta(i,l,m)} ,$$

where $Z_\theta(i,l,m)$ is a suitable normalization constant. Lastly, if $i = 0$ so that we are jumping from the NULL word onto a possibly different word, we set $d(i'|0,l) = p_0$. Aside from making the NULL word have uniform jump probability, the above emission parameters are modeled to favor a jumping to an adjacent English word.

4 Combining IBM Model 2 and the HMM

In deriving the new HMM surrogate, our main goal was to allow the current alignment to know as much as possible about the previous alignment variable and still have a likelihood that factors as that of IBM Model 2 (Simion et al., 2013; Koehn, 2008). We combine IBM Model 2 and the HMM by incorporating the generation of words using the structure of both models. The model we introduce, IBM2-HMM, is displayed in Fig 2.

Consider a target-source sentence pair (e, f) with $|e| = l$ and $|f| = m$. For source sentence positions j and $j+1$ we have source words f_j and f_{j+1} and we assign a joint probability involving the alignments a_j and a_{j+1} as:

$$q(j, a_j, a_{j+1}, l, m) \quad = \tag{5}$$
$$t(f_j|e_{a_j})d(a_j|j,l,m)t(f_{j+1}|e_{a_{j+1}})d(a_{j+1}|a_j,l) . \tag{6}$$

From the equation above, we note that we use the IBM Model 2's word generation method for position j and the HMM generative structure for position $j+1$. The generative nature of the above procedure introduces dependency between adjacent words two at a time. Since we want to mimic the HMM's structure as much as possible, we devise our likelihood function to mimic the HMM's dependency between alignments using q. Essentially, we move the source word position j from 1 to m and allow for overlapping terms when $j \in \{2, \ldots, m-1\}$. In what follows, we describe this representation in detail.

The likelihood in Eq. 16 is actually the sum of two likelihoods which use equations Eq. 5 and 6 repeatedly. To this end, we will discuss how our objective is actually

$$\frac{1}{n}\sum_{k=1}^{n} \log \sum_{a^{(k)}, b^{(k)}} p(f^{(k)}, a^{(k)}, b^{(k)}|e^{(k)}) , \tag{7}$$

where $a^{(k)}$ and $b^{(k)}$ both are alignment vectors whose components are independent and can take on any values in $[l_k]_0$. To see how $p(f, a, b|e)$ comes about, note that we could generate the sentence f by generating pairs $(1,2), (3,4), (5,6), \ldots$ using equations Eqs. 5 and 6 for each pair. Taking all this together, the upshot of our discussion is that generating the pair (e, f) in this way gives us that the likelihood for an alignment a would be given by:

$$p_1(f, a|e) = \prod_{j \text{ odd}}^{m-1} q(j, a_j, a_{j+1}, l, m) . \tag{8}$$

Using the same idea as above, we could also skip the first target word position and generate pairs $(2,3), (4,5), \ldots$ using Eqs. 5 and 6. Under this second generative method, the joint probability for f and alignment b is:

$$p_2(f, b|e) = \prod_{j \text{ even}}^{m-1} q(j, b_j, b_{j+1}, l, m) , \tag{9}$$

Finally, we note that if m is even we do not generate f_1 and f_m under p_2 but we do generate these words under p_1. Similarly, if m is odd we do not generate f_1 under p_2 and we do not generate f_m under p_1; however in this case as in the first, we still generate these missing words under the other generative method. Using $p(f, a, b|e) = p_1(f, a|e)p_2(f, b|e)$ and factoring the log-likelihood as in IBM Model 1 and 2 (Koehn, 2008), we get the log-likelihood in Fig 2. Finally, we note that our model's log-likelihood could be viewed as the sum of the log-likelihoods of a model which generates (e, f) using p_1 and another model which generates sentences using p_2. These models share parameters but generate words using different recipes, as discussed above.

5 The parameter estimation for IBM2-HMM

To fully optimize our new model (over t, λ, and θ), we can use an EM algorithm in the same fashion as

Input: Define E, F, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 2.

Parameters:

- A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.
- A parameter $\lambda > 0$ for distortion centering.
- A parameter $\theta > 0$ for emission centering.

Constraints:

$$\forall e \in E, f \in D(e), t(f|e) \geq 0 \quad (10)$$

$$\forall e \in E, \sum_{f \in D(e)} t(f|e) = 1 \quad (11)$$

$$\forall i \in [l_k]_0, j \in [m_k], d(i|j, l_k, m_k) \geq 0 \quad (12)$$

$$\forall j \in [m_k], \sum_{i \in [l_k]_0} d(i|j, l_k, m_k) = 1 \quad (13)$$

$$\forall i, i' \in [l_k]_0, d(i'|i, l_k) \geq 0 \quad (14)$$

$$\forall i \in [l_k]_0, \sum_{i' \in [l_k]_0} d(i'|i, l_k) = 1 \quad (15)$$

Objective: Maximize

$$\frac{1}{n} \sum_{k=1}^{n} \sum_{j=1}^{m_k - 1} \log \sum_{i=0}^{l_k} \sum_{i'=0}^{l_k} q(j, i, i', l_k, m_k) \quad (16)$$

with respect to the parameters $t(f|e)$, $d(i'|i, l)$ $d(i|j, l, m)$, and $q(j, i, i', l_k, m_k)$ set as

$$t(f_j^{(k)}|e_i^{(k)}) d(i|j, l, m) t(f_{j+1}^{(k)}|e_{i'}) d(i'|i, l) \quad (17)$$

Figure 2: The IBM2-HMM Optimization Problem. We use equation (5) within the likelihood definition.

(Dyer et al., 2013). Specifically, for the model in question the EM algorithm still applies but we have to use a gradient-based algorithm within the learning step. On the other hand, since such a gradient-based method introduces the necessary complication of a learning rate, we could also optimize the objective by picking θ and λ via cross-validation and using a multinomial EM algorithm for the learning of the lexical t terms. For our experiments, we opted for this simpler choice: we derived a multinomial EM algorithm and cross-validated the centering parameters for the distortion and emission terms. With λ and θ fixed, the derivation of this algorithm is very similar to the one used for IBM2-HMM's convex relaxation and this uses the path discussed in (Simion et al., 2015a) and (Simion et al., 2015b). We detail the EM algorithm for the convex relaxation below.

6 A Convex HMM Surrogate

In this section we detail a procedure to get a convex relaxation for IBM2-HMM. Let $(\mathbf{t}, \mathbf{d})$ be all the parameters of the HMM. As a first step in getting a convex HMM, one could follow the path developed in (Simion et al., 2015a) and directly replace the HMM's objective terms

$$\prod_{j=1}^{m_k} t(f_j^{(k)}|e_{a_j^k}^{(k)}) d(a_j^{(k)}|a_{j-1}^{(k)}, l_k)$$

by

$$\left(\prod_{j=1}^{m_k} t(f_j^{(k)}|e_{a_j^k}^{(k)}) d(a_j^{(k)}|a_{j-1}^{(k)}, l_k)\right)^{\frac{1}{2m_k}} .$$

In particular, the geometric mean function $h(x_1, \ldots, h_{2m_k}) = (\prod_{j=1}^{2m_k} x_j)^{\frac{1}{2m_k}}$ is convex ((Boyd and Vandenberghe, 2004)) and, for a given sentence pair $(e^{(k)}, f^{(k)})$ with alignment $a^{(k)}$ we can find a projection matrix $\mathbf{P}$ so that $\mathbf{P}(\mathbf{t}, \mathbf{d}) = (\tilde{\mathbf{t}}, \tilde{\mathbf{d}})$ where $\tilde{\mathbf{t}} = \{t(f_j^{(k)}|e_{a_j^k}^{(k)})\}_{j=1}^{m_k}$ and $\tilde{\mathbf{d}} = \{d(a_j^{(k)}|a_{j-1}^{(k)}, l_k)\}_{j=1}^{m_k}$ are exactly the parameters used in the term above (in particular, $\mathbf{t}, \mathbf{d}$ are the set of all parameters while $\tilde{\mathbf{t}}, \tilde{\mathbf{d}}$ are the set of parameters for the specific training pair k; $\mathbf{P}$ projects from the full space onto only the parameters used for training pair k). Given this, we then have that $g(\mathbf{t}, \mathbf{d}) = h(\mathbf{P}(\mathbf{t}, \mathbf{d})) = h(\tilde{\mathbf{t}}, \tilde{\mathbf{d}})$ is convex and, by composition, so is $\log g(\mathbf{t}, \mathbf{d})$ (see (Simion et al., 2015a; Boyd and Vandenberghe, 2004) for details; the main idea lies in the fact that as linear transformations preserve convexity, so do compositions of convex functions with increasing convex functions such as $\log$). Finally, if we run this plan for all terms in the objective, the new objective is convex since it is the sum of convex functions (the new optimization problem is convex as it has linear constraints). Although this gives a convex program, we observed that the powers being so small made the optimized probabilities very uninformative (i.e. uniform). The above makes sense: no matter what the parameters are, we will easily get the 1 we seek

for each term in the objective since all terms are taken to a low ($\frac{1}{2m_k}$) power .

Since this direct relaxation does not yield fruit, we next could turn to our model. Developing its relaxation in the vein of (Simion et al., 2015a), we could be to let $d(i|j,l,m)$ and $d(i'|i,l)$ be multinomial probabilities (that is, these parameters would not have centering parameters λ and θ and would be just standard probabilities as in the GIZA++ versions of the HMM and IBM Model 2 (Och and Ney, 2003)) and replace all the terms $q(j,i',i,l,m)$ in (16) by $(q(j,i',i,l,m))^{\frac{1}{4}}$. Although this method is feasible, experiments showed that the relaxation is not very competitive and performs on par with IBM Model 2; this relaxation is far in performance from the HMM even though we are relaxing (only) the product of 4 terms (lastly, we mention that we tried other variants were we replaced $d(i|j,l,m)d(i'|i,l)$ by $d(i,i'|j,l,m)$ so that we would have only three terms; unfortunately, this last attempt also produced parameters that were "too uniform").

The above analysis motivates why we defined our model as we did: we now have only two terms to relax. In particular, to rectify the above, we left in place the structure discussed in Section 3 and made λ and θ be tuning parameters which we can cross-validate for on a small held-out data set. This last constraint effectively removes the distortion and emission parameters from the model but we still maintain the structural property of these parameters: we maintain their favoring the diagonal or adjacent alignment. To get the relaxation, we replace $q(j,i,i',l,m)$ by

$$p(j,i,i',l,m) \propto \sqrt{t(f_j^{(k)}|e_i^{(k)})t(f_{j+1}^{(k)}|e_{i'})}$$

and set the proportionality constant to be $d(i|j,l,m)d(i'|i,l)$. Using this setup we now have a convex objective to optimize over. In particular, we've formulated a convex relaxation of the IBM2-HMM problem which, like the Support Vector Machine, includes parameters that can be cross-validated over (Boyd and Vandenberghe, 2004).

Input: Define E, F, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 2. Pick $\lambda, \theta > 0$ as in Section 3 via cross-validation.

Parameters:

• A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.

Constraints:

$$\forall e \in E, f \in D(e), t(f|e) \geq 0 \quad (18)$$

$$\forall e \in E, \sum_{f \in D(e)} t(f|e) = 1 \quad (19)$$

Objective: Maximize

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{j=1}^{m_k-1}\log\sum_{i=0}^{l_k}\sum_{i'=0}^{l_k} p(j,i,i',l_k,m_k) \quad (20)$$

with respect to the parameters $t(f|e)$ and $p(j,i,i',l_k,m_k)$ set as

$$\sqrt{t(f_j^{(k)}|e_i^{(k)})}d(i|j,l,m)\sqrt{t(f_{j+1}^{(k)}|e_{i'})}d(i'|i,l)$$

Figure 3: The IBM2-HMM convex relaxation optimization problem. Note that the distortions $d(i|j,l,,m)$ and emissions $d(i'|i,l)$ are constants held fixed and parameterized by cross-validated parameters λ and θ as in Section 3.

7 An EM algorithm for the convex surrogate

The EM algorithm for the convex relaxation of our surrogate is given in Fig 4. As the model's objective is the sum of the objectives of two models generated by a multinomial rule, we can get a very succinct EM algorithm. For more details on this and a similar derivation, please refer to (Simion et al., 2015a), (Koehn, 2008) or (Simion et al., 2015b). For this algorithm, we again note that the distortion and emission parameters are constants so that the only estimation that needs to be conducted is on the lexical t terms.

To be specific, we have that the M step requires optimizing

$$\frac{1}{n}\sum_{k=1}^{n}\log\sum_{a^{(k)},b^{(k)}} q(a^{(k)},b^{(k)}|e^{(k)},f^{(k)})p(f^{(k)},a^{(k)},b^{(k)}|e^{(k)}).$$

In the above, we have that

$$q(a^{(k)}, b^{(k)} | e^{(k)}, f^{(k)})$$

are constants proportional to

$$\prod_{j=1}^{m_k - 1} \sqrt{t(f_j^{(k)} | e^{(k)}_{a_j^{(k)}}) t(f_{j+1}^{(k)} | e^{(k)}_{a_{j+1}^{(k)}})} \prod_{j=2}^{m_k} \sqrt{t(f_j^{(k)} | e^{(k)}_{b_j^{(k)}}) t(f_{j+1}^{(k)} | e^{(k)}_{b_{j+1}^{(k)}})}$$

and gotten through the E step. This optimization step is very similar to the regular Model 2 M step since the β drops down using $\log t^\beta = \beta \log t$; the exact same count-based method can be applied. The upshot of this is given in Fig 4; similar to the logic above for 2_{HC}, we can get the EM algorithm for 2_{H}.

8 Decoding methods for IBM2-HMM

When computing the optimal alignment we wanted to compare our model with the HMM as closely as possible. Because of this, the most natural method of evaluating the quality of the parameters would be to use the same rule as the HMM. Specifically, for a sentence pair (e, f) with $|e| = l$ and $|f| = m$, in HMM decoding we aim to find $(a_1 \dots a_m)$ which maximizes

$$\max_{a_1,\dots,a_m} \prod_{j=1}^{m} t(f_j | e_{a_j}) d(a_j | a_{j-1}, l).$$

As is standard, dynamic programming can now be used to find the Viterbi alignment. Although there are a number of ways we could define the optimal alignment, we felt that the above would be the best since it tests dependance between alignment variables and allows for easy comparison with the GIZA++ HMM. Finding the optimal alignment under the HMM setting is labelled "HMM" in Table 1.

We can also find the optimal alignment by taking the objective literally (see (Simion et al., 2014) for a similar argument dealing with the convex relaxation of IBM Model 2) and computing

$$\max_{a_1 \dots a_m} p_1(f, a|e) p_2(f, a|e).$$

Above, we are asking for the optimal alignment that yields the highest probability alignment through generating technique p_1 and p_2. This method of decoding is a lot like the HMM style and also relies on dynamic programming. In this case we have the recursion for Q_{Joint} given by

$$Q_{Joint}(1, i) = t(f_1 | e_i) d^2(i | 1, l, m) \ ,$$

$\forall i \in [l]_0$, and

$$Q_{Joint}(j, i') = t^2(f_j | e_{i'}) d(i' | j, l, m) M_{Joint}(j-1, i') \ ,$$

where $M_{Joint}(j-1, i')$ is

$$M_{Joint}(j-1, i') = \max_{i=0}^{l} \{ d(i' | i, l) Q_{Joint}(j-1, i) \} \ ,$$

$\forall\, 2 \le j \le m, \forall\, i' \in [l]_0$. The alignment results gotten by decoding with this method is labelled "Joint" in Table 1.

Input: Define E, F, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \dots n$, $D(e)$ for $e \in E$ as in Section 2. Two parameters $\lambda, \theta > 0$ picked by cross-validation so that the distortions and emissions are constants obeying the structure in Section 3. An integer T specifying the number of passes over the data.
Parameters:
• A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.
Initialization:
• $\forall e \in E,\ f \in D(e)$, set $t(f|e) = \frac{1}{D(e)}$.
EM Algorithm: Expectation
for all $k = 1 \dots N$ **do**
  for all $j = 1 \dots m_k$ **do**
    $\delta = 0$
    $\Delta = 0$
    for all $i = 0 \dots l_k$ **do**
      for all $i' = 0 \dots l_k$ **do**
        $\delta[i, i'] = p(j, i', i, l_k, m_k)$
        $\Delta += \delta[i, i']$
    for all $i = 0 \dots l_k$ **do**
      for all $i' = 0 \dots l_k$ **do**
        $\delta[i, i'] = \frac{\delta[i, i']}{\Delta}$
        $counts(f_j^{(k)}, e_i^{(k)}) += \delta[i, i']$
        $counts(e_i^{(k)}) += \delta[i, i']$
        $counts(f_{j+1}^{(k)}, e_{i'}^{(k)}) += \delta[i, i']$
        $counts(e_{i'}^{(k)}) += \delta[i, i']$
EM Algorithm: Maximization
for all $e \in E$ **do**
  for all $f \in D(e)$ **do**
    $t(f|e) = \frac{counts(e,f)}{counts(e)}$
Output: t parameters.

Figure 4: Pseudocode for the EM algorithm of the IBM2-HMM's convex relaxation. As the distortion and emission parameters are constants, the algorithm is very similar to that of IBM Model 1.

9 Experiments

In this section we describe experiments using the IBM2-HMM optimization problem combined with the EM algorithm for parameter estimation.

9.1 Data Sets

We use data from the bilingual word alignment workshop held at HLT-NAACL 2003 (Michalcea and Pederson, 2003). We use the Canadian Hansards bilingual corpus, with 743,989 English-French sentence pairs as training data, 37 sentences of development data, and 447 sentences of test data (note that we use a randomly chosen subset of the original training set of 1.1 million sentences, similar to the setting used in (Moore, 2004)). The development and test data have been manually aligned at the word level, annotating alignments between source and target words in the corpus as either "sure" (S) or "possible" (P) alignments, as described in (Och and Ney, 2003). As is standard, we lower-cased all words before giving the data to GIZA++ and we ignored NULL word alignments in our computation of alignment quality scores.

9.2 Methodology

We test several models in our experiments. In particular, we empirically evaluate our models against the GIZA++ IBM Model 3 and HMM, as well as the FastAlign IBM Model 2 implementation of (Dyer et al., 2013) that uses Variational Bayes. For each of our models, we estimated parameters and got alignments in turn using models in the source-target and target-source directions; using the same setup as (Simion et al., 2013), we present the gotten intersected alignments. In training, we employ the standard practice of initializing non-convex alignment models with simpler non-convex models. In particular, we initialize, the GIZA++ HMM with IBM Model 2, IBM Model 2 with IBM Model 1, and IBM2-HMM and IBM Model 3 with IBM Model 2 preceded by Model 1. Lastly, for FastAlign, we initialized all parameters uniformly since this empirically was a more favorable initialization, as discussed in (Dyer et al., 2013).

We measure the performance of the models in terms of *Precision*, *Recall*, *F-Measure*, and *AER* using only sure alignments in the definitions of the first three metrics and sure and possible alignments in the definition of *AER* , as in (Simion et al., 2013) and (Marcu et al., 2006). For our experiments, we report results in both AER (lower is better) and F-Measure (higher is better) (Och and Ney, 2003).

Table 1 shows the alignment summary statistics for the 447 sentences present in the Hansard test data. We present alignments quality scores using either the FastAlign IBM Model 2, the GIZA++ HMM, and our model and its relaxation using either the "HMM" or "Joint" decoding. First, we note that in deciding the decoding style for IBM2-HMM, the HMM method is better than the Joint method. We expected this type of performance since HMM decoding introduces positional dependance among the entire set of words in the sentence, which is shown to be a good modeling assumption (Vogel et al., 1996).

From the results in Table 1 we see that the HMM outperforms all other models, including IBM2-HMM and its convex relaxation. However, IBM2-HMM is not far in AER performance from the HMM and both it and its relaxation do better than FastAlign or IBM Model 3 (the results for IBM Model 3 are not presented; a one-directional English-French run of $1^5 2^5 3^{15}$ gave AER and F-Measure numbers of 0.1768 and 0.6588, respectively, and this was behind both the IBM Model 2 FastAlign and our models).

As a further set of experiments, we also appended an IBM Model 1 or IBM Model 2 objective to our models's original objectives, so that the constraints and parameters are the same but now we are maximizing the average of two log-likelihoods. With regard to the EM optimization, we would only need to add another δ parameter: we'd now have probabilities $\delta_1[i] \propto t(f_j^{(k)}|e_i^{(k)})d(i|j,l_l,m_k)$ (this is for IBM Model 2 smoothing; we have $d = 1$ for IBM 1 smoothing) and $\delta_2[i,i'] \propto p(j,i,i'.l_k,m_k)$ in the EM Algorithm that results (for more, see (Simion et al., 2015a)). We note that the appended IBM Model 2 objective is still convex if we fix the distortions' λ parameter and then optimize for the t parameters via EM (thus, model 2_{HC} is still convex). For us, there were significant gains, especially in the convex model. The results for all these experiments are shown in Table 2, with IBM 2 smoothing for the convex model displayed in the rightmost column.

Finally, we also tested our model in the full

Table 2: Alignment quality results for IBM2-HMM and its relaxation using IBM 1 and IBM 2 smoothing (in this case, "smoothing" means adding these log-likelihoods to the original objective as in (Simion et al., 2013). For the convex relaxation of IBM2-HMM, we can only smooth by adding in the convex IBM Model 1 objective, or by adding in an IBM Model 2 objective where the distortions are taken to be constants (these distortions are identical to the ones that are used within the relaxation itself and are cross-validated for optimal λ).

SMT pipeline using the cdec system (Dyer et al., 2013). For our experiments, we compared our models' alignments (gotten by training $1^5 2^5_{\text{H}}$ and 2^5_{HC}) against the alignments gotten by the HMM ($1^5 2^5 H^5$), IBM Model 4 ($1^5 H^5 3^3 4^3$), and FastAlign. Unfortunately, we found that all 4 systems led to roughly the same BLEU score of 40 on a Spanish-English training set of size 250000 which was a subset of version 7 of the Europarl dataset (Dyer et al., 2013). For our development and test sets, we used data each of size roughly 1800 and we preprocessed all data by considering only sentences of size less than 80 and filtering out sentences which had a very large (or small) ratio of target and source sentence lengths. Although the SMT results were not a success in that our gains were not significant, we felt that the experiments at least highlight that our model mimics the HMM's alignments even though its structure is much more local. Lastly, we in regards to the new convex model's performance, we observe much better alignment quality than any other convex alignment models in print, for example, (Simion et al., 2015a).

10 Conclusions and Future Work

Our work has explored some of the details of a new model which combines the structure of IBM Model 2 the alignment HMM Model. We've shown that this new model and its convex relaxation performs very close to the standard GIZA++ implementation of the HMM. Bridging the gap between the HMM and convex models proves difficult for a number of reasons (Guo and Schuurmans, 2007). In this paper, we have introduced a new set of ideas aimed at tightening this gap.

Abstract

Verbal comprehension questions appear very frequently in Intelligence Quotient (IQ) tests, which measure human's verbal ability including the understanding of the words with multiple senses, the synonyms and antonyms, and the analogies among words. In this work, we explore whether such tests can be solved automatically by the deep learning technologies for text data. We found that the task was quite challenging, and simply applying existing technologies like word embedding could not achieve a good performance, due to the multiple senses of words and the complex relations among words. To tackle these challenges, we propose a novel framework to automatically solve the verbal IQ questions by leveraging improved word embedding by jointly considering the multi-sense nature of words and the relational information among words. Experimental results have shown that the proposed framework can not only outperform existing methods for solving verbal comprehension questions but also exceed the average performance of the Amazon Mechanical Turk workers involved in the study.

1 Introduction

The Intelligence Quotient (IQ) test (Stern, 1914) is a test of intelligence designed to formally study the success of an individual in adapting to a specific situation under certain conditions. Common IQ tests measure various types of abilities such as verbal, mathematical, logical, and reasoning skills. These tests have been widely used in the study of psychology, education, and career development. In the community of artificial intelligence, agents have been invented to fulfill many interesting and challenging tasks like face recognition, speech recognition, handwriting recognition, and question answering. However, as far as we know, there are very limited studies of developing an agent to solve IQ tests, which in some sense is more challenging, since even common human beings do not always succeed on such tests. Considering that IQ test scores have been widely considered as a measure of *intelligence*, we think it is worth further investigating whether we can develop an agent that can solve IQ test questions.

The commonly used IQ tests contain several types of questions like verbal, mathematical, logical, and picture questions, among which a large proportion (near 40%) are verbal questions (Carter, 2005). The recent progress on deep learning for natural language processing (NLP), such as word embedding technologies, has advanced the ability of machines (or AI agents) to understand the meaning of words and the relations among words. This inspires us to solve the verbal questions in IQ tests by leveraging the word embedding technologies. However, our attempts show that a straightforward application of word embedding does not result in satisfactory performances. This is actually understandable. Standard word embedding technologies learn one embedding vector for each word based on the co-occurrence information in a text corpus. However, verbal comprehension questions in IQ tests usually consider the multiple senses of a word (and often focus on the rare senses), and the complex relations among (polysemous) words. This has clearly exceeded the capability of standard word embedding

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 541–550,
Austin, Texas, November 1-5, 2016.

technologies.

To tackle the aforementioned challenges, we propose a novel framework that consists of three components.

First, we build a classifier to recognize the specific type (e.g., analogy, classification, synonym, and antonym) of verbal questions. For different types of questions, different kinds of relationships need to be considered and the solvers could have different forms. Therefore, with an effective question type classifier, we may solve the questions in a divide-and-conquer manner.

Second, we obtain distributed representations of words and relations by leveraging a novel word embedding method that considers the multi-sense nature of words and the relational knowledge among words (or their senses) contained in dictionaries. In particular, for each polysemous word, we retrieve its number of senses from a dictionary, and conduct clustering on all its context windows in the corpus. Then we attach the example sentences for every sense in the dictionary to the clusters, such that we can tag the polysemous word in each context window with a specific word sense. On top of this, instead of learning one embedding vector for each *word*, we learn one vector for each *pair of word-sense*. Furthermore, in addition to learning the embedding vectors for words, we also learn the embedding vectors for relations (e.g., synonym and antonym) at the same time, by incorporating relational knowledge into the objective function of the word embedding learning algorithm. That is, the learning of word-sense representations and relation representations interacts with each other, such that the relational knowledge obtained from dictionaries is effectively incorporated.

Third, for each type of question, we propose a specific solver based on the obtained distributed word-sense representations and relation representations. For example, for analogy questions, we find the answer by minimizing the distance between word-sense pairs in the question and the word-sense pairs in the candidate answers.

We have conducted experiments using a combined IQ test set to test the performance of our proposed framework. The experimental results show that our method can outperform several baseline methods for verbal comprehension questions on IQ tests. We further deliver the questions in the test set to human beings through Amazon Mechanical Turk[1]. The average performance of the human beings is even a little lower than that of our proposed method.

2 Related Work

2.1 Verbal Questions in IQ Test

In common IQ tests, a large proportion of questions are verbal comprehension questions, which play an important role in deciding the final IQ scores. For example, in Wechsler Adult Intelligence Scale (Wechsler, 2008), which is among the most famous IQ test systems, the full-scale IQ is calculated from two IQ scores: Verbal IQ and Performance IQ, and around 40% of questions in a typical test are verbal comprehension questions. Verbal questions can test not only the verbal ability (e.g., understanding polysemy of a word), but also the reasoning ability and induction ability of an individual. According to previous studies (Carter, 2005), verbal questions mainly have the types elaborated in Table 1, in which the correct answers are highlighted in bold font.

Analogy-I questions usually take the form "A is to B as C is to ?". One needs to choose a word D from a given list of candidate words to form an analogical relation between pair (A, B) and pair (C, D). Such questions test the ability of identifying an implicit relation from word pair (A, B) and apply it to compose word pair (C, D). Note that the Analogy-I questions are also used as a major evaluation task in the *word2vec* models (Mikolov et al., 2013). Analogy-II questions require two words to be identified from two given lists in order to form an analogical relation like "A is to ? as C is to ?". Such questions are a bit more difficult than the Analogy-I questions since the analogical relation cannot be observed directly from the questions, but need to be searched for in the word pair combinations from the candidate answers. Classification questions require one to identify the word that is different (or dissimilar) from others in a given word list. Such questions are also known as *odd-one-out*, which have been studied in (Pintér et al., 2012). Classification questions test the ability to summarize the majority

[1] http://www.mturk.com/

Type	Example
Analogy-I	Isotherm is to temperature as isobar is to? (i) atmosphere, (ii) wind, (iii) **pressure**, (iv) latitude, (v) current.
Analogy-II	Identify two words (one from each set of brackets) that form a connection (analogy) when paired with the words in capitals: CHAPTER (**book**, verse, read), ACT (stage, audience, **play**).
Classification	Which is the odd one out? (i) calm, (ii) **quiet**, (iii) relaxed, (iv) serene, (v) unruffled.
Synonym	Which word is closest to IRRATIONAL? (i)intransigent, (ii) irredeemable, (iii) unsafe, (iv) lost, (v) **nonsensical**.
Antonym	Which word is most opposite to MUSICAL? (i) **discordant**, (ii) loud, (iii) lyrical, (iv) verbal, (v) euphonious.

Table 1: Types of verbal questions.

sense of the words and identify the outlier. Synonym questions require one to pick one word out of a list of words such that it has the closest meaning to a given word. Synonym questions test the ability of identifying all senses of the candidate words and selecting the correct sense that can form a synonymous relation to the given word. Antonym questions require one to pick one word out of a list of words such that it has the opposite meaning to a given word. Antonym questions test the ability of identifying all senses of the candidate words and selecting the correct sense that can form an antonymous relation to the given word. (Turney, 2008; Turney, 2011) studied the analogy, synonym and antonym problem using a supervised classification approach.

Although there are some efforts to solve mathematical, logical, and picture questions in IQ test (Sanghi and Dowe, 2003; Strannegard et al., 2012; Kushmany et al., 2014; Seo et al., 2014; Hosseini et al., 2014; Weston et al., 2015), there have been very few efforts to develop automatic methods to solve verbal questions.

2.2 Deep Learning for Text Mining

Building distributed word representations (Bengio et al., 2003), a.k.a. word embeddings, has attracted increasing attention in the area of machine learning. Different from conventional *one-hot* representations of studies or distributional word representations based on co-occurrence matrix between words such as LSA (Dumais et al., 1988) and LDA (Blei et al., 2003), distributed word representations are usually low-dimensional dense vectors trained with neural networks by maximizing the likelihood of a text corpus. Recently, a series of works applied deep learning techniques to learn high-quality word representations (Collobert and Weston, 2008; Mikolov et al., 2013; Pennington et al., 2014).

Nevertheless, since the above works learn word representations mainly based on the word co-occurrence information, it is quite difficult to obtain high quality embeddings for those words with very little context information; on the other hand, a large amount of noisy or biased context could give rise to ineffective word embeddings. Therefore, it is necessary to introduce extra knowledge into the learning process to regularize the quality of word embedding. Some efforts have paid attention to learn word embedding in order to address knowledge base completion and enhancement (Bordes et al., 2011; Socher et al., 2013; Weston et al., 2013a), and some other efforts have tried to leverage knowledge to enhance word representations (Luong et al., 2013; Weston et al., 2013b; Fried and Duh, 2014; Celikyilmaz et al., 2015). Moreover, all the above models assume that one word has only one embedding no matter whether the word is polysemous or not, which might cause some confusion for the polysemous words. To solve the problem, there are several efforts like (Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014). However, these models do not leverage any extra knowledge (e.g., relational knowledge) to enhance word representations.

3 Solving Verbal Questions

In this section, we introduce our proposed framework to solve the verbal questions, which consists of the following three components.

3.1 Classification of Question Types

The first component of the framework is a question classifier, which identifies different types of verbal questions. Since different types of questions have their unique ways of expression, the classification task is relatively easy, and we therefore take a simple approach to fulfill the task. Specifically, we regard each verbal question as a short document and use the TF·IDF features to build its representation. Then we train an SVM classifier with linear kernel on a portion of labeled question data, and apply it to other

questions. The question labels include Analogy-I, Analogy-II, Classification, Synonym, and Antonym. We use the *one-vs-rest* training strategy to obtain a linear SVM classifier for each question type.

3.2 Embedding of Word-Senses and Relations

The second component of our framework leverages deep learning technologies to learn distributed representations for words (i.e. word embedding). Note that in the context of verbal question answering, we have some specific requirements on this learning process. Verbal questions in IQ tests usually consider the multiple senses of a word (and focus on the rare senses), and the complex relations among (polysemous) words, such as synonym and antonym relation. Figure 1 shows an example of the multi-sense of words and the relations among word senses. We can see that *irrational* has three senses. Its first sense has an antonym relation with the second sense of *rational*, while its second sense has a synonym relation with *nonsensical* and an antonym relation with the first sense of *rational*.

The above challenge has exceeded the capability of standard word embedding technologies. To address this problem, we propose a novel approach that considers the multi-sense nature of words and integrate the relational knowledge among words (or their senses) into the learning process. In particular, our approach consists of two steps. The first step aims at labeling a word in the text corpus with its specific sense, and the second step employs both the labeled text corpus and the relational knowledge contained in dictionaries to simultaneously learn embeddings for both word-sense pairs and relations.

3.2.1 Multi-Sense Identification

First, we learn a single-sense word embedding by using the skip-gram method in *word2vec* (Mikolov et al., 2013).

Second, we gather the context windows of all occurrences of a word used in the skip-gram model, and represent each context by a weighted average of the pre-learned embedding vectors of the context words. We use TF·IDF to define the weighting function, where we regard each context window of the word as a short document to calculate the document frequency. Specifically, for a word w_0, each of its context window can be denoted by $(w_{-N}, \cdots, w_0, \cdots, w_N)$. Then we represent the window by calculating the weighted average of the pre-learned embedding vectors of the context words as $\xi = \frac{1}{2N}\sum_{i=-N, i\neq 0}^{N} g_{w_i} v_{w_i}$,where g_{w_i} is the TF·IDF score of w_i, and v_{w_i} is the pre-learned embedding vector of w_i. After that, for each word, we use spherical k-means to cluster all its context representations, where cluster number k is set as the number of senses of this word in the online dictionary.

Third, we match each cluster to the corresponding sense in the dictionary. On one hand, we represent each cluster by the average embedding vector of all those context windows included in the cluster. For example, suppose word w_0 has k senses and thus it has k clusters of context windows, we denote the average embedding vectors for these clusters as $\bar{\xi}_1, \cdots, \bar{\xi}_k$. On the other hand, since the online dictionary uses some descriptions and example sentences to interpret each word sense, we can represent each word sense by the average embedding of those words including its description words and the words in the corresponding example sentences. Here, we assume the representation vectors (based on the online dictionary) for the k senses of w_0 are $\zeta_1, \cdots, \zeta_k$. After that, we consecutively match each cluster to its closest word sense in terms of the distance computed in the word embedding space:

$$(\bar{\xi}_{i'}, \zeta_{j'}) = \underset{i,j=1,\cdots,k}{\operatorname{argmin}} d(\bar{\xi}_i, \zeta_j), \tag{1}$$

where $d(\cdot,\cdot)$ calculates the Euclidean distance and $(\bar{\xi}_{i'}, \zeta_{j'})$ is the first matched pair of window cluster and word sense. Here, we simply take a greedy strategy. That is, we remove $\bar{\xi}_{i'}$ and $\zeta_{j'}$ from the cluster vector set and the sense vector set, and recursively run (1) to find the next matched pair till all the pairs are found. Finally, each word occurrence in the corpus is relabeled by its associated word sense, which will be used to learn the embeddings for word-sense pairs in the next step.

3.2.2 Co-Learning Word-Sense Pair Representations and Relation Representations

After relabeling the text corpus, different occurrences of a polysemous word may correspond to its different senses, or more accurately word-sense pairs. We then learn the embeddings for word-

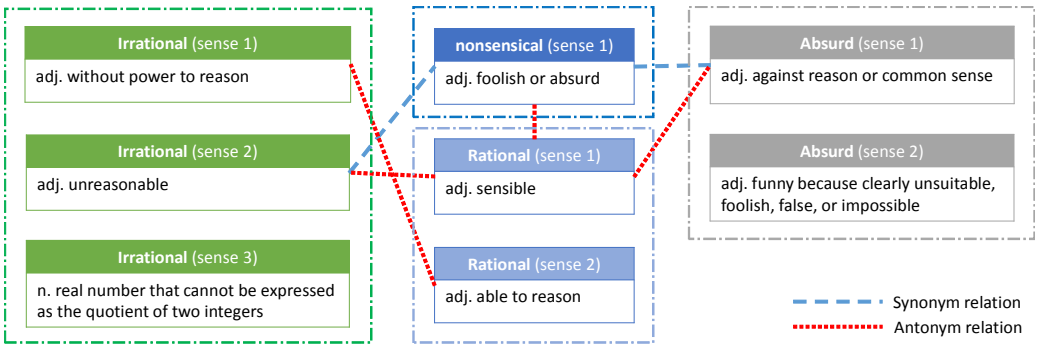

Figure 1: An example on the multi-sense of words and the relations between word senses.

sense pairs and relations (obtained from dictionaries, such as synonym and antonym) simultaneously, by integrating relational knowledge into the objective function of the word embedding learning model like skip-gram. We propose to use a function E_r as described below to capture the relational knowledge.

Specifically, the existing relational knowledge extracted from dictionaries, such as synonym, antonym, etc., can be naturally represented in the form of a triplet (*head*, *relation*, *tail*) (denoted by $(h_i, r, t_j) \in S$, where S is the set of relational knowledge), which consists of two word-sense pairs (i.e. word h with its i-th sense and word t with its j-th sense), $h, t \in W$ (W is the set of words) and a relationship $r \in R$ (R is the set of relationships). To learn the relation representations, we make an assumption that relationships between words can be interpreted as translation operations and they can be represented by vectors. The principle in this model is that if the relationship (h_i, r, t_j) exists, the representation of the word-sense pair t_j should be close to that of h_i plus the representation vector of the relationship r, i.e. $h_i + r$; otherwise, $h_i + r$ should be far away from t_j. Note that this model learns word-sense pair representations and relation representations in a unified continuous embedding space.

According to the above principle, we define E_r as a margin-based regularization function over the set of relational knowledge S,

$$E_r = \sum_{\substack{(h_i,r,t_j)\in S \\ (h^{'},r,t^{'})\in S'_{(h_i,r,t_j)}}} \left[\gamma + d(h_i + r, t_j) - d(h^{'} + r, t^{'})\right]_+ .$$

Here $[X]_+ = \max(X, 0)$, $\gamma > 0$ is a margin hyper-parameter, and $d(\cdot, \cdot)$ is the Euclidean distance between two words in the embedding space.The set of corrupted triplets $S'_{(h,r,t)}$ is defined as $S'_{(h_i,r,t_j)} = \{(h^{'}, r, t)\} \bigcup \{(h, r, t^{'})\}$,which is constructed from S by replacing either the head word-sense pair or the tail word-sense pair by another randomly selected word with its randomly selected sense.

To avoid the trivial solution that simply increases the norms of representation vectors, we use an additional soft norm constraint on the relation representations as $r_i = 2\sigma(x_i) - 1$, where $\sigma(\cdot)$ is the sigmoid function $\sigma(x_i) = 1/(1 + e^{-x_i})$, r_i is the i-th dimension of relation vector r, and x_i is a latent variable, which guarantees that every dimension of the relation representation vector is within the range $(-1, 1)$.

By combining the skip-gram objective function and the regularization function derived from relational knowledge, we get the combined objective $J_r = \alpha E_r - L$ that incorporates relational knowledge into the word-sense pair embedding calculation process, where α is the combination coefficient. Our goal is to minimize J_r, which can be optimized using back propagation neural networks. Figure 2 shows the structure of the proposed model.By using this model, we can obtain the distributed representations for both word-sense pairs and relations simultaneously.

3.3 Solvers for Each Type of Questions

3.3.1 Analogy-I

For the Analogy-I questions like "A is to B as C is to ?", we answer them by optimizing:

$$D = \underset{\substack{i_b,i_a,i_c,i_{d'};\\ D'\in T}}{\operatorname{argmax}} \; cos(v_{(B,i_b)} - v_{(A,i_a)} + v_{(C,i_c)}, v_{(D',i_{d'})}) \tag{2}$$

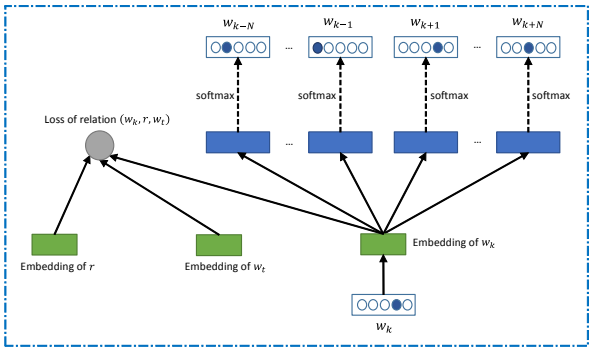

Figure 2: The structure of the proposed model.

where T contains all the candidate answers, cos means cosine similarity, and $i_b, i_a, i_c, i_{d'}$ are the indexes for the word senses of B, A, C, D' respectively. Finally D is selected as the answer.

3.3.2 Analogy-II

As the form of the Analogy-II questions is like "A is to ? as C is to ?" with two lists of candidate answers, we can apply an optimization method as below to select the best (B, D) pair,

$$\underset{\substack{i_{b'}, i_a, i_c, i_{d'}; \\ B' \in T_1, D' \in T_2}}{\operatorname{argmax}} cos(v_{(B', i_{b'})} - v_{(A, i_a)} + v_{(C, i_c)}, v_{(D', i_{d'})}), \tag{3}$$

where T_1, T_2 are two lists of candidate words. Thus we get the answers B and D that can form an analogical relation between word pair (A, B) and word pair (C, D) under a certain specific word sense combination.

3.3.3 Classification

For the Classification questions, we leverage the property that words with similar co-occurrence information are distributed close to each other in the embedding space. The candidate word that is not similar to others does not have similar co-occurrence information to other words in the training corpus, and thus this word should be far away from other words in the word embedding space. Therefore we first calculate a group of mean vectors $m_{i_{w_1}, \cdots, i_{w_N}}$ of all the candidate words with any possible word senses as below $m_{i_{w_1}, \cdots, i_{w_N}} = \frac{1}{N} \sum_{w_j \in T} v_{(w_j, i_{w_j})}$, where T is the set of candidate words, N is the capacity of T, w_j is a word in T; $i_{w_j} (j = 1, \cdots, N; i_{w_j} = 1, \cdots, k_{w_j})$ is the index for the word senses of w_j, and $k_{w_j} (j = 1, \cdots, N)$ is the number of word senses of w_j. Therefore, the number of the mean vectors is $M = \prod_{j=1}^{N} k_{w_j}$. As both N and k_{w_j} are very small, the computation cost is acceptable. Then, we choose the word with such a sense that its closest sense to the corresponding mean vector is the largest among the candidate words as the answer, i.e.,

$$w = \underset{w_j \in T}{\operatorname{argmax}} \min_{i_{w_j}; l=1, \cdots, M} d(v_{(w_j, i_{w_j})}, m_l). \tag{4}$$

3.3.4 Synonym

For the Synonym questions, we empirically explored two solvers. For the first solver, we also leverage the property that words with similar co-occurrence information are located closely in the word embedding space. Therefore, given the question word w_q and the candidate words w_i, we can find the answer by solving:

$$w = \underset{i_{w_q}, i_{w_j}; w_j \in T}{\operatorname{argmin}} d(v_{(w_j, i_{w_j})}, v_{(w_q, i_{w_q})}), \tag{5}$$

where T is the set of candidate words. The second solver is based on the minimization objective of the translation distance between entities in the relational knowledge model (2). Specifically, we calculate the offset vector between the embedding of question word w_q and each word w_j in the candidate list. Then, we set the answer w as the candidate word with which the offset is the closest to the representation vector of the synonym relation r_s, i.e.,

$$w = \underset{i_{w_q}, i_{w_j}; w_j \in T}{\operatorname{argmin}} \big| |v_{(w_j, i_{w_j})} - v_{(w_q, i_{w_q})}| - r_s \big|. \tag{6}$$

In practice, we found the second solver performs better (the results are listed in Section 4). For our baseline embedding model skip-gram, since it does not assume the relation representations explicitly, we use the first solver for it.

3.3.5 Antonym

Similar to solving the Synonym questions, we explored two solvers for Antonym questions as well. That is, the first solver (7) is based on the small offset distance between semantically close words whereas the second solver (8) leverages the translation distance between two words' offset and the embedding vector of the antonym relation. The first solver is based on the fact that since an antonym and

its original word have similar co-occurrence information from which the embedding vectors are derived, the embedding vectors of both words with antonym relation will still lie closely in the embedding space.

$$w = \underset{i_{w_q}, i_{w_j}; w_j \in T}{\operatorname{argmin}} d(v_{(w_j, i_{w_j})}, v_{(w_q, i_{w_q})}), \quad (7)$$

$$w = \underset{i_{w_q}, i_{w_j}; w_j \in T}{\operatorname{argmin}} \big| |v_{(w_j, i_{w_j})} - v_{(w_q, i_{w_q})}| - r_a \big|, \quad (8)$$

Here T is the set of candidate words and r_a is the representation vector of the antonym relation. Again we found that the second solver performs better. Similarly, for skip-gram, the first solver is applied.

4 Experiments

We conduct experiments to examine whether our proposed framework can achieve satisfying results on verbal comprehension questions.

4.1 Data Collection

4.1.1 Training Set for Word Embedding

We trained word embeddings on a publicly available text corpus named *wiki2014*[2], which is a large text snapshot from Wikipedia. After being preprocessed by removing all the *html* meta-data and replacing the digit numbers by English words, the final training corpus contains more than 3.4 billion word tokens, and the number of unique words, i.e. the vocabulary size, is about 2 million.

4.1.2 IQ Test Set

According to our study, there is no online dataset specifically released for verbal comprehension questions, although there are many online IQ tests for users to play with. In addition, most of the online tests only calculate the final IQ scores but do not provide the correct answers. Therefore, we only use the online questions to train the verbal question classifier described in Section 3.1. Specifically, we manually collected and labeled 30 verbal questions from the online IQ test Websites[3] for each of the five types (i.e. Analogy-I, Analogy-II, Classification, Synonym, and Antonym) and trained an *one-vs-rest* SVM classifier for each type. The total accuracy on the training set itself is 95.0%. The classifier was then applied in the test set below.

We collected a set of verbal comprehension questions associated with correct answers from published IQ test books, such as (Carter, 2005; Carter, 2007; Pape, 1993; Ken Russell, 2002), and we used this collection as the test set to evaluate the effectiveness of our new framework. In total, this test set contains 232 questions with the corresponding answers.[4] The number of each question type (i.e., Analogy-I, Analogy-II, Classification, Synonym, Antonym) are respectively $50, 29, 53, 51, 49$.

4.2 Compared Methods

In our experiments, we compare our new relation knowledge powered model to several baselines.

Random Guess Model (RG). Random guess is the most straightforward way for an agent to solve questions. In our experiments, we used a random guess agent which would select an answer randomly regardless of what the question was. To measure the performance of random guess, we ran each task for 5 times and calculated the average accuracy.

Human Performance (HP). Since IQ tests are designed to evaluate human intelligence, it is quite natural to leverage human performance as a baseline. To collect human answers on the test questions, we delivered them to human beings through Amazon Mechanical Turk (AMT), a crowd-sourcing Internet marketplace that allows people to participate in Human Intelligence Tasks. In our study, we published five AMT jobs, one job corresponding to one specific question type. The jobs were delivered to 200 people. To control the quality of the collected results, we used several strategies: (i) we imposed high restrictions on the workers by requiring all the workers to be native English speakers in North America and to be AMT Masters (who have demonstrated high accuracy on previous tasks on AMT marketplace); (ii) we recruited a large number of workers in order to guarantee the statistical confidence in their performances; (iii) we tracked their age distribution and education background, which

[2] http://en.wikipedia.org/wiki/Wikipedia:Database_download

[3] http://wechsleradultintelligencescale.com/

[4] It can be downloaded from https://www.dropbox.com/s/o0very1gwv3mrt5/VerbalQuestions.zip?dl=0.

are very similar to those of the overall population in the U.S.

Latent Dirichlet Allocation Model (LDA). This baseline model leveraged one of the most common classical distributional word representations, i.e. Latent Dirichlet Allocation (LDA) (Blei et al., 2003). In particular, we trained word representations using LDA on *wiki2014* with the topic number 1000.

Skip-Gram Model (SG). In this baseline, we applied the word embedding trained by skip-gram (Mikolov et al., 2013) (denoted by **SG-1**) on *wiki2014*. In particular, we set the window size as 5, the embedding dimension as 500, the negative sampling count as 3, and the epoch number as 3. In addition, we also employed a pre-trained word embedding by Google[5] with the dimension of 300 (denoted by **SG-2**).

Glove. Another powerful word embedding model (Pennington et al., 2014). **Glove** configurations are the same as those in running **SG-1**.

Multi-Sense Model (MS). In this baseline, we applied the multi-sense word embedding models proposed in (Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014) (denoted by **MS-1**, **MS-2** and **MS-3** respectively). For **MS-1**, we directly used the published multi-sense word embedding vectors by the authors[6], in which they set 10 senses for the top 5% most frequent words. For **MS-2** and **MS-3**, we get the embedding vectors by usingf the released codes from the authors using the same configurations as **MS-1**.

Relation Knowledge Powered Model (RK). This is our proposed method in Section 3. In particular, when learning the embedding on *wiki2014*, we set the window size as 5, the embedding dimension as 500, the negative sampling count as 3, and the epoch number as 3. We adopted the online Longman Dictionary as the dictionary used in multi-sense clustering. We used a public relation knowledge set, WordRep (Gao et al., 2014), for relation training.

4.3 Experimental Results

4.3.1 Accuracy of Question Classifier

We applied the question classifier trained in Section 4.1.2 on the test set, and got the total accuracy 93.1%. For RG and HP, the question classifier was not needed. For other methods, the wrongly classified questions were also sent to the corresponding wrong solver to find an answer. If the solver returned an empty result (which was usually caused by invalid input format, e.g., an Analogy-II question was wrongly input to the Classification solver), we would randomly select an answer.

4.3.2 Overall Accuracy

Table 2 demonstrates the accuracy of answering verbal questions by using all the approaches mentioned in Section 4.2. The numbers for all the models are mean values from five repeated runs. From this table, we observe: (i) RK can achieve the best overall accuracy than all the other methods. In particular, RK can raise the overall accuracy by about 4.63% over HP[7]. (ii) RK is empirically superior to the skip-gram models SG-1/SG-2 and Glove. According to our understanding, the improvement of RK over SG-1/SG-2/Glove comes from two aspects: multi-sense and relational knowledge. Note that the performance difference between MS-1/MS-2/MS-3 and SG-1/SG-2/Glove is not significant, showing that simply changing single-sense word embedding to multi-sense word embedding does not bring too much benefit. One reason is that the rare word-senses do not have enough training data (contextual information) to produce high-quality word embedding. By further introducing the relational knowledge among word-senses, the training for rare word-senses will be linked to the training of their related word-senses. As a result, the embedding quality of the rare word-senses will be improved. (iii) RK is empirically superior than the two multi-sense algorithms MS-1, MS-2 and MS-3, demonstrating the effectiveness brought by adopting fewer model parameters and using an online dictionary in building the multi-sense embedding model.

These results are quite impressive, indicating the potential of using machines to comprehend human knowledge and even achieve a comparable level of human intelligence.

4.3.3 Accuracy on Different Question Types

Table 2 reports the accuracy of answering various types of verbal questions by each method. From the

[5] https://code.google.com/p/word2vec/

Table 2: Accuracy of different methods among different human groups.

table, we can observe that the SG and MS models can achieve competitive accuracy on certain question types (like Synonym) compared with HP. After incorporating knowledge into learning word embedding, our RK model can improve the accuracy over all question types. Moreover, the table shows that RK can result in a big improvement over HP on the question types of Synonym and Classification.

To sum up, the experimental results have demonstrated the effectiveness of the proposed RK model compared with several baseline methods. Although the test set is not large, the generalization of RK to other test sets should not be a concern due to the unsupervised nature of our model.

5 Conclusions

We investigated how to automatically solve verbal comprehension questions in IQ Tests by using word embedding techniques. In particular, we proposed a three-step framework: (i) to recognize the specific type of a verbal comprehension question by a classifier, (ii) to leverage a novel deep learning model to co-learn the representations of both word-sense pairs and relations among words (or their senses), (iii) to design dedicated solvers, based on the obtained word-sense pair representations and relation representations, for addressing each type of questions. Experimental results have demonstrated that this novel framework can achieve better performance than existing methods for solving verbal comprehension questions and even exceed the average performance of the Amazon Mechanical Turk workers involved in the experiments.

Abstract

In this paper we address the question of how to render sequence-level networks better at handling structured input. We propose a machine reading simulator which processes text incrementally from left to right and performs shallow reasoning with memory and attention. The reader extends the Long Short-Term Memory architecture with a memory network in place of a single memory cell. This enables adaptive memory usage during recurrence with neural attention, offering a way to weakly induce relations among tokens. The system is initially designed to process a single sequence but we also demonstrate how to integrate it with an encoder-decoder architecture. Experiments on language modeling, sentiment analysis, and natural language inference show that our model matches or outperforms the state of the art.

1 Introduction

How can a sequence-level network induce relations which are presumed latent during text processing? How can a recurrent network attentively memorize longer sequences in a way that humans do? In this paper we design a machine reader that automatically learns to understand text. The term machine reading is related to a wide range of tasks from answering reading comprehension questions (Clark et al., 2013), to fact and relation extraction (Etzioni et al., 2011; Fader et al., 2011), ontology learning (Poon and Domingos, 2010), and textual entailment (Dagan et al., 2005). Rather than focusing on a specific task, we develop a general-purpose reading simulator, drawing inspiration from human language processing and the fact language comprehension is incremental with readers continuously extracting the meaning of utterances on a word-by-word basis.

In order to understand texts, our machine reader should provide facilities for extracting and representing meaning from natural language text, storing meanings internally, and working with stored meanings to derive further consequences. Ideally, such a system should be robust, open-domain, and degrade gracefully in the presence of semantic representations which may be incomplete, inaccurate, or incomprehensible. It would also be desirable to simulate the behavior of English speakers who process text sequentially, from left to right, fixating nearly every word while they read (Rayner, 1998) and creating partial representations for sentence prefixes (Konieczny, 2000; Tanenhaus et al., 1995).

Language modeling tools such as recurrent neural networks (RNN) bode well with human reading behavior (Frank and Bod, 2011). RNNs treat each sentence as a sequence of words and recursively compose each word with its previous *memory*, until the meaning of the whole sentence has been derived. In practice, however, sequence-level networks are met with at least three challenges. The first one concerns model training problems associated with vanishing and exploding gradients (Hochreiter, 1991; Bengio et al., 1994), which can be partially ameliorated with gated activation functions, such as the Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), and gradient clipping (Pascanu et al., 2013). The second issue relates to memory compression problems. As the input sequence gets compressed and blended into a single dense vector, suf-

Austin, Texas, November 1-5, 2016.

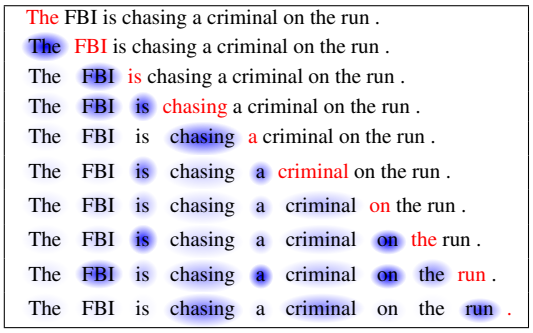

Figure 1: Illustration of our model while reading the sentence *The FBI is chasing a criminal on the run.* Color *red* represents the current word being fixated, *blue* represents memories. Shading indicates the degree of memory activation.

ficiently large memory capacity is required to store past information. As a result, the network generalizes poorly to long sequences while wasting memory on shorter ones. Finally, it should be acknowledged that sequence-level networks lack a mechanism for handling the structure of the input. This imposes an inductive bias which is at odds with the fact that language has inherent structure. In this paper, we develop a text processing system which addresses these limitations while maintaining the incremental, generative property of a recurrent language model.

Recent attempts to render neural networks more structure aware have seen the incorporation of external memories in the context of recurrent neural networks (Weston et al., 2015; Sukhbaatar et al., 2015; Grefenstette et al., 2015). The idea is to use multiple memory slots outside the recurrence to piece-wise store representations of the input; read and write operations for each slot can be modeled as an attention mechanism with a recurrent controller. We also leverage memory and attention to empower a recurrent network with stronger memorization capability and more importantly the ability to discover relations among tokens. This is realized by inserting a memory network module in the update of a recurrent network together with attention for memory addressing. The attention acts as a weak inductive module discovering relations between input tokens, and is trained without direct supervision. As a point of departure from previous work, the memory network we employ is internal to the recurrence, thus strengthening the interaction of the two and leading to a representation learner which is able to reason over shallow structures. The resulting model, which we term Long Short-Term Memory-Network (LSTMN), is a reading simulator that can be used for sequence processing tasks.

Figure 1 illustrates the reading behavior of the LSTMN. The model processes text incrementally while learning which past tokens in the memory and to what extent they relate to the current token being processed. As a result, the model induces undirected relations among tokens as an intermediate step of learning representations. We validate the performance of the LSTMN in language modeling, sentiment analysis, and natural language inference. In all cases, we train LSTMN models end-to-end with task-specific supervision signals, achieving performance comparable or better to state-of-the-art models and superior to vanilla LSTMs.

2 Related Work

Our machine reader is a recurrent neural network exhibiting two important properties: it is incremental, simulating human behavior, and performs shallow structure reasoning over input streams.

Recurrent neural network (RNNs) have been successfully applied to various sequence modeling and sequence-to-sequence transduction tasks. The latter have assumed several guises in the literature such as machine translation (Bahdanau et al., 2014), sentence compression (Rush et al., 2015), and reading comprehension (Hermann et al., 2015). A key contributing factor to their success has been the ability to handle well-known problems with exploding or vanishing gradients (Bengio et al., 1994), leading to models with gated activation functions (Hochreiter and Schmidhuber, 1997; Cho et al., 2014), and more advanced architectures that enhance the information flow within the network (Koutník et al., 2014; Chung et al., 2015; Yao et al., 2015).

A remaining practical bottleneck for RNNs is memory compression (Bahdanau et al., 2014): since the inputs are recursively combined into a single memory representation which is typically too small in terms of parameters, it becomes difficult to accurately memorize sequences (Zaremba and Sutskever, 2014). In the encoder-decoder architecture, this problem can be sidestepped with an attention mechanism which learns soft alignments *between* the decoding states and the encoded memories (Bahdanau

et al., 2014). In our model, memory and attention are added *within* a sequence encoder allowing the network to uncover lexical relations between tokens.

The idea of introducing a structural bias to neural models is by no means new. For example, it is reflected in the work of Socher et al. (2013a) who apply recursive neural networks for learning natural language representations. In the context of recurrent neural networks, efforts to build modular, structured neural models date back to Das et al. (1992) who connect a recurrent neural network with an external memory stack for learning context free grammars. Recently, Weston et al. (2015) propose Memory Networks to explicitly segregate memory storage from the computation of neural networks in general. Their model is trained end-to-end with a memory addressing mechanism closely related to soft attention (Sukhbaatar et al., 2015) and has been applied to machine translation (Meng et al., 2015). Grefenstette et al. (2015) define a set of differentiable data structures (stacks, queues, and dequeues) as memories controlled by a recurrent neural network. Tran et al. (2016) combine the LSTM with an external memory block component which interacts with its hidden state. Kumar et al. (2016) employ a structured neural network with episodic memory modules for natural language and also visual question answering (Xiong et al., 2016).

Similar to the above work, we leverage memory and attention in a recurrent neural network for inducing relations between tokens as a module in a larger network responsible for representation learning. As a property of soft attention, all intermediate relations we aim to capture are soft and differentiable. This is in contrast to shift-reduce type neural models (Dyer et al., 2015; Bowman et al., 2016) where the intermediate decisions are hard and induction is more difficult. Finally, note that our model captures undirected lexical relations and is thus distinct from work on dependency grammar induction (Klein and Manning, 2004) where the learned head-modifier relations are directed.

3 The Machine Reader

In this section we present our machine reader which is designed to process structured input while retaining the incrementality of a recurrent neural network. The core of our model is a Long Short-Term Memory (LSTM) unit with an extended memory tape that explicitly simulates the human memory span. The model performs implicit relation analysis between tokens with an attention-based memory addressing mechanism at every time step. In the following, we first review the standard Long Short-Term Memory and then describe our model.

3.1 Long Short-Term Memory

A Long Short-Term Memory (LSTM) recurrent neural network processes a variable-length sequence $x = (x_1, x_2, \cdots, x_n)$ by incrementally adding new content into a single memory slot, with gates controlling the extent to which new content should be memorized, old content should be erased, and current content should be exposed. At time step t, the memory c_t and the hidden state h_t are updated with the following equations:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ \hat{c}_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot [h_{t-1}, x_t] \tag{1}$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \hat{c}_t \tag{2}$$

$$h_t = o_t \odot \tanh(c_t) \tag{3}$$

where i, f, and o are gate activations. Compared to the standard RNN, the LSTM uses additive memory updates and it separates the memory c from the hidden state h, which interacts with the environment when making predictions.

3.2 Long Short-Term Memory-Network

The first question that arises with LSTMs is the extent to which they are able to memorize sequences under recursive compression. LSTMs can produce a list of state representations during composition, however, the next state is always computed from the current state. That is to say, given the current state h_t, the next state h_{t+1} is conditionally independent of states $h_1 \cdots h_{t-1}$ and tokens $x_1 \cdots x_t$. While the recursive state update is performed in a Markov manner, it is assumed that LSTMs maintain unbounded memory (i.e., the current state alone summarizes well the tokens it has seen so far). This assumption may fail in practice, for example when the sequence is long

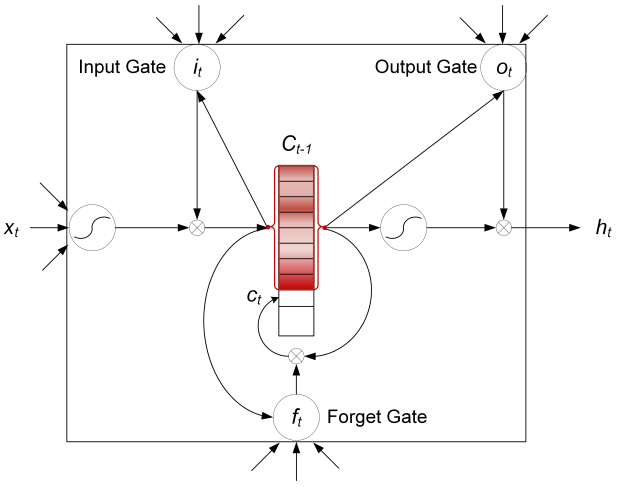

Figure 2: Long Short-Term Memory-Network. Color indicates degree of memory activation.

or when the memory size is not large enough. Another undesired property of LSTMs concerns modeling structured input. An LSTM aggregates information on a token-by-token basis in sequential order, but there is no explicit mechanism for reasoning over structure and modeling relations between tokens.

Our model aims to address both limitations. Our solution is to modify the standard LSTM structure by replacing the memory cell with a memory network (Weston et al., 2015). The resulting Long Short-Term Memory-Network (LSTMN) stores the contextual representation of each input token with a unique memory slot and the size of the memory grows with time until an upper bound of the memory span is reached. This design enables the LSTM to reason about relations between tokens with a neural attention layer and then perform non-Markov state updates. Although it is feasible to apply both write and read operations to the memories with attention, we concentrate on the latter. We conceptualize the *read* operation as attentively linking the current token to previous memories and selecting useful content when processing it. Although not the focus of this work, the significance of the *write* operation can be analogously justified as a way of incrementally updating previous memories, e.g., to correct wrong interpretations when processing garden path sentences (Ferreira and Henderson, 1991).

The architecture of the LSTMN is shown in Figure 2 and the formal definition is provided as follows. The model maintains two sets of vectors stored in a hidden state tape used to interact with the environment (e.g., computing attention), and a memory tape used to represent what is actually stored in memory.[1] Therefore, each token is associated with a hidden vector and a memory vector. Let x_t denote the current input; $C_{t-1} = (c_1, \cdots, c_{t-1})$ denotes the current memory tape, and $H_{t-1} = (h_1, \cdots, h_{t-1})$ the previous hidden tape. At time step t, the model computes the relation between x_t and $x_1 \cdots x_{t-1}$ through $h_1 \cdots h_{t-1}$ with an attention layer:

$$a_i^t = v^{\mathrm{T}} \tanh(W_h h_i + W_x x_t + W_{\tilde{h}} \tilde{h}_{t-1}) \quad (4)$$

$$s_i^t = \mathrm{softmax}(a_i^t) \quad (5)$$

This yields a probability distribution over the hidden state vectors of previous tokens. We can then compute an adaptive summary vector for the previous hidden tape and memory tape denoted by $\tilde{c}_t$ and $\tilde{h}_t$, respectively:

$$\begin{bmatrix} \tilde{h}_t \\ \tilde{c}_t \end{bmatrix} = \sum_{i=1}^{t-1} s_i^t \cdot \begin{bmatrix} h_i \\ c_i \end{bmatrix} \quad (6)$$

and use them for computing the values of c_t and h_t in the recurrent update as:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ \hat{c}_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot [\tilde{h}_t, x_t] \quad (7)$$

$$c_t = f_t \odot \tilde{c}_t + i_t \odot \hat{c}_t \quad (8)$$

$$h_t = o_t \odot \tanh(c_t) \quad (9)$$

where v, W_h, W_x and $W_{\tilde{h}}$ are the new weight terms of the network.

A key idea behind the LSTMN is to use attention for inducing relations between tokens. These relations are soft and differentiable, and components of a larger representation learning network. Although it is appealing to provide direct supervision for the attention layer, e.g., with evidence collected from a dependency treebank, we treat it as a submodule being optimized within the larger network in a downstream task. It is also possible to have a more structured relational reasoning module by stacking multiple memory and hidden layers in an alternating fashion, resembling a stacked LSTM (Graves,

[1] For comparison, LSTMs maintain a hidden vector and a memory vector; memory networks (Weston et al., 2015) have a set of key vectors and a set of value vectors.

2013) or a multi-hop memory network (Sukhbaatar et al., 2015). This can be achieved by feeding the output h_t^k of the lower layer k as input to the upper layer $(k+1)$. The attention at the $(k+1)$th layer is computed as:

$$a_{i,k+1}^t = v^{\mathrm{T}} \tanh(W_h h_i^{k+1} + W_l h_t^k + W_{\tilde{h}} \tilde{h}_{t-1}^{k+1}) \quad (10)$$

Skip-connections (Graves, 2013) can be applied to feed x_t to upper layers as well.

4 Modeling Two Sequences with LSTMN

Natural language processing tasks such as machine translation and textual entailment are concerned with modeling two sequences rather than a single one. A standard tool for modeling two sequences with recurrent networks is the encoder-decoder architecture where the second sequence (also known as the *target*) is being processed conditioned on the first one (also known as the *source*). In this section we explain how to combine the LSTMN which applies attention for intra-relation reasoning, with the encoder-decoder network whose attention module learns the inter-alignment between two sequences. Figures 3a and 3b illustrate two types of combination. We describe the models more formally below.

Shallow Attention Fusion Shallow fusion simply treats the LSTMN as a separate module that can be readily used in an encoder-decoder architecture, in lieu of a standard RNN or LSTM. As shown in Figure 3a, both encoder and decoder are modeled as LSTMNs with intra-attention. Meanwhile, inter-attention is triggered when the decoder reads a target token, similar to the inter-attention introduced in Bahdanau et al. (2014).

Deep Attention Fusion Deep fusion combines inter- and intra-attention (initiated by the decoder) when computing state updates. We use different notation to represent the two sets of attention. Following Section 3.2, C and H denote the target memory tape and hidden tape, which store representations of the target symbols that have been processed so far. The computation of intra-attention follows Equations (4)–(9). Additionally, we use $A = [\alpha_1, \cdots, \alpha_m]$ and $Y = [\gamma_1, \cdots, \gamma_m]$ to represent the source memory tape and hidden tape, with m being the length of the source sequence conditioned upon. We compute inter-attention between the input at time step t and tokens in the entire source sequence as follows:

$$b_j^t = u^{\mathrm{T}} \tanh(W_\gamma \gamma_j + W_x x_t + W_{\tilde{\gamma}} \tilde{\gamma}_{t-1}) \quad (11)$$

$$p_j^t = \mathrm{softmax}(b_j^t) \quad (12)$$

After that we compute the adaptive representation of the source memory tape $\tilde{\alpha}_t$ and hidden tape $\tilde{\gamma}_t$ as:

$$\begin{bmatrix} \tilde{\gamma}_t \\ \tilde{\alpha}_t \end{bmatrix} = \sum_{j=1}^{m} p_j^t \cdot \begin{bmatrix} \gamma_j \\ \alpha_j \end{bmatrix} \quad (13)$$

We can then transfer the adaptive source representation $\tilde{\alpha}_t$ to the target memory with another gating operation r_t, analogous to the gates in Equation (7).

$$r_t = \sigma(W_r \cdot [\tilde{\gamma}_t, x_t]) \quad (14)$$

The new target memory includes inter-alignment $r_t \odot \tilde{\alpha}_t$, intra-relation $f_t \odot \tilde{c}_t$, and the new input information $i_t \odot \hat{c}_t$:

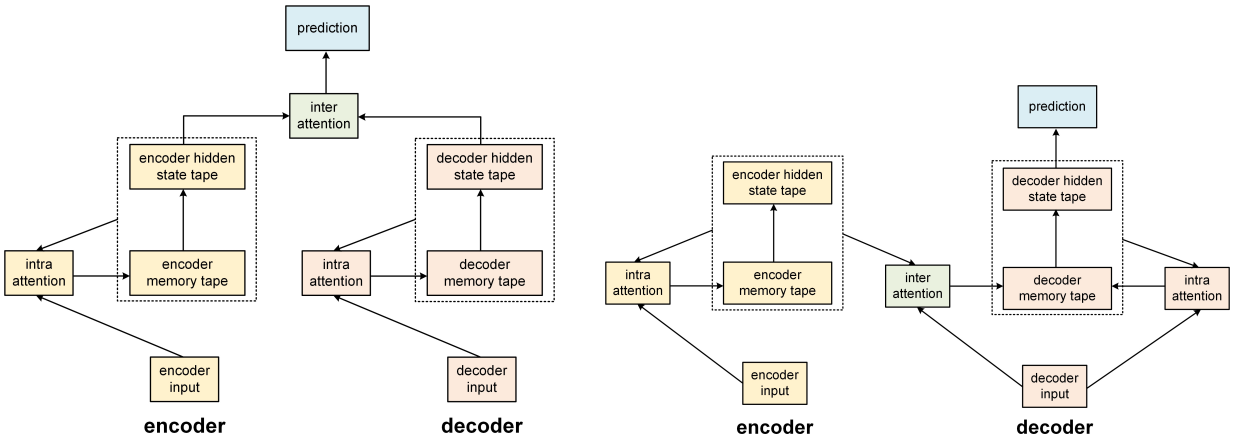
$$c_t = r_t \odot \tilde{\alpha}_t + f_t \odot \tilde{c}_t + i_t \odot \hat{c}_t \quad (15)$$

$$h_t = o_t \odot \tanh(c_t) \quad (16)$$

As shown in the equations above and Figure 3b, the major change of deep fusion lies in the recurrent storage of the inter-alignment vector in the target memory network, as a way to help the target network review source information.

5 Experiments

In this section we present our experiments for evaluating the performance of the LSTMN machine reader. We start with language modeling as it is a natural testbed for our model. We then assess the model's ability to extract meaning representations for generic sentence classification tasks such as sentiment analysis. Finally, we examine whether the LSTMN can recognize the semantic relationship between two sentences by applying it to a natural language inference task. Our code is available at `https://github.com/cheng6076/SNLI-attention`.



(a) Decoder with shallow attention fusion.

(b) Decoder with deep attention fusion.

Figure 3: LSTMNs for sequence-to-sequence modeling. The encoder uses intra-attention, while the decoder incorporates both intra- and inter-attention. The two figures present two ways to combine the intra- and inter-attention in the decoder.

dLSTM	3	109
LSTMN	3	**102**

Table 1: Language model perplexity on the Penn Treebank. The size of memory is 300 for all models.

5.1 Language Modeling

Our language modeling experiments were conducted on the English Penn Treebank dataset. Following common practice (Mikolov et al., 2010), we trained on sections 0–20 (1M words), used sections 21–22 for validation (80K words), and sections 23–24 (90K words for testing). The dataset contains approximately 1 million tokens and a vocabulary size of 10K. The average sentence length is 21. We use perplexity as our evaluation metric: $PPL = \exp(NLL/T)$, where NLL denotes the negative log likelihood of the entire test set and T the corresponding number of tokens. We used stochastic gradient descent for optimization with an initial learning rate of 0.65, which decays by a factor of 0.85 per epoch if no significant improvement has been observed on the validation set. We renormalize the gradient if its norm is greater than 5. The mini-batch size was set to 40. The dimensions of the word embeddings were set to 150 for all models.

In this suite of experiments we compared the LSTMN against a variety of baselines. The first one is a Kneser-Ney 5-gram language model (KN5) which generally serves as a non-neural baseline for the language modeling task. We also present perplexity results for the standard RNN and LSTM models. We also implemented more sophisticated LSTM architectures, such as a stacked LSTM (sLSTM), a gated-feedback LSTM (gLSTM; Chung et al. (2015)) and a depth-gated LSTM (dLSTM; Yao et al. (2015)). The gated-feedback LSTM has feedback gates connecting the hidden states across multiple time steps as an adaptive control of the information flow. The depth-gated LSTM uses a depth gate to connect memory cells of vertically adjacent layers. In general, both gLSTM and dLSTM are able to capture long-term dependencies to some degree, but they do not explicitly keep past memories. We set the number of layers to 3 in this experiment, mainly to agree with the language modeling experiments of Chung et al. (2015). Also note that that there are no single-layer variants for gLSTM and dLSTM; they have to be implemented as multi-layer systems. The hidden unit size of the LSTMN and all comparison models (except KN5) was set to 300.

The results of the language modeling task are shown in Table 1. Perplexity results for KN5 and RNN are taken from Mikolov et al. (2015). As can be seen, the single-layer LSTMN outperforms these

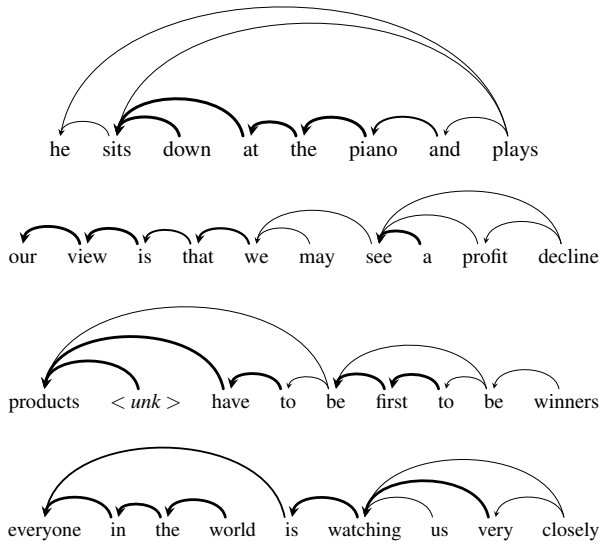

Figure 4: Examples of intra-attention (language modeling). Bold lines indicate higher attention scores. Arrows denote which word is being focused when attention is computed, but not the direction of the relation.

two baselines and the LSTM by a significant margin. Amongst all deep architectures, the three-layer LSTMN also performs best. We can study the memory activation mechanism of the machine reader by visualizing the attention scores. Figure 4 shows four sentences sampled from the Penn Treebank validation set. Although we explicitly encourage the reader to attend to any memory slot, much attention focuses on recent memories. This agrees with the linguistic intuition that long-term dependencies are relatively rare. As illustrated in Figure 4 the model captures some valid lexical relations (e.g., the dependency between *sits* and *at*, *sits* and *plays*, *everyone* and *is*, *is* and *watching*). Note that arcs here are undirected and are different from the directed arcs denoting head-modifier relations in dependency graphs.

5.2 Sentiment Analysis

Our second task concerns the prediction of sentiment labels of sentences. We used the Stanford Sentiment Treebank (Socher et al., 2013a), which contains fine-grained sentiment labels (very positive, positive, neutral, negative, very negative) for 11,855 sentences. Following previous work on this dataset, we used 8,544 sentences for training, 1,101 for validation, and 2,210 for testing. The average sentence length is 19.1. In addition, we also performed a binary classification task (positive, negative) after removing the neutral label. This resulted in 6,920 sentences for training, 872 for validation and 1,821 for testing. Table 2 reports results on both fine-grained and binary classification tasks.

Models	Fine-grained	Binary
RAE (Socher et al., 2011)	43.2	82.4
RNTN (Socher et al., 2013b)	45.7	85.4
DRNN (Irsoy and Cardie, 2014)	49.8	86.6
DCNN (Blunsom et al., 2014)	48.5	86.8
CNN-MC (Kim, 2014)	48.0	88.1
T-CNN (Lei et al., 2015)	**51.2**	**88.6**
PV (Le and Mikolov, 2014)	48.7	87.8
CT-LSTM (Tai et al., 2015)	51.0	88.0
LSTM (Tai et al., 2015)	46.4	84.9
2-layer LSTM (Tai et al., 2015)	46.0	86.3
LSTMN	**47.6**	**86.3**
2-layer LSTMN	**47.9**	**87.0**

Table 2: Model accuracy (%) on the Sentiment Treebank (test set). The memory size of LSTMN models is set to 168 to be compatible with previously published LSTM variants (Tai et al., 2015).

We experimented with 1- and 2-layer LSTMNs. For the latter model, we predict the sentiment label of the sentence based on the averaged hidden vector passed to a 2-layer neural network classifier with ReLU as the activation function. The memory size for both LSTMN models was set to 168 to be compatible with previous LSTM models (Tai et al., 2015) applied to the same task. We used pretrained `300-D Glove 840B` vectors (Pennington et al., 2014) to initialize the word embeddings. The gradient for words with `Glove` embeddings, was scaled by 0.35 in the first epoch after which all word embeddings were updated normally.

We used Adam (Kingma and Ba, 2015) for optimization with the two momentum parameters set to 0.9 and 0.999 respectively. The initial learning rate was set to 2E-3. The regularization constant was 1E-4 and the mini-batch size was 5. A dropout rate of 0.5 was applied to the neural network classifier.

We compared our model with a wide range of top-performing systems. Most of these models (including ours) are LSTM variants (third block in Table 2), recursive neural networks (first block), or convolu-

tional neural networks (CNNs; second block). Recursive models assume the input sentences are represented as parse trees and can take advantage of annotations at the phrase level. LSTM-type models and CNNs are trained on sequential input, with the exception of CT-LSTM (Tai et al., 2015) which operates over tree-structured network topologies such as constituent trees. For comparison, we also report the performance of the paragraph vector model (PV; Le and Mikolov (2014); see Table 2, second block) which neither operates on trees nor sequences but learns distributed document representations parameterized directly.

The results in Table 2 show that both 1- and 2-layer LSTMNs outperform the LSTM baselines while achieving numbers comparable to state of the art. The number of layers for our models was set to be comparable to previously published results. On the fine-grained and binary classification tasks our 2-layer LSTMN performs close to the best system T-CNN (Lei et al., 2015). Figure 5 shows examples of intra-attention for sentiment words. Interestingly, the network learns to associate sentiment important words such as *though* and *fantastic* or *not* and *good*.

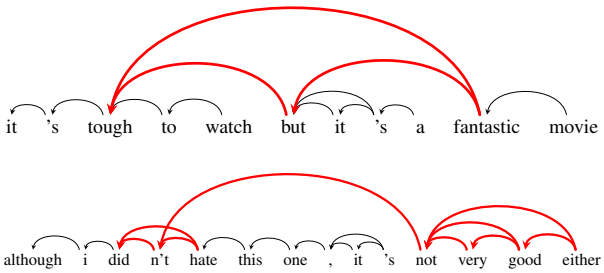

Figure 5: Examples of intra-attention (sentiment analysis). Bold lines (red) indicate attention between sentiment important words.

5.3 Natural Language Inference

The ability to reason about the semantic relationship between two sentences is an integral part of text understanding. We therefore evaluate our model on recognizing textual entailment, i.e., whether two premise-hypothesis pairs are entailing, contradictory, or neutral. For this task we used the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015), which contains premise-hypothesis pairs and target labels indicating their relation. After removing sentences with unknown labels, we end up with 549,367 pairs for training, 9,842 for development and 9,824 for testing. The vocabulary size is 36,809 and the average sentence length is 22. We performed lower-casing and tokenization for the entire dataset.

Recent approaches use two sequential LSTMs to encode the premise and the hypothesis respectively, and apply neural attention to reason about their logical relationship (Rocktäschel et al., 2016; Wang and Jiang, 2016). Furthermore, Rocktäschel et al. (2016) show that a non-standard encoder-decoder architecture which processes the hypothesis conditioned on the premise results significantly boosts performance. We use a similar approach to tackle this task with LSTMNs. Specifically, we use two LSTMNs to read the premise and hypothesis, and then match them by comparing their hidden state tapes. We perform average pooling for the hidden state tape of each LSTMN, and concatenate the two averages to form the input to a 2-layer neural network classifier with ReLU as the activation function.

We used pre-trained `300-D Glove 840B` vectors (Pennington et al., 2014) to initialize the word embeddings. Out-of-vocabulary (OOV) words were initialized randomly with Gaussian samples (μ=0, σ=1). We only updated OOV vectors in the first epoch, after which all word embeddings were updated normally. The dropout rate was selected from [0.1, 0.2, 0.3, 0.4]. We used Adam (Kingma and Ba, 2015) for optimization with the two momentum parameters set to 0.9 and 0.999 respectively, and the initial learning rate set to 1E-3. The mini-batch size was set to 16 or 32. For a fair comparison against previous work, we report results with different hidden/memory dimensions (i.e., 100, 300, and 450).

We compared variants of our model against different types of LSTMs (see the second block in Table 3). Specifically, these include a model which encodes the premise and hypothesis independently with two LSTMs (Bowman et al., 2015), a shared LSTM (Rocktäschel et al., 2016), a word-by-word attention model (Rocktäschel et al., 2016), and a matching LSTM (mLSTM; Wang and Jiang (2016)). This model sequentially processes the hypothesis, and at each position tries to match the current word with an attention-weighted representation of the premise (rather than basing its predictions on whole sentence embeddings). We also compared our mod-

Models	h	$\|\theta\|_M$	Test
BOW concatenation	—	—	59.8
LSTM (Bowman et al., 2015)	100	221k	77.6
LSTM-att (Rocktäschel et al., 2016)	100	252k	83.5
mLSTM (Wang and Jiang, 2016)	300	1.9M	86.1
LSTMN	100	260k	81.5
LSTMN shallow fusion	100	280k	84.3
LSTMN deep fusion	100	330k	84.5
LSTMN shallow fusion	300	1.4M	85.2
LSTMN deep fusion	300	1.7M	85.7
LSTMN shallow fusion	450	2.8M	86.0
LSTMN deep fusion	450	3.4M	**86.3**

Table 3: Parameter counts $|\theta|_M$, size of hidden unit h, and model accuracy (%) on the natural language inference task.

els with a bag-of-words baseline which averages the pre-trained embeddings for the words in each sentence and concatenates them to create features for a logistic regression classifier (first block in Table 3).

LSTMNs achieve better performance compared to LSTMs (with and without attention; 2nd block in Table 3). We also observe that fusion is generally beneficial, and that deep fusion slightly improves over shallow fusion. One explanation is that with deep fusion the inter-attention vectors are recurrently memorized by the decoder with a gating operation, which also improves the information flow of the network. With standard training, our deep fusion yields the state-of-the-art performance in this task. Although encouraging, this result should be interpreted with caution since our model has substantially more parameters compared to related systems. We could compare different models using the same number of total parameters. However, this would inevitably introduce other biases, e.g., the number of hyper-parameters would become different.

6 Conclusions

In this paper we proposed a machine reading simulator to address the limitations of recurrent neural networks when processing inherently structured input. Our model is based on a Long Short-Term Memory architecture embedded with a memory network, explicitly storing contextual representations of input tokens without recursively compressing them. More importantly, an intra-attention mechanism is employed for memory addressing, as a way to induce undirected relations among tokens. The attention layer is not optimized with a direct supervision signal but with the entire network in downstream tasks. Experimental results across three tasks show that our model yields performance comparable or superior to state of the art.

Although our experiments focused on LSTMs, the idea of building more structure aware neural models is general and can be applied to other types of networks. When direct supervision is provided, similar architectures can be adapted to tasks such as dependency parsing and relation extraction. In the future, we hope to develop more linguistically plausible neural architectures able to reason over nested structures and neural models that learn to discover compositionality with weak or indirect supervision.

On Generating Characteristic-rich Question Sets for QA Evaluation

Abstract

We present a semi-automated framework for constructing factoid question answering (QA) datasets, where an array of question characteristics are formalized, including structure complexity, function, commonness, answer cardinality, and paraphrasing. Instead of collecting questions and manually characterizing them, we employ a reverse procedure, first generating a kind of graph-structured logical forms from a knowledge base, and then converting them into questions. Our work is the first to generate questions with explicitly specified characteristics for QA evaluation. We construct a new QA dataset with over 5,000 logical form-question pairs, associated with answers from the knowledge base, and show that datasets constructed in this way enable fine-grained analyses of QA systems. The dataset can be found in https://github.com/ysu1989/GraphQuestions.

1 Introduction

Factoid question answering (QA) has gained great attention recently, owing to the fast growth of large knowledge bases (KBs) such as DBpedia (Lehmann et al., 2014) and Freebase (Bollacker et al., 2008), which avail QA systems of comprehensive and precise knowledge of encyclopedic scope (Yahya et al., 2012; Berant et al., 2013; Cai and Yates, 2013; Kwiatkowski et al., 2013; Berant and Liang, 2014; Fader et al., 2014; Reddy et al., 2014; Bao et al., 2014; Zou et al., 2014; Yao and Van Durme, 2014; Yih et al., 2015; Sun et al., 2015; Dong et al., 2015; Yao, 2015; Berant and Liang, 2015). With the blossoming of QA systems, evaluation is becoming an increasingly important problem. QA datasets, consisting of a set of questions with ground-truth answers, are critical for both comparing existing systems and gaining insights to develop new systems.

Questions have rich *characteristics*, constituting dimensions along which question difficulty varies. Some questions are difficult due to their complex semantic structure (*"Who was the coach when Michael Jordan stopped playing for the Chicago Bulls?"*), while some others may be difficult because they require a precise quantitative analysis over the answer space (*"What is the best-selling smartphone in 2015?"*). Many other characteristics shall be considered too, e.g., what topic a question is about (questions about common topics may be easier to answer) and how many answers there are (it is harder to achieve a high recall in case of multiple answers). Worse still, due to the flexibility of natural language, different people often describe the same question in different ways, i.e., paraphrasing. It is important for a QA system to be robust to paraphrasing.

A QA dataset explicitly specifying such question characteristics allows for fine-grained inspection of system performance. However, to the best of our knowledge, none of the existing QA datasets (Voorhees and Tice, 2000; Berant et al., 2013; Cai and Yates, 2013; Lopez et al., 2013; Bordes et al., 2015; Serban et al., 2016) provides question characteristics. In this work, we make the first attempt to generate questions with explicitly specified characteristics, and examine the impact of various question characteristics in QA.

We present a semi-automated framework (Figure 1) to construct QA datasets with characteristic

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 562–572,
Austin, Texas, November 1-5, 2016.

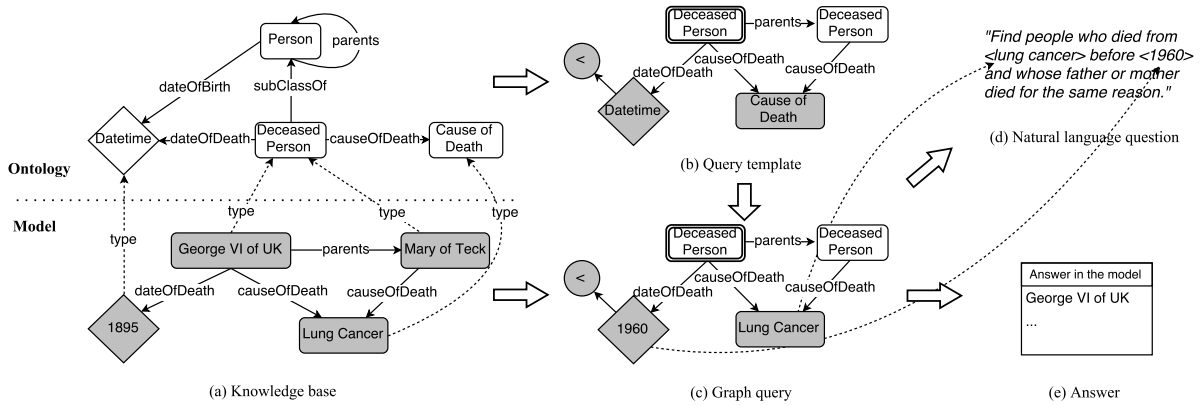

Figure 1: Running example of our framework. Graph queries are first generated from a knowledge base. After refinement (not shown), graph queries are sent to human annotators and converted into natural language questions. Answers are collected from the knowledge base.

specification from a knowledge base. The framework revolves around an intermediate *graph query* representation, which helps to formalize question characteristics and collect answers. We first automatically generate graph queries from a knowledge base, and then employ human annotators to convert graph queries into questions.

Automating graph query generation brings with it the challenge of assessing the quality of graph queries and filtering out bad ones. Our framework tackles the challenge by combining structured information in the knowledge base and statistical information from the Web. First, we identify *redundant components* in a graph query and develop techniques to remove them. Furthermore, based on the frequency of entities, classes, and relations mined from the Web, we quantify the *commonness* of a graph query and filter out too rare ones.

We employ a semi-automated approach for the conversion from graph query to natural language question, which provides two levels of paraphrasing: Common lexical forms of an entity (e.g., "*Queen Elizabeth*" and "*Her Majesty the Queen*" for `ElizabethII`) mined from the Web are used as entity paraphrases, and the remaining parts of a question are paraphrased by annotators. As a result, dozens of paraphrased questions can be produced for a single graph query.

To demonstrate the usefulness of question characteristics in QA evaluation, we construct a new dataset with over 5,000 questions based on Freebase using the proposed framework, and extensively evaluate several QA systems. A couple of new findings about system performance and question difficulty are discussed. For example, different from the results based on previous QA datasets (Yao et al., 2014), we find that semantic parsing in general works better than information extraction on our dataset. Information extraction based QA systems have trouble dealing with questions requiring aggregation or with multiple answers. A holistic understanding of the whole question is often needed for hard questions. The experiments point out an array of issues that future QA systems may need to solve.

2 Related Work

Early QA research has extensively studied problems like question taxonomy, answer type, and knowledge sources (Burger et al., 2001; Hirschman and Gaizauskas, 2001; Voorhees and Tice, 2000). This work mainly targets factoid questions with one or more answers that are guaranteed to exist in a KB.

A few KB-based QA datasets have been proposed recently. QALD (Lopez et al., 2013) and FREE917 (Cai and Yates, 2013) contain hundreds of hand-crafted questions. QALD also indicates whether a question requires aggregation. Both based on single Freebase triples, SIMPLEQUESTIONS (Bordes et al., 2015) employ human annotators to formulate questions, while Serban et al. (2016) use a recurrent neural network to automatically formulate questions. They are featured by a large size, but the questions only concern single triples, while our framework can generate ques-

tions involving multiple triples and various functions. Wang et al. (2015) generate question-answer pairs for closed domains like basketball. They also first generate logical forms (λ-DCS formulae (Liang, 2013) in their case), and then convert logical forms into questions via crowdsourcing. Logical forms are first converted into canonical questions to help crowdsourcing workers. Different from previous works, we put a particular focus on generating questions with diversified characteristics in a systematic way, and examining the impact of different question characteristics in QA.

Another attractive way for QA dataset construction is to collect questions from search engine logs (Bendersky and Croft, 2009). For example, WEBQUESTIONS (Berant et al., 2013) contains thousands of popular questions from Google search, and Yih et al. (2016) have manually annotated these questions with logical forms. However, automatic characterization of questions is hard, while manual characterization is costly and requires expertise. Moreover, users' search behavior is shaped by search engines (Aula et al., 2010). Due to the inadequacy of current search engines to answer advanced questions, users may adapt themselves accordingly and mostly ask simple questions. Thus questions collected in this way, to some extent, may still not well reflect the true distribution of user information needs, nor does it fully exploit the potential of KB-based QA. Collecting answers is yet another challenge for this approach. Yih et al. (2016) show that only 66% of the WEBQUESTIONS answers, which were collected via crowdsourcing, are completely correct. On the other hand, although questions generated from a KB may not follow the distribution of user information needs, it has the advantage of explicit question characteristics, and enables programmatic configuration of question generation. Also, answer collecting is automated without involving human labor and errors.

3 Background

3.1 Knowledge Base

In this work, we mainly concern knowledge bases storing knowledge about entities and relations in the form of triples (simply *knowledge bases* hereafter). Suppose $\mathcal{E}$ is a set of entities, $\mathcal{L}$ a set of literals ($\mathcal{I} = \mathcal{E} \cup \mathcal{L}$ is also called *individuals*), $\mathcal{C}$ a set of classes, and $\mathcal{R}$ a set of directed relations, a knowledge base $\mathcal{K}$ consists of two parts: an *ontology* $\mathcal{O} \subseteq \mathcal{C} \times \mathcal{R} \times \mathcal{C}$ and a *model* $\mathcal{M} \subseteq \mathcal{E} \times \mathcal{R} \times (\mathcal{C} \cup \mathcal{E} \cup \mathcal{L})$. In other words, an ontology specifies classes and relations between classes, and a model consists of *facts* about individuals. Such knowledge bases can be naturally represented as a directed graph, e.g., Figure 1(a). Literal classes such as `Datetime` are represented as diamonds, and other classes are rounded rectangles. Individuals are shaded. We assume relations are typed, i.e., each relation is associated with a set of *domain* and *range* classes. Facts of a relation must be compatible with its domain and range constraints. Without loss of generality, we use Freebase (June 2013 version) in this work for compatibility with the to-be-tested QA systems. It has 24K classes, 65K relations, 41M entities, and 596M facts.

3.2 Graph Query

Motivated by the graph-structured nature of knowledge bases, we adopt a graph-centric approach. We hinge on a formal representation named *graph query* (e.g., Figure 1(c)), developed on the basis of Yih et al. (2015) and influenced by λ-DCS (Liang, 2013).

Syntax. A graph query q is a connected directed graph built on a given knowledge base $\mathcal{K}$. It comprises three kinds of nodes: (1) *Question node* (double rounded rectangle), a free variable. (2) *Ungrounded node* (rounded rectangle or diamond), an existentially quantified variable. (3) *Grounded node* (shaded rounded rectangle or diamond), an individual. In addition, there are *functions* (shaded circle) such as $<$ and `count` applied on a node. Nodes are typed, each associated with a class. Nodes are connected by directed edges representing relations. Entities on the grounded nodes are called *topic entities*.

Semantics. Graph query is a strict subset of λ-calculus. For example, the graph query in Figure 1(c) can be written in λ-calculus (an existentially quantified variable is imposed by $<$):

$$\begin{aligned}\lambda x.\exists y.\exists z.&\texttt{type}(x, \texttt{DeceasedPerson})\\ &\wedge \texttt{type}(y, \texttt{DeceasedPerson})\\ &\wedge \texttt{type}(z, \texttt{Datetime}) \wedge \texttt{parents}(x, y)\\ &\wedge \texttt{causeOfDeath}(x, \texttt{LungCancer})\\ &\wedge \texttt{causeOfDeath}(y, \texttt{LungCancer})\\ &\wedge \texttt{dateOfDeath}(x, z) \wedge <(z, 1960).\end{aligned}$$

The *answer* of a graph query q, denoted as $[\![q]\!]_{\mathcal{K}}$, can be easily obtained from $\mathcal{K}$. For example, if $\mathcal{K}$ is stored in a RDF triplestore, then q can be automatically converted into a SPARQL query and run against $\mathcal{K}$ to get the answer. Compared with Yih et al. (2015), graph queries are not constrained to be tree-structured, which grants us a higher expressivity. For example, linguistic phenomena like anaphora (e.g., Figure 1(d)) become easier to model.

4 Automatic Graph Query Generation

Our framework proceeds as follows: (1) Generate *query templates* from a knowledge base, ground the templates to generate graph queries, and collect answers (this section). (2) Refine graph queries to retain high-quality ones (Section 5). (3) Convert graph queries into questions via crowdsourcing (Section 6).

We now describe an algorithm to generate the query template shown in Figure 1(b) (excluding the function for now). For simplicity, we will focus on the case of a single question node. Nevertheless, the proposed framework can be extended to generate graph queries with multiple question nodes. The algorithm takes as input an ontology (Figure 1(a)) and the desired number of edges. All the operations are conducted in a random manner to avoid systematic biases in query generation. The `DeceasedPerson` class is first selected as the question node. We then iteratively grow it by adding neighboring nodes and edges in the ontology. In each iteration, an existing node is selected, and a new edge, which might introduce a new node, is appended to it. For example, the relation `causeOfDeath`, whose domain includes `DeceasedPerson`, is first appended to the question node, and then one of its range classes, `CauseOfDeath`, is added as a new node. When a node with the class `CauseOfDeath` already exists, it is possible to add an edge without introducing a new node. The same relation or class can be added multiple times, e.g., "*parent of parent*".

Topic entities like `LungCancer` play an important role in a question. A query template contains some template nodes that can be grounded with different topic entities to generate different graph queries. We randomly choose a few nodes as template. It may cause problems. For example, grounding one node may make some others redundant. We conduct a formal study on this in Section 5.1.

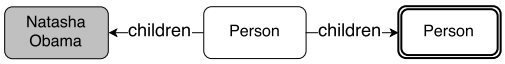

Figure 2: Mutual exclusivity example. Entities on different nodes should be different.

Functions such as counting and comparatives are pervasive in real-life questions, e.g., "*how many*", "*the most recent*", and "*people older than*", but are scarce in existing QA datasets. We incorporate functions as an important question characteristic, and consider nine common functions, grouped into three categories: counting (`count`), superlative (`max`, `min`, `argmax`, `argmin`), and comparative ($>$, $\geq$, $<$, $\leq$). More functions can be incorporated in the future. See Appendix A for examples. We randomly add functions to compatible nodes in query templates. In the running example, the $<$ function imposes the constraint that only people who passed away before a certain date should be considered. Each query will have at most one function.

We then ground the template nodes with individuals to generate graph queries. A grounding is valid if the individuals conform with the class of the corresponding template nodes, and the resulted answer is not empty. For example, by grounding `CauseOfDeath` with `LungCancer` and `Datetime` with `1960`, we get the graph query in Figure 1(c). A query template can render multiple groundings.

Finally, we convert a graph query into a SPARQL query and execute it using Virtuoso Open-Source 7 to collect answers. We further impose *mutual exclusivity* in SPARQL queries, that is, the entities on any two nodes in a graph query should be different. Consider the example in Figure 2, which is asking for the siblings of Natasha Obama. Wihout mutual exclusivity, however, Natash Obama herself will also be included as an answer, which is not desired.

5 Query Refinement

Since graph queries are randomly generated, some of them may not correspond to an interesting question. Next we study two query characteristics, *redundancy* and *commonness*, based on which we provide mechanisms for automatic query refinement.

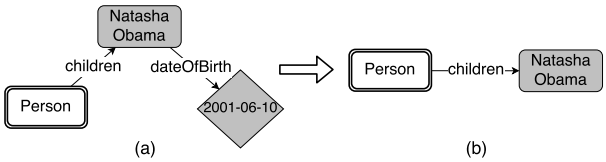

Figure 3: Query minimization example: (a) Graph query with redundant components. (b) Graph query after minimization.

Figure 4: Uncommon query example. It is uncommon to ask for somebody's great-great-grandparents.

5.1 Query Redundancy and Minimization

Some components (nodes and edges) in a graph query may not effectively impose any constraint on the answer. The query in Figure 3(a) is to "*find the US president whose child is Natasha Obama, **and Natasha Obama was born on 2001-06-10***". Intuitively, the bold-faced clause does not change the answer of the question. Correspondingly, the `dateOfBirth` edge and the date node are redundant. As a comparison, removing any component from the query in Figures 3(b) will change the answer. Formally, given a knowledge base $\mathcal{K}$, a component in a graph query q is *redundant* iff. removing it does not change the answer $[\![q]\!]_{\mathcal{K}}$.

Redundancy can be desired or not. In a question, redundant information may be inserted to reduce ambiguity. In Figure 3(a), if one uses "*Natasha*" to refer to `NatashaObama`, there comes ambiguity since it may be matched with many other entities. The additional information "*who was born on 2001-06-10*" then helps. Next we describe an algorithm to remove redundancy from queries. One can choose to either only generate queries with no redundant component, or intentionally generate redundant queries and test QA systems in presence of redundancy.

We manage to generate *minimal* queries, for which there exists no sub-query having the same answer. An important theorem, as we prove in Appendix B, is the equivalency of minimality and non-redundancy: A query is minimal *iff.* it has no redundant component. This renders a simple algorithm for query minimization, which directly detects and removes the redundant components in a query. We first examine every edge (in an arbitrary order), and remove an edge if it is redundant. Redundant nodes will then become disconnected to the question node and are thus eliminated. It is easy to prove that the produced query (e.g., Figure 3(b)) is minimal, and has the same answer as the original query.

5.2 Commonness Checking

We now quantify the *commonness* of graph queries. The benefits of this study are two-fold. First, it provides a refinement mechanism to reduce too rare queries. Second, commonness is itself an important question characteristic. It is interesting to examine its impact on question difficulty. Consider the example in Figure 4, which asks for "*the great-great-grandparents of Ernest Solvay*". It is minimal and logically plausible. Few users, however, are likely to come up with it. Ernest Solvay is famous for the Solvay Conferences, but few people outside the science community may know him. Although `Person` and `parents` are common, asking for the great-great-grandparents is quite uncommon.

A query is more common if users would more likely come up with it. We define the commonness of a query q as its *probability* $p(q)$ of being picked among all possible queries from a knowledge base. The problem then boils down to estimating $p(q)$. It is hard, if not impossible, to exhaust the whole query space. We thus make the following simplification. We break down query commonness by components, assuming mutual independence between components, and omit functions:

$$p(q) = \prod_{i \in \mathcal{I}_q} p(i) \times \prod_{c \in \mathcal{C}_q} p(c) \times \prod_{r \in \mathcal{R}_q} p(r), \qquad (1)$$

where $\mathcal{I}_q, \mathcal{C}_q, \mathcal{R}_q$ are the *multi-set* of the individuals, classes, and relations in q, respectively. Repeating components are thus accumulated (c.f. Figure 4).

We propose a data-driven method, using statistical information from the Web, to estimate $p(i)$, $p(c)$, and $p(r)$. Other methods like domain-knowledge based estimation are also applicable if available. We start with entity probability $p(e)$ (excluding literals for now). If users mention an entity more frequently, its probability of being observed in a question should be higher. We use a large entity linking dataset, FACC1 (Gabrilovich et al., 2013), which identifies around 10 billion mentions of Freebase entities in over 1 billion web documents. The estimated linking precision and recall are 80-85% and 70-85%, re-

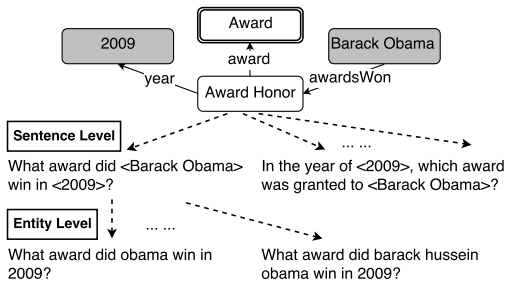

Figure 5: Question generation and paraphrasing.

spectively. Suppose entity e has $n(e)$ mentions, then $p(e) = \frac{n(e)}{\sum_{e' \in \mathcal{E}} n(e')}$. For a class c, probability $p(c)$ is higher if it has more frequently mentioned entities. If we use $e \in c$ to indicate e is an instance of c, then $p(c) = \frac{\sum_{e \in c} n(e)}{\sum_{c' \in \mathcal{C}} \sum_{e \in c'} n(e)}$. Estimating $p(r)$ requires relation extraction from texts, which is hard. We make the following simplification: If (e_1, r, e_2) is a fact in the knowledge base, we increase $n(r)$ by 1 if e_1 and e_2 co-occur in a document. This suffices to distinguish common relations from uncommon ones. We then define $p(r) = \frac{n(r)}{\sum_{r' \in \mathcal{R}} n(r')}$. Finally, we use frequency information from the knowledge base to smooth the probabilities, e.g., to avoid zero probabilities. The probability of literals are solely determined by the frequency information from the knowledge base. Refer to Appendix C for the resulted probability distributions.

6 Natural Language Conversion

In order to ensure naturalness and diversity, we employ human annotators to manually convert graph queries into natural language questions. We manage to provide two levels of paraphrasing (Figure 5). Each query is sent to multiple annotators for sentence-level paraphrasing. In addition, we use different lexical forms of an entity mined from FACC1 for entity-level paraphrasing. We provide a ranked list of common lexical forms and the corresponding frequency for each topic entity. For example, the lexical form list for `UnitedStatesOfAmerica` is "*us*" (108M), "*united states*" (44M), "*usa*" (22M), etc. Finally, graph queries are automatically translated into SPARQL queries to collect answers.

Natural language generation (NLG) (Wen et al., 2015; Serban et al., 2016; Dušek and Jurčíček, 2015) would be a good complement to our framework, the combination of which can lead to a fully-automated pipeline to generate QA datasets. For example, Serban et al. (2016) automatically convert Freebase triples into questions with a neural network. More sophisticated NLG techniques able to handle graph queries involving multiple relations and various functions are an interesting future direction.

7 Experiments

We have constructed a new QA dataset, named GRAPHQUESTIONS, using the proposed framework, and tested several QA systems to show that it enables fine-grained inspection of QA systems.

7.1 Dataset Construction

We first randomly generated a set of minimal graph queries, and removed the ones whose commonness is below a certain threshold. The remaining graph queries were then screened by graduate students, and a *canonical* question was generated for each query, with each being verified by at least two students. We recruited 160 crowdsourcing workers from Amazon MTurk to generate sentence-level paraphrases of the canonical questions. Trivial paraphrases (e.g., "*which city*" vs. "*what city*") were manually removed to retain a high diversity in paraphrasing. At most 3 entity-level paraphrases were used for each sentence-level paraphrase.

7.2 Dataset Analysis

GRAPHQUESTIONS contains 500 graph queries, 2,460 sentence-level paraphrases, and 5,166 questions[2]. The dataset presents a high diversity and covers a wide range of domains including `People`, `Astronomy`, `Medicine`, etc. Specifically, it contains 148, 506, 596, 376 and 3,026 distinct domains, classes, relations, topic entities, and words, respectively. We evenly split GRAPHQUESTIONS into a training set and a testing set. All the paraphrases of the same graph query are in the same set.

While there are other question characteristics derivable from graph query, we will focus on the following ones: *structure complexity*, *function*, *commonness*, *paraphrasing*, and *answer cardinality*. We

[2]For each query template, we only generate one graph query, but one can also generate multiple graph queries, and easily get the corresponding questions by replacing the topic entities. This will significantly increase the total number of questions, and can be helpful in training.

	# of edges			Function				$\log_{10}(p(q))$				$\|\mathbf{A}\|$	
	1	2	3	none	count	super.	comp.	$[-40, 30)$	$[-30, 20)$	$[-20, 10)$	$[-10, 0)$	1	> 1
# of graph queries	321	144	35	350	61	42	47	60	135	283	22	332	168
# of questions	3094	1648	424	3855	710	332	269	653	1477	2766	270	3487	1679

Table 1: Characteristic statistics. $|\mathbf{A}|$ is answer cardinality. Refer to Appendix D for paraphrase and other fine-grained distributions.

Question	Domain	Answer	# of edges	Function	$\log_{10}(p(q))$	$\|\mathbf{A}\|$
Find terrorist organizations involved in **September 11 attacks**.	Terrorism	alQaeda	1	none	-16.67	1
The **September 11 attacks** were carried out with the involvement of what terrorist organizations?						
Who did **nine eleven**?						
How many children of **Eddard Stark** were born in **Winterfell**?	Fictional Universe	3	2	count	-23.34	1
Winterfell is the home of how many of **Eddard Stark**'s children?						
What's the number of **Ned Stark**'s children whose birthplace is **Winterfell**?						
In which month does the average rainfall of **New York City** exceed **86** mm?	Travel	March, August ...	3	comp.	-37.84	7
Rainfall averages more than **86** mm in **New York City** during which months?						
List the calendar months when **NYC** averages in excess of **86** millimeters of rain?						

Table 2: Example questions and characteristics. Three sentence-level paraphrases are shown for each graph query, with the last one also involving entity-level paraphrasing. Topic entities are bold-faced. More examples can be found in Appendix D.

use the number of edges to quantify structure complexity, and limit it to at most 3. Commonness is limited to $\log_{10}(p(q)) \geq -40$ (c.f. Eq. 1). As shown in Section 7.4.2, such questions are already very hard for existing QA systems. Nevertheless, the proposed framework can be used to generate questions with different characteristic distributions. Some statistics are shown in Table 1 and more fine-grained statistics can be found in Appendix D.

Several example questions are shown in Table 2. Sentence-level paraphrasing requires to handle both commands (the first example) and "*Wh*" questions, light verbs ("*Who did nine eleven?*"), and changes of syntactic structure ("*The September 11 attacks were carried out with the involvement of what terrorist organizations?*"). Entity-level paraphrasing tests the capability of QA systems on abbreviation ("*NYC*" for `New York City`), world knowledge ("*Her Majesty the Queen*" for `ElizabethII`), or even common typos ("*Shakspeare*" for `WilliamShakespeare`). Numbers and dates are also common, e.g., "*Which computer operating system was released on Sept. the 20th, 2008?*"

We compare several QA datasets constructed from Freebase, shown in Table 3. Datasets focusing on single-relation questions are of a larger scale, but are also of a significant lack in question characteristics. Overall GRAPHQUESTIONS presents the highest diversity in question characteristics.

7.3 Setup

We evaluate three QA systems whose source code is publicly available: SEMPRE (Berant et al., 2013), PARASEMPRE (Berant and Liang, 2014), and JACANA (Yao and Van Durme, 2014). SEMPRE and PARASEMPRE follow the semantic parsing paradigm. SEMPRE conducts a bottom-up beam-based parsing on questions to find the best logical form. PARASEMPRE, in a reverse manner, enumerates a set of logical forms, generates a canonical utterance for each logical form, and ranks logical forms according to how well the canonical utterance paraphrases the input question. In contrast, JACANA follows the information extraction paradigm, and builds a classifier to directly predict whether an individual is the answer. They all use Freebase.

The main metric for answer quality is the average F1 score, following Berant and Liang (2014). Because a question can have more than one answer, individual precision, recall, and F1 scores are first computed on each question and then averaged. When a system generates no response for a question,

Dataset	# of Questions	# of Multi-relation	Function (count/super./comp.)	Commonness	Paraphrase	Multi-answer
GRAPHQUESTIONS (this work)	5166	2072	710 / 332 / 269	+	+	+
WEBQUESTIONSSP (Yih et al., 2016)[1]	4737	2075	2 / 168 / 334	-	-	+
FREE917 (Cai and Yates, 2013)	917	229	185 / 0 / 0	-	-	+
Serban et al. (2016)	30M	0	0 / 0 / 0	-	-	-
SIMPLEQUESTIONS (Bordes et al., 2015)	108K	0	0 / 0 / 0	-	-	-

Table 3: Comparison of QA datasets constructed from Freebase. GRAPHQUESTIONS is the richest in question characteristics.

System	F1	Time/s
SEMPRE	10.80	56.19
PARASEMPRE	12.79	18.43
JACANA	5.08	2.01

Table 4: Overall performance on GRAPHQUESTIONS.

precision is 1, recall is 0, and F1 is 0. Average runtime is used for efficiency. Results are shown in percentage. Systems are trained on the training set using the suggested configurations (Appendix E). We use student's t test at $p = 0.05$ for significance test.

7.4 Results

7.4.1 Overall Evaluation

Compared with the scores on WEBQUESTIONS (30%-40%), the scores on GRAPHQUESTIONS are lower (Table 4). This is because GRAPHQUESTIONS contains questions over a broader range of difficulty levels. For example, it is more diverse in topics (Appendix D); also the scores become much closer when excluding paraphrasing (Section 7.4.2).

JACANA achieves a comparable F1 score with SEMPRE and PARASEMPRE on WEBQUESTIONS (Yao et al., 2014). On GRAPHQUESTIONS, however, SEMPRE and PARASEMPRE significantly outperform JACANA (both $p < 0.0001$). The following experiments will give more insights about where the performance difference comes from. On the other hand, JACANA is much faster, showing an advantage of information extraction. The semantic parsing systems spend a lot of time on executing SPARQL queries. Bypassing SPARQL and directly working on the knowledge base may be a promising way to speed up semantic parsing on large knowledge bases (Yih et al., 2015).

[2]WEBQUESTIONSSP is WEBQUESTIONS with manually annotated logical forms. Only those with a full logical form are included (4737 / 5810).

7.4.2 Fine-grained Evaluation

With explicitly specified question characteristics, we are able to further inspect QA systems.

Structure Complexity. We first break down system performance by structure. Answer quality is in general sensitive to the complexity of question structure: As the number of edges increases, F1 score decreases (Figure 6(a)). The tested systems often fail to take into account auxiliary constraints in a question. For example, for "*How many children of Ned Stark were born in Winterfell?*" SEMPRE fails to identify the constraint "*born in Winterfell*", so it also considers Ned Stark's bastard son, Jon Snow, as an answer, who was not born in Winterfell. Answering questions involving multiple relations using large knowledge bases remain an open problem. The large size of knowledge bases prohibits exhaustive search, so smarter algorithms are needed to efficiently prune the answer space. Berant and Liang (2015) point out an interesting direction, leveraging agenda-based parsing with imitation learning for efficient search in the answer space.

Function. In terms of functions, while SEMPRE and PARASEMPRE perform well on `count` questions, all the tested systems perform poorly on questions with superlatives or comparatives (Figure 6(b)). JACANA has trouble dealing with functions because it does not conduct quantitative analysis over the answer space. SEMPRE and PARASEMPRE do not generate logical forms with superlatives and comparatives, so they cannot answer such questions well.

Commonness. Not surprisingly, more common questions are in general easier to answer (Figure 6(c)). An interesting observation is that SEMPRE's performance gets worse on the most common questions. The cause is likely rooted in how the QA systems construct their candidate answer sets. PARASEMPRE and JACANA exhaustively construct candidate sets, while SEMPRE employs a bottom-up beam search, making it more sensitive to the size of

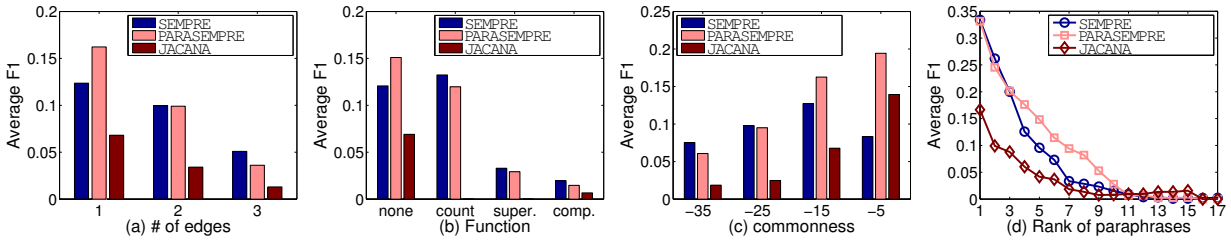

Figure 6: Performance breakdown by (a) structure complexity, (b) function, (c) commonness, and (d) paraphrase. Note that in (c) $x = -5$ indicates the commonness range $-10 \leq \log_{10}(p(q)) < 0$.

the candidate answer space. Common entities like `UnitedStatesOfAmerica` are often featured by a high degree in knowledge bases (e.g., 1 million neighboring entities), which dramatically increases the size of the candidate answer space. During SEMPRE's iterative beam search, many correct logical forms may have fallen off beam before getting into the final candidate set. We checked the percentage of questions for which the correct logical form is in the final candidate set, and found that it decreased from 19.8% to 16.7% when commonness increased from -15 to -5, providing an evidence for the intuition.

Paraphrasing. It is critical for a system to tolerate the wording varieties of users. We make the first effort to evaluate QA systems on paraphrasing. For each system, we rank, in descending order, all the paraphrases derived from the same graph query by their F1 score achieved by the system, and then compute the average F1 score of each rank. In Figure 6(d), the decreasing rate of a curve thus describes a system's robustness to paraphrasing; the higher, the less robust. All the systems achieve a reasonable score on the top-1 paraphrases, i.e., when a system can choose the paraphrase it can best answer. The F1 scores drop quickly in general. On the fourth-ranked paraphrases, the F1 score of SEMPRE, PARASEMPRE, and JACANA are respectively only 37.65%, 53.2%, and 36.2% of their score on the top-1 paraphrases. Leveraging paraphrasing in its model, PARASEMPRE does seem to be more robust. The results show that how to handle paraphrased questions is still a challenging problem.

Answer Cardinality. SEMPRE and JACANA get a significantly lower F1 score (both $p < 0.0001$) on multi-answer questions (Table 5), mainly coming from a decrease on recall. The decrease of PARASEMPRE is not significant (p=0.29). The particularly significant decrease of JACANA demonstrates the difficulty of training a classifier that can predict all of the answers correctly; semantic parsing is more robust in this case. The precision of SEMPRE is high because it generates no response for many questions. Note that under the current definition, the average F1 score is not the harmonic mean of the average precision and recall (c.f. Section 7.3).

System	$\|\mathbf{A}\|$	Prec.	Rec.	F1
SEMPRE	1	59.81	16.11	12.68
	> 1	62.38	9.17	6.78
PARASEMPRE	1	17.42	17.58	13.25
	> 1	19.65	17.23	11.82
JACANA	1	14.77	6.56	6.56
	> 1	11.80	1.43	1.98

Table 5: Performance breakdown by answer cardinality $|\mathbf{A}|$.

8 Conclusion

We proposed a framework to generate characteristic-rich questions for question answering (QA) evaluation. Using the proposed framework, we constructed a new and challenging QA dataset, and extensively evaluated several QA systems. The findings point out an array of issues that future QA research may need to solve.

Abstract

In multilingual question answering, either the question needs to be translated into the document language, or vice versa. In addition to *direction*, there are multiple *methods* to perform the translation, four of which we explore in this paper: word-based, 10-best, context-based, and grammar-based. We build a feature for each combination of translation *direction* and *method*, and train a model that learns optimal feature weights. On a large forum dataset consisting of posts in English, Arabic, and Chinese, our novel *learn-to-translate* approach was more effective than a strong baseline ($p < 0.05$): translating all text into English, then training a classifier based only on English (original or translated) text.

1 Introduction

Question answering (QA) is a specific form of the information retrieval (IR) task, where the goal is to find relevant well-formed answers to a posed question. Most QA pipelines consist of three main stages: (a) preprocessing the question and collection, (b) retrieval of candidate answers in the collection, and (c) ranking answers with respect to their relevance to the question and return the top N answers. The types of questions can range from factoid (e.g., "What is the capital of France?") to causal (e.g., "Why are trees green?"), and opinion questions (e.g., "Should USA lower the drinking age?").

The most common approach to *multilingual QA* (MLQA) has been to translate all content into its most probable English translation via machine translation (MT) systems. This strong baseline, which we refer to as *one-best MT* (`1MT`), has been successful in prior work (Hartrumpf et al., 2009; Lin and Kuo, 2010; Shima and Mitamura, 2010). However, recent advances in cross-lingual IR (CLIR) show that one can do better by representing the translation space as a probability distribution (Ture and Lin, 2014). In addition, MT systems perform substantially worse with user-generated text, such as web forums (Van der Wees et al., 2015), which provide extra motivation to consider alternative translation approaches for higher recall. To our knowledge, it has yet to be shown whether these recent advancements in CLIR transfer to MLQA.

We introduce a novel answer ranking approach for MLQA (i.e., *Learning to Translate* or `L2T`), a model that learns the optimal translation of question and/or candidate answer, based on how well it discriminates between good and bad answers. We achieve this by introducing a set of features that encapsulate lexical and semantic similarities between a question and a candidate answer through various translation strategies (Section 3.1). The model then learns feature weights for each combination of translation *direction* and *method*, through a discriminative training process (Section 3.2). Once a model is trained, it can be used for MLQA, by sorting each candidate answer in the collection by model score. Instead of learning a single model to score candidate answers in any language, it might be meaningful to train a separate model that can learn to discriminate between good and bad answers in each language. This can let each model learn *feature weights custom to*

Austin, Texas, November 1-5, 2016.

the language, therefore allowing a more fine-grained ranking (Section 3.4). We call this alternative approach *Learning to Custom Translate* (L2CT).

Experiments on the DARPA Broad Operational Language Technologies (BOLT) IR task[1] confirm that L2T yields statistically significant improvements over a strong baseline ($p < 0.05$), in three out of four experiments. L2CT outperformed the baseline as well, but was not more effective than L2T.

2 Related Work

For the last decade or so, research in QA has mostly been driven by annual evaluation campaigns like TREC,[2] CLEF,[3] and NTCIR.[4] Most earlier work relied on either rule-based approaches where a set of rules were manually crafted for each type of question, or IR-like approaches where each pair of question and candidate answer was scored using retrieval functions (e.g., BM25 (Robertson et al., 2004)). On the other hand, training a classifier for ranking candidate answers allows the exploitation of various features extracted from the question, candidate answer, and surrounding context (Madnani et al., 2007; Zhang et al., 2007). In fact, an explicit comparison at 2007 TREC confirmed the superiority of machine learning-based (ML-based) approaches (F-measure 35.9% vs 38.7%) (Zhang et al., 2007). Learning-to-rank approaches have also been applied to QA successfully (Agarwal et al., 2012).

Previous ML-based approaches have introduced useful features from many aspects of natural language, including lexical (Brill et al., 2001; Attardi et al., 2001), syntactic (Alfonseca et al., 2001; Katz et al., 2005), semantic (Cui et al., 2005; Katz et al., 2005; Alfonseca et al., 2001; Hovy et al., 2001), and discourse features, such as coreference resolution (Morton, 1999), or identifying temporal/spatial references (Saquete et al., 2005; Harabagiu and Bejan, 2005), which are especially useful for "why" and "how" questions (Kolomiyets and Moens, 2011). Additionally, semantic role labeling and dependency trees are other forms of semantic analysis used widely in NLP applications (Shen and Lapata, 2007; Cui et al., 2005).

When dealing with multilingual collections, most prior approaches translate all text into English beforehand, then treat the task as monolingual retrieval (previously referred to as 1MT). At recent evaluation campaigns like CLEF and NTCIR,[5] almost all teams simply obtained the one-best question translation, treating some online MT system as a black box (Adafre and van Genabith, 2009; Hartrumpf et al., 2009; Martinez-Gonzalez et al., 2009; Lin and Kuo, 2010; Shima and Mitamura, 2010), with few notable exceptions that took term importance (Ren et al., 2010), or semantics (Munoz-Terol et al., 2009) into account. Even for non-factoid MLQA, most prior work does not focus on the translation component (Luo et al., 2013; Chaturvedi et al., 2014).

Contributions. Ture and Lin described three methods for translating queries into the collection language in a probabilistic manner, improving *document retrieval* effectiveness over a one-best translation approach (2014). Extending this idea to MLQA appears as a logical next step, yet most prior work relies solely on the one-best translation of questions or answers (Ko et al., 2010b; García-Cumbreras et al., 2012; Chaturvedi et al., 2014), or selects the best translation out of few options (Sacaleanu et al., 2008; Mitamura et al., 2006). Mehdad et al. reported improvements by including the top ten translations (instead of the single best) and computing a distance-based entailment score with each (2010). While Espla-Gomis et al. argue that using MT as a black box is more convenient (and modular) (2012), there are potential benefits from a closer integration between statistical MT and multilingual retrieval (Nie, 2010). To the best of our knowledge, there is no prior work in the literature, where the ***optimal query and/or answer translation is learned via machine learning***. This is our main contribution, with which we outperform the state of the art.

In addition to learning the optimal translation, we ***learn the optimal subset of the training data for a given task***, where the criteria of whether we include a certain data instance is based on either the source language of the sentence, or the language in which the sentence was annotated. Training data selection strategies have not been studied extensively in the

[5] Most recent MLQA tracks were in 2008 (CLEF) and 2010 (NTCIR).

QA literature, therefore the effectiveness of our simple language-related criteria can provide useful insights to the community.

When there are multiple independent approaches for ranking question-answer pairs, it is required to perform a *post-retrieval merge*: each approach generates a ranked list of answers, which are then merged into a final ranked list. This type of system combination approach has been applied to various settings in QA research. Merging at the document-level is common in IR systems (e.g., (Tsai et al., 2008)), and has shown to improve multilingual QA performance as well (García-Cumbreras et al., 2012). Many QA systems combine answers obtained by different variants of the underlying model (e.g., (Brill et al., 2001) for monolingual, (Ko et al., 2010a; Ko et al., 2010b) for multilingual QA). We are not aware, however, of any prior work that has explored the ***merging of answers that are generated by language-specific ranking models***. Although this does not show increased effectiveness in our experiments, we believe that it brings a new perspective to the problem.

3 Approach

Our work is focused on a specific stage of the QA pipeline, namely *answer ranking*: Given a natural-language question q and k candidate answers $s_1, \ldots, s_k$, we score each answer in terms of its relevance to q. In our case, candidate answers are sentences extracted from all documents retrieved in the previous stage of the pipeline (using Indri (Metzler and Croft, 2005)). Hereafter, sentence and answer might be used interchangeably.

While our approach is not language-specific, we assume (for simplicity) that questions are in English, whereas sentences are in either English, Arabic, or Chinese. Non-English answers are translated back into English before returning to user.

Our approach is not limited to any question type, factoid or non-factoid. Our main motivation is to provide good QA quality on any multilingual Web collection. This entails finding answers to questions where there is no single answer, and for which human agreement is low. We aim to build a system that can successfully retrieve relevant information from open-domain and informal-language content. In this scenario, two assumptions made by many of the prior approaches fail:

1) We can accurately classify questions via template patterns (Chaturvedi et al. argue that this does not hold for non-factoid questions (2014))

2) We can accurately determine the relevance of an answer, based on its automatic translation into English (Wees et al. show how recall decreases when translating user-generated text (2015))

To avoid these assumptions, we opted for a more adaptable approach, in which question-answer relevance is modeled as a function of features, intended to capture the relationship between the question and sentence text. Also, instead of relying solely on a single potentially incorrect English translation, we increase our chances of a hit by translating both the question and the candidate answer, using four different translation methods. Our main features, described throughout this section, are based on lexical similarity computed using these translations. The classifier is trained on a large number of question-answer pairs, each labeled by a human annotator with a binary relevance label.[6]

3.1 Representation

In MLQA, since questions and answers are in different languages, most approaches translate both into an intermediary language (usually English). Due to the error-prone nature of MT, valuable information often gets "lost in translation". These errors are especially noticeable when translating informal text or less-studied languages (Van der Wees et al., 2015).

Translation Direction. We perform a *two-way translation* to better retain the original meaning: in addition to translating each non-English sentence into English, we also translate the English questions into Arabic and Chinese (using multiple translation methods, described below). For each question-answer pair, we have two "views": comparing translated question to the original sentence (i.e., *collection-language* (CL) view); and comparing original question to the translated sentence (i.e., *question-language* (QL) view).

Translation Method. When translating text for retrieval tasks like QA, including a variety of alterna-

[6] Annotators score each answer from 1 to 5. We label any score of 3 or higher as relevant.

tive translations is as important as finding the most accurate translation, especially for non-factoid questions, where capturing (potentially multiple) underlying topics is essential. Recent work in cross-language IR (CLIR) has shown that incorporating probabilities from the internal representations of an MT system to "translate" the question can accomplish this, outperforming standard one-best translation (Ture and Lin, 2014). We hypothesize that these improvements transfer to multilingual QA as well.

In addition to *translation directions*, we explored four *translation methods* for converting the English question into a probabilistic representation (in Arabic and Chinese). Each method builds a probability distribution for every question word, expressing the translation space in the collection language. More details of first three methods can be found in (Ture and Lin, 2014), while fourth method is a novel query translation method adapted from the neural network translation model described in (Devlin et al., 2014).

Word: In MT, a word alignment is a many-to-many mapping between source- and target-language words, learned without supervision, at the beginning of the training pipeline (Och, 2003). These alignments can be converted into word translation probabilities for CLIR (Darwish and Oard, 2003).

For example, in an English-Arabic parallel corpus, if an English word appears m times in total and is aligned to a certain Arabic word k times, we assign a probability of $\frac{k}{m}$ for this translation. This simple idea has performed greatly in IR for generating a probability distribution for query word translations.

Grammar: Probabilities are derived from a synchronous context-free grammar, which is a typical translation model found in MT systems (Ture and Lin, 2014). The grammar contains rules r that follow the form $\alpha \mid \beta \mid \mathcal{A} \mid \ell(r)$, stating that source-language word α can be translated into target-language word β with an associated likelihood value $\ell(r)$ ($\mathcal{A}$ represents word alignments). For each rule r that applies to the question, we identify each source word s_j. From the word alignment information included in the rule, we can find all target words that s_j is aligned to. By processing all the rules to accumulate likelihood values, we construct translation probabilities for each word in the question.

10-best: Statistical MT systems retrieve a ranked list of translations, not a single best. Ture and Lin exploited this to obtain word translation probabilities from the top 10 translations of the question (2014). For each question word w, we can extract which grammar rules were used to produce the translation – once we have the rules, word alignments allow us to find all target-language words that w translates into. By doing this for each question translation, we construct a probability distribution that defines the translation space of each question word.

Context: Neural network-based MT models learn context-dependent word translation probabilities – the probability of a target word is dependent on the source word it aligns to, as well as a 5-word window of context (Devlin et al., 2014). For example, if the Spanish word "placer" is aligned to the English word "pleasure", the model will not only learn from this word-to-word alignment but also consider the source sentence context (e.g., "Fue un placer conocerte y tenerte unos meses."). However, since short questions might lack full sentence context, our model should have the flexibility to translate under partial or no context. Instead of training the NN-base translation model on full, well-formed sentences, we custom-fit it for question translation: words in the context window are randomly masked by replacing it with a special filler token <F>. This teaches the model how to accurately translate with full, partial context, or no context. For the above example, we generate partial contexts such as "fue un placer <F> y" or "<F> <F> placer conocerte y". Since there are many possibilities, if the context window is large, we randomly sample a few of the possibilities (e.g., 4 out of 9) per training word.

In Figure 1, we display the probabilistic structure produced the *grammar-based* translation method, when implemented as described above. Each English word in the question is translated into a probabilistic structure, consisting of Chinese words and corresponding probabilities that represent how much weight the method decides to put on that specific word. Similar structures are learned with the other three translation methods.

We are not aware of any other MLQA approach that represents the question-answer pair based on their probabilistic translation space.

Figure 1: Probabilistic grammar-based translation of example question. The example question "Tell me about child labor in Africa" is simplified by our preprocessing engine to "child labor africa".

3.2 Features

Given two different translation directions (*CL* and *QL*), and four different translation methods (*Word*, *Grammar*, *10-best*, *Context*), our strategy is to leverage a machine learning process to determine how helpful each signal is with respect to the end task. For this, we introduced separate question-answer similarity features based on each combination of translation direction and method.

Collection-language Features. In order to compute a single real-valued vector to represent the question in the collection language (*LexCL*), we start with the probabilistic structure representing the question translation (e.g., Figure 1 is one such structure when the translation method is *grammar-based*). For each word in the collection-language vocabulary, we compute a weight by averaging its probability across the terms in the probabilistic structure.

$$v_{q\text{grammar}}(w) = \text{avg}_i \Pr(w|q_i) \quad (1)$$

where w is a non-Engish word and $\Pr(w|q_i)$ is the probability of w in the probability distribution corresponding to the i^{th} query term.

Figure 2 shows the real-valued vector computed based on the probabilistic question translation in Figure 1. The Chinese word translated as "child labor" has a weight of 0.32, 0.36, and 0 in the probability distributions of the three query terms, respectively. Averaging these three values results in the final weight of 0.23 in $v_{q\text{grammar}}$ in Figure 2. Notice that these weights are normalized by construction.

Similarly, a candidate answer s in Chinese is represented by normalized word frequencies:

$$v_s(w) = \frac{\text{freq}(w|s)}{\sum_{w'} \text{freq}(w'|s)} \quad (2)$$

Given the two vectors, we compute the cosine similarity. Same process is repeated for the other three translation methods. The four lexical collection-language similarity features are collectively called *LexCL*.

Feature category	Question repr. ($v_{q'}$)	Sentence repr. ($v_{s'}$)	Feature Value
LexCL	$v_{q\text{word}}$	v_s	cosine $(v_{q'}, v_{s'})$
	$v_{q\text{10best}}$	v_s	
	$v_{q\text{context}}$	v_s	
	$v_{q\text{grammar}}$	v_s	
LexQL	v_q	$v_{s\text{1best}}$	

Table 1: List of features used in `L2T`, and how the values are computed from vector representations.

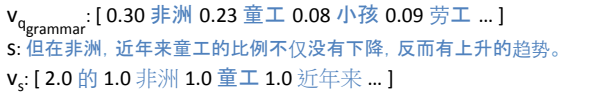

Figure 2: Vector representation of grammar-translated question ($q$grammar) and sentence (s).

Question-language Features. As mentioned before, we also obtain a similarity value by translating the sentence (s_{1best}) and computing the cosine similarity with the original question (q). v_q and $v_{s\text{1best}}$ are computed using Equation 2. Although it is possible to translate the sentence into English using the same four methods, we only used the one-best translation due to the computational cost. Hence, we have only one lexical similarity feature in the QL view (call *LexQL*).

The computation process for the five *lexical similarity* features is summarized in Table 1. After computation, feature weights are learned via a maximum-entropy model.[7] Although not included in the figure or table, we also include the same set of features from the sentence preceding the answer (within the corresponding forum post), in order to represent the larger discourse.

3.3 Data Selection

In order to train a machine learning model with our novel features, we need positive and negative examples of question-answer pairs (i.e., (q, s)). For this, for each training question, our approach is to hire

[7] Support vector machines yielded worse results.

human annotators to label sentences retrieved from the non-English collections used in our evaluation. It is possible to label the sentences in the source language (i.e., Arabic or Chinese) or in the question language (i.e., translated into English). In this section, we explore the question of whether it is useful to distinguish between these two independently created labels, and whether this redundancy can be used to improve the machine learning process.

We hypothesize two reasons why selecting training data based on language might benefit MLQA:
i) The translation of non-English candidate answers might lack in quality, so annotators are likely to judge some relevant answers as non-relevant. Hence, training a classifier on this data might lead to a tendency to favor English answers.
ii) For the question-answer pairs that were annotated in both languages, we can remove noisy (i.e., labeled inconsistently by annotators) instances from the training set.

The question of annotation is an unavoidable part of evaluation of MLQA systems, so finding the optimal subset for training is a relevant problem. In order to explore further, we generated six subsets with respect to (a) the original *language* of the answer, or (b) the language of *annotation* (i.e., based on original text or its English translation):
en: Sentences from the English corpus.
ar/ch: Sentences from the Arabic / Chinese corpus (regardless of how it was judged).
consist: All sentences except those that were judged inconsistently.
src+: Sentences judged only in original text, or judged in both consistently.
en+: Sentences that are either judged only in English, or judged in both original and English translation consistently.
all: All sentences.

These subsets were determined based on linguistically motivated heuristics, but choosing the most suitable one (for a given task) is done via machine learning (see Section 4).

3.4 Language-specific Ranking

Scoring Arabic sentences with respect to a question is inherently different than scoring English (or Chinese) sentences. The quality of resources, grammar, etc., as well as other internal dynamics might differ greatly across languages. We hypothesize that there is no one-size-fits-all model, so the parameters that work best for English retrieval might not be as useful when scoring sentences in Arabic, and/or Chinese.

Our proposed solution is to apply a separate classifier, custom-tuned to each collection, and retrieve three *single-language ranked lists* (i.e., in English, Arabic, and Chinese). In addition to comparing each custom-tuned, language-specific classifier to a single, language-independent one, we also use this idea to propose an approach for MLQA:
L2CT(n) Retrieve answers from each language using separate classifiers (call these lists English-only, Arabic-only, and Chinese-only), take the best answers from each language, then merge them into a mixed-language set of n answers.

We compare this to the standard approach:
L2T(n) Retrieve up to n mixed-language answers using a single classifier.

Four heuristics were explored for merging lists in the L2CT approach.[8] Two common approaches are *uniform* and *alternate* merging (Savoy, 2004):
Uniform: A straightforward merge can be achieved by using the classifier scores (i.e., probability of answer relevance, given question) to sort all answers, across all languages, and include the top n in the final list of answers. Classifier scores are normalized into the [0,1] range for comparability.
Alternate: We alternate between the lists, picking one answer at a time from each, stopping when the limit n has been reached.

Since answers are expected in English, there is a natural preference for answers that were originally written English, avoiding noisy text due to translation errors. However, it is also important not to restrict answers entirely to English sources, since that would defeat the purpose of searching in a multilingual collection. We implemented the following methods to account for language preferences:
English first: We keep all sufficiently-confident (i.e., normalized score above a fixed threshold) answers from the English-only list first, and start including answers from Arabic- and Chinese-only lists only if the limit of n answers has not been reached.

[8] In addition to these heuristics, the optimal merge could be learned from training data, as a "learning to rank" problem. This is out of the scope of this paper, but we plan to explore the idea in the future.

Weighted: Similar to *Uniform*, but we weight the normalized scores before sorting. The optimal weights can be learned by using a grid-search procedure and a cross-validation split.

4 Evaluation

In order to perform controlled experiments and gain more insights, we split our evaluation into four separate tasks: three tasks focus on retrieving answers from posts written in a specified language (*English-only*, *Arabic-only*, or *Chinese-only*) [9], and the last task is not restricted to any language (*Mixed-language*). All experiments were conducted on the DARPA BOLT-IR task. The collection consists of 12.6M Arabic, 7.5M Chinese, and 9.6M English Web forum posts. All runs use a set of 45 non-factoid (mostly opinion and causal) English questions, from a range of topics. All questions and forum posts were processed with an information extraction (IE) toolkit (Boschee et al., 2005), which performs sentence-splitting, named entity recognition, coreference resolution, parsing, and part-of-speech tagging.

All non-English posts were translated into English (one-best only), and all questions were translated into Arabic and Chinese (probabilistic translation methods from Section 3.1). For all experiments, we used the same state-of-the-art English↔Arabic (En-Ar) and English↔Chinese (En-Ch) MT systems (Devlin et al., 2014). Models were trained on parallel corpora from NIST OpenMT 2012, in addition to parallel forum data collected as part of the BOLT program (10M En-Ar words; 30M En-Ch words). Word alignments were learned with GIZA++ (Och and Ney, 2003) (five iterations of IBM Models 1–4 and HMM).

After all preprocessing, features were computed using the original post and question text, and their translations. Training data were created by having annotators label all sentences of the top 200 documents retrieved by Indri from each collection (for each question). Due to the nature of retrieval tasks, training data usually contains an unbalanced portion of negative examples. Hence, we split the data into balanced subsets (each sharing the same set of positively labeled data) and train multiple classifiers, then take a majority vote when predicting.

For testing, we froze the set of candidate answers and applied the trained classifier to each question-answer pair, generating a ranked list of answers for each question. This ranked list was evaluated by average precision (AP).[10] Due to the size and redundancy of the collections, we sometimes end up with over 1000 known relevant answers for a question. So it is neither reasonable nor meaningful to compute AP until we reach 100% recall (e.g., 11-point AP) for these cases. Instead, we computed AP-k, by accumulating precision values at every relevant answer until we get k relevant answers.[11] In order to provide a single metric for the test set, it is common to report the mean average precision (MAP), which in this case is the average of the AP-k values across all questions.

Baseline. As described earlier, the baseline system computes similarity between question text and the one-best translation of the candidate answer (we run the sentence through our state-of-the-art MT system). After translation, we compute similarity via scoring the match between the parse of the question text and the parse of the candidate answer, using our finely-tuned IE toolkit [reference removed for anonymization]. This results in three different similarity features: matching the tree node similarity, edge similarity, and full tree similarity. Feature weights are then learned by training this classifier discriminatively on the training data described above. This already performs competitively, outperforming the simpler baseline where we compute a single similarity score between question and translated text, and matching the performance of the system by Chaturvedi et al. on the BOLT evaluation (2014). Baseline MAP values are reported on the leftmost column of Table 2.

Data effect. In the baseline approach, we do not perform any data selection, and use all available data for training the classifier. In order to test our hypothesis that selecting a linguistically-motivated subset of the training data might help, we used 10-fold cross-validation to choose the optimal data set

[9] Shortened as *Eng*, *Arz*, and *Cmn*, respectively.

[10] Many other metrics (e.g., NDCG, R-precision) were explored during BOLT, and results were very similar.

[11] k was fixed to 20 in our evaluation, although we verified that conclusions do not change with varying k.

(among seven options described in Section 3.3). Results indicate that including English or Arabic sentences when training a classifier for Chinese-only QA is a bad idea, since effectiveness increases when restricted to Chinese sentences (`lang=ch`). On the other hand, for the remaining three tasks, the most effective training data set is `annot=en+consist`. These selections are consistent across all ten folds, and the difference is statistically significant for all but Arabic-only. The second column in Table 2 displays the MAP achieved when data selection is applied before training the baseline model.

Feature effect. To measure the impact of our novel features, we trained classifiers using either *LexCL*, *LexQL*, or *both* feature sets (Section 3.2). In these experiments, the data is fixed to the optimal subset found earlier. Results are summarized on right side of Table 2. Statistically significants improvements over *Baseline*/*Baseline+Data selection* are indicated with single/double underlining.

For Arabic-only QA, adding *LexQL* features yields greatest improvements over the baseline, while the same statement holds for *LexCL* features for the Chinese-only task. For the English-only and mixed-language tasks, the most significant increase in MAP is observed with all of our probabilistic bilingual features. For all but Arabic-only QA, the MAP is statistically significantly better ($p < 0.05$) than the baseline; for Chinese-only and mixed-language tasks, it also outperforms baseline plus data selection ($p < 0.05$).[12] All of this indicates the effectiveness of our probabilistic question translation, as well as our data selection strategy.

Task	Base	+Data	+Feats
Cmn	0.416	0.425 (*ch*)	0.451 (*LexCL*)
Arz	0.421	0.423 (*en+*)	0.425 (*LexQL*)
Eng	0.637	0.657 (*en+*)	0.660 (*all*)
Mixed	0.665	0.675 (*en+*)	0.681 (*all*)

Table 2: `L2T` evaluated using MAP with 10-fold cross-validation for each task. A statistically significant increase over Baseline/Base+Data is shown by single/double underlining ($p < 0.05$).

Understanding the contribution of each of the four *LexCL* features is also important. To gain insight, we trained a classifier using all *LexCL* features (using the optimal data subset learned earlier for each task), and then incrementally removed one of the features, and tested on the same task. This controlled experiment revealed that the *word* translation feature is most useful for Chinese-only QA (i.e., removing it produces largest drop in MAP, 0.6 points), whereas *context* translation appears to be most useful (by a slighter margin) in Arabic-only QA. In the former case, the diversity provided by word translation might be useful at increasing recall in retrieving Chinese answers. In retrieving Arabic answers, using context to disambiguate the translation might be useful at increasing precision. This result further emphasizes the importance of a customized translation approach for MLQA.

Furthermore, to test the effectiveness of the probabilistic translation approach (Section 3.1), we replaced all *LexCL* features with a single lexical similarity feature computed from the one-best question translation. This resulted in lower MAP: 0.427 to 0.423 for Arabic-only, and 0.451 to 0.425 for Chinese-only task ($p < 0.01$), supporting the hypothesis that *probabilistic translation is more effective than the widely-used one-best translation*. In fact, almost all gains in Chinese-only QA seems to be coming from the probabilistic translation.

For a robustness test, we let cross-validation select the best combination of (*data*, *feature*), mimicking a less controlled, real-world setting. In this case, the best MAP for the Arabic-, Chinese-, English-only, and Mixed-language tasks are 0.403, 0.448, 0.657, and 0.679, respectively. In all but Arabic-only, these are statistically significantly better ($p < 0.05$) than not tuning the feature set or training data (i.e., Baseline). This result suggests that our approach can be used for any MLQA task out of the box, and provide improvements.

Learning to Custom Translate (`L2CT`). We took the ranked list of answers output by each language-specific model, and merged all of them into a ranked list of mixed-language answers. For the *weighted* heuristic, we tried three values for the weight. In Table 3, we see that training separate classifiers for each subtask does not bring overall improvements to the end task. Amongst merging strategies,

[12] Note that bilingual features are not expected to help on the English-only task, and the improvements come solely from data selection.

the most effective were *weighted* (weights for each query learned by performing a grid-search on other queries) and *English first* – however, both are statistically indistinguishable from the single classifier baseline. In the latter case, the percentage of English answers is highest (88%), which might not be desirable. Depending on the application, the ratio of languages can be adjusted with an appropriate merging method. For instance, *alternate* and *norm* heuristics tend to represent languages almost equally.

Approach			(En-Ch-Ar) %	MAP
L2T			64-19-16	0.681
L2CT	Uniform		24-35-41	0.548
	Alt.		32-34-34	0.574
	Eng. First		88-6-6	0.668
	Weight	2	37-30-34	0.599
		5	51-24-25	0.654
		10	61-20-19	0.669

Table 3: L2T vs. L2CT for multilingual QA.

Even though we get lower MAP in the overall task, Table 2 suggests that it is worthwhile customizing classifiers for each subtask (e.g., the Chinese responses in the ranked list of L2CT are more relevant than *Single*.). The question of how to effectively combine the results into a mixed-language list, however, remains an open question.

5 Conclusions

We introduced L2T, a novel approach for MLQA, inspired from recent success in CLIR research. To our knowledge, this is the first use of probabilistic translation methods for this task, and the first attempt at using machine learning to learn the optimal question translation.

We also proposed L2CT, which uses language-specific classifiers to treat the ranking of English, Arabic, and Chinese answers as three separate subtasks, by applying a separate classifier for each language. While post-retrieval merging has been studied in the past, we have not come across any work that applies this idea specifically to create a language-aware ranking for MLQA.

Our experimental analysis shows the importance of data selection when dealing with annotations on source and translated text, and the effect of combining translation methods. L2T improved answer ranking effectiveness significantly for Chinese-only, English-only, and mixed-language QA.

Although results did not support the hypothesis that *learning a custom classifier* for the retrieval of each language would outperform the *single classifier* baseline, we think that more research is needed to fully understand how language-specific modeling can benefit MLQA. More sophisticated merging of multiple ranked lists of answers need to be explored. Learning to rank between answers from different languages might be more effective than heuristics. This would allow us to predict the final language ratio, based on many features (e.g., general collection statistics, quality of candidate answers, question category and complexity, MT system confidence levels) to merge question-answer pairs.

An even more comprehensive use of machine learning would be to learn word-level translation scores, instead of relying on translation probabilities from the bilingual dictionary, resulting in a fully customized translation. Similar approaches have appeared in learning-to-rank literature for monolingual IR (Bendersky et al., 2010), but not for multilingual retrieval. Another extension of this work would be to apply the same translation for translating answers into the question language (in addition to question translation). By doing this, we would be able to capture the semantics of each answer much better, since we have discussed that one-best translation discards a lot of potentially useful information.

Finally, since one of the take-away messages of our work is that a deeper understanding of linguistic context can improve QA effectiveness via more sophisticated question translation, we are hoping to see even more improvements by creating features based on word embeddings. One potential next step is to learn bilingual embeddings directly for the task of QA, for which we have started adapting some related work (Bai et al., 2010).

Acknowledgements

Jacob Devlin has provided great help in the design and implementation of the context-based question translation approach. We would also like to thank the anonymous reviewers for their helpful feedback.

Abstract

We study the problem of identifying individuals based on their characteristic gaze patterns during reading of arbitrary text. The motivation for this problem is an unobtrusive biometric setting in which a user is observed during access to a document, but no specific challenge protocol requiring the user's time and attention is carried out. Existing models of individual differences in gaze control during reading are either based on simple aggregate features of eye movements, or rely on parametric density models to describe, for instance, saccade amplitudes or word fixation durations. We develop flexible semiparametric models of eye movements during reading in which densities are inferred under a Gaussian process prior centered at a parametric distribution family that is expected to approximate the true distribution well. An empirical study on reading data from 251 individuals shows significant improvements over the state of the art.

1 Introduction

Eye-movement patterns during skilled reading consist of brief fixations of individual words in a text that are interleaved with quick eye movements called *saccades* that change the point of fixation to another word. Eye movements are driven both by low-level visual cues and high-level linguistic and cognitive processes related to text understanding; as a reflection of the interplay between vision, cognition, and motor control during reading they are frequently studied in cognitive psychology (Kliegl et al., 2006; Rayner, 1998). Computational models (Engbert et al., 2005; Reichle et al., 1998) as well as models based on machine learning (Matties and Søgaard, 2013; Hara et al., 2012) have been developed to study how gaze patterns arise based on text content and structure, facilitating the understanding of human reading processes.

A central observation in these and earlier psychological studies (Huey, 1908; Dixon, 1951) is that eye movement patterns strongly differ between individuals. Holland et al. (2012) and Landwehr et al. (2014) have developed models of individual differences in eye movement patterns during reading, and studied these models in a biometric problem setting where an individual has to be identified based on observing her eye movement patterns while reading arbitrary text. Using eye movements during reading as a biometric feature has the advantage that it suffices to observe a user during a routine access to a device or document, without requiring the user to react to a specific challenge protocol. If the observed eye movement sequence is unlikely to be generated by an authorized individual, access can be terminated or an additional verification requested. This is in contrast to approaches where biometric identification is based on eye movements in response to an artificial visual stimulus, for example a moving (Kasprowski and Ober, 2004; Komogortsev et al., 2010; Rigas et al., 2012b; Zhang and Juhola, 2012) or fixed (Bednarik et al., 2005) dot on a computer screen, or a specific image stimulus (Rigas et al., 2012a).

The model studied by Holland & Komogortsev (2012) uses aggregate features (such as average fixation duration) of the observed eye movements. Landwehr et al. (2014) showed that readers can be identified more accurately with a model that captures aspects of individual-specific distributions over

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 585–594,
Austin, Texas, November 1-5, 2016.

eye movements, such as the distribution over fixation durations or saccade amplitudes for word refixations, regressions, or next-word movements. Some of these distributions need to be estimated from very few observations; a key challenge is thus to design models that are flexible enough to capture characteristic differences between readers yet robust to sparse data. Landwehr et al. (2014) used a fully parametric approach where all densities are assumed to be in the gamma family; gamma distributions were shown to approximate the true distribution of interest well for most cases (see Figure 1). This model is robust to sparse data, but might not be flexible enough to capture all differences between readers.

The model we study in this paper follows ideas developed by Landwehr et al. (2014), but employs more flexible semiparametric density models. Specifically, we place a Gaussian process prior over densities that concentrates probability mass on densities that are close to the gamma family. Given data, a posterior distribution over densities is derived. If data is sparse, the posterior will still be sharply peaked around distributions in the gamma family, reducing the effective capacity of the model and minimizing overfitting. However, given enough evidence in the data, the model will also deviate from the gamma-centered prior—depending on the kernel function chosen for the GP prior, any density function can in principle be represented. Integrating over the space of densities weighted by the posterior yields a marginal likelihood for novel observations from which predictions are inferred. We empirically study this model in the same setting as studied by Landwehr et al. (2014), but using an order of magnitude more individuals. Identification error is reduced by more than a factor of three compared to the state of the art.

The rest of the paper is organized as follows. After defining the problem setting in Section 2, Section 3 presents the semiparametric probabilistic model. Section 4 discusses inference, Section 5 presents an empirical study on reader identification.

2 Problem Setting

Assume R different readers, indexed by $r \in \{1, \ldots, R\}$, and let $\mathcal{X} = \{\mathbf{X}_1, \ldots, \mathbf{X}_n\}$ denote a set of texts. Each $r \in \mathcal{R}$ generates a set of eye movement patterns $\mathcal{S}^{(r)} = \{\mathbf{S}_1^{(r)}, \ldots, \mathbf{S}_n^{(r)}\}$ on $\mathcal{X}$, by

$$\mathbf{S}_i^{(r)} \sim p(\mathbf{S}|\mathbf{X}_i, r, \mathbf{\Gamma})$$

where $p(\mathbf{S}|\mathbf{X}_i, r, \mathbf{\Gamma})$ is a reader-specific distribution over eye movement patterns given a text $\mathbf{X}_i$. Here, r is a variable indicating the reader generating the sequence, and $\mathbf{\Gamma}$ is a true but unknown model that defines all reader-specific distributions. We assume that $\mathbf{\Gamma}$ can be broken down into reader-specific models, $\mathbf{\Gamma} = (\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_k)$, such that the distribution

$$p(\mathbf{S}|\mathbf{X}_i, r, \mathbf{\Gamma}) = p(\mathbf{S}|\mathbf{X}_i, \boldsymbol{\gamma}_r) \tag{1}$$

is defined by the partial model $\boldsymbol{\gamma}_r$. We aggregate the observations of all readers on the training data into a variable $\mathcal{S}^{(1:R)} = (\mathcal{S}^{(1)}, \ldots, \mathcal{S}^{(R)})$.

We follow a Bayesian approach, defining a prior $p(\mathbf{\Gamma})$ over the joint model that factorizes into priors over reader-specific models, $p(\mathbf{\Gamma}) = \prod_{r=1}^{R} p(\boldsymbol{\gamma}_r)$. At test time, we observe novel eye movement patterns $\bar{\mathcal{S}} = \{\bar{\mathbf{S}}_1, \ldots, \bar{\mathbf{S}}_m\}$ on a novel set of texts $\bar{\mathcal{X}} = \{\bar{\mathbf{X}}_1, \ldots, \bar{\mathbf{X}}_m\}$ generated by an unknown reader $r \in \mathcal{R}$. We assume a uniform prior over readers, that is, each $r \in \mathcal{R}$ is equally likely to be observed at test time. The goal is to infer the most likely reader to have generated the novel eye movement patterns. In a Bayesian setting, this means inferring the most likely reader given the training observations $(\mathcal{X}, \mathcal{S}^{(1:R)})$ and test observation $(\bar{\mathcal{X}}, \bar{\mathcal{S}})$:

$$r_* = \arg\max_{r \in \mathcal{R}} p(r|\bar{\mathcal{X}}, \bar{\mathcal{S}}, \mathcal{X}, \mathcal{S}^{(1:R)}). \tag{2}$$

We can rewrite Equation 2 to

$$\begin{aligned} r_* &= \arg\max_{r \in \mathcal{R}} p(\bar{\mathcal{S}}|r, \bar{\mathcal{X}}, \mathcal{X}, \mathcal{S}^{(1:R)}) && (3) \\ &= \arg\max_{r \in \mathcal{R}} \int p(\bar{\mathcal{S}}|r, \bar{\mathcal{X}}, \mathbf{\Gamma}) p(\mathbf{\Gamma}|\mathcal{X}, \mathcal{S}^{(1:R)}) \mathrm{d}\mathbf{\Gamma} \\ &= \arg\max_{r \in \mathcal{R}} \int p(\bar{\mathcal{S}}|\bar{\mathcal{X}}, \boldsymbol{\gamma}_r) p(\boldsymbol{\gamma}_r|\mathcal{X}, \mathcal{S}^{(r)}) \mathrm{d}\boldsymbol{\gamma}_r && (4) \end{aligned}$$

where

$$p(\bar{\mathcal{S}}|\bar{\mathcal{X}}, \boldsymbol{\gamma}_r) = \prod_{i=1}^{m} p(\bar{\mathbf{S}}_i|\bar{\mathbf{X}}_i, \boldsymbol{\gamma}_r) \tag{5}$$

$$p(\boldsymbol{\gamma}_r|\mathcal{X}, \mathcal{S}^{(r)}) \propto p(\boldsymbol{\gamma}_r) \prod_{i=1}^{n} p(\mathbf{S}_i^{(r)}|\mathbf{X}_i, \boldsymbol{\gamma}_r). \tag{6}$$

In Equation 3 we exploit that readers are uniformly chosen at test time, and in Equation 4 we exploit the factorization $p(\boldsymbol{\Gamma}) = \prod_{r=1}^{R} p(\boldsymbol{\gamma}_r)$ of the prior, which together with Equation 1 entails a factorization $p(\boldsymbol{\Gamma}|\mathcal{X}, \mathcal{S}^{(1:R)}) = \prod_{r=1}^{R} p(\boldsymbol{\gamma}_r|\mathcal{X}, \mathcal{S}^{(r)})$ of the posterior. Note that Equation 4 states that at test time we predict the reader r for which the marginal likelihood (that is, after integrating out the reader-specific model γ_r) of the test observations is highest. The next section discusses the reader-specific models $p(\mathbf{S}|\mathbf{X}, \boldsymbol{\gamma}_r)$ and prior distributions $p(\boldsymbol{\gamma}_r)$.

3 Probabilistic Model

The probabilistic model we employ follows the general structure proposed by Landwehr et al. (2014), but employs semiparametric density models and allows for fully Bayesian inference. To reduce notational clutter, let $\boldsymbol{\gamma} \in \{\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_R\}$ denote a particular reader-specific model, and let $\mathbf{X} \in \mathcal{X}$ denote a text. An eye movement pattern is a sequence $\mathbf{S} = ((s_1, d_1), \ldots, (s_T, d_T))$ of gaze fixations, consisting of a fixation position s_t (position in text that was fixated) and duration $d_t \in \mathbb{R}$ (length of fixation in milliseconds). In our experiments, individual sentences are presented in a single line on screen, thus we only model a horizontal gaze position $s_t \in \mathbb{R}$. We model $p(\mathbf{S}|\mathbf{X}, \boldsymbol{\gamma})$ as a dynamic process that successively generates fixation positions s_t and durations d_t in $\mathbf{S}$, reflecting how a reader generates a sequence of saccades in response to a text stimulus $\mathbf{X}$:

$$p(\mathbf{S}|\mathbf{X}, \boldsymbol{\gamma}) = p(s_1, d_1|\mathbf{X}, \boldsymbol{\gamma}) \prod_{t=2}^{T} p(s_t, d_t|s_{t-1}, \mathbf{X}, \boldsymbol{\gamma}),$$

where $p(s_t, d_t|s_{t-1}, \mathbf{X}, \boldsymbol{\gamma})$ models the generation of the next fixation position and duration given the old fixation position s_{t-1}. In the psychological literature, four different *saccade types* are distinguished: a reader can refixate the current word (*refixation*), fixate the next word in the text (*next word movement*), move the fixation to a word after the next word, that is, skip one or more words (*forward skip*), or regress to fixate a word occurring earlier in the text (*regression*), see, e.g., Heister et al. (2012). We observe empirically that for each saccade type, there is a characteristic distribution over saccade amplitudes and fixation durations, and that both approximately follow gamma distributions—see Figure 1. We therefore model $p(s_t, d_t|s_{t-1}, \mathbf{X}, \boldsymbol{\gamma})$ using a mixture over distributions for the four different saccade types. At each time t, the model first draws a saccade type $u_t \in \{1, 2, 3, 4\}$, and then draws a saccade amplitude a_t and fixation duration d_t from type-specific distributions $p(a|u_t, s_{t-1}, \mathbf{X}, \boldsymbol{\gamma})$ and $p(d|u_t, \boldsymbol{\gamma})$. More formally,

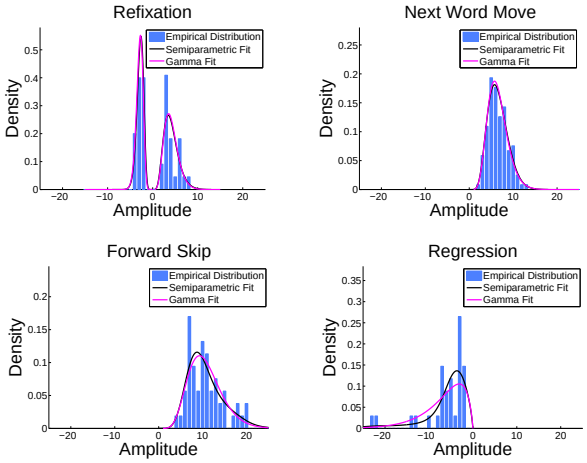

Figure 1: Empirical distributions of saccade amplitudes in training data for first individual, with fitted Gamma distributions and semiparametric distribution fits.

$$u_t \sim p(u|\boldsymbol{\pi}) \tag{7}$$
$$a_t \sim p(a|u_t, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha}) \tag{8}$$
$$d_t \sim p(d|u_t, \boldsymbol{\delta}), \tag{9}$$

where $\boldsymbol{\gamma} = (\boldsymbol{\pi}, \boldsymbol{\alpha}, \boldsymbol{\delta})$ is decomposed into components $\boldsymbol{\pi}$, $\boldsymbol{\alpha}$, and $\boldsymbol{\delta}$. Afterwards, the model updates the fixation position according to $s_t = s_{t-1} + a_t$, concluding the definition of $p(s_t, d_t|s_{t-1}, \mathbf{X}, \boldsymbol{\gamma})$. Figure 2 shows a slice in the dynamical model.

The distribution $p(u|\boldsymbol{\pi})$ over saccade types (Equation 7) is multinomial with parameter vector $\boldsymbol{\pi} \in \mathbb{R}^4$. The distributions over amplitudes and durations (Equations 8 and 9) are modeled semiparametrically as discussed in the following subsections.

3.1 Model of Saccade Amplitudes

We first discuss the amplitude model $p(a|u_t, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha})$ (Equation 8). We first define a distribution $p(a|u_t, \boldsymbol{\alpha})$ over amplitudes for saccade type u_t, and subsequently discuss conditioning on the text $\mathbf{X}$ and old fixation position s_{t-1},

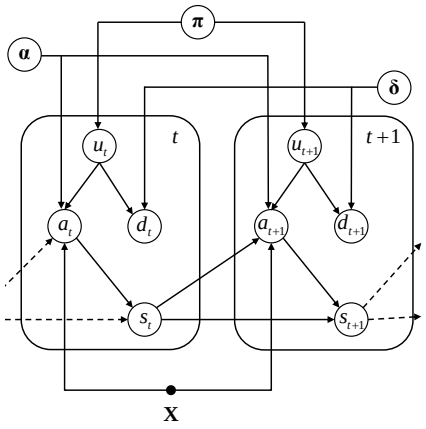

Figure 2: Plate notation of of a slice in the dynamic model.

leading to $p(a|u_t, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha})$. We define

$$p(a|u_t = 1, \boldsymbol{\alpha}) = \begin{cases} \mu\alpha_1(a) & : a > 0 \\ (1-\mu)\bar{\alpha}_1(-a) & : a \leq 0 \end{cases} \quad (10)$$

where μ is a mixture weight and α_1, $\bar{\alpha}_1$ are densities defining the distribution over positive and negative amplitudes for the saccade type *refixation*, and

$$p(a|u_t = 2, \boldsymbol{\alpha}) = \alpha_2(a) \quad (11)$$

$$p(a|u_t = 3, \boldsymbol{\alpha}) = \alpha_3(a) \quad (12)$$

$$p(a|u_t = 4, \boldsymbol{\alpha}) = \alpha_4(-a) \quad (13)$$

where $\alpha_2(a)$, $\alpha_3(a)$, and $\alpha_4(a)$ are densities defining the distribution over amplitudes for the remaining saccade types. Finally, the distribution

$$p(s_1|\mathbf{X}, \boldsymbol{\alpha}) = \alpha_0(s_1) \quad (14)$$

over the initial fixation position is given by another density function α_0. The variables μ, α_0, α_1, $\bar{\alpha}_1$, α_2, α_3, and α_4 are aggregated into model component $\boldsymbol{\alpha}$. For resolving the most likely reader at test time (Equation 4), densities in $\boldsymbol{\alpha}$ will be integrated out under a prior based on Gaussian processes (Section 3.3) using MCMC inference (Section 4).

Given the old fixation position s_{t-1}, the text $\mathbf{X}$, and the chosen saccade type u_t, the amplitude is constrained to fall within a specific interval. For instance, for a refixation the amplitude has to be chosen such that the novel fixation position lies within the beginning and the end of the currently fixated word; a regression implies an amplitude that is negative and makes the novel fixation position lie before the beginning of the currently fixated word. These constraints imposed by the text structure define the conditional distribution $p(a|u_t, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha})$. More formally, $p(a|u_t, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha})$ is the distribution $p(a|u_t, \boldsymbol{\alpha})$ conditioned on $a \in [l, r]$, that is,

$$p(a|u_t, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha}) = p(a|a \in [l, r], u_t, \boldsymbol{\alpha}),$$

where l and r are the minimum and maximum amplitude consistent with the constraints. Recall that for a distribution over a continuous variable x given by density $\alpha(x)$, the distribution over x conditioned on $x \in [l, r]$ is given by the truncated density

$$\alpha(x|x \in [l, r]) = \begin{cases} \frac{\alpha(x)}{\int_l^r \alpha(\bar{x})\mathrm{d}\bar{x}} & : x \in [l, r] \\ 0 & : x \notin [l, r]. \end{cases} \quad (15)$$

We derive $p(a|u_t, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha})$ by truncating the distributions given by Equations 10 to 13 to the minimum and maximum amplitude consistent with the current fixation position s_{t-1} and text $\mathbf{X}$. Let w_l° (w_r°) denote the position of the left-most (right-most) character of the currently fixated word, and let w_l^+, w_r^+ denote these positions for the next word in $\mathbf{X}$. Let furthermore $l^\circ = w_l^\circ - s_{t-1}$, $r^\circ = w_r^\circ - s_{t-1}$, $l^+ = w_l^+ - s_{t-1}$, and $r^+ = w_r^+ - s_{t-1}$. Then

$$p(a|u_t = 1, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha}) = \begin{cases} \mu\alpha_1(a|a \in [0, r^\circ]) : a > 0 \\ (1-\mu)\bar{\alpha}_1(-a|a \in [l^\circ, 0]) : a \leq 0 \end{cases} \quad (16)$$

$$p(a|u_t = 2, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha}) = \alpha_2(a|a \in [l^+, r^+]) \quad (17)$$

$$p(a|u_t = 3, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha}) = \alpha_3(a|a \in (r^+, \infty)) \quad (18)$$

$$p(a|u_t = 4, s_{t-1}, \mathbf{X}, \boldsymbol{\alpha}) = \alpha_4(-a|a \in (-\infty, l^\circ)) \quad (19)$$

defines the appropriately truncated distributions.

3.2 Model of Fixation Durations

The model for fixation durations (Equation 9) is similarly specified by saccade type-specific densities,

$$p(d|u_t = u, \boldsymbol{\delta}) = \delta_u(d) \quad \text{for } u \in \{1, 2, 3, 4\} \quad (20)$$

and a density for the initial fixation durations

$$p(d_1|\mathbf{X}, \boldsymbol{\delta}) = \delta_0(d_1) \quad (21)$$

where $\delta_0, ..., \delta_4$ are aggregated into model component $\boldsymbol{\delta}$. Unlike saccade amplitude, the fixation duration is not constrained by the text structure and accordingly densities are not truncated. This concludes the definition of the model $p(\mathbf{S}|\mathbf{X}, \boldsymbol{\gamma})$.

3.3 Prior Distributions

The prior distribution over the entire model $\boldsymbol{\gamma}$ factorizes over the model components as

$$p(\boldsymbol{\gamma}|\lambda,\rho,\kappa) = \tag{22}$$
$$p(\boldsymbol{\pi}|\lambda)p(\mu|\rho)p(\bar{\alpha}_1|\kappa)\prod_{i=0}^{4}p(\alpha_i|\kappa)\prod_{i=0}^{4}p(\delta_i|\kappa)$$

where $p(\boldsymbol{\pi}) = \mathrm{Dir}(\boldsymbol{\pi}|\lambda)$ is a symmetric Dirichlet prior and $p(\mu) = \mathrm{Beta}(\mu|\rho)$ is a Beta prior. The key challenge is to develop appropriate priors for the densities defining saccade amplitude $(p(\bar{\alpha}_1|\kappa), p(\alpha_i|\kappa))$ and fixation duration $(p(\delta_i|\kappa))$ distributions. Empirically, we observe that amplitude and duration distributions tend to be close to gamma distributions—see the example in Figure 1.

Our goal is to exploit the prior knowledge that distributions tend to be closely approximated by gamma distributions, but allow the model to deviate from the gamma assumption in case there is enough evidence in the data. To this end, we define a prior over densities that concentrates probability mass around the gamma family. For all densities $f \in \{\bar{\alpha}_1, \alpha_0, ..., \alpha_4, \delta_0, ..., \delta_4\}$, we employ identical prior distributions $p(f|\kappa)$. Intuitively, the prior is given by first drawing a density function from the gamma family and then drawing the final density from a Gaussian process (with covariance function κ) centered at this function. More formally, let

$$\mathcal{G}(x|\boldsymbol{\eta}) = \frac{\exp(\boldsymbol{\eta}^\mathsf{T}\mathbf{u}(x))}{\int \exp(\boldsymbol{\eta}^\mathsf{T}\mathbf{u}(x'))\mathrm{d}x'} \tag{23}$$

denote the gamma distribution in exponential family form, with sufficient statistics $\mathbf{u}(x) = (\log(x), x)^\mathsf{T}$ and parameters $\boldsymbol{\eta} = (\eta_1, \eta_2)$. Let $p(\boldsymbol{\eta})$ denote a prior over the gamma parameters, and define

$$p(f|\kappa) = \int p(\boldsymbol{\eta})p(f|\boldsymbol{\eta},\kappa)\mathrm{d}\boldsymbol{\eta} \tag{24}$$

where $p(f|\boldsymbol{\eta},\kappa)$ is given by drawing

$$g \sim \mathcal{GP}(0,\kappa) \tag{25}$$

from a Gaussian process prior $\mathcal{GP}(0,\kappa)$ with mean zero and covariance function κ, and letting

$$f(x) = \frac{\exp(\boldsymbol{\eta}^\mathsf{T}\mathbf{u}(x) + g(x))}{\int \exp(\boldsymbol{\eta}^\mathsf{T}\mathbf{u}(x') + g(x'))\mathrm{d}x'}. \tag{26}$$

Note that decreasing the variance of the Gaussian process means regularizing $g(x)$ towards zero, and therefore Equation 26 towards Equation 23. This concludes the specification of the prior $p(\boldsymbol{\gamma}|\lambda,\rho,\kappa)$.

The density model defined by Equations 24 to 26 draws on ideas from the large body of literature on GP-based density estimation, for example by Adams et al. (2009), Leonard (1978), or Tokdar et al. (2010), and semiparametric density estimation, e.g. as discussed by Yang (2009), Lenk (2003) or Hjort & Glad (1995). However, note that existing density estimation approaches are not applicable off-the-shelf as in our domain distributions are truncated differently at each observation due to constraints that arise from the way eye movements interact with the text structure (Equations 16 to 19).

4 Inference

To solve Equation 4, we need to integrate for each $r \in \mathcal{R}$ over the reader-specific model $\boldsymbol{\gamma}_r$. To reduce notational clutter, let $\boldsymbol{\gamma} \in \{\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_R\}$ denote a reader-specific model, and let $\mathcal{S} \in \{\mathcal{S}^{(1)}, \ldots, \mathcal{S}^{(R)}\}$ denote the eye movement observations of that reader on the training texts $\mathcal{X}$. We approximate

$$\int p(\bar{\mathcal{S}}|\bar{\mathcal{X}},\boldsymbol{\gamma})p(\boldsymbol{\gamma}|\mathcal{X},\mathcal{S})\mathrm{d}\boldsymbol{\gamma} \approx \frac{1}{K}\sum_{k=1}^{K}p(\bar{\mathcal{S}}|\bar{\mathcal{X}},\boldsymbol{\gamma}^{(k)})$$

by a sample $\boldsymbol{\gamma}^{(1)}, \ldots, \boldsymbol{\gamma}^{(K)}$ of models drawn by

$$\boldsymbol{\gamma}^{(k)} \sim p(\boldsymbol{\gamma}|\mathcal{X},\mathcal{S},\lambda,\rho,\kappa),$$

where $p(\boldsymbol{\gamma}|\mathcal{X},\mathcal{S},\lambda,\rho,\kappa)$ is the posterior as given by Equation 6 but with the dependence on the prior hyperparameters λ,ρ,κ made explicit. Note that with $\mathcal{X}$ and $\mathcal{S}$, all saccade types u_t are observed. Together with the factorizing prior (Equation 22), this means that the posterior factorizes according to

$$p(\boldsymbol{\gamma}|\mathcal{X},\mathcal{S},\lambda,\rho,\kappa) = p(\boldsymbol{\pi}|\mathcal{X},\mathcal{S},\lambda)p(\mu|\mathcal{X},\mathcal{S},\rho)$$
$$\cdot\, p(\bar{\alpha}_1|\mathcal{X},\mathcal{S},\kappa)\prod_{i=0}^{4}p(\alpha_i|\mathcal{X},\mathcal{S},\kappa)\prod_{i=0}^{4}p(\delta_i|\mathcal{X},\mathcal{S},\kappa)$$

as is easily seen from the graphical model in Figure 2. Obtaining samples $\boldsymbol{\pi}^{(k)} \sim p(\boldsymbol{\pi}|\mathcal{X},\mathcal{S})$ and $\mu^{(k)} \sim p(\mu|\mathcal{X},\mathcal{S})$ is straightforward because their prior distributions are conjugate to the likelihood terms. Let now $f \in \{\bar{\alpha}_1, \alpha_0, ..., \alpha_4, \delta_0, ..., \delta_4\}$

denote a particular density in the model. The posterior $p(f|\mathcal{X}, \mathcal{S}, \kappa)$ is proportional to the prior $p(f|\kappa)$ (Equation 24) multiplied by the likelihood of all observations that are generated by this density, that is, that are generated according to Equation 14, 16, 17, 18, 19, 20, or 21. Let $\mathbf{y} = (y_1, \ldots, y_{|\mathbf{y}|})^\mathsf{T} \in \mathbb{R}^{|\mathbf{y}|}$ denote the vector of all observations generated from density f, and let $\mathbf{l} = (l_1, \ldots, l_{|\mathbf{l}|})^\mathsf{T} \in \mathbb{R}^{|\mathbf{l}|}$, $\mathbf{r} = (r_1, \ldots, r_{|\mathbf{r}|})^\mathsf{T} \in \mathbb{R}^{|\mathbf{r}|}$ denote the corresponding left and right boundaries of the truncation intervals (again see Equations 14 to 21), where for densities that are not truncated we take $l_i = 0$ and $r_i = \infty$ throughout. Then the likelihood of the observations generated from f is

$$p(\mathbf{y}|f, \mathbf{l}, \mathbf{r}) = \prod_{i=1}^{|\mathbf{y}|} f(y_i | y_i \in [l_i, r_i]) \qquad (27)$$

and the posterior over f is given by

$$p(f|\mathcal{X}, \mathcal{S}, \kappa) \propto p(f|\kappa) p(\mathbf{y}|f, \mathbf{l}, \mathbf{r}). \qquad (28)$$

Note that $\mathbf{y}$, $\mathbf{l}$ and $\mathbf{r}$ are observable from $\mathcal{X}$, $\mathcal{S}$.

We obtain samples from the posterior given by Equation 28 from a Metropolis-Hastings sampler that explores the space of densities $f : \mathbb{R} \to \mathbb{R}$, generating density samples $f^{(1)}, ..., f^{(K)}$. A density f is given by a combination of gamma parameters $\boldsymbol{\eta} \in \mathbb{R}^2$ and function $g : \mathbb{R} \to \mathbb{R}$; specifically, f is obtained by multiplying the gamma distribution with parameters $\boldsymbol{\eta}$ by $\exp(g)$ and normalizing appropriately (Equation 26). During sampling, we explicitly represent a density sample $f^{(k)}$ by its gamma parameters $\boldsymbol{\eta}^{(k)}$ and function $g^{(k)}$. The proposal distribution of the Metropolis-Hastings sampler is

$$q(\boldsymbol{\eta}^{(k+1)}, g^{(k+1)} | \boldsymbol{\eta}^{(k)}, g^{(k)}) = p(g^{(k+1)}|\kappa) \mathcal{N}(\boldsymbol{\eta}^{(k+1)} | \boldsymbol{\eta}^{(k)}, \sigma^2 \mathbf{I})$$

where $p(g^{(k+1)}|\kappa)$ is the probability of $g^{(k+1)}$ according to the GP prior $\mathcal{GP}(0, \kappa)$ (Equation 25), and $\mathcal{N}(\boldsymbol{\eta}^{(k+1)} | \boldsymbol{\eta}^{(k)}, \sigma^2 \mathbf{I})$ is a symmetric proposal that randomly perturbs the old state $\boldsymbol{\eta}^{(k)}$ according to a Gaussian. In every iteration k a proposal $\boldsymbol{\eta}^\star, g^\star \sim q(\boldsymbol{\eta}, g | \boldsymbol{\eta}^{(k)}, g^{(k)})$ is drawn based on the old state $(\boldsymbol{\eta}^{(k)}, g^{(k)})$. The acceptance probability is $A(\boldsymbol{\eta}^\star, g^\star | \boldsymbol{\eta}^{(k)}, g^{(k)}) = \min(1, Q)$ with

$$Q = \frac{q(\boldsymbol{\eta}^{(k)}, g^{(k)} | \boldsymbol{\eta}^\star, g^\star) p(\boldsymbol{\eta}^\star) p(g^\star|\kappa) p(\mathbf{y}|f^\star, \mathbf{l}, \mathbf{r})}{q(\boldsymbol{\eta}^\star, g^\star | \boldsymbol{\eta}^{(k)}, g^{(k)}) p(\boldsymbol{\eta}^{(k)}) p(g^{(k)}|\kappa), p(\mathbf{y}|f^{(k)}, \mathbf{l}, \mathbf{r})}.$$

Here, $p(\boldsymbol{\eta}^\star)$ is the prior probability of gamma parameters $\boldsymbol{\eta}^\star$ (Section 3.3) and $p(\mathbf{y}|f^\star, \mathbf{l}, \mathbf{r})$ is given by Equation 27 where $f^\star$ is obtained from $\boldsymbol{\eta}^\star$, $g^\star$ according to Equation 26.

To compute the likelihood terms $p(\mathbf{y}|f^{(k)}, \mathbf{l}, \mathbf{r})$ (Equation 27) and also to compute the likelihood of test data under a model (Equation 5), the density $f : \mathbb{R} \to \mathbb{R}$ needs to be evaluated. According to Equation 26, f is represented by parameter vector $\boldsymbol{\eta}$ together with the nonparametric function $g : \mathbb{R} \to \mathbb{R}$. As usual when working with distributions over functions in a Gaussian process framework, the function g only needs to be represented at those points for which we need to evaluate it. Clearly, this includes all observations of saccade amplitudes and fixation durations observed in the training and test set. However, we also need to evaluate the normalizer in Equation 26, and (for $f \in \{\alpha_1, \bar{\alpha}_1, \alpha_2, \alpha_3, \alpha_4\}$) the additional normalizer required when truncating the distribution (see Equation 15). As these integrals are one-dimensional, they can be solved relatively accurately using numerical integration; we use 2-point Newton-Cotes quadrature. Newton-Cotes integration requires the evaluation (and thus representation) of g at an additional set of equally spaced supporting points.

When the set of test observations $\bar{\mathcal{S}}, \bar{\mathcal{X}}$ is large, the need to evaluate $p(\bar{\mathcal{S}}|\bar{\mathcal{X}}, \boldsymbol{\gamma}^{(k)})$ for all $\boldsymbol{\gamma}_k$ and all test observations leads to computational challenges. In our experiments, we use a heuristic to reduce computational load. While generating samples, densities are only represented at the training observations and the supporting points needed for Newton-Cotes integration. We then estimate the mean of the posterior by $\hat{\boldsymbol{\gamma}} = \frac{1}{K} \sum_{k=1}^K \boldsymbol{\gamma}^{(k)}$, and approximate $\frac{1}{K} \sum_{k=1}^K p(\bar{\mathcal{S}}|\bar{\mathcal{X}}, \boldsymbol{\gamma}^{(k)}) \approx p(\bar{\mathcal{S}}|\bar{\mathcal{X}}, \hat{\boldsymbol{\gamma}})$. To evaluate $p(\bar{\mathcal{S}}|\bar{\mathcal{X}}, \hat{\boldsymbol{\gamma}})$, we infer the approximate value of the density $\hat{\boldsymbol{\gamma}}$ at a test observation by linearly interpolating based on the available density values at the training observations and supporting points.

5 Empirical Study

We conduct a large-scale study of biometric identification performance using the same setup as discussed by Landwehr et al. (2014) but a much larger set of individuals (251 rather than 20).

Eye movement records for 251 individuals are

obtained from an EyeLink II system with a 500-Hz sampling rate (SR Research, Ongoode, Ontario, Canada) while reading sentences from the *Potsdam Sentence Corpus* (Kliegl et al., 2006). There are 144 sentences in the corpus, which we split into equally sized sets of training and test sentences. Individuals read between 100 and 144 sentences, the training (testing) observations for one individual are the observations on those sentences in the training (testing) set of sentences that the individual has read. Results are averaged over 10 random train-test splits. Each sentence is shown as a single line on the screen.

We study the semiparametric model discussed in Section 3 with MCMC inference as presented in Section 4 (denoted *Semiparametric*[1]). We employ a squared exponential covariance function $\kappa(x, x') = \alpha \exp\left(-\frac{\|x-x'\|^2}{2\sigma^2}\right)$, where the multiplicative constant α is tuned on the training data by cross-validation and the bandwidth σ is set to the average distance between points in the training data. The Beta and Dirichlet parameters λ and ρ are set to one (Laplace smoothing), the prior $p(\boldsymbol{\eta})$ for the Gamma parameters is uninformative. We use backoff-smoothing as discussed by Landwehr et al. (2014). We initialize the sampler with the maximum-likelihood Gamma fit and perform 10000 sampling iterations, 5000 of which are burn-in iterations. As a baseline, we study the model by Landwehr et al. (2014) (*Landwehr et al.*) and simplified versions proposed by them that only use saccade type and amplitude (*Landwehr et al. (TA)*) or saccade type (*Landwehr et al. (T)*). We also study the weighted and unweighted version of the feature-based model of Holland & Komogortsev (2012) with a feature set adapted to the Potsdam Sentence Corpus data as described in Landwehr et al. (2014).

We note that there are two recent extensions of the feature-based model (by Rigas et al. (2016) and Abdulin & Komogortsev (2015)) that are unfortunately not applicable in our empirical setting but might yield improved results in other scenarios. Rigas et al. (2016) study a model that is focused on representing reader-specific differences in saccadic vigor and acceleration, which are both derived from the dynamics of saccadic velocity. In the preprocessed data set that we use, saccadic velocities are not available, therefore we do not make use of velocities in our model and cannot easily compare against their model. Abdulin & Komogortsev (2015) study a model that is based on features that relate eye move-

ments to the 2D text structure, that is, to the way words are arranged into lines in a text. As in our empirical study each sentence is presented as a single line on screen, this 2D structure does not exist. Moreover, Abdulin & Komogortsev (2015) only report accuracy improvements for their method in a setting where individuals have to be identified in the future based on data collected in the past (*aging test*), which is not the focus of our study.

We first study multiclass identification accuracy. All test observations of one particular individual constitute one test example; the task is to infer the individual that has generated these test observations. Multiclass identification accuracy is the fraction of cases in which the correct individual is identified. Table 1 shows multiclass identification accuracy for all methods, including variants of *Semiparametric* discussed below. We observe that *Semiparametric* outperforms *Landwehr et al.*, reducing the error by more than a factor of three. Consistent with results reported in Landwehr et al. (2014), *Holland & K. (unweighted)* is less accurate than *Landwehr et al.*, but more accurate than the simplified variants. We next study how the amount of data available at test time—that is, the amount of time we can observe a reader before having to make a decision—influences accuracy. Figure 3 (left) shows identification accuracy as a function of the fraction of test data available, obtained by randomly removing a fraction of sentences from the test set. We observe that identification accuracy steadily improves with more test observations for all methods. Figure 3 (right) shows identification accuracy when varying the number R of individuals that need to be distinguished. We randomly draw a subset of R individuals from the set

of 251 individuals, and perform identification based on only these individuals. Results are averaged over 10 such random draws. As expected, accuracy improves if fewer individuals need to be distinguished.

We next study a binary setting in which for each individual and each set of test observations a decision has to be made whether or not the test observations have been generated by that individual. This setting more closely matches typical use cases for the deployment of a biometric system. Let $\bar{\mathcal{X}}$ denote the text being read at test time, and let $\bar{\mathcal{S}}$ denote the observed eye movement sequences. Our model infers for each reader $r \in \mathcal{R}$ the marginal likelihood $p(\bar{\mathcal{S}}|r, \bar{\mathcal{X}}, \mathcal{X}, \mathcal{S}^{(1:R)})$ of the eye movement observations under the reader-specific model (Equation 3). The binary decision is made by dividing this marginal likelihood by the average marginal likelihood assigned to the observations by all reader-specific models, and comparing the result to a threshold τ. Figure 4 shows the fraction of false accepts as a function of false rejects as the threshold τ is varied, averaged over all individuals. The *Landwehr et al.* model and variants also assign a

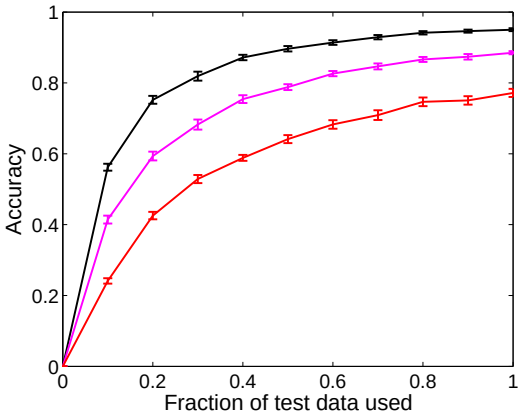

Figure 6: Multiclass accuracy over number of test observations with standard errors for *Semiparametric* variants.

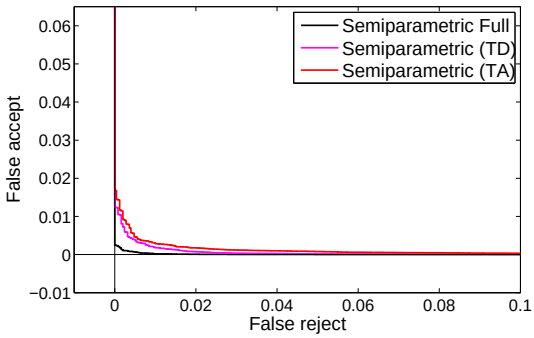

Figure 7: False-accept over false-reject rate when varying τ for the *Semiparametric* variants.

reader-specific likelihood to novel test observations; we compute the same statistics again by normalizing the likelihood and comparing to a threshold τ. Finally, *Holland & K. (unweighted)* and *Holland & K. (weighted)* compute a similarity measure for each combination of individual and set of test observations, which we normalize and threshold analogously. We observe that *Semiparametric* accomplishes a false-reject rate of below 1% at virtually no false accepts; *Landwehr et al.* and variants tend to perform better than *Holland & K. (unweighted)* and *Holland & K. (weighted)*. Table 2 shows the error under the curve for the experiment shown in Figure 4, as well as for variants of *Semiparametric* discussed below.

We finally study the contribution of the individual model components for saccade type, saccade amplitude, and fixation duration (see Figure 2) by removing the corresponding model components, as in Landwehr et al. (2014). By *Semiparametric (TD)* we denote a variant of *Semiparametric* in which the variable a_t and the corresponding distribution is removed, that is, only the distribution over the saccade type and duration is modeled. *Semiparametric (TA)* denotes a variant in which the variable d_t and the corresponding distribution is removed. Figure 6 shows identification accuracy as a function of the fraction of test data available for model variants *Semiparametric (TD)* and *Semiparametric (TA)* in comparison to *Semiparametric*; results for these variants are also included in Table 1. Figure 7 shows the fraction of false accepts as a function of false rejects in the binary classification setting discussed above for these two model variants; Table 2 includes area under the curve results for the experiment shown in Figure 7. We observe that accuracy is substantially reduced when removing any model component. Note that if both the amplitude and duration components of the model are removed, it becomes identical to the model *Landwehr et al. (T)*.

Training the joint model for all 251 individuals takes 46 hours on a single eight-core CPU (Intel Xeon E5520, 2.27GHz); predicting the most likely individual to have generated a set of 72 test sentences takes less than 2 seconds.

6 Conclusions

We have studied the problem of identifying readers unobtrusively during reading of arbitrary text. For fitting reader-specific distributions, we employ a Bayesian semiparametric approach that infers densities under a Gaussian process prior centered at the gamma family of distributions, striking a balance between robustness to sparse data and modeling flexibility. In an empirical study with 251 individuals, the model was shown to reduce identification error by more than a factor of three compared to earlier approaches to reader identification proposed by Landwehr et al. (2014) and Holland & Komogortsev (2012).

Inducing Domain-Specific Sentiment Lexicons from Unlabeled Corpora

William L. Hamilton, Kevin Clark, Jure Leskovec, Dan Jurafsky
Department of Computer Science, Stanford University, Stanford CA, 94305
wleif,kevclark,jure,jurafsky@stanford.edu

Abstract

A word's sentiment depends on the domain in which it is used. Computational social science research thus requires sentiment lexicons that are specific to the domains being studied. We combine domain-specific word embeddings with a label propagation framework to induce accurate domain-specific sentiment lexicons using small sets of seed words, achieving state-of-the-art performance competitive with approaches that rely on hand-curated resources. Using our framework we perform two large-scale empirical studies to quantify the extent to which sentiment varies across time and between communities. We induce and release historical sentiment lexicons for 150 years of English and community-specific sentiment lexicons for 250 online communities from the social media forum Reddit. The historical lexicons show that more than 5% of sentiment-bearing (non-neutral) English words completely switched polarity during the last 150 years, and the community-specific lexicons highlight how sentiment varies drastically between different communities.

1 Introduction

Inducing domain-specific sentiment lexicons is crucial to computational social science (CSS) research. Sentiment lexicons allow us to analyze key subjective properties of texts like opinions and attitudes (Taboada et al., 2011). But lexical sentiment is hugely influenced by context. The word *soft* has a very different sentiment in an online sports community than it does in one dedicated to toy animals (Figure 1). *Terrific* once had a highly negative connotation; now it is essentially synonymous with *good* (Figure 2). Without domain-specific lexicons, social scientific analyses can be misled by sentiment assignments biased towards domain-general contexts, neglecting factors like genre, community-specific vernacular, or demographic variation (Deng et al., 2014; Hovy, 2015; Yang and Eisenstein, 2015).

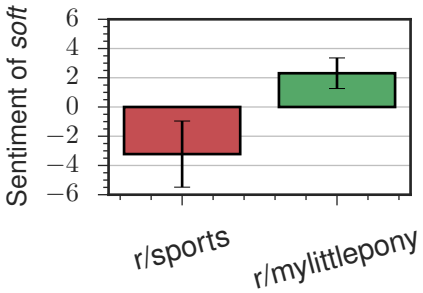

Figure 1: The sentiment of *soft* in different online communities. Sentiment values computed using SENTPROP (Section 3) on comments from Reddit communities illustrate how sentiment depends on social context. Bootstrap-sampled standard deviations provide a measure of confidence with the scores.

Using experts or crowdsourcing to construct domain-specific sentiment lexicons is expensive and often time-consuming (Mohammad and Turney, 2010; Fast et al., 2016), and is especially problematic when non-standard language (as in historical documents or obscure social media forums) prevents annotators from understanding the sociolinguistic context of the data.

Web-scale sentiment lexicons can be automatically induced for large socially-diffuse domains, such as the internet-at-large (Velikovich et al., 2010) or all of Twitter (Tang et al., 2014). However, to study sentiment in domain-specific cases—financial documents, historical texts, or tight-knit social me-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 595–605,
Austin, Texas, November 1-5, 2016.

dia forums—such generic lexicons may be inaccurate, and even introduce harmful biases (Loughran and McDonald, 2011).[1] Researchers need a principled and accurate framework for inducing lexicons that are specific to their domain of study.

To meet these needs, we introduce SENTPROP, a framework to learn accurate sentiment lexicons from small sets of seed words and domain-specific corpora. SENTPROP combines the well-known method of label propagation with advances in word embeddings, and unlike previous approaches, is designed to be accurate even when using modestly-sized domain-specific corpora ($\sim 10^7$ tokens). Our framework also provides *confidence scores* along with the learned lexicons, which allows researchers to quantify uncertainty in a principled manner.

The key contributions of this work are:

1. A simple state-of-the-art sentiment induction algorithm, combining high-quality word vector embeddings with a label propagation approach.
2. A novel bootstrap-sampling framework for inferring confidence scores with the sentiment values.
3. Two large-scale studies that reveal how sentiment depends on both social and historical context.
   (a) We induce community-specific sentiment lexicons for the largest 250 "subreddit" communities on the social-media forum Reddit, revealing substantial variation in word sentiment between communities.
   (b) We induce historical sentiment lexicons for 150 years of English, revealing that $>5\%$ of words switched polarity during this time.

To the best of our knowledge, this is the first work to systematically analyze the domain-dependency of sentiment at a large-scale, across hundreds of years and hundreds of user-defined online communities.

All of the inferred lexicons along with code for SENTPROP and all methods evaluated are made available in the SOCIALSENT package released with this paper.[2] The SOCIALSENT package provides a benchmark toolkit for inducing sentiment lexicons, including implementations of previously published algorithms (Velikovich et al., 2010; Rothe et al., 2016), which are not otherwise publicly available.

[2] http://nlp.stanford.edu/projects/socialsent

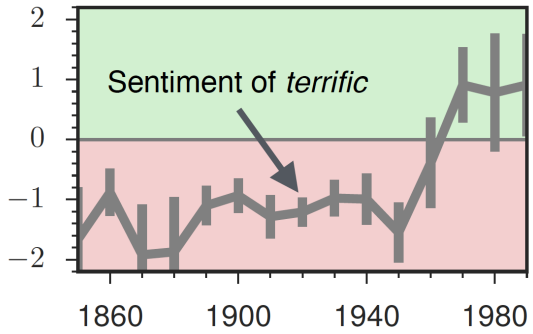

Figure 2: The sentiment of *terrific* changed from negative to positive over the last 150 years. Sentiment values and bootstrapped confidences were computed using SENTPROP on historical data (see Section 6).

2 Related work

Our work builds upon a wealth of previous research on inducing sentiment lexicons, along two threads:

Corpus-based approaches use seed words and patterns in unlabeled corpora to induce domain-specific lexicons. These patterns may rely on syntactic structures (Hatzivassiloglou and McKeown, 1997; Jijkoun et al., 2010; Rooth et al., 1999; Thelen and Riloff, 2002; Widdows and Dorow, 2002), which can be domain-specific and brittle (e.g., in social media lacking usual grammatical structures). Other models rely on general co-occurrence (Igo and Riloff, 2009; Riloff and Shepherd, 1997; Turney and Littman, 2003). Often corpus-based methods exploit distant-supervision signals (e.g., review scores, emoticons) specific to certain domains (Asghar et al., 2015; Blair-Goldensohn et al., 2008; Bravo-Marquez et al., 2015; Choi and Cardie, 2009; Severyn and Moschitti, 2015; Speriosu et al., 2011; Tang et al., 2014). An effective corpus-based approach that does not require distant-supervision—which we adapt here—is to construct lexical graphs using word co-occurrences and then to perform some form of label propagation over these graphs (Huang et al., 2014; Velikovich et al., 2010). Recent work has also learned transformations of word-vector representations in order to induce sentiment lexicons (Rothe et al., 2016). Fast et al. (2016) combine word vectors with crowdsourcing to produce domain-independent topic lexicons.

Dictionary-based approaches use hand-curated lexical resources—usually WordNet (Fellbaum, 1998)—in order to propagate sentiment from seed

Domain	Positive seed words	Negative seed words
Standard English	good, lovely, excellent, fortunate, pleasant, delightful, perfect, loved, love, happy	bad, horrible, poor, unfortunate, unpleasant, disgusting, evil, hated, hate, unhappy
Finance	successful, excellent, profit, beneficial, improving, improved, success, gains, positive	negligent, loss, volatile, wrong, losses, damages, bad, litigation, failure, down, negative
Twitter	love, loved, loves, awesome, nice, amazing, best, fantastic, correct, happy	hate, hated, hates, terrible, nasty, awful, worst, horrible, wrong, sad

Table 1: Seed words. The seed words were manually selected to be context insensitive (without knowledge of the test lexicons).

labels (Esuli and Sebastiani, 2006; Hu and Liu, 2004; Kamps et al., 2004; Rao and Ravichandran, 2009; San Vicente et al., 2014; Takamura et al., 2005; Tai and Kao, 2013). There is an implicit consensus that dictionary-based approaches will generate higher-quality lexicons, due to their use of these clean, hand-curated resources; however, they are not applicable in domains lacking such a resource (e.g., most historical texts).

Most previous work seeks to enrich or enlarge existing lexicons (Qiu et al., 2009; San Vicente et al., 2014; Velikovich et al., 2010), emphasizing recall over precision. This recall-oriented approach is motivated by the need for massive polarity lexicons in tasks like web-advertising (Velikovich et al., 2010). In contrast to these previous efforts, the goal of this work is to induce high-quality lexicons that are accurate to a specific social context.

Algorithmically, our approach is inspired by Velikovich et al. (2010). We extend Velikovich et al. (2010) by incorporating high-quality word vector embeddings, a new graph construction approach, an alternative label propagation algorithm, and a bootstrapping method to obtain confidence values. Together these improvements, especially the high-quality word vectors, allow our corpus-based method to even outperform the state-of-the-art dictionary-based approach.

3 Framework

Our framework, SENTPROP, is designed to meet four key desiderata:

1. **Resource-light:** Accurate performance without massive corpora or hand-curated resources.
2. **Interpretable**: Uses small seed sets of "paradigm" words to maintain interpretability and avoid ambiguity in sentiment values.
3. **Robust**: Bootstrap-sampled standard deviations provide a measure of confidence.
4. **Out-of-the-box**: Does not rely on signals that are specific to only certain domains.

SENTPROP involves two steps: constructing a lexical graph from unlabeled corpora and propagating sentiment labels over this graph.

3.1 Constructing a lexical graph

Lexical graphs are constructed from distributional word embeddings learned on unlabeled corpora.

Distributional word embeddings

The first step in our approach is to build high-quality semantic representations for words using a vector space model (VSM). We embed each word $w_i \in \mathcal{V}$ as a vector $\mathbf{w}_i$ that captures information about its co-occurrence statistics with other words (Landauer and Dumais, 1997; Turney and Pantel, 2010). This VSM approach has a long history in NLP and has been highly successful in recent applications (see Levy et al., 2015 for a survey).

When recreating known lexicons, we used a number of publicly available embeddings (Section 4).

In the cases where we learned embeddings ourselves, we employed an SVD-based method to construct the word-vectors. First, we construct a matrix $\mathbf{M}^{PPMI} \in \mathbb{R}^{|\mathcal{V}|\times|\mathcal{V}|}$ with entries given by

$$\mathbf{M}^{PPMI}_{i,j} = \max\left\{\log\left(\frac{\hat{p}(w_i, w_j)}{\hat{p}(w)\hat{p}(w_j)}\right), 0\right\}, \quad (1)$$

where $\hat{p}$ denotes smoothed empirical probabilities of word (co-)occurrences within fixed-size sliding windows of text.[3] $\mathbf{M}^{PPMI}_{i,j}$ is equal to a smoothed variant of the positive pointwise mutual information between words w_i and w_j (Levy et al., 2015). Next, we compute $\mathbf{M}^{PPMI} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$, the truncated singular value decomposition of $\mathbf{M}^{PPMI}$. The vector

[3] We use contexts of size four on each side and context-distribution smoothing with $c = 0.75$ (Levy et al., 2015).

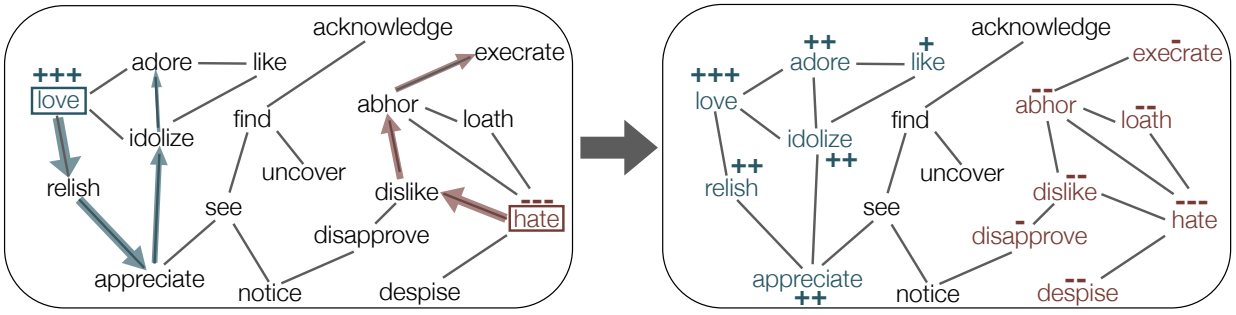

Figure 3: Visual summary of the SENTPROP algorithm.

embedding for word w_i is then given by

$$\mathbf{w}_i^{\text{SVD}} = (\mathbf{U})_i \,. \tag{2}$$

Excluding the singular value weights, Σ, has been shown known to dramatically improve embedding quality (Turney and Pantel, 2010; Bullinaria and Levy, 2012). Following standard practices, we learn embeddings of dimension 300.

We found that this SVD-based method significantly outperformed word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) on preliminary experiments with the domain-specific data we used (see Section 4).

Defining the graph edges

Given a set of word embeddings, a weighted lexical graph is constructed by connecting each word with its nearest k neighbors within the semantic space (according to cosine-similarity). The weights of the edges are set as

$$\mathbf{E}_{i,j} = \arccos\left(-\frac{\mathbf{w_i}^\top \mathbf{w_j}}{\|\mathbf{w_i}\|\|\mathbf{w_j}\|}\right). \tag{3}$$

3.2 Propagating polarities from a seed set

Once a weighted lexical graph is constructed, we propagate sentiment labels over this graph using a random walk method (Zhou et al., 2004). A word's polarity score for a seed set is proportional to the probability of a random walk from the seed set hitting that word (Figure 3).

Let $\mathbf{p} \in \mathbb{R}^{|\mathcal{V}|}$ be a vector of word-sentiment scores constructed using seed set $\mathcal{S}$ (e.g., ten negative words); $\mathbf{p}$ is initialized to have $\frac{1}{|\mathcal{V}|}$ in all entries. And let $\mathbf{E}$ be the matrix of edge weights given by equation (3). First, we construct a symmetric transition matrix from $\mathbf{E}$ by computing $\mathbf{T} = \mathbf{D}^{\frac{1}{2}}\mathbf{E}\mathbf{D}^{\frac{1}{2}}$, where $\mathbf{D}$ is a matrix with the column sums of $\mathbf{E}$ on the diagonal. Next, using $\mathbf{T}$ we iteratively update $\mathbf{p}$ until numerical convergence:

$$\mathbf{p}^{(t+1)} = \beta\mathbf{T}\mathbf{p}^{(t)} + (1-\beta)\mathbf{s}, \tag{4}$$

where $\mathbf{s}$ is a vector with values set to $\frac{1}{|\mathcal{S}|}$ in the entries corresponding to the seed set $\mathcal{S}$ and zeros elsewhere. The β term controls the extent to which the algorithm favors local consistency (similar labels for neighbors) vs. global consistency (correct labels on seed words), with lower βs emphasizing the latter.

To obtain a final polarity score for a word w_i, we run the walk using both positive and negative seed sets, obtaining positive ($\mathbf{p}^P(w_i)$) and negative ($\mathbf{p}^N(w_i)$) label scores. We then combine these values into a positive-polarity score as $\bar{\mathbf{p}}^P(w_i) = \frac{\mathbf{p}^P(w_i)}{\mathbf{p}^P(w_i)+\mathbf{p}^N(w_i)}$ and standardize the final scores to have zero mean and unit variance (within a corpus).

3.3 SENTPROP variants

Many variants of the random walk approach and related label propagation techniques exist in the literature (San Vicente et al., 2014; Velikovich et al., 2010; Zhou et al., 2004; Zhu and Ghahramani, 2002; Zhu et al., 2003). For example, there are differences in how to normalize the transition matrix in the random walks (Zhou et al., 2004) and variants of label propagation, e.g. where the labeled seeds are clamped to the correct values (Zhu and Ghahramani, 2002) or where only shortest-paths through the graph are used for propagation (Velikovich et al., 2010).

We experimented with a number of these approaches and found little difference in their performance. We opted to use the random walk method because it had a slight edge in terms of performance

in preliminary experiments[4] and because it produces well-behaved distributions over label scores, whereas Zhu and Ghahramani (2002)'s method and its variants produce extremely peaked distributions. We do note report in detail on all the label propagation variants here, but the SOCIALSENT package contains a full suite of these methods.

3.4 Bootstrap-sampling for robustness

Propagated sentiment scores are inevitably influenced by the seed set, and it is important for researchers to know the extent to which polarity values are simply the result of corpus artifacts that are correlated with these seeds words. We address this issue by using a bootstrap-sampling approach to obtain confidence regions over our sentiment scores. We bootstrap by running our propagation over B random equally-sized subsets of the positive and negative seed sets. Computing the standard deviation of the bootstrap-sampled polarity scores provides a measure of confidence and allows the researcher to evaluate the robustness of the assigned polarities. We set $B = 50$ and used 7 words per random subset (full seed sets are size 10; see Table 1).

4 Recreating known lexicons

We validate our approach by recreating known sentiment lexicons in the three domains: Standard English, Twitter, and Finance. Table 1 lists the seed words used in each domain.

Standard English: To facilitate comparison with previous work, we focus on the well-known General Inquirer lexicon (Stone et al., 1966). We also use the continuous valence (i.e., polarity) scores collected by Warriner et al. (2013) in order to evaluate the fine-grained performance of our framework. We test our framework's performance using two different embeddings: off-the-shelf Google news embeddings constructed from 10^{11} tokens[5] and embeddings we constructed from the 2000s decade of the Corpus of Historical American English (COHA), which contains $\sim 2 \times 10^7$ words in each decade, from 1850 to 2000 (Davies, 2010). The COHA corpus allows us to test how the algorithms deal with this smaller historical corpus, which is important since we will use the COHA corpus to infer historical sentiment lexicons (Section 6).

Finance: Previous work found that general purpose sentiment lexicons performed very poorly on financial text (Loughran and McDonald, 2011), so a finance-specific sentiment lexicon (containing binary labels) was hand-constructed for this domain (ibid.). To test against this lexicon, we constructed embeddings using a dataset of $\sim 2 \times 10^7$ tokens from financial 8K documents (Lee et al., 2014).

Twitter: Numerous works attempt to induce Twitter-specific sentiment lexicons using supervised approaches and features unique to that domain (e.g., follower graphs; Speriosu et al., 2011). Here, we emphasize that we can induce an accurate lexicon using a simple domain-independent and resource-light approach, with the implication that lexicons can easily be induced for related social media domains without resorting to complex supervised frameworks. We evaluate our approach using the test set from the 2015 SemEval task 10E competition (Rosenthal et al., 2015), and we use the embeddings constructed by Rothe et al. (2016).[6]

4.1 Baselines and state-of-the-art comparisons

We compare SENTPROP against standard baselines and state-of-the-art approaches. The PMI baseline of Turney and Littman (2003) computes the pointwise mutual information between the seeds and the targets without using propagation. The baseline method of Velikovich et al. (2010) is similar to our method but uses an alternative propagation approach and raw co-occurrence vectors instead of learned embeddings. Both these methods require raw corpora, so they function as baselines in cases where we do not use off-the-shelf embeddings. We also compare against DENSIFIER, a state-of-the-art method that learns orthogonal transformations of word vectors instead of propagating labels (Rothe et al., 2016). Lastly, on standard English we compare against a state-of-the-art WordNet-based method, which performs label propagation over a WordNet-derived graph (San Vicente et al., 2014). Several variant baselines, all of which SENTPROP

[4] $>2\%$ improvement across metrics on the standard and historical English datasets described in Section 4.

[5] `https://code.google.com/p/word2vec/`

[6] The official SemEval task 10E involved fully-supervised learning, so we do not use their evaluation setup.

Method	AUC	Ternary F1	τ
SENTPROP	90.6	58.6	0.44
DENSIFIER	**93.3**	**62.1**	**0.50**
WordNet	89.5	58.7	0.34
Majority	–	24.8	–

(a) Corpus methods outperform WordNet on standard English. Using word-vector embeddings learned on a massive corpus (10^{11} tokens), we see that both corpus-based methods outperform the WordNet-based approach overall.

Method	AUC	Ternary F1	τ
SENTPROP	86.0	**60.1**	0.50
DENSIFIER	**90.1**	59.4	**0.57**
Sentiment140	86.2	57.7	0.51
Majority	–	24.9	–

(b) Corpus approaches are competitive with a distantly supervised method on Twitter. Using Twitter embeddings learned from $\sim 10^9$ tokens, we see that the semi-supervised corpus approaches using small seed sets perform very well.

Method	AUC	Ternary F1
SENTPROP	**91.6**	**63.1**
DENSIFIER	80.2	50.3
PMI	86.1	49.8
Velikovich et al. (2010)	81.6	51.1
Majority	–	23.6

(c) SENTPROP performs best with domain-specific finance embeddings. Using embeddings learned from financial corpus ($\sim 2 \times 10^7$ tokens) , SENTPROP significantly outperforms the other methods.

Method	AUC	Ternary F1	τ
SENTPROP	**83.8**	**53.0**	**0.28**
DENSIFIER	77.4	46.6	0.19
PMI	70.6	41.9	0.16
Velikovich et al. (2010)	52.7	32.9	0.01
Majority	–	24.3	–

(d) SENTPROP performs well on standard English even with 1000x reduction in corpus size. SENTPROP maintains strong performance even when using embeddings learned from the 2000s decade of COHA (only $2 \times \sim 10^7$ tokens).

Table 2: Results on recreating known lexicons.

outperforms, are omitted for brevity (e.g., using word-vector cosines in place of PMI in Turney and Littman (2003)'s framework). Code for all these variants is available in the SOCIALSENT package.

4.2 Evaluation setup

We evaluate the approaches according to (i) their binary classification accuracy (ignoring the neutral class, as is common in previous work), (ii) ternary classification performance (positive vs. neutral vs. negative)[7], and (iii) Kendall τ rank-correlation with continuous human-annotated polarity scores.

For all methods in the ternary-classification condition, we use the class-mass normalization method (Zhu et al., 2003) to label words as positive, neutral, or negative. This method assumes knowledge of the label distribution—i.e., how many positive/negative vs. neutral words there are—and simply assigns labels to best match this distribution.

4.3 Evaluation results

Tables 2a-2d summarize the performance of our framework along with baselines and other state-of-the-art approaches. Our framework significantly outperforms the baselines on all tasks, outperforms a state-of-the-art approach that uses WordNet on standard English (Table 2a), and is competitive with Sentiment140 on Twitter (Table 2b), a distantly-supervised approach that uses signals from emoticons (Mohammad and Turney, 2010). DENSIFIER also performs extremely well, outperforming SENTPROP when off-the-shelf embeddings are used (Tables 2a and 2b). However, SENTPROP significantly outperforms all other approaches when using the domain-specific embeddings (Tables 2c and 2d).

Overall our results show that SENTPROP— a relatively simple method, which combines high-quality word vectors embeddings with standard label propagation — can perform at a state-of-the-art level, even performing competitively with methods relying on hand-curated lexical graphs. Unlike previous published approaches, SENTPROP is able to maintain high accuracy even when modest-sized domain-specific corpora are used. In cases where very large corpora are available and where there is an abundance of training data, DENSIFIER performs extremely well, since it was designed for this sort of setting (Rothe et al., 2016).

[7]Only GI contains words explicitly marked neutral, so for ternary evaluations in Twitter and Finance we sample neutral words from GI to match its neutral-vs-not distribution.

We found that the baseline method of Velikovich et al. (2010), which our method is closely related to, performed relatively poorly with these domain-specific corpora. This indicates that using high-quality word-vector embeddings can have a drastic impact on performance. However, it is worth noting that Velikovich et al. (2010)'s method was designed for high recall with massive corpora, so its poor performance in our regime is not surprising.

Lastly, we found that the choice of embedding method could have a drastic impact. Preliminary experiments on the COHA data showed that using word2vec SGNS vectors (with default settings) instead of our SVD-based embeddings led to a $>40\%$ performance drop for SENTPROP across all measures and a $>10\%$ performance drop for DENSIFIER. It is possible that certain settings of word2vec could perform better, but previous work has shown that SVD-based methods have superior results on smaller datasets and rare-word similarity tasks (Levy et al., 2015; Hamilton et al., 2016), so this result is not surprising.

5 Inducing community-specific lexicons

As a first large-scale study, we investigate how sentiment depends on the social context in which a word is used. It is well known that there is substantial sociolinguistic variation between different communities, whether these communities are defined geographically (Trudgill, 1974) or via underlying sociocultural differences (Labov, 2006). However, no previous work has systematically investigated community-specific variation in word sentiment at a large scale. Yang and Eisenstein (2015) exploit social network structure in Twitter to infer a small number (1-10) of communities and analyzed sentiment variation via a supervised framework. Our analysis extends this line of work by analyzing the sentiment across hundreds of user-defined communities using only unlabeled corpora and a small set of "paradigm" seed words (the Twitter seed words outlined in Table 1).

In our study, we induced sentiment lexicons for the top-250 (by comment-count) subreddits from the social media forum Reddit.[8] We used all the 2014 comment data to induce the lexicons, with words lower cased and comments from bots and deleted users removed.[9] Sentiment was induced for the top-5000 non-stop words in each subreddit (again, by comment-frequency).

5.1 Examining the lexicons

Analysis of the learned lexicons reveals the extent to which sentiment can differ across communities. Figure 4 highlights some words with opposing sentiment in two communities: in `r/TwoXChromosomes` (`r/TwoX`), a community dedicated to female perspectives and gender issues, the words *crazy* and *insane* have negative polarity, which is not true in the `r/sports` community, and, vice-versa, words like *soft* are positive in `r/TwoX` but negative in `r/sports`.

To get a sense of how much sentiment differs across communities in general, we selected a random subset of 1000 community pairs and examined the correlation in their sentiment values for highly sentiment-bearing words (Figure 5). We see that the distribution is noticeably skewed, with many community pairs having highly uncorrelated sentiment values. The 1000 random pairs were selected such that each member of the pair overlapped in at least half of their top-5000 word vocabulary. We then computed the correlation between the sentiments in these community-pairs. Since sentiment is noisy and relatively uninteresting for neutral words, we compute $\tau_{25\%}$, the Kendall-τ correlation over the top-25% most sentiment bearing words shared between the two communities.

Analysis of individual pairs reveals some interesting insights about sentiment and inter-community dynamics. For example, we found that the sentiment correlation between `r/TwoX` and `r/TheRedPill` ($\tau_{25\%} = 0.58$), two communities that hold conflicting views and often attack each other[10], was actually higher than the sentiment correlation between `r/TwoX` and `r/sports` ($\tau_{25\%} = 0.41$), two communities that are entirely unrelated. This result suggests that conflicting communities may have

[8] Subreddits are user-created topic-specific forums.

[9] https://archive.org/details/2015_reddit_comments_corpus

[10] This conflict is well-known on Reddit; for example, both communities mention each others' names along with *fuck*-based profanity in the same comment far more than one would expect by chance ($\chi^2_1 > 6.8$, $p < 0.01$ for both). `r/TheRedPill` is dedicated to male empowerment.

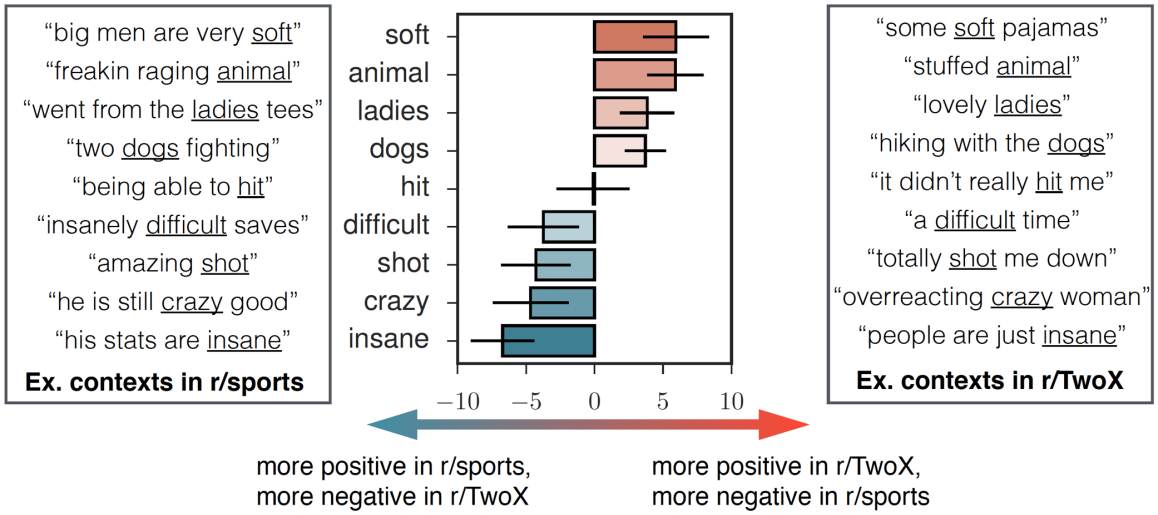

Figure 4: Word sentiment differs drastically between a community dedicated to sports (`r/sports`) and one dedicated to female perspectives and gender issues (`r/TwoX`). Words like *soft* and *animal* have positive sentiment in `r/TwoX` but negative sentiment in `r/sports`, while the opposite holds for words like *crazy* and *insane*.

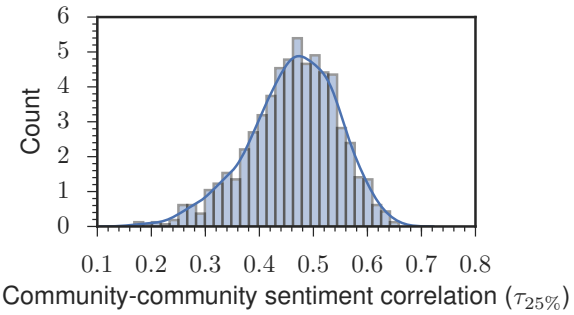

Figure 5: There is a long tail of communities with very different word sentiments. Some communities have very similar sentiment (e.g., `r/sports` and `r/hockey`), while other community pairs differ drastically (e.g., `r/sports` and `r/TwoX`).

more similar sentiment in their language compared to communities that are entirely unrelated.

6 Inducing diachronic sentiment lexicons

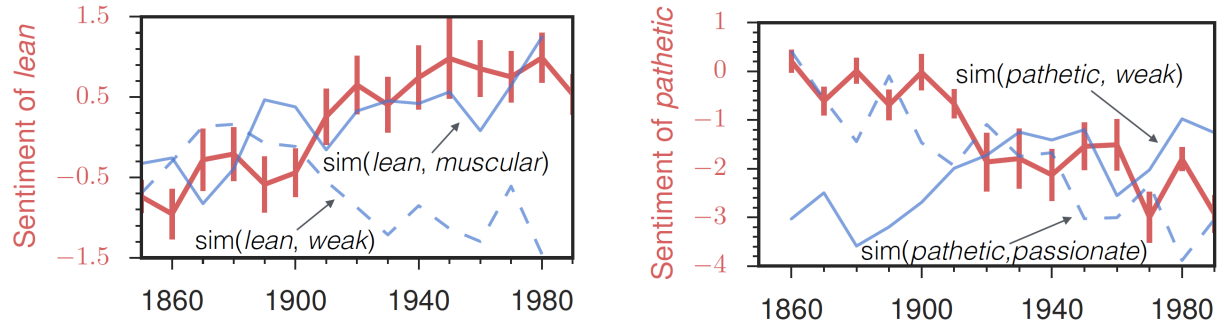
Sentiment also depends on the historical time-period in which a word is used. To investigate this dependency, we use our framework to analyze how word polarities have shifted over the last 150 years. The phenomena of *amelioration* (words becoming more positive) and *pejoration* (words becoming more negative) are well-discussed in the linguistic literature (Traugott and Dasher, 2001); however, no comprehensive polarity lexicons exist for historical data (Cook and Stevenson, 2010). Such lexicons are crucial to the growing body of work on NLP analyses of historical text (Piotrowski, 2012) which are informing diachronic linguistics (Hamilton et al., 2016), the digital humanities (Muralidharan and Hearst, 2012), and history (Hendrickx et al., 2011).

Our work is inspired by the only previous work on automatically inducing historical sentiment lexicons, Cook and Stevenson (2010); they use the PMI method and a full modern sentiment lexicon as their seed set, which relies on the assumption that all these words have not changed in sentiment. In contrast, in addition to our different algorithm, we use a small seed set of words that were manually selected based on having strong and stable sentiment over the last 150 years (Table 1; confirmed via historical entries in the Oxford English Dictionary).

6.1 Examining the lexicons

We constructed lexicons from COHA, since it was carefully constructed to be genre balanced (e.g., compared to the Google N-Grams; Pechenick et al., 2015). We built lexicons for all adjectives with counts above 100 in a given decade and also for the top-5000 non-stop words within each year. In both these cases we found that $>5\%$ of sentiment-bearing (positive/negative) words completely switched polarity during this 150-year time-period and $>25\%$ of all words changed their sentiment label (including switches to/from neutral).[11] The prevalence of

[11] We defined the thresholds for polar vs. neutral using the class-mass normalization method and compared scores aver-



(a) *Lean* becomes more positive. *Lean* underwent amelioration, becoming more similar to *muscular* and less similar to *weak*.

(b) *Pathetic* becomes more negative. *Pathetic* underwent pejoration, becoming similar to *weak* and less similar to *passionate*.

Figure 6: Examples of amelioration and pejoration.

full polarity switches highlights the importance of historical sentiment lexicons for work on diachronic linguistics and cultural change.

Figure 6a shows an example amelioration detected by this method: the word *lean* lost its negative connotations associated with "weakness" and instead became positively associated with concepts like "muscularity" and "fitness". Figure 6b shows an example pejoration, where *pathetic*, which used to be more synonymous with *passionate*, gained stronger negative associations with the concepts of "weakness" and "inadequacy" (Simpson et al., 1989). In both these cases, semantic similarities computed using our learned historical word vectors were used to contextualize the shifts.

Some other well-known examples of sentiment changes captured by our framework include the semantic bleaching of *sorry*, which shifted from negative and serious ("he was in a sorry state") to uses as a neutral discourse marker ("sorry about that") and *worldly*, which used to have negative connotations related to materialism and religious impurity ("sinful worldly pursuits") but now is frequently used to indicate sophistication ("a cultured, worldly woman") (Simpson et al., 1989). Our hope is that the full lexicons released with this work will spur further examinations of such historical shifts in sentiment, while also facilitating CSS applications that require sentiment ratings for historical text.

7 Conclusion

SentProp allows researchers to easily induce robust and accurate sentiment lexicons that are relevant to their particular domain of study. Such lexicons are crucial to CSS research, as evidenced by our two studies showing that sentiment depends strongly on both social and historical context.

Our methodological comparisons show that simply combining label propagation with high-quality word vector embeddings can achieve state-of-the-art performance competitive with methods that rely on hand-curated dictionaries, and the code package released with this work contains a full benchmark toolkit for this area, including implementations of several variants of SentProp. We hope these tools will facilitate future quantitative studies on the domain-dependency of sentiment.

Of course, the sentiment lexicons induced by SentProp are not perfect, which is reflected in the uncertainty associated with our bootstrap-sampled estimates. However, we believe that these user-constructed, domain-specific lexicons, which quantify uncertainty, provide a more principled foundation for CSS research compared to domain-general sentiment lexicons that contain unknown biases. In the future our method could also be integrated with supervised domain-adaption (e.g.,Yang and Eisenstein, 2015) to further improve these domain-specific results.

Abstract

Aspect-level sentiment classification is a fine-grained task in sentiment analysis. Since it provides more complete and in-depth results, aspect-level sentiment analysis has received much attention these years. In this paper, we reveal that the sentiment polarity of a sentence is not only determined by the content but is also highly related to the concerned aspect. For instance, "*The appetizers are ok, but the service is slow.*", for aspect *taste*, the polarity is positive while for *service*, the polarity is negative. Therefore, it is worthwhile to explore the connection between an aspect and the content of a sentence. To this end, we propose an Attention-based Long Short-Term Memory Network for aspect-level sentiment classification. The attention mechanism can concentrate on different parts of a sentence when different aspects are taken as input. We experiment on the SemEval 2014 dataset and results show that our model achieves state-of-the-art performance on aspect-level sentiment classification.

1 Introduction

Sentiment analysis (Nasukawa and Yi, 2003), also known as opinion mining (Liu, 2012), is a key NLP task that receives much attention these years. Aspect-level sentiment analysis is a fine-grained task that can provide complete and in-depth results. In this paper, we deal with aspect-level sentiment classification and we find that the sentiment polarity of a sentence is highly dependent on both content and aspect. For example, the sentiment polarity of "*Staffs are not that friendly, but the taste covers all.*" will be positive if the aspect is *food* but negative when considering the aspect *service*. Polarity could be opposite when different aspects are considered.

Neural networks have achieved state-of-the-art performance in a variety of NLP tasks such as machine translation (Lample et al., 2016), paraphrase identification (Yin et al., 2015), question answering (Golub and He, 2016) and text summarization (Rush et al., 2015). However, neural network models are still in infancy to deal with aspect-level sentiment classification. In some works, target dependent sentiment classification can be benefited from taking into account target information, such as in Target-Dependent LSTM (TD-LSTM) and Target-Connection LSTM (TC-LSTM) (Tang et al., 2015a). However, those models can only take into consideration the target but not aspect information which is proved to be crucial for aspect-level classification.

Attention has become an effective mechanism to obtain superior results, as demonstrated in image recognition (Mnih et al., 2014), machine translation (Bahdanau et al., 2014), reasoning about entailment (Rocktäschel et al., 2015) and sentence summarization (Rush et al., 2015). Even more, neural attention can improve the ability to read comprehension (Hermann et al., 2015). In this paper, we propose an attention mechanism to enforce the model to attend to the important part of a sentence, in response to a specific aspect. We design an aspect-to-sentence attention mechanism that can concentrate

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 606–615,
Austin, Texas, November 1-5, 2016.

on the key part of a sentence given the aspect.

We explore the potential correlation of aspect and sentiment polarity in aspect-level sentiment classification. In order to capture important information in response to a given aspect, we design an attention-based LSTM. We evaluate our approach on a benchmark dataset (Pontiki et al., 2014), which contains restaurants and laptops data.

The main contributions of our work can be summarized as follows:

- We propose attention-based Long Short-Term memory for aspect-level sentiment classification. The models are able to attend different parts of a sentence when different aspects are concerned. Results show that the attention mechanism is effective.
- Since aspect plays a key role in this task, we propose two ways to take into account aspect information during attention: one way is to concatenate the aspect vector into the sentence hidden representations for computing attention weights, and another way is to additionally append the aspect vector into the input word vectors.
- Experimental results indicate that our approach can improve the performance compared with several baselines, and further examples demonstrate the attention mechanism works well for aspect-level sentiment classification.

The rest of our paper is structured as follows: Section 2 discusses related works, Section 3 gives a detailed description of our attention-based proposals, Section 4 presents extensive experiments to justify the effectiveness of our proposals, and Section 5 summarizes this work and the future direction.

2 Related Work

In this section, we will review related works on aspect-level sentiment classification and neural networks for sentiment classification briefly.

2.1 Sentiment Classification at Aspect-level

Aspect-level sentiment classification is typically considered as a classification problem in the literature. As we mentioned before, aspect-level sentiment classification is a fine-grained classification task. The majority of current approaches attempt to detecting the polarity of the entire sentence, regardless of the entities mentioned or aspects. Traditional approaches to solve those problems are to manually design a set of features. With the abundance of sentiment lexicons (Rao and Ravichandran, 2009; Perez-Rosas et al., 2012; Kaji and Kitsuregawa, 2007), the lexicon-based features were built for sentiment analysis (Mohammad et al., 2013). Most of these studies focus on building sentiment classifiers with features, which include bag-of-words and sentiment lexicons, using SVM (Mullen and Collier, 2004). However, the results highly depend on the quality of features. In addition, feature engineering is labor intensive.

2.2 Sentiment Classification with Neural Networks

Since a simple and effective approach to learn distributed representations was proposed (Mikolov et al., 2013), neural networks advance sentiment analysis substantially. Classical models including Recursive Neural Network (Socher et al., 2011; Dong et al., 2014; Qian et al., 2015), Recursive Neural Tensor Network (Socher et al., 2013), Recurrent Neural Network (Mikolov et al., 2010; Tang et al., 2015b), LSTM (Hochreiter and Schmidhuber, 1997) and Tree-LSTMs (Tai et al., 2015) were applied into sentiment analysis currently. By utilizing syntax structures of sentences, tree-based LSTMs have been proved to be quite effective for many NLP tasks. However, such methods may suffer from syntax parsing errors which are common in resource-lacking languages.

LSTM has achieved a great success in various NLP tasks. TD-LSTM and TC-LSTM (Tang et al., 2015a), which took target information into consideration, achieved state-of-the-art performance in target-dependent sentiment classification. TC-LSTM obtained a target vector by averaging the vectors of words that the target phrase contains. However, simply averaging the word embeddings of a target phrase is not sufficient to represent the semantics of the target phrase, resulting a suboptimal performance.

Despite the effectiveness of those methods, it is still challenging to discriminate different sentiment polarities at a fine-grained aspect level. Therefore, we are motivated to design a powerful neural network which can fully employ aspect information for sentiment classification.

3 Attention-based LSTM with Aspect Embedding

3.1 Long Short-term Memory (LSTM)

Recurrent Neural Network(RNN) is an extension of conventional feed-forward neural network. However, standard RNN has the gradient vanishing or exploding problems. In order to overcome the issues, Long Short-term Memory network (LSTM) was developed and achieved superior performance (Hochreiter and Schmidhuber, 1997). In the LSTM architecture, there are three gates and a cell memory state. Figure 1 illustrates the architecture of a standard LSTM.

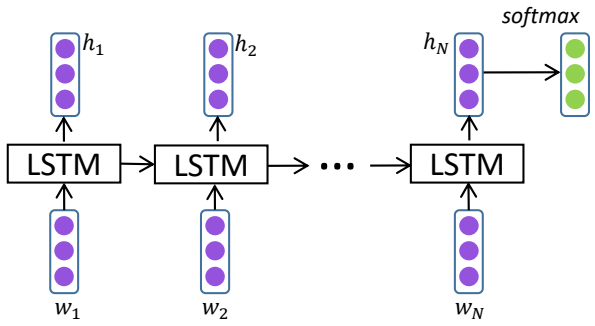

Figure 1: The architecture of a standard LSTM. $\{w_1, w_2, \ldots, w_N\}$ represent the word vector in a sentence whose length is N. $\{h_1, h_2, \ldots, h_N\}$ is the hidden vector.

More formally, each cell in LSTM can be computed as follows:

$$X = \begin{bmatrix} h_{t-1} \\ x_t \end{bmatrix} \quad (1)$$

$$f_t = \sigma(W_f \cdot X + b_f) \quad (2)$$

$$i_t = \sigma(W_i \cdot X + b_i) \quad (3)$$

$$o_t = \sigma(W_o \cdot X + b_o) \quad (4)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot tanh(W_c \cdot X + b_c) \quad (5)$$

$$h_t = o_t \odot tanh(c_t) \quad (6)$$

where $W_i, W_f, W_o \in \mathbb{R}^{d \times 2d}$ are the weighted matrices and $b_i, b_f, b_o \in \mathbb{R}^d$ are biases of LSTM to be learned during training, parameterizing the transformations of the input, forget and output gates respectively. σ is the sigmoid function and $\odot$ stands for element-wise multiplication. x_t includes the inputs of LSTM cell unit, representing the word embedding vectors w_t in Figure 1. The vector of hidden layer is h_t.

We regard the last hidden vector h_N as the representation of sentence and put h_N into a $softmax$ layer after linearizing it into a vector whose length is equal to the number of class labels. In our work, the set of class labels is {*positive*, *negative*, *neutral*}.

3.2 LSTM with Aspect Embedding (AE-LSTM)

Aspect information is vital when classifying the polarity of one sentence given aspect. We may get opposite polarities if different aspects are considered. To make the best use of aspect information, we propose to learn an embedding vector for each aspect.

Vector $v_{a_i} \in \mathbb{R}^{d_a}$ is represented for the embedding of aspect i, where d_a is the dimension of aspect embedding. $A \in \mathbb{R}^{d_a \times |A|}$ is made up of all aspect embeddings. To the best of our knowledge, it is the first time to propose aspect embedding.

3.3 Attention-based LSTM (AT-LSTM)

The standard LSTM cannot detect which is the important part for aspect-level sentiment classification. In order to address this issue, we propose to design an attention mechanism that can capture the key part of sentence in response to a given aspect. Figure 2 represents the architecture of an Attention-based LSTM (AT-LSTM).

Let $H \in \mathbb{R}^{d \times N}$ be a matrix consisting of hidden vectors $[h_1, \ldots, h_N]$ that the LSTM produced, where d is the size of hidden layers and N is the length of the given sentence. Furthermore, v_a represents the embedding of aspect and $e_N \in \mathbb{R}^N$ is a vector of 1s. The attention mechanism will produce an attention weight vector α and a weighted hidden

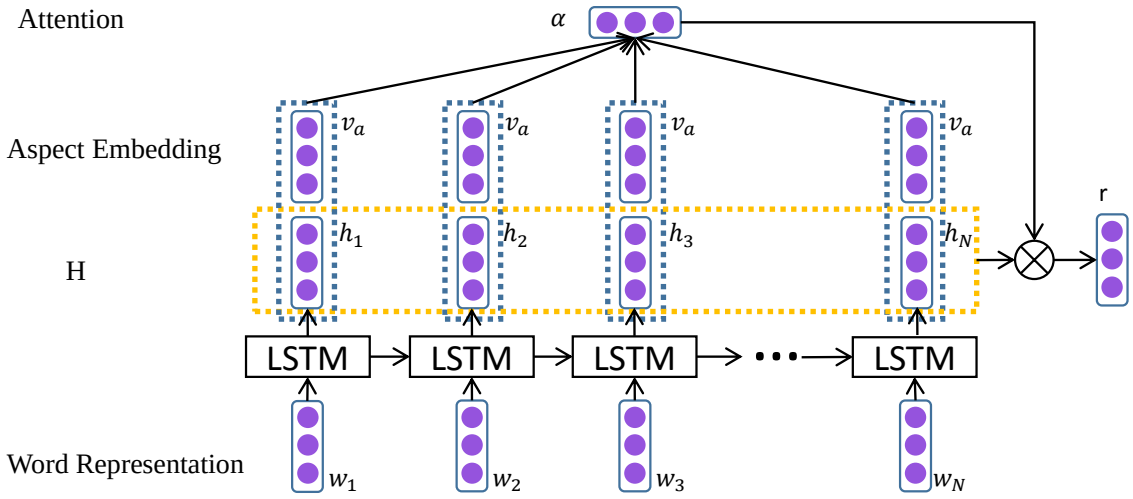

Figure 2: The Architecture of Attention-based LSTM. The aspect embeddings have been used to decide the attention weights along with the sentence representations. $\{w_1, w_2, \ldots, w_N\}$ represent the word vector in a sentence whose length is N. v_a represents the aspect embedding. α is the attention weight. $\{h_1, h_2, \ldots, h_N\}$ is the hidden vector.

representation r.

$$M = tanh(\begin{bmatrix} W_h H \\ W_v v_a \otimes e_N \end{bmatrix}) \quad (7)$$

$$\alpha = softmax(w^T M) \quad (8)$$

$$r = H\alpha^T \quad (9)$$

where, $M \in \mathbb{R}^{(d+d_a)\times N}$, $\alpha \in \mathbb{R}^N$, $r \in \mathbb{R}^d$. $W_h \in \mathbb{R}^{d\times d}$, $W_v \in \mathbb{R}^{d_a \times d_a}$ and $w \in \mathbb{R}^{d+d_a}$ are projection parameters. α is a vector consisting of attention weights and r is a weighted representation of sentence with given aspect. The operator in 7 (a circle with a multiplication sign inside, OP for short here) means: $v_a \otimes e_N = [v; v; \ldots; v]$, that is, the operator repeatedly concatenates v for N times, where e_N is a column vector with N 1s. $W_v v_a \otimes e_N$ is repeating the linearly transformed v_a as many times as there are words in sentence.

The final sentence representation is given by:

$$h^* = tanh(W_p r + W_x h_N) \quad (10)$$

where, $h^* \in \mathbb{R}^d$, W_p and W_x are projection parameters to be learned during training. We find that this works practically better if we add $W_x h_N$ into the final representation of the sentence, which is inspired by (Rocktäschel et al., 2015).

The attention mechanism allows the model to capture the most important part of a sentence when different aspects are considered.

h^* is considered as the feature representation of a sentence given an input aspect. We add a linear layer to convert sentence vector to e, which is a real-valued vector with the length equal to class number $|C|$. Then, a $softmax$ layer is followed to transform e to conditional probability distribution.

$$y = softmax(W_s h^* + b_s) \quad (11)$$

where W_s and b_s are the parameters for $softmax$ layer.

3.4 Attention-based LSTM with Aspect Embedding (ATAE-LSTM)

The way of using aspect information in AE-LSTM is letting aspect embedding play a role in computing the attention weight. In order to better take advantage of aspect information, we append the input aspect embedding into each word input vector. The structure of this model is illustrated in 3. In this way, the output hidden representations $(h_1, h_2, ..., h_N)$ can have the information from the input aspect (v_a). Therefore, in the following step that compute the attention weights, the inter-

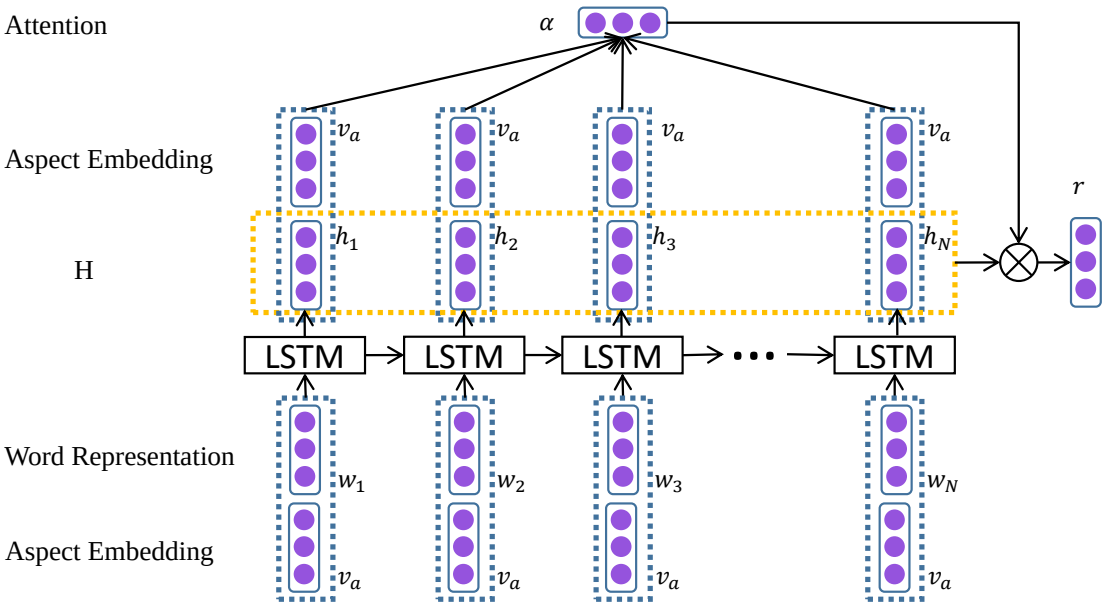

Figure 3: The Architecture of Attention-based LSTM with Aspect Embedding. The aspect embeddings have been take as input along with the word embeddings. $\{w_1, w_2, \ldots, w_N\}$ represent the word vector in a sentence whose length is N. v_a represents the aspect embedding. α is the attention weight. $\{h_1, h_2, \ldots, h_N\}$ is the hidden vector.

dependence between words and the input aspect can be modeled.

3.5 Model Training

The model can be trained in an end-to-end way by backpropagation, where the objective function (loss function) is the cross-entropy loss. Let y be the target distribution for sentence, $\hat{y}$ be the predicted sentiment distribution. The goal of training is to minimize the cross-entropy error between y and $\hat{y}$ for all sentences.

$$loss = -\sum_i \sum_j y_i^j log\hat{y}_i^j + \lambda||\theta||^2 \qquad (12)$$

where i is the index of sentence, j is the index of class. Our classification is three way. λ is the L_2 - regularization term. θ is the parameter set.

Similar to standard LSTM, the parameter set is $\{W_i, b_i, W_f, b_f, W_o, b_o, W_c, b_c, W_s, b_s\}$. Furthermore, word embeddings are the parameters too. Note that the dimension of W_i, W_f, W_o, W_c changes along with different models. If the aspect embeddings are added into the input of the LSTM cell unit, the dimension of W_i, W_f, W_o, W_c will be enlarged correspondingly. Additional parameters are listed as follows:

AT-LSTM: The aspect embedding A is added into the set of parameters naturally. In addition, W_h, W_v, W_p, W_x, w are the parameters of attention. Therefore, the additional parameter set of AT-LSTM is $\{A, W_h, W_v, W_p, W_x, w\}$.

AE-LSTM: The parameters include the aspect embedding A. Besides, the dimension of W_i, W_f, W_o, W_c will be expanded since the aspect vector is concatenated. Therefore, the additional parameter set consists of $\{A\}$.

ATAE-LSTM: The parameter set consists of $\{A, W_h, W_v, W_p, W_x, w\}$. Additionally, the dimension of W_i, W_f, W_o, W_c will be expanded with the concatenation of aspect embedding.

The word embedding and aspect embedding are optimized during training. The percentage of out-of-vocabulary words is about 5%, and they are randomly initialized from $U(-\epsilon, \epsilon)$, where $\epsilon = 0.01$.

In our experiments, we use AdaGrad (Duchi et al., 2011) as our optimization method, which has

improved the robustness of SGD on large scale learning task remarkably in a distributed environment (Dean et al., 2012). AdaGrad adapts the learning rate to the parameters, performing larger updates for infrequent parameters and smaller updates for frequent parameters.

4 Experiment

We apply the proposed model to aspect-level sentiment classification. In our experiments, all word vectors are initialized by Glove[1] (Pennington et al., 2014). The word embedding vectors are pre-trained on an unlabeled corpus whose size is about 840 billion. The other parameters are initialized by sampling from a uniform distribution $U(-\epsilon, \epsilon)$. The dimension of word vectors, aspect embeddings and the size of hidden layer are 300. The length of attention weights is the same as the length of sentence. Theano (Bastien et al., 2012) is used for implementing our neural network models. We trained all models with a batch size of 25 examples, and a momentum of 0.9, L_2-regularization weight of 0.001 and initial learning rate of 0.01 for AdaGrad.

4.1 Dataset

We experiment on the dataset of SemEval 2014 Task 4[2] (Pontiki et al., 2014). The dataset consists of customers reviews. Each review contains a list of aspects and corresponding polarities. Our aim is to identify the aspect polarity of a sentence with the corresponding aspect. The statistics is presented in Table 1.

4.2 Task Definition

Aspect-level Classification Given a set of pre-identified aspects, this task is to determine the polarity of each aspect. For example, given a sentence, "*The restaurant was too expensive.*", there is an aspect *price* whose polarity is negative. The set of aspects is {*food*, *price*, *service*, *ambience*, *anecdotes/miscellaneous*}. In the dataset of SemEval 2014 Task 4, there is only restaurants data that has aspect-specific polarities. Table 2 illustrates the comparative results.

[1]Pre-trained word vectors of Glove can be obtained from `http://nlp.stanford.edu/projects/glove/`

[2]The introduction about SemEval 2014 can be obtained from `http://alt.qcri.org/semeval2014/`

Asp.	Positive		Negative		Neural	
	Train	Test	Train	Test	Train	Test
Fo.	867	302	209	69	90	31
Pr.	179	51	115	28	10	1
Se.	324	101	218	63	20	3
Am.	263	76	98	21	23	8
An.	546	127	199	41	357	51
Total	2179	657	839	222	500	94

Table 1: Aspects distribution per sentiment class. {*Fo., Pr., Se, Am., An.*} refer to {*food, price, service, ambience, anecdotes/miscellaneous*}. "*Asp.*" refers to aspect.

Models	Three-way	Pos./Neg.
LSTM	82.0	88.3
TD-LSTM	82.6	89.1
TC-LSTM	81.9	89.2
AE-LSTM	82.5	88.9
AT-LSTM	83.1	89.6
ATAE-LSTM	**84.0**	**89.9**

Table 2: Accuracy on aspect level polarity classification about restaurants. *Three-way* stands for 3-class prediction. *Pos./Neg.* indicates binary prediction where ignoring all neutral instances. Best scores are in bold.

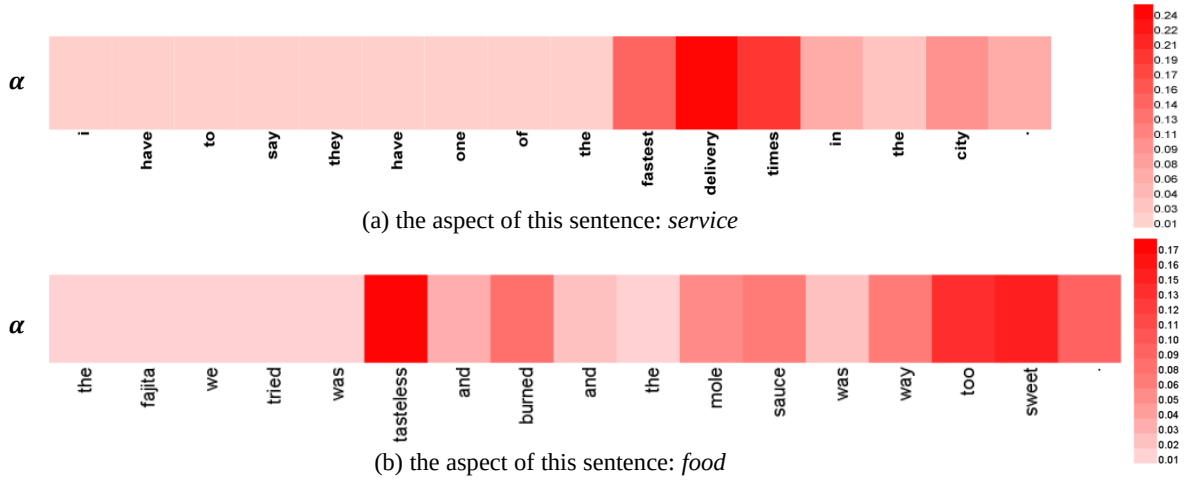
Aspect-Term-level Classification For a given set of aspects term within a sentence, this task is to determine whether the polarity of each aspect term is positive, negative or neutral. We conduct experiments on the dataset of SemEval 2014 Task 4. In the sentences of both restaurant and laptop datasets, there are the location and sentiment polarity for each occurrence of an aspect term. For example, there is an aspect term *fajitas* whose polarity is negative in sentence "*I loved their fajitas.*".

Experiments results are shown in Table 3 and Table 4. Similar to the experiment on aspect-level classification, our models achieve state-of-the-art performance.

4.3 Comparison with baseline methods

We compare our model with several baselines, including LSTM, TD-LSTM, and TC-LSTM.

LSTM: Standard LSTM cannot capture any aspect information in sentence, so it must get the same



(a) the aspect of this sentence: *service*

(b) the aspect of this sentence: *food*

Figure 4: Attention Visualizations. The aspects of (a) and (b) are *service* and *food* respectively. The color depth expresses the importance degree of the weight in attention vector α. From (a), attention can detect the important words from the whole sentence dynamically even though multi-semantic phrase such as "*fastest delivery times*" which can be used in other areas. From (b), attention can know multi-keypoints if more than one keypoint existing.

Models	Three-way	Pos./Neg.
LSTM	74.3	-
TD-LSTM	75.6	-
AE-LSTM	76.6	89.6
ATAE-LSTM	**77.2**	**90.9**

Table 3: Accuracy on aspect term polarity classification about restaurants. *Three-way* stands for 3-class prediction. *Pos./Neg.* indicates binary prediction where ignoring all neutral instances. Best scores are in bold.

Models	Three-way	Pos./Neg.
LSTM	66.5	-
TD-LSTM	68.1	-
AE-LSTM	**68.9**	87.4
ATAE-LSTM	68.7	**87.6**

Table 4: Accuracy on aspect term polarity classification about laptops. *Three-way* stands for 3-class prediction. *Pos./Neg.* indicates binary prediction where ignoring all neutral instances. Best scores are in bold.

sentiment polarity although given different aspects. Since it cannot take advantage of the aspect information, not surprisingly the model has worst performance.

TD-LSTM: TD-LSTM can improve the performance of sentiment classifier by treating an aspect as a target. Since there is no attention mechanism in TD-LSTM, it cannot "know" which words are important for a given aspect.

TC-LSTM: TC-LSTM extended TD-LSTM by incorporating a target into the representation of a sentence. It is worth noting that TC-LSTM performs worse than LSTM and TD-LSTM in Table 2. TC-LSTM added target representations, which was obtained from word vectors, into the input of the LSTM cell unit.

In our models, we embed aspects into another vector space. The embedding vector of aspects can be learned well in the process of training. ATAE-LSTM not only addresses the shortcoming of the unconformity between word vectors and aspect embeddings, but also can capture the most important information in response to a given aspect. In addition, ATAE-LSTM can capture the important and different parts of a sentence when given different aspects.

4.4 Qualitative Analysis

It is enlightening to analyze which words decide the sentiment polarity of the sentence given an aspect. We can obtain the attention weight α in Equation 8 and visualize the attention weights accordingly.

Figure 4 shows the representation of how attention focuses on words with the influence of a given aspect. We use a visualization tool Heml (Deng

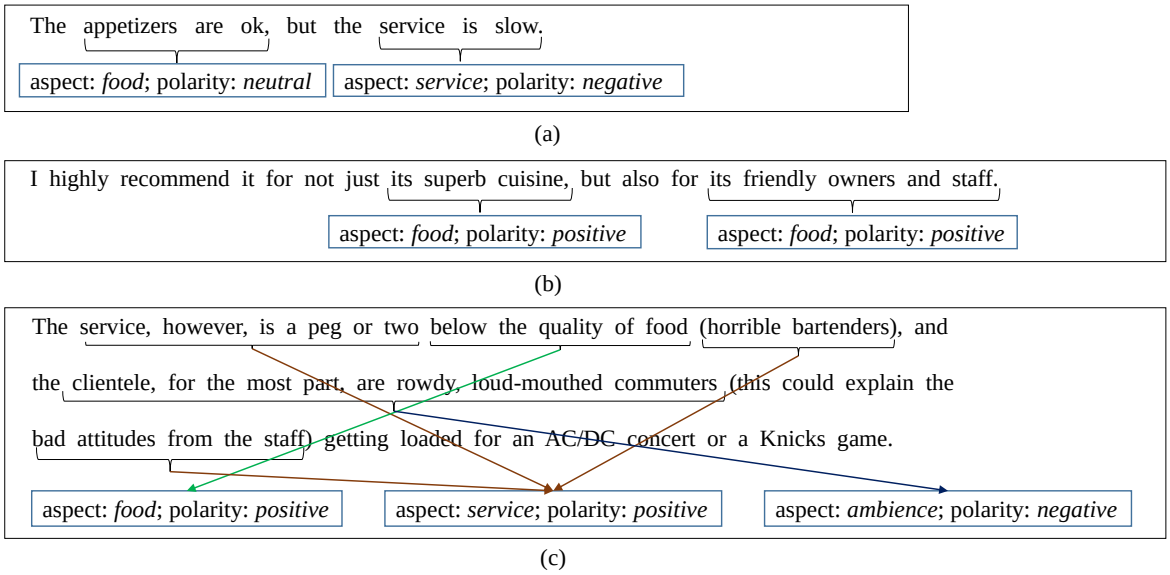


Figure 5: Examples of classification. (a) is an instance with different aspects. (b) represents that our model can focus on where the keypoints are and not disturbed by the privative word *not*. (c) stands for long and complicated sentences. Our model can obtain correct sentiment polarity.

et al., 2014) to visualize the sentences. The color depth indicates the importance degree of the weight in attention vector α, the darker the more important. The sentences in Figure 4 are "*I have to say they have one of the fastest delivery times in the city* ." and "*The fajita we tried was tasteless and burned and the mole sauce was way too sweet.*". The corresponding aspects are *service* and *food* respectively. Obviously attention can get the important parts from the whole sentence dynamically. In Figure 4 (a), "*fastest delivery times*" is a multi-word phrase, but our attention-based model can detect such phrases if *service* can is the input aspect. Besides, the attention can detect multiple keywords if more than one keyword is existing. In Figure 4 (b), *tastless* and *too sweet* are both detected.

4.5 Case Study

As we demonstrated, our models obtain the state-of-the-art performance. In this section, we will further show the advantages of our proposals through some typical examples.

In Figure 5, we list some examples from the test set which have typical characteristics and cannot be inferred by LSTM. In sentence (a), "*The appetizers are ok, but the service is slow.*", there are two aspects *food* and *service*. Our model can discriminate different sentiment polarities with different aspects. In sentence (b), "*I highly recommend it for not just its superb cuisine, but also for its friendly owners and staff.*", there is a negation word *not*. Our model can obtain correct polarity, not affected by the negation word who doesn't represent negation here. In the last instance (c), "*The service, however, is a peg or two below the quality of food (horrible bartenders), and the clientele, for the most part, are rowdy, loud-mouthed commuters (this could explain the bad attitudes from the staff) getting loaded for an AC/DC concert or a Knicks game.*", the sentence has a long and complicated structure so that existing parser may hardly obtain correct parsing trees. Hence, tree-based neural network models are difficult to predict polarity correctly. While our attention-based LSTM can work well in those sentences with the help of attention mechanism and aspect embedding.

5 Conclusion and Future Work

In this paper, we have proposed attention-based LSTMs for aspect-level sentiment classification. The key idea of these proposals are to learn aspect

embeddings and let aspects participate in computing attention weights. Our proposed models can concentrate on different parts of a sentence when different aspects are given so that they are more competitive for aspect-level classification. Experiments show that our proposed models, AE-LSTM and ATAE-LSTM, obtain superior performance over the baseline models.

Though the proposals have shown potentials for aspect-level sentiment analysis, different aspects are input separately. As future work, an interesting and possible direction would be to model more than one aspect simultaneously with the attention mechanism.

Abstract

In aspect-based sentiment analysis, extracting aspect terms along with the opinions being expressed from user-generated content is one of the most important subtasks. Previous studies have shown that exploiting connections between aspect and opinion terms is promising for this task. In this paper, we propose a novel joint model that integrates recursive neural networks and conditional random fields into a unified framework for explicit aspect and opinion terms co-extraction. The proposed model learns high-level discriminative features and double propagates information between aspect and opinion terms, simultaneously. Moreover, it is flexible to incorporate hand-crafted features into the proposed model to further boost its information extraction performance. Experimental results on the dataset from SemEval Challenge 2014 task 4 show the superiority of our proposed model over several baseline methods as well as the winning systems of the challenge.

1 Introduction

Aspect-based sentiment analysis (Pang and Lee, 2008; Liu, 2011) aims to extract important information, e.g., opinion targets, opinion expressions, target categories, and opinion polarities, from user-generated content, such as microblogs, reviews, etc. This task was first studied by Hu and Liu (2004a; 2004b), followed by Popescu and Etzioni (2005), Zhuang et al. (2006), Zhang et al. (2010), Qiu et al. (2011), Li et al. (2010). In aspect-based sentiment analysis, one of the goals is to extract explicit aspects of an entity from text, along with the opinions being expressed. For example, in a restaurant review *"I have to say they have one of the fastest delivery times in the city."*, the aspect term is *delivery times*, and the opinion term is *fastest*.

Among previous work, one of the approaches is to accumulate aspect and opinion terms from a seed collection without label information, by utilizing syntactic rules or modification relations between them (Qiu et al., 2011; Liu et al., 2013b). In the above example, if we know *fastest* is an opinion word, then *delivery times* is probably inferred to be an aspect because *fastest* is its modifier. However, this approach largely relies on hand-coded rules and is restricted to certain Part-of-Speech (POS) tags, e.g., opinion words are restricted to be adjectives. Another approach focuses on feature engineering based on predefined lexicons, syntactic analysis, etc. (Jin and Ho, 2009; Li et al., 2010). A sequence labeling classifier is then built to extract aspect and opinion terms. This approach requires extensive efforts for designing hand-crafted features and only combines features linearly for classification which ignores higher order interactions.

To overcome the limitations of existing methods, we propose a novel model, named Recursive Neural Conditional Random Fields (RNCRF). Specifically, RNCRF consists of two main components. The first component is a recursive neural network (RNN)[1] (Socher et al., 2010) based on a dependency tree of each sentence. The goal is to learn a high-level feature representation for each word in the context of each sentence and make the representation learning for aspect and opinion terms interactive through the underlying dependency structure among them. The output of the RNN is then fed into a Conditional Random Field (CRF) (Lafferty et al., 2001) to learn a discriminative mapping from high-

[1]Note that in this paper, RNN stands for recursive neural network instead of recurrent neural network.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 616–626,
Austin, Texas, November 1-5, 2016.

level features to labels, i.e., *aspects*, *opinions*, or *others*, so that context information can be well captured. Our main contributions are to use RNN for encoding aspect-opinion relations in high-level representation learning and to present a joint optimization approach based on maximum likelihood and backpropagation to learn the RNN and CRF components simultaneously. In this way, the label information of aspect and opinion terms can be dually propagated from parameter learning in CRF to representation learning in RNN. We conduct expensive experiments on the dataset from SemEval challenge 2014 task 4 (subtask 1) (Pontiki et al., 2014) to verify the superiority of RNCRF over several baseline methods as well as the winning systems of the challenge.

2 Related Work

2.1 Aspects and Opinions Co-Extraction

Hu et al. (2004a) proposed to extract product aspects through association mining, and opinion terms by augmenting a seed opinion set using synonyms and antonyms in WordNet. In follow-up work, syntactic relations are further exploited for aspect/opinion extraction (Popescu and Etzioni, 2005; Wu et al., 2009; Qiu et al., 2011). For example, Qiu et al. (2011) used syntactic relations to double propagate and augment the sets of aspects and opinions. Although the above models are unsupervised, they heavily depend on predefined rules for extraction and are restricted to specific types of POS tags for product aspects and opinions. Jin et al. (2009), Li et al. (2010), Jakob et al. (2010) and Ma et al. (2010) modeled the extraction problem as a sequence tagging problem and proposed to use HMMs or CRFs to solve it. These methods rely on rich hand-crafted features and do not consider interactions between aspect and opinion terms explicitly. Another direction is to use word alignment model to capture opinion relations among a sentence (Liu et al., 2012; Liu et al., 2013a). This method requires sufficient data for modeling desired relations.

Besides explicit aspects and opinions extraction, there are also other lines of research related to aspect-based sentiment analysis, including aspect classification (Lakkaraju et al., 2014; McAuley et al., 2012), aspect rating (Titov and McDonald, 2008; Wang et al., 2011; Wang and Ester, 2014), domain-specific and target-dependent sentiment classification (Lu et al., 2011; Ofek et al., 2016; Dong et al., 2014; Tang et al., 2015).

2.2 Deep Learning for Sentiment Analysis

Recent studies have shown that deep learning models can automatically learn the inherent semantic and syntactic information from data and thus achieve better performance for sentiment analysis (Socher et al., 2011b; Socher et al., 2012; Socher et al., 2013; Glorot et al., 2011; Kalchbrenner et al., 2014; Kim, 2014; Le and Mikolov, 2014). These methods generally belong to sentence-level or phrase/word-level sentiment polarity predictions. Regarding aspect-based sentiment analysis, Irsoy et al. (2014) applied deep recurrent neural networks for opinion expression extraction. Dong et al. (2014) proposed an adaptive recurrent neural network for target-dependent sentiment classification, where targets or aspects are given as input. Tang et al. (2015) used Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) for the same task. Nevertheless, there is little work in aspects and opinions co-extraction using deep learning models.

To the best of our knowledge, the work of Liu et al. (2015) and Yin et al. (2016) are the most related to ours. Liu et al. (2015) proposed to combine recurrent neural network and word embeddings to extract explicit aspects. However, the proposed model simply uses recurrent neural network on top of word embeddings, and thus its performance heavily depends on the quality of word embeddings. In addition, it fails to explicitly model dependency relations or compositionalities within certain syntactic structure in a sentence. Recently, Yin et al. (2016) proposed an unsupervised learning method to improve word embeddings using dependency path embeddings. A CRF is then trained with the embeddings independently in the pipeline.

Different from (Yin et al., 2016), our model does not focus on developing a new unsupervised word embedding methods, but encodes the information of dependency paths into RNN for constructing syntactically meaningful and discriminative hidden representations with labels. Moreover, we integrate RNN and CRF into a unified framework and develop a joint optimization approach, instead of training word

embeddings and a CRF separately as in (Yin et al., 2016). Note that Weiss et al. (2015) proposed to combine deep learning and structured learning for language parsing which can be learned by structured perceptron. However, they also separate neural network training with structured prediction.

2.3 Recursive Neural Networks

Among deep learning methods, RNN has shown promising results on various NLP tasks, such as learning phrase representations (Socher et al., 2010), sentence-level sentiment analysis (Socher et al., 2013), language parsing (Socher et al., 2011a), and question answering (Iyyer et al., 2014). The tree structures used for RNNs include constituency tree and dependency tree. In a constituency tree, all the words lie at leaf nodes, each internal node represents a phrase or a constituent of a sentence, and the root node represents the entire sentence (Socher et al., 2010; Socher et al., 2012; Socher et al., 2013). In a dependency tree, each node including terminal and nonterminal nodes, represents a word, with dependency connections to other nodes (Socher et al., 2014; Iyyer et al., 2014). The resultant model is known as dependency-tree RNN (DT-RNN). An advantage of using dependency tree over the other is the ability to extract word-level representations considering syntactic relations and semantic robustness. Therefore, we adopt DT-RNN in this work.

3 Problem Statement

Suppose that we are given a training set of customer reviews in a specific domain, denoted by $S = \{s_1, ..., s_N\}$, where N is the number of review sentences. For any $s_i \in S$, there may exist a set of aspect terms $A_i = \{a_{i1}, ..., a_{il}\}$, where each $a_{ij} \in A_i$ can be a single word or a sequence of words expressing explicitly some aspect of an entity, and a set of opinion terms $O_i = \{o_{i1}, ..., o_{im}\}$, where each o_{ir} can be a single word or a sequence of words expressing the subjective sentiment of the comment holder. The task is to learn a classifier to extract the set of aspect terms A_i and the set of opinion terms O_i from each review sentence $s_i \in S$.

This task can be formulated as a sequence tagging problem by using the BIO encoding scheme. Specifically, each review sentence s_i is composed of a sequence of words $s_i = \{w_{i1}, ..., w_{in_i}\}$. Each word $w_{ip} \in s_i$ is labeled as one out of the following 5 classes: BA (beginning of aspect), IA (inside of aspect), BO (beginning of opinion), IO (inside of opinion), and O (others). Let $\mathbf{L} = \{\text{BA}, \text{IA}, \text{BO}, \text{IO}, \text{O}\}$. We are also given a test set of review sentences denoted by $S' = \{s'_1, ..., s'_{N'}\}$, where N' is the number of test reviews. For each test review $s'_i \in S'$, our objective is to predict the class label $y'_{iq} \in \mathbf{L}$ for each word w'_{iq}. Note that a sequence of predictions with BA at the beginning followed by IA are indication of one aspect, which is similar for opinion terms.[2]

4 Recursive Neural CRFs

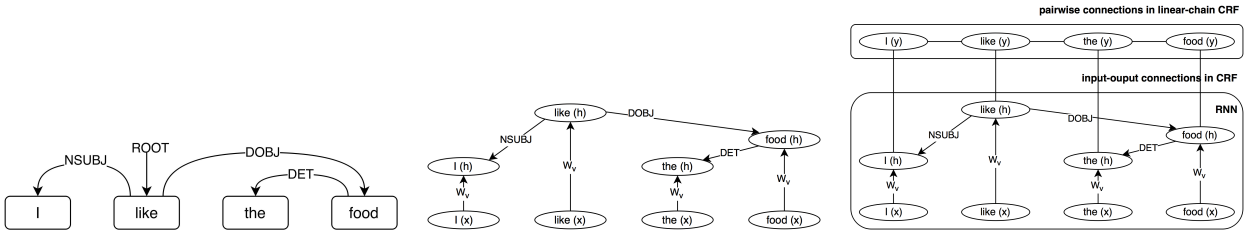
As described in Section 1, RNCRF consists of two main components: 1) a DT-RNN to learn a high-level representation for each word in a sentence, and 2) a CRF to take the learned representation as input to capture context around each word for explicit aspect and opinion terms extraction. Next, we present these two components in details.

4.1 Dependency-Tree RNNs

We begin by associating each word w in our vocabulary with a feature vector $x \in \mathbb{R}^d$, which corresponds to a column of a word embedding matrix $W_e \in \mathbb{R}^{d \times v}$, where v is the size of the vocabulary. For each sentence, we build a DT-RNN based on the corresponding dependency parse tree with word embeddings as initialization. An example of the dependency parse tree is shown in Figure 1(a), where each edge starts from the parent and points to its dependent with a syntactic relation.

In a DT-RNN, each node n, including leaf nodes, internal nodes and the root node, in a specific sentence is associated with a word w, an input feature vector x_w, and a hidden vector $h_n \in \mathbb{R}^d$ of the same dimension as x_w. Each dependency relation r is associated with a separate matrix $W_r \in \mathbb{R}^{d \times d}$. In addition, a common transformation matrix $W_v \in \mathbb{R}^{d \times d}$ is introduced to map the word embedding x_w at node n to its corresponding hidden vector h_n.

[2] In this work we focus on extraction of aspect and opinion terms, not polarity predictions on opinion terms. Polarity prediction can be done by either post-processing on the extracted opinion terms or redefining the BIO labels by encoding the polarity information.



(a) Example of a dependency tree. (b) Example of a DT-RNN tree structure. (c) Example of a RNCRF structure.

Figure 1: Examples of dependency tree, DT-RNN structure and RNCRF structure for a review sentence.

Along with a particular dependency tree, a hidden vector h_n is computed from its own word embedding x_w at node n with the transformation matrix W_v and its children's hidden vectors $h_{\text{child(n)}}$ with the corresponding relation matrices $\{W_r\}$'s. For instance, given the parse tree shown in Figure 1(a), we first compute the leaf nodes associated with the words *I* and *the* using W_v as follows,

$$\begin{aligned} h_{\text{I}} &= f(W_v \cdot x_{\text{I}} + b), \\ h_{\text{the}} &= f(W_v \cdot x_{\text{the}} + b), \end{aligned}$$

where f is a nonlinear activation function and b is a bias term. In this paper, we adopt $tanh(\cdot)$ as the activation function. Once the hidden vectors of all the leaf nodes are generated, we can recursively generate hidden vectors for interior nodes using the corresponding relation matrix W_r and the common transformation matrix W_v as follows,

$$\begin{aligned} h_{\text{food}} &= f(W_v \cdot x_{\text{food}} + W_{\text{DET}} \cdot h_{\text{the}} + b), \\ h_{\text{like}} &= f(W_v \cdot x_{\text{like}} + W_{\text{DOBJ}} \cdot h_{\text{food}} \\ &\quad + W_{\text{NSUBJ}} \cdot h_{\text{I}} + b). \end{aligned}$$

The resulting DT-RNN is shown in Figure 1(b). In general, a hidden vector for any node n associated with a word vector x_w can be computed as follows,

$$h_n = f\left(W_v \cdot x_w + b + \sum_{k \in \mathcal{K}_n} W_{r_{nk}} \cdot h_k\right), \quad (1)$$

where $\mathcal{K}_n$ denotes the set of children of node n, r_{nk} denotes the dependency relation between node n and its child node k, and h_k is the hidden vector of the child node k. The parameters of DT-RNN, $\Theta_{\text{RNN}} = \{W_v, W_r, W_e, b\}$, are learned during training.

4.2 Integration with CRFs

CRFs are a discriminative graphical model for structured prediction. In RNCRF, we feed the output of DT-RNN, i.e., the hidden representation of each word in a sentence, to a CRF. Updates of parameters for RNCRF are carried out successively from the top to bottom, by propagating errors through CRF to the hidden layers of RNN (including word embeddings) using backpropagation through structure (BPTS) (Goller and Küchler, 1996).

Formally, for each sentence s_i, we denote the input for CRF by $\mathbf{h}_i$, which is generated by DT-RNN. Here $\mathbf{h}_i$ is a matrix with columns of hidden vectors $\{h_{i1}, ..., h_{in_i}\}$ to represent a sequence of words $\{w_{i1}, ..., w_{in_i}\}$ in a sentence s_i. The model computes a structured output $\mathbf{y}_i = \{y_{i1}, ..., y_{in_i}\} \in \mathbf{Y}$, where $\mathbf{Y}$ is a set of possible combinations of labels in label set $\mathbf{L}$. The entire structure can be represented by an undirected graph $G = (V, E)$ with cliques $c \in C$. In this paper, we employed linear-chain CRF, which has two different cliques: unary cliques (U) representing input-output connection, and pairwise cliques (P) representing adjacent output connections, as shown in Figure 1(c). During inference, the model aims to output $\hat{\mathbf{y}}$ with the maximum conditional probability $p(\mathbf{y}|\mathbf{h})$. (We drop the subscript i here for simplicity.) The probability is computed from potential outputs of the cliques:

$$p(\mathbf{y}|\mathbf{h}) = \frac{1}{Z(\mathbf{h})} \prod_{c \in C} \psi_c(\mathbf{h}, \mathbf{y}_c), \quad (2)$$

where $Z(\mathbf{h})$ is the normalization term, and $\psi_c(\mathbf{h}, \mathbf{y}_c)$ is the potential of clique c, computed as $\psi_c(\mathbf{h}, \mathbf{y}_c) = \exp\langle W_c, F(\mathbf{h}, \mathbf{y}_c)\rangle$, where the RHS is the exponential of a linear combination of feature vector $F(\mathbf{h}, \mathbf{y}_c)$ for clique c, and the weight vector W_c is tied for unary and pairwise cliques. We

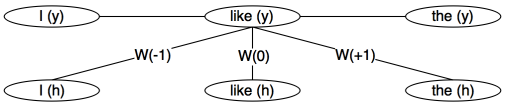


Figure 2: An example for computing input-ouput potential for the second position *like*.

also incorporate a context window of size $2T+1$ when computing unary potentials (T is a hyper-parameter). Thus, the potential of unary clique at node k can be written as

$$\psi_U(\mathbf{h}, y_k) = \exp\Bigg((W_0)_{y_k} \cdot h_k + \sum_{t=1}^{T} (W_{-t})_{y_k} \cdot h_{k-t} + \sum_{t=1}^{T} (W_{+t})_{y_k} \cdot h_{k+t} \Bigg), \quad (3)$$

where W_0, W_{+t} and W_{-t} are weight matrices of the CRF for the current position, the t-th position to the right, and the t-th position to the left within context window, respectively. The subscript y_k indicates the corresponding row in the weight matrix.

For instance, Figure 2 shows an example of window size 3. At the second position, the input features for *like* are composed of the hidden vectors at position 1 (h_{I}), position 2 (h_{like}) and position 3 (h_{the}). Therefore, the conditional distribution for the entire sequence $\mathbf{y}$ in Figure 1(c) can be calculated as

$$p(\mathbf{y}|\mathbf{h}) = \frac{1}{Z(\mathbf{h})} \exp\Bigg(\sum_{k=1}^{4} (W_0)_{y_k} \cdot h_k + \sum_{k=2}^{4} (W_{-1})_{y_k} \cdot h_{k-1} + \sum_{k=1}^{3} (W_{+1})_{y_k} \cdot h_{k+1} + \sum_{k=1}^{3} V_{y_k, y_{k+1}} \Bigg),$$

where the first three terms in the exponential of the RHS consider unary clique while the last term considers the pairwise clique with matrix V representing pairwise state transition score. For simplicity in description on parameter updates, we denote the log-potential for clique $c \in \{U, P\}$ by $g_c(\mathbf{h}, \mathbf{y}_c) = \langle W_c, F(\mathbf{h}, \mathbf{y}_c) \rangle$.

4.3 Joint Training for RNCRF

Through the objective of maximum likelihood, updates for parameters of RNCRF are first conducted on the parameters of the CRF (unary weight matrices $\Theta_U = \{W_0, W_{+t}, W_{-t}\}$ and pairwise weight matrix V) by applying chain rule to log-potential updates. Below is the gradient for Θ_U (updates for V are similar through the log-potential of pairwise clique $g_P(y'_k, y'_{k+1})$):

$$\triangle \Theta_U = \frac{\partial - \log p(\mathbf{y}|\mathbf{h})}{\partial g_U(\mathbf{h}, y'_k)} \cdot \frac{\partial g_U(\mathbf{h}, y'_k)}{\partial \Theta_U}, \quad (4)$$

where

$$\frac{\partial - \log p(\mathbf{y}|\mathbf{h})}{\partial g_U(\mathbf{h}, y'_k)} = -(1_{y_k = y'_k} - p(y'_k|\mathbf{h})), \quad (5)$$

and y'_k represents possible label configuration of node k. The hidden representations of each word and the parameters of DT-RNN are updated subsequently by applying chain rule with (5) through BPTS as follows,

$$\triangle h_{\text{root}} = \frac{\partial - \log p(\mathbf{y}|\mathbf{h})}{\partial g_U(\mathbf{h}, y'_{\text{root}})} \cdot \frac{\partial g_U(\mathbf{h}, y'_{\text{root}})}{\partial h_{\text{root}}}, \quad (6)$$

$$\triangle h_{k \neq \text{root}} = \frac{\partial - \log p(\mathbf{y}|\mathbf{h})}{\partial g_U(\mathbf{h}, y'_k)} \cdot \frac{\partial g_U(\mathbf{h}, y'_k)}{\partial h_k} + \triangle h_{\text{par(k)}} \cdot \frac{\partial h_{\text{par}(k)}}{\partial h_k}, \quad (7)$$

$$\triangle \Theta_{\text{RNN}} = \sum_{k=1}^{K} \frac{\partial - \log p(\mathbf{y}|\mathbf{h})}{\partial h_k} \cdot \frac{\partial h_k}{\partial \Theta_{\text{RNN}}}, \quad (8)$$

where h_{root} represents the hidden vector of the word pointed by ROOT in the corresponding DT-RNN. Since this word is the topmost node in the tree, it only inherits error from the CRF output. In (7), $h_{\text{par}(k)}$ denotes the hidden vector of the parent node of node k in DT-RNN. Hence the lower nodes receive error from both the CRF output and error propagation from parent node. The parameters within DT-RNN, Θ_{RNN}, are updated by applying chain rule with respect to updates of hidden vectors, and aggregating among all associated nodes, as shown in (8). The overall procedure of RNCRF is summarized in Algorithm 1.

5 Discussion

The best performing system (Toh and Wang, 2014) for SemEval challenge 2014 task 4 (subtask 1) employed CRFs with extensive hand-crafted features including those induced from dependency trees. However, their experiments showed that the addition of the features induced from dependency relations does not improve the performance. This indicates

Algorithm 1 Recursive Neural CRFs

Input: A set of customer review sequences: $S = \{s_1, ..., s_N\}$, and feature vectors of d dimensions for each word $\{x_w\}$'s, window size T for CRFs
Output: Parameters: $\Theta = \{\Theta_{\text{RNN}}, \Theta_U, V\}$
Initialization: Initialize W_e using *word2vec*. Initialize W_v and $\{W_r\}$'s randomly with uniform distribution between $\left[-\frac{\sqrt{6}}{\sqrt{2d+1}}, \frac{\sqrt{6}}{\sqrt{2d+1}}\right]$. Initialize W_0, $\{W_{+t}\}$'s, $\{W_{-t}\}$'s, V, and b with all 0's

the difficulty of incorporating dependency structure explicitly as input features, which motivates the design of our model to use DT-RNN to encode dependency between words for feature learning. The most important advantage of RNCRF is the ability to learn the underlying dual propagation between aspect and opinion terms from the tree structure itself. Specifically as shown in Figure 1(c), where the aspect is *food* and the opinion expression is *like*. In the dependency tree, *food* depends on *like* with the relation *DOBJ*. During training, RNCRF computes the hidden vector h_{like} for *like*, which is also obtained from h_{food}. As a result, the prediction for *like* is affected by h_{food}. This is one-way propagation from *food* to *like*. During backpropagation, the error for *like* is propagated through a top-down manner to revise the representation h_{food}. This is the other-way propagation from *like* to *food*. Therefore, the dependency structure together with the learning approach help to enforce the dual propagation of aspect-opinion pairs as long as the dependency relation exists, either directly or indirectly.

5.1 Adding Linguistic/Lexicon Features

RNCRF is an end-to-end model, where feature engineering is not necessary. However, it is flexible to incorporate light hand-crafted features into RNCRF to further boost its performance, such as features from POS tags, name-list, or sentiment lexicon. These features could be appended to the hidden vector of each word, but keep fixed during training, unlike learnable neural inputs and the CRF weights as described in Section 4.3. As will be shown in experiments, RNCRF without any hand-crafted features slightly outperforms the best performing systems that involve heavy feature engineering efforts, and RNCRF with light feature engineering can achieve even better performance.

Domain	Training	Test	Total
Restaurant	3,041	800	3,841
Laptop	3,045	800	3,845
Total	6,086	1,600	7,686

Table 1: SemEval Challenge 2014 task 4 dataset

6 Experiment

6.1 Dataset and Experimental Setup

We evaluate our model on the dataset from SemEval Challenge 2014 task 4 (subtask 1), which includes reviews from two domains: restaurant and laptop[3]. The detailed description of the dataset is given in Table 1. As the original dataset only includes manually annotate labels for aspect terms but not for opinion terms, we manually annotated opinion terms for each sentence by ourselves to facilitate our experiments.

For word vector initialization, we train word embeddings with word2vec (Mikolov et al., 2013) on the Yelp Challenge dataset[4] for the restaurant domain and on the Amazon reviews dataset[5] (McAuley et al., 2015) for the laptop domain. The Yelp dataset contains 2.2M restaurant reviews with 54K vocabulary size. For the Amazon reviews, we only extracted the electronic domain that contains 1M reviews with 590K vocabulary size. We vary different dimensions for word embeddings and chose 300 for both domains. Empirical sensitivity studies on different dimensions of word embeddings are also conducted. Dependency trees are generated using Stanford Dependency Parser (Klein and Manning, 2003). Regarding CRFs, we implement a linear-chain CRF using CRFSuite (Okazaki, 2007). Because of the relatively small size of training data and a large number of parameters, we perform pre-training on the parameters of DT-RNN with cross-

[3]Experiments with more publicly available datasets, e.g. restaurant review dataset from SemEval Challenge 2015 task 12 will be conducted in our future work.

[4]http://www.yelp.com/dataset_challenge

[5]http://jmcauley.ucsd.edu/data/amazon/links.html

entropy error, which is a common strategy for deep learning (Erhan et al., 2009). We implement mini-batch stochastic gradient descent (SGD) with a batch size of 25, and an adaptive learning rate (AdaGrad) initialized at 0.02 for pretraining of DT-RNN, which runs 4 epochs for the restaurant domain and 5 epochs for the laptop domain. For parameter learning of the joint model RNCRF, we implement SGD with a decaying learning rate initialized at 0.02. We also try with varying context window size, and use 3 for the laptop domain and 5 for the restaurant domain, respectively. All parameters are chosen by cross validation.

As discussed in Section 5.1, hand-crafted features can be easily incorporated into RNCRF. We generate three types of simple features based on POS tags, name-list and sentiment lexicon to show further improvement by incorporating these features. Following (Toh and Wang, 2014), we extract two sets of name list from the training data for each domain, where one includes high-frequency aspect terms, and the other includes high-probability aspect words. These two sets are used to construct two lexicon features, i.e. we build a 2D binary vector: if a word is in a set, the corresponding value is 1, otherwise 0. For POS tags, we use Stanford POS tagger (Toutanova et al., 2003), and convert them to universal POS tags that have 15 different categories. We then generate 15 one-hot POS tag features. For sentiment lexicon, we use the collection of commonly used opinion words (around 6,800) (Hu and Liu, 2004a). Similar to name list, we create a binary feature to indicate whether the word belongs to opinion lexicon. We denote by RNCRF+F the proposed model with the three types of features.

Compared to the winning systems of SemEval Challenge 2014 task 4 (subtask 1), RNCRF or RNCRF+F uses additional labels of opinion terms for training. Therefore, to conduct fair comparison experiments with the winning systems, we implement RNCRF-O by omitting opinion labels to train our model (i.e., labels become "BA", "IA", "O"). Accordingly, we denote by RNCRF-O+F the RNCRF-O model with the three additional types of hand-crafted features.

6.2 Experimental Results

We compare our model with several baselines:

- **CRF-1**: a linear-chain CRF with standard linguistic features including word string, stylistics, POS tag, context string, and context POS tags.
- **CRF-2**: a linear-chain CRF with both standard linguistic features and dependency information including head word, dependency relations with parent token and child tokens.
- **LSTM**: an LSTM network built on top of word embeddings proposed by (Liu et al., 2015). We keep original settings in (Liu et al., 2015) but replace their word embeddings with ours (300 dimension). We try different hidden layer dimensions (50, 100, 150, 200) and reported the best result with size 50.
- **LSTM+F**: the above LSTM model with the three additional types of hand-crafted features as with RNCRF.
- **SemEval-1**, **SemEval-2**: the top two winning systems for SemEval challenge 2014 task 4 (subtask 1).
- **WDEmb+B+CRF**[6]: the model proposed by (Yin et al., 2016) using word and dependency path embeddings combined with linear context embedding features, dependency context embedding features and hand-crafted features (i.e., feature engineering) as CRF input.

The comparison results are shown in Table 2 for both the restaurant domain and the laptop domain. Note that we provide the same annotated dataset (both aspect labels and opinion labels are included for training) for CRF-1, CRF-2 and LSTM for fair comparison. It is clear that our proposed model RNCRF achieves superior performance compared with most of the baseline models. The performance is even better by adding simple hand-crafted features, i.e., RNCRF+F, with 0.92% and 3.87% absolute improvement over the best system in the challenge for aspect extraction for the restaurant domain and the laptop domain, respectively. This shows the advantage of

[6]We report the best results from the original paper (Yin et al., 2016).

Table 3: Impact of different components.

combining high-level continuous features and discrete hand-crafted features. Though CRFs usually show promising results in sequence tagging problems, they fail to achieve comparable performance when lacking of extensive features (e.g., CRF-1). By adding dependency information explicitly in CRF-2, the result only improves slightly for aspect extraction. Alternatively, by incorporating dependency information into a deep learning model (e.g., RNCRF), the result shows more than 7% improvement for aspect extraction and 2% for opinion extraction.

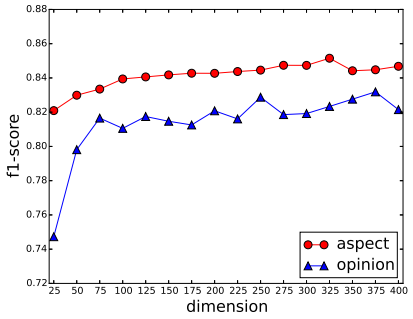
By removing the labels for opinion terms, RNCRF-O produces inferior results than RNCRF because the effect of dual propagation of aspect and opinion pairs disappears with the absence of opinion labels. This verifies our previous assumption that DT-RNN could learn the interactive effects within aspects and opinions. However, the performance of RNCRF-O is still comparable to the top systems and even better with the addition of simple linguistic features: 0.24% and 2.71% superior than the best system in the challenge for the restaurant domain and the laptop domain, respectively. This shows the robustness of our model even without additional opinion labels.

LSTM has shown comparable results for aspect extraction (Liu et al., 2015). However, in their work, they used well-pretrained word embeddings by training with large corpus or extensive external resources, e.g., chunking, and NER. To compare their model with RNCRF, we re-implement LSTM with the same word embedding strategy and labeling resources as ours. The results show that our model outperforms LSTM in aspect extraction by 2.90% and 4.10% for the restaurant domain and the laptop domain, respectively. We conclude that a standard LSTM model fails to extract the relations between aspect and opinion terms. Even with the addition of same linguistic features, LSTM is still inferior than RNCRF itself in terms of aspect extraction. Moreover, our result is comparable with WDEmb+B+CRF in the restaurant domain and better in the laptop domain (+3.26%). Note that WDEmb+B+CRF appended dependency context information into CRF while our model encode such information into high-level representation learning.

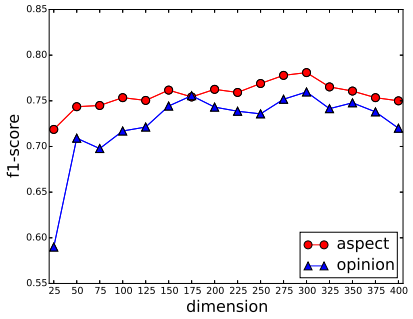
To test the impact of each component of RNCRF and the three types of hand-crafted features, we conduct experiments on different model settings:

- **DT-RNN+SoftMax**: rather than using a CRF, a softmax classifier is used on top of DT-RNN.
- **CRF+word2vec**: a linear-chain CRF with word embeddings only without using DT-RNN.
- **RNCRF+POS/NL/Lex**: the RNCRF model with POS tag or name list or sentiment lexicon feature(s).

The comparison results are shown in Table 3. Similarly, both aspect and opinion term labels are provided for training for each of the above models. Firstly, RNCRF achieves much better results compared to DT-RNN+SoftMax (+11.60% and +10.72% for the restaurant domain and the laptop domain in aspect extraction). This is because DT-RNN fails to fully exploit context information for sequence labeling, which, in contrast, can be achieved by CRF. Secondly, RNCRF outperforms CRF+word2vec, which proves the importance of



(a) On the restaurant domain.



(b) On the laptop domain.

Figure 3: Sensitivity studies on word embeddings.

DT-RNN for modeling interactions between aspects and opinions. Hence, the combination of DT-RNN and CRF inherits the advantages from both models. Moreover, by separately adding hand-crafted features, we can observe that name-list-based features and the sentiment lexicon feature are most effective for aspect extraction and opinion extraction, respectively. This may be explained by the fact that name-list-based features usually contain informative evident for aspect terms and sentiment lexicon provides explicit indication about opinions.

Besides the comparison experiments, we also conduct sensitivity test for our proposed model in terms of word vector dimensions. We tested a set of different dimensions ranging from 25 to 400, with 25 increment. The sensitivity plot is shown in Figure 3. The performance for aspect extraction is smooth with different vector lengths for both domains. For restaurant domain, the result is stable when dimension is larger than or equal to 100, with the highest at 325. For the laptop domain, the best result is at dimension 300, but with relatively small variations. For opinion extraction, the performance reaches a good level when the dimension is larger than or equal to 75 for the restaurant domain and 125 for the laptop domain. This proves the stability and robustness of our model.

7 Conclusion

We have presented a joint model, RNCRF, that achieves the state-of-the-art performance for explicit aspect and opinion term extraction on a benchmark dataset. With the help of DT-RNN, high-level features can be learned by encoding the underlying dual propagation of aspect-opinion pairs. RNCRF combines the advantages of DT-RNNs and CRFs, and thus outperforms the traditional rule-based methods in terms of flexibility, because aspect terms and opinion terms are not only restricted to certain observed relations and POS tags. Compared to feature engineering methods with CRFs, the proposed model saves much effort in composing features, and it is able to extract higher-level features obtained from non-linear transformations.

Abstract

Opinionated expression extraction is a central problem in fine-grained sentiment analysis. Most existing works focus on either generic subjective expression or aspect expression extraction. However, in opinion mining, it is often desirable to mine the aspect specific opinion expressions (or aspect-sentiment phrases) containing both the aspect and the opinion. This paper proposes a hybrid generative-discriminative framework for extracting such expressions. The hybrid model consists of (i) an unsupervised generative component for modeling the semantic coherence of terms (words/phrases) based on their collocations across different documents, and (ii) a supervised discriminative sequence modeling component for opinion phrase extraction. Experimental results using Amazon.com reviews demonstrate the effectiveness of the approach that significantly outperforms several state-of-the-art baselines.

1 Introduction

Aspect based sentiment analysis is one of the main frameworks in opinion mining (Liu and Zhang, 2012). Most of the websites only display the aggregated ratings of products but people are more interested in fine-grained opinions that capture aspect specific properties in reviews. Therefore, it is desirable to have a holistic approach to mine aspect specific opinion expressions containing both aspect and opinion terms within the sentence context as a composite aspect-sentiment phrase (e.g., "had to flash firmware everyday", "clear directions in voice" etc.) and further group them under coherent aspect categories. Apart from knowing the key issues in products that are often expressed via aspect-sentiment phrases, they are also useful in applications such as comparing similar products and summarizing their important features where it is more convenient to have the aspect-sentiment phrases rather than generic aspect/sentiment words lacking the natural aspect opinion correspondence in the right context. They can also be applied to the various tasks such as sentiment classification, comparative aspect evaluations, aspect rating prediction, etc.

The thread of research in (Brody and Elhadad, 2010; Titov and McDonald, 2008; Zhao et al., 2010; Mei et al., 2007; Jo and Oh, 2011) focus on extracting and grouping aspect and opinion words via generative models but lack the natural aspect opinion correspondence (e.g., in the manner they appear in sentences). (Wang et al., 2016; Fei et al., 2016) can discover aspect specific opinion unigrams but does not focus on phrases. The thread on fine grained opinion expressions (Wiebe et al., 2005; Choi et al., 2006; Breck et al., 2007) focus on subjective expression extraction which are generic instead of aspect specific. Formally, the task can be stated as follows:

Given a set of reviews, for each sentence, $s = (w_1, \ldots w_n)$, with the head aspect $(HA), w_{HA=i}, i \in [1, n]$, discover a sub-sequence $(w_p, \ldots w_q)$ where $p \leq i \leq q$ that best describes the aspect-sentiment phrase containing the head aspect. We refer head aspect to the word describing

Research performed during author's internship at University of Houston

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 627–637,
Austin, Texas, November 1-5, 2016.

fine-grained property of product. Further, group these phrases under relevant aspect categories. The examples below show labeled aspect-sentiment phrases within [[ ]] with the head aspect (HA) italicized:

- I've been very happy with it so far done a [[*firmware* update without a hitch]].
- After less than two years, the [[*signal* became spotty]].

In this paper, we propose a novel hybrid model to solve the problem. We call this Phrase Sentiment Model (PSM). PSM is capable of extracting a myriad of expression types covering: verb phrases ("screen has poor viewability"), noun, adjective or adverbial phrase ("recurrent black screen of death", "quite stable and fast connection"), implied positive ("voice activated directions"), implied negative ("requires reboot every few hours") etc. The hybrid framework facilitates holistic modeling that caters for varied expression types (leveraging its discriminative sequence model) and also grouping them under relevant aspect categories with context (exploiting its generative framework). Our approach is also context and polarity independent facilitating generic aspect-sentiment phrase extraction in any domain.

Further, we propose a novel sampling scheme based on Generalized Pólya urn models that optimizes phrasal collocations to improve coherence. To the best of our knowledge, a hybrid framework has not been attempted before for opinion phrase extraction. Additionally, the paper produced a labeled dataset of aspect specific opinion phrases across 4 domains containing more than 5200 sentences coded with phrase boundaries across both positive and negative polarities which will be released to serve as a language resource. Experimental evaluation shows that our approach outperformed the baselines by a large margin.

2 Related Work

Subjective expression extraction (Choi et al., 2005) has traditionally used sequence models (e.g., CRFs). Various parsing, syntactic, lexical and dictionary based features (Kim and Hovy, 2006; Jakob and Gurevych, 2010; Kobayashi et al., 2007) have been used for subjective expression extraction. In (Yang and Cardie, 2013; Johansson and Moschitti, 2011) dependency relations were also used for opinion expression extraction. Sauper et al., (2011) employs an HMM over words and model the latent topics as states in an HMM to discover the product properties (often aspects) and its associated attributes (pos/neg) polarities separately. In Yang and Cardie, (2012) a semi-CRF based approach is used which allow sequence labeling at segment level and (Yang and Cardie, 2014) employed semi-CRF for opinion expression intensity and polarity classification. However, all the above works focus on generic subjective expressions as opposed to aspect specific opinion-sentiment phrases.

In (Choi et al., 2006; Yang and Cardie, 2013) joint models were proposed for identifying opinion holders and expression, relations among them in news articles. In (Johansson and Moschitti, 2011) a re-ranking approach was used on the output of a sequence model to improve opinion expression extraction. In (Li et al., 2015; Mukherjee, 2016) subjective expressions implying a negative opinion were discovered using sequence models and markov networks; while in (Berend, 2011) supervised keyphrase extraction was used for phrase extraction. These works mostly relied on word level features under the first-order Markov assumption. Above works are tailored for only expression extraction and do not group coherent phrases under relevant aspect categories.

Another thread of research involves topic phrase mining. Wang et al., (2007) proposes a Topical n-gram model (TNG) that mines phrases based on statistical collocation. Lindsey et al., (2012) employ hierarchical Pitman-Yor process to model phrases. In Fei et al., (2014), Generalized Pólya urn model (LDA-P-GPU) was used to group the candidate noun phrases. In (El-Kishky et al., 2014; Liu et al., 2015), frequency based information were used for mining phrases that are good for generic phrases but cannot model relevant yet longer phrases due to their infrequency. Thus, they are unable to capture long phrases containing both aspect and opinion. The models TNG and LDA-P-GPU are closest to our task as they can discover relevant aspect expressions that can contain opinions and are considered as baselines.

Next there are works that generate phrasal

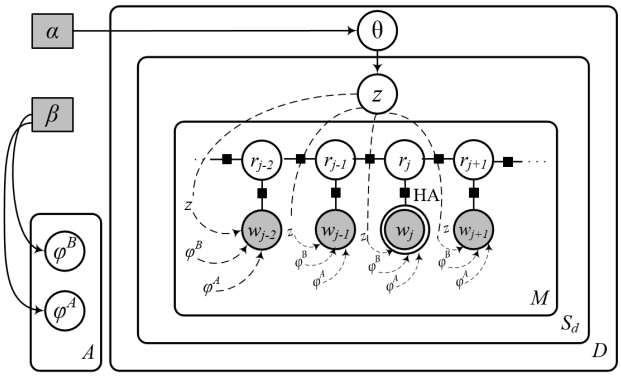

Figure 1: Plate Notation of PSM

datasets. In SemEval 2015, Aspect based Sentiment Analysis Task (Pontiki et al., 2015), a dataset was produced that had annotations for aspect phrases. The focus was on aspect phrases as opposed to aspect-sentiment phrases. The MPQA 2.0 corpus (Wiebe et al., 2005) has some labeled opinion expressions, but they are generic subjective expressions as opposed to aspect-sentiment phrases (see Section 1) we find in reviews.

Zhao et al., (2011) extracts topical phrase in tweets using relevance and interestingness. Wu et al., (2009) proposed a phrase dependency parsing approach to extract product feature (aspect expression) and opinion expression and the relation between them. They considered all noun and verb phrases (NPs, VPs) as product features and its surrounding dictionary opinion words as opinions. Features were constructed using phrase dependency tree to extract relation among all product features and opinions that were later used in aspect and opinion expression extraction. Although, Wu et al., (2009) doesn't discover aspect specific opinion phrases, its use of NPs in extracting candidate opinion phrases is similar to Fei et al., (2014) which is considered as a baseline.

3 Phrase Sentiment Model (PSM)

PSM is a hybrid between generative and discriminative modeling that combines the best of both worlds. Its generative modeling lays the foundation for emission of aspects and aspect specific opinion phrases in documents, while its discriminative sequence modeling component (via an embedded CRF) facilitates aspect specific opinion phrase extraction.

As noted in Titov and McDonald (2008), modeling entire reviews as documents tend to correspond to the global properties of a product (e.g., brand, name, etc.) resulting in rather overlapping aspects. To avoid this, we perform sentence level modeling that helps improve aspect sharpness. A review sentence s_d of N words, is denoted as $w_{d,s,j} = \{w_{d,s,1}, w_{d,s,2} \dots w_{d,s,N}\}$ where each $w_{d,s,j}$ is one of the V words in the vocabulary. There can be exponential number of phrase sequence possible for each sentence s_d i.e. $\langle w_{d,s,j} \rangle_{j=st}^{j=st+len-1}$ of arbitrary length $len (len = 1$ for words; $len > 1$ for phrases) starting at an index $st \in [0, |s_d|]$. We observed that most of opinion expression are centered around the head aspect thereby causing the space of potential opinion expressions to be quite sparse. We took advantage of following observation and trained a sequence model (e.g., CRF) for phrase sequence tagging as described in the next subsection. We generated $M = 5$ best sequence labelings of each sentence $s_d (s_d^{m \in 1 \dots M})$ via forward Viterbi and backward A^* search[1]. Hence, our vocabulary is the union of unigrams and n-grams discovered by CRF over M best sequence labeling, i.e., the model's vocabulary, $V = \{w_{d,s,j}\} \cup \{\langle w_{d,s_d^m,j} \rangle_{j=st}^{j=st+len-1}\} \; \forall d, s, j, len, st, m.$

In PSM, for each aspect a, we model its aspect specific terms (words/phrases) distributions and aspect background word distributions using multinomials φ_a^A and φ_a^B, drawn from $Dir(\beta)$ over the vocabulary $v_{1 \dots V}$. For each domain d, we first draw a domain specific aspect distribution $\theta_d \sim Dir(\alpha)$. Next, for each review sentence (document), s_d of a domain, d we draw an aspect, $z_{d,s} \sim Mult(\theta_d)$. We assume that each sentence evaluates one aspect which mostly holds true in the review domain. We associate a latent switch variable for each word $r_{d,s,j}$ and each phrase $\langle r_{d,s_d^m,j} \rangle_{j=st}^{j=st+len-1}$ of vocabulary where each switch variable $r \in \{0, 1\}$. To generate each term $\langle w_{d,s_d^m,j} \rangle_{j=st}^{j=st+len-1}$ of the labeled sequence $s_d^{m \in \{1 \dots M\}}$, we first set the switch variables for the sentence, s_d via the discriminative CRF model, i.e. $\langle r_{d,s_d^m,j} \rangle_{j=1}^{j=|s_d|} \leftarrow \frac{1}{Z} exp\left(\sum_j \sum_k \lambda_k f_k \left(r_{j-1}, r_j, w_j\right)\right)$ by fitting a previously trained CRF model. The switch variables, $r \in \{1, 0\}$ for a particular tagging s_d^m of

[1]Value of M was tuned via pilot experiments using the CRF++ toolkit (Kudo, 2009)

sentence s_d span over all its words and take values $r = 1$ for words being part of an aspect specific opinion phrase or $r = 0$ for aspect background words, upon observing all words in s_d. Finally, depending upon the aspect, $z_{d,s}$ and the switch variable $r_{d,s,j}$, we emit (unigram) terms in the sentence as follows:

$$w_{d,s,j} \sim \begin{cases} Mult(\varphi^A_{z_{d,s}}) & \text{if } r_{d,s,j} = 1 \\ Mult(\varphi^B_{z_{d,s}}) & \text{if } r_{d,s,j} = 0 \end{cases} \quad (1)$$

and for phrasal terms (i.e., when $\langle r_{d,s^m_d,j}\rangle_{j=1}^{j=st+len-1} = 1 \forall$ valid st and len), we emit $\langle w_{d,s^m_d,j}\rangle_{j=st}^{j=st+len-1} \sim Mult(\varphi^A_{z_{d,s}})$.

3.1 Inference

We employ MCMC Gibbs sampling for posterior inference. As latent variables z and r belong to different levels, we hierarchically sample z and then r for each sweep of a Gibbs iteration as follows:

$$p(z_{d,s} = a|Z_{\neg d,s}, R_{\neg d,s}, W_{\neg d,s}) \propto \frac{(n^s_{d,a})_{\neg d,s}+\alpha}{(n^s_{d,(\cdot)})_{\neg d,s}+A\alpha} \times \left[\left(\prod_{v=1}^{V} \frac{\Gamma(n^A_{a,v}+\beta)}{\Gamma((n^A_{a,v})_{\neg d,s}+\beta)}\right) / \left(\frac{\Gamma(n^A_{a,(\cdot)}+V\beta)}{\Gamma((n^A_{a,(\cdot)})_{\neg d,s}+V\beta)}\right)\right] \times \left[\left(\prod_{v=1}^{V} \frac{\Gamma(n^B_{a,v}+\beta)}{\Gamma((n^B_{a,v})_{\neg d,s}+\beta)}\right) / \left(\frac{\Gamma(n^B_{a,(\cdot)}+V\beta)}{\Gamma((n^B_{a,(\cdot)})_{\neg d,s}+V\beta)}\right)\right] \quad (2)$$

Samplers for r consist of three cases: (i) individual aspect-specific opinion words, (ii) individual background words, and (iii) phrasal opinion:

$$p(r_{d,s,j} = 1|z_{d,s} = a, w_{d,s,j} = v, \ldots) \propto \frac{(n^A_{a,v})_{\neg d,s,j}+\beta)}{(n^A_{a,(\cdot)})_{\neg d,s,j}+V\beta)} \times p_{CRF}(r_{d,s,j-1}, r_{d,s,j} = 1|v) \quad (3)$$

$$p(r_{d,s,j} = 0|z_{d,s} = a, w_{d,s,j} = v, \ldots) \propto \frac{(n^B_{a,v})_{\neg d,s,j}+\beta)}{(n^B_{a,(\cdot)})_{\neg d,s,j}+V\beta)} \times p_{CRF}(r_{d,s,j-1}, r_{d,s,j} = 0|v) \quad (4)$$

$$p(\langle r_{d,s,j} = 1\rangle_{j=st}^{j=st+len-1}|z_{d,s} = a, \langle w_{d,s,j} = v'\rangle_{j=st}^{j=st+len-1}, \ldots) \propto \frac{(n^A_{a,v})_{\neg d,s,j}+\beta)}{(n^A_{a,(\cdot)})_{\neg d,s,j}+V\beta)} \times p_{CRF}(r_{d,s,j=st-1}, r_{d,s,j=st} = 1, r_{d,s,j=st+1} = 1, \ldots r_{d,s,j=st+len-1} = 1|v') \quad (5)$$

where $n^s_{d,a}$ denotes the # of sentences in domain d assigned to aspect a, $n^A_{a,v}, n^B_{a,v}$ denote the # of times term v was assigned to aspect a in the aspect specific opinion, and aspect specific background language models respectively. A count variable with subscript $(\cdot)$ signifies the marginalized sum over the latter index and $\neg$ denotes the discounted counts. The sampler in (5) computes the likelihood of a sequence of contiguous terms, $\langle r_{d,s,j} = 1\rangle_{j=st}^{j=st+len-1}$ forming an aspect ($z_{d,s} = a$) specific opinion phrase, v' starting at index $j = st$ and of length len, where $v' = \langle w_{d,s,j}\rangle_{j=st}^{j=st+len-1}$. The sequence probabilities, p_{CRF} in equations (3, 4, 5) can be obtained as follows.

Let $\mathbf{w} = (w_{t=1} \ldots w_{t=T})$ denote the sequence of observed words in a sentence, and let each observation w_t have a label $y_t \in Y$ indicating whether w_t is part of a aspect specific opinion phrase, where $Y = \{1, 0\}$. We consider a first order Markov linear-chain CRF in our hybrid model. We define the Markovian transition and forward-backward variables of our embedded CRF as follows:

$$\psi_t(j, i, w) = p(y_t = j|y_{t-1} = i)p(w_t = w|y_t = j) \quad (6)$$

$$\alpha_t(j) = \textstyle\sum_{i\in Y} \psi_t(j, i, w_t)\alpha_{t-1}(i) \quad (7)$$

$$\beta_t(j) = \textstyle\sum_{j\in Y} \psi_{t+1}(j, i, w_{t+1})\beta_{t+1}(j) \quad (8)$$

where $\alpha_1(j) = \psi_1(j, y_0, w_1)$ and $\beta_T(i) = 1$. This lays the foundation for expressing the sequence probabilities, p_{CRF} in closed form as follows:

$$p_{CRF}(y_{t-1}, y_t|w) \propto \alpha_{t-1}(y_{t-1})\psi_t(y_t, y_{t-1}, w_t)\beta_t(y_t) \quad (9)$$

$$p_{CRF}(y_{t-2}, y_{t-1}, y_t|w) \propto \alpha_{t-2}(y_{t-2})\psi_{t-1}(y_{t-1}, y_{t-2}, w_{t-1})\psi_t(y_t, y_{t-1}, w_t)\beta_t(y_t) \quad (10)$$

Eq. (9) is used for computing the sequence probabilities for individual opinion/background words for samplers in eq. (3, 4) while eq. (10) and its extensions are used for computing the sequence probabilities in the phrase samplers in eq. (5). The values for $\psi_t, \alpha_t, \beta_t$ are obtained from a previously trained CRF model upon fitting to the current sentence s_d for which sampling is being performed.

3.2 Embedded CRF Training

We employ linear-chain CRFs (Lafferty et al., 2001) for modeling phrases. While word (W) and Part-Of-Speech (POS) tag features are effective in various sequence modeling tasks (Yang and Cardie, 2014; Yang and Cardie, 2012), in our problem context, (W+POS) features are insufficient as they do not consider the head aspect (HA) and its relevant positional/contextual features, i.e., how do different POS tags, syntactic units (chunks), polar sentiments appear in proximity to the head aspect? Hence, centering on the HA, we propose a set of pivot features to model context.

Pivot Features: We consider five feature families:
POS Tags (T): DT, IN, JJ, MD, NN, RB, VB, etc.
Phrase Chunks (C): ADJP, ADVP, NP, PP, VP, etc.
Prefixes (P): *anti, in, mis, non, pre, sub, un,* etc.

Category	Feature Template	Example of feature apperaing in a sentence
1^{st} order features $W_{i+j}; -4 \leq j \leq 4$ $W \in \{T, C, P, S, SP\}$	SP_{i+j}	$SP_{i-1} = NEG$; previous term of HA is of NEG polarity,. . . have this terrible *voice* on the . . .
	S_{i+j}	$S_{i-2} = ing$; suffix of 2^{nd} previous term of head aspect is "ing", . . . kept dropping the *signal* . . .
	. . .	. . .
2^{nd} order features $W_{i+j}, Y_{i+j}; -4 \leq j \leq 4$ $W, Y \in \{T, C, P, S, SP\}$	$T_{i+j}, T_{i+j'}$	$T_{i-2} = JJ, T_{i-1} = VBZ, \cdots$ frequently drops *connection*. . .
	$T_{i+j}, C_{i+j'}$	$T_{i+2} = RB, C_{i+3} = ADJP$; . . . *screen* clarity is good. . .
	. . .	. . .
3^{rd} order features $W_{i+j}, Y_{i+j}, Z_{i+j}; -4 \leq j \leq 4$ $W, Y, Z \in \{T, C, P, S, SP\}$	$T_{i+j}, S_{i+j'}, T_{i+j''}$	$T_{i+2} = JJ, P_{i+4} = un, T_{i+4} = JJ$; . . . *screen* is blank and unresponsive. . .
	. . .	. . .

Table 1: Pivot Templates: Subscript i denotes the index of the head aspect, HA (italicized). Subscript j denotes the index relative to i

Suffixes (S): *able, est, ful, ic, ing, ive, ness* etc.
Word Sentiment Polarity (SP): POS, NEG, NEU

Pivoting on the head aspect, we look forward and backward to generate a family of binary features defined by a specific template (see Table 1). Each template generates several features that capture various positional context around the HA. Additionally, we consider up to 3^{rd} order pivot features allowing us to model various dependencies as features. For polarity, we used the opinion lexicon[2] derived from (Hu and Liu, 2004).

Feature Templates: Table 1 details the templates for features pivoting on the head aspect. Various features from these templates coupled with the value of the current sequence tag at y_t or a combination of current and previous labels y_t, y_{t-1} serve as our linear chain features (LCF), $f(y_{i-1}, y_i, w)$. Further, the index i for LCF can refer to any word in the sentence and not necessarily the head aspect, yielding us a very rich feature space.

Learning the CRF λs: Given a set of training examples $\{\mathbf{w_i}, \overline{y_t}\}$ where $\overline{y_t}$ are the correct sequence tags, we estimate the CRF $\Lambda = \{\lambda_k\}$parameters by minimizing the negative log-likelihood (NLL),

$$\Lambda = argmin_\Lambda(C \sum_i \log(p(\overline{y_t}|\mathbf{w_i}, \Lambda)) + \sum_k \lambda_k^2) \quad (11)$$

Where $p(\overline{y_t}|\mathbf{w}, \Lambda) \propto exp(\sum_k \sum_t \lambda_k f_k(y_{t-1}, y_t, w))$, C is the soft-margin parameter, and the term $\sum_k \lambda_k^2$ indicates L_2 regularization on the feature weights, λ_k. The training set for learning the embedded CRF models λs is detailed in Table 3 (col 1, 2).

[2]http://www.cs.uic.edu/∼liub/FBS/opinion-lexicon-English.rar

4 Optimizing Phrasal Collocations

Topic models can be described in terms of a simple Pólya urn (SPU) sampling schemes in the sense that when a particular term (word or phrase) is drawn from a topic, count of that term is incremented in that topic. This enforces the topic distribution to tend towards these terms over time as frequency of them increases. Therefore, the posterior of generative topic models often favors terms with high frequency e.g., unigrams, while phrasal terms are ranked lower due to their lower frequencies. This is undesirable for phrase extraction.

In contrast, Generalized Pőlya urn (GPU) model differs from SPU in its sampling process. When a certain term is drawn, the count of that term increases as well as it also increases the count of terms which are similar to drawn word/phrases via pseudo-counts for promotion. Thus, GPU caters for promotion of others terms in a principled manner. It has been previously used for unigram topic modeling in (Mimno et al., 2011). In this work we leverage it for phrases.

4.1 Proposed PSM-GPU model

We optimize the collocations of relevant aspect words and phrases in the GPU framework in two ways:

Word to phrase: Intuitively, if an aspect word is assigned to a topic then that topic should represent that aspect and to all other phrases in that aspect's phrase set (i.e., phrases containing that aspect) should belong to the same topic. Thus, when an aspect word is assigned to a topic then each phrase in its aspect set is promoted with a small count in that topic.
Phrase to word: When a phrase $\langle w_{d,s,j} \rangle_{j=st}^{j=st+len-1}$ is assigned to a topic, each component word $w_{d,s,j}$ where $j \in [st, st+len-1]$ in it is also promoted with a certain small count, i.e., each word of that phrase is also assigned to that topic by a certain amount.

We now define the term promotion matrix, A for the GPU framework. Every element of $A, A_{w,w'}$ refers to the promotion pseudocount, i.e., whenever a w was seen in an urn, we increment the count by $A_{w,w'}$ of $w^{'}$. $w, w^{'}$ can be word or phrases.

$$A_{w,w'} = \begin{cases} 1 & \text{if } w = w^{'} \\ \sigma & \text{if } w \text{ is an aspect word,} \\ & w^{'} \text{is a phrase} \in \text{Phrase set of } w \\ \delta & w^{'} \text{is a word} \in \text{Phrase } w \\ 0 & \text{otherwise} \end{cases} \quad (12)$$

To improve the ranking of phrases, the value of σ is kept greater than δ. Empirically values are given section 5.1.

4.2 PSM-GPU Inference

Accounting the GPU process above, the approximate Gibbs samplers for z and r take the following form:

$$p(z_{d,s} = a | Z_{\neg d,s}, R_{\neg d,s}, W_{\neg d,s}) \propto \left[\frac{(n^s_{d,a})_{\neg d,s} + \alpha)}{(n^s_{d,(\cdot)})_{\neg d,s} + A\alpha)} \right] \times \frac{\left(\prod_{v=1}^{V} \frac{\Gamma(\sum_{w'=1}^{V} (A_{v,w'} * n^A_{a,w'}) + \beta)}{\Gamma(\sum_{w'=1}^{V} (A_{v,w'} * n^A_{a,w'})_{\neg d,s} + \beta)} \right)}{\left(\frac{\Gamma(\sum_{v=1}^{V} \sum_{w'=1}^{V} (A_{v,w'} * n^A_{a,w'}) + V\beta)}{\Gamma(\sum_{v=1}^{V} \sum_{w'=1}^{V} (A_{v,w'} * n^A_{a,w'})_{\neg d,s} + V\beta)} \right)} \times \left[\left(\prod_{v=1}^{V} \frac{\Gamma(n^B_{a,v} + \beta)}{\Gamma((n^B_{a,v})_{\neg d,s} + \beta)} \right) / \left(\frac{\Gamma(n^B_{a,(\cdot)} + V\beta)}{\Gamma((n^B_{a,(\cdot)})_{\neg d,s} + V\beta)} \right) \right] \quad (13)$$

$$p(r_{d,s,j} = 1 | z_{d,s} = a, w_{d,s,j} = v, \ldots) \propto \frac{\sum_{w'=1}^{V} (A_{v,w'} * n^A_{a,w'})_{\neg d,s,j} + \beta)}{\sum_{v=1}^{V} \sum_{w'=1}^{V} (A_{v,w'} * n^A_{a,w'})_{\neg d,s,j} + V\beta} \times p_{CRF}(r_{d,s,j-1}, r_{d,s,j} = 1 | v) \quad (14)$$

Similarly, phrasal opinion switch variable can be derived. The sampler for individual background words remains unchanged.

5 Experimental Evaluation

In this section, we evaluate our proposed models. We first detail our dataset, followed by baselines and results.

5.1 Dataset and Parameter Settings

Domain	Pos. Labeled Phrase	Neg. Labeled Phrase	Positive	Negative	Total
Router	414	1256	1937	5291	7228
GPS	948	672	2473	2231	4704
Mouse	376	477	1421	2591	4012
Keyboard	398	660	912	1539	2451

Table 3: Statistics of dataset of four domain

Dataset Statistics: For CRF training, we created a phrase labeled dataset of aspect opinion phrases using product reviews from Amazon across 4 domains each spanning 4 head aspects. In this work, head aspects for a domain are known a priori either directly using unsupervised topic induction or guided by domain knowledge (e.g. using aspect models such as (Zhao et al., 2010; Chen et al., 2013; Mukherjee and Liu, 2012)). Our focus is on phrase extraction and grouping. We labeled the positive and negative opinion phrases spans (Table 3; col 2, 3) in the reviews following the annotation schemes in (Wilson et al., 2005) for embedded CRF training in PSM. Table 3 details our labeled data for CRF training. This phrase boundary labeled dataset (Table 3; col 2, 3) is "orthogonal" or disjoint from the data where the PSM model was fit and evaluated (Table 3, col 4, 5). This avoids overfitting and makes a fair case for all the experiments of PSM.
Preprocessing and Parameter Setting: We removed the stopwords, punctuation, special characters and words appearing less than 5 times in each domain. For all models, posterior estimates of latent variables were taken with a sampling lag of 50 iterations post burn-in phase (of 200 iterations) with 2,000 iterations in total. Dirichlet priors were set to $\alpha = 50/K$, where K is the number of topics (empirically set to 10 via pilot) and $\beta = 0.1$. The CRF parameters $C = 1$ and GPU parameters $\sigma = 0.05$ and $\delta = 0.01$ were estimated using cross validation.

5.2 Baselines

We consider the following relevant phrase extraction models as our baselines:

PSM-GPU	sMC-GPU	LDA-P-GPU
Router→Connection:"updating firmware secure connection", "dropping connection", "connection excellent", "instability wireless connection", "crashes entire connection", *"updating"*, "kills current connection including downloads", "affected plugged connection",*"cable radio frequency connection", "halfway"*	**Router→Connection:** *"connection big time", "signal weak time connection", "connection time stable"*, "lose connection", "internet connection speed dropped", *"stop working lot connection"*, "started dropping internet connection", "started dropping connection", "drop wireless connection drops wired connection", "connection dropping problems"	**Router→Connection:** *"drops", "times day internet connection"*, "internet connection multiple times", *"internet connection times", "internet connection minutes"*, "dropping internet connection", "broadband internet connection", "extremely slow internet connection", "lost internet connection",*"internet connection couple"*
GPS→Screen:"poor screen contrast daylight", *"direction screen missing poor screen contrast"*, "slow screen size makes useless", "screen turned", *"turn", "nothing screen"*, "night screen bit bright", "screen unpredictable directions", "lacks faster screen refresh rate", "smoother screen refresh"	**GPS→Screen:** *"bright"*, "excellent nice touch screen", *"touch screen n't"*, "nice big touch screen", "touch screen big size", *"smaller", "touch screen but nice", "screen accurate spoken direction"*, "touch screen nice", "nice slim touch screen"	**GPS→Screen:** *"smaller screen but dont"*, "wide screen", *"nothing but screen", "ok but screen", "screen but normal", "screen size"*, "large screen", "better traffic features cons touch screen", *"screen real estate than", "than years screen"*

Table 2: Example aspect specific opinion phrases (comma delimited in order) discovered by PSM-GPU, sMC-GPU, LDA-P-GPU. Errors are italicized and marked in red.

LDA with phrases (LDA-P): As aspect-sentiment phrases are often noun phrases, a basic approach is to include the noun phrases (extracted using a parser) as separate terms in the corpus.

Topical N-gram (TNG): The TNG model in (Wang et al., 2007) extends LDA to model n-grams of arbitrary length. As aspects often appear close to their opinion in the sentence, topical n-grams for each aspect form a natural baseline. We used the authors original implementation in the MALLET toolbox.

LDA-P with GPU (LDA-P-GPU): This model is due to (Fei et al., 2014) and is tailored for phrase extraction in opinion mining. It employs LDA with noun phrases in the GPU framework to rank the aspect phrases higher in their topics. Our implementations of LDA-P and LDA-P-GPU use the noun phrases discovered by the Stanford Parser.

semi-Markov CRF with GPU(sMC-GPU): This model builds over the model of (Yang and Cardie, 2012) that used dependency tree features and semi-CRF to model the arbitrarily long expressions. We used these expression spans as multiword in vocabulary. Then we employ GPU based sampling with LDA proposed by (Fei et al., 2014) to collocate opinion expressions.

5.3 Qualitative Analysis

To assess the quality of extracted expressions, we labeled the topics following instructions in (Mimno et al., 2011). First, each topic was labeled as coherent or incoherent and an aspect name was given if the topic was coherent. Each topic was presented as a list of top 45 terms in descending order of their probabilities under that topic. A topic was considered coherent if the terms in the topic were semantically related to each other.

Next, for coherent topics, their terms were labeled as correct (if the terms semantics was relevant to the topic) or incorrect (otherwise). Two human judges were used in the annotation. Agreements being high ($\kappa > 0.78$), disagreements were resolved upon consensus among judges.

Table 2 reports the top 10 terms(words/phrases) for aspect 'connection' (Router domain) and aspect 'screen'(GPS domain) across PSM-GPU, sMC-GPU and LDA-P-GPU (the two closest competitor). We note that PSM-GPUs phrases are more expressive compared to sMC-GPU because sMC-GPU is prone to have longer phrases due to segment features but PSM's switch variable captured more relevant aspect specific opinion expressions. sMC-GPU has better

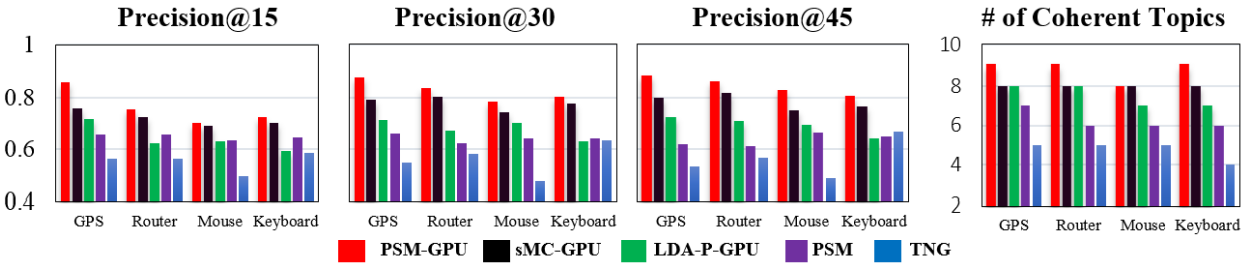

Figure 2: Charts from left to right are Topical words Precision@15, Precision@30, Precision@45 of coherent topics of each model and last one is number of coherent topics of each model.

Table 4: Sentiment classification: Precision, Recall, F1 and accuracy from top to down for each domain and each model

phrases compared to LDA-P-GPU because the latter only considers noun phrases which may not always be semantically coherent under an aspect. The qualitative results of other baselines TNG and LDA-P were worse than that of LDA-P-GPU and hence omitted due to space constraints. However, the subsequent experiments compare all models quantitatively.

5.4 Quantitative Analysis

We consider the following metrics and tasks:

Average Precision: Figure 2 shows the average Precision@n (p@n) for $n = 15, 30, 45$ of all coherent topics for each model in each domain. We note that PSM-GPU achieves the highest precision for all domains significantly ($p < 0.01$) outperforming its closest competitor sMC-GPU. sMC-GPU tends to discover longer phrases due to segment features in semi-CRF and combined with GPU gains the maximum strength among other baselines. Next in order are LDA-P-GPU, PSM, and TNG. We have not shown the result of LDA-P as its top terms didn't contain enough phrases and its precision scores were quite lower compared to other models. But it is worthwhile to note that PSM outperforms LDA-P-GPU (2nd best competitor) at lower ranks which is more important (e.g., in majority domains for $p@15$) and shows its effectiveness. It is a bit unfair to compare PSM with sMC-GPU because PSM is lacking phrase rank optimization whereas sMC-GPU enforces it, and the $p@n$ metric uses rank position as its goodness criterion. However, we will see that in an actual application task, both PSM and PSM-GPU does better than sMC-GPU. Also, we observed that p@45 is higher compare to p@15 or p@30. The reason is even though we are promoting the phrases using GPU it is not able to remove some aspect opinion words from top 15 terms due to their high occurrence in phrases. For e.g. Table 2 has opinion words like "updating", "turn" which are considered incorrect because of non-phrasal terms.

# of coherent topics: Figure 2 (rightmost chart) shows the number of coherent topics produced by each model. A model that can discover more coherent topics is better. We find that PSM-GPU can discover more coherent topics with phrases than its baselines across all domains. The trends of other models are similar to $p@n$ and can be analogously explained.

We note that the Topic Coherence (TC) metric in (Mimno et al., 2011) which is often used to approximate coherence in unigram topic models as it correlates with human notions of coherence, uses co-document frequency of individual words in topics.

However, in our problem as phrases are sparse, their co-document frequency is far lower than words. Hence, the TC metric is not directly applicable. Our measure of coherence is based on human judgment (achieves high agreements, $\kappa > 0.78$ see Section 5.3) and from Table 2 we can see the discovered phrases do reflect coherence. Hence, to evaluate the phrases quantitatively, we employ an actual sentiment classification task that uses the posterior of our models (top phrases) as features. This is reasonable because the estimated topics (when used as features) improve sentiment classification, it shows that they are meaningful and capable of capturing latent sentiment that govern polarities.

Sentiment Classification: For this task, instead of using all the words as features, we used the posterior on φ^A (top 50 terms of φ^A) as features. For all models, all possible n-grams of top 50 terms are also considered as features. We trained SVMs[3] (using the SVMLight toolkit) with the features described above. Evaluation for this task employed 5-fold cross validation on the data in Table 3 (col 4, 5). For each test fold, the features were induced upon fitting the aspect extraction models on the training data of that fold. From Table 4 we note that both PSM-GPU and PSM outperform all competitors on average F1 across all domains. More specifically, we note that PSM alone that uses no rank optimization performs better than sMC-GPU employing phrasal rank optimization under GPU scheme. We believe this is due to PSM's switching component that can discover correct aspect/sentiment terms (sufficient for polarity classification) and rank it higher based on frequency even though the expressive aspect specific phrases remain ranked lower. sMC-GPU tends to have longer phrases so it does well, however, under GPU, longer phrases may not be promoted well as they lack anchor aspect terms under a relevant topic. LDA-P-GPU uses standard (Noun Phrases) NPs for phrases with rank optimization and hence is the next in performance order as NPs may not capture opinion well. TNG does not perform as well as it relies on multiword collocation as opposed to NP/VP for phrase extraction. LDA-P's performance is lowest as it cannot rank the relevant NPs high. PSM-GPU has the right balance of phrase boundary span and phrasal rank optimization via GPU that makes it significantly outperform ($p < 0.01$) all competitors.

[3]Using an RBF kernel ($C = 10, g = 0.01$) which performed best upon tuning various SVM parameters via cross validation.

Domain	Precision	Recall	F1	Acc.
Router	69.68	67.3	68.4	67.9
GPS	66.47	68.6	67.5	68.00
Mouse	87.24	80.5	83.4	86.9
Keyboard	85.45	70.9	77.1	81.1

Table 5: Domain ablation result on polarity classification

Sequence Model Sensitivity: To assess the robustness of the hybrid framework, we evaluate the sensitivity of the embedded CRF model via domain ablation. We choose the best performer PSM-GPU and ablate each domain during its CRF training. We repeat the previous experiment on sentiment classification using the ablated model. From the results in Table 5, we note that the reduction in precision is relatively more than that of recall. However, the F1 score does not drop significantly (compared to Table 4) for any domain showing the robustness of the hybrid framework. We note that even with some skewness in the labeled data (Table 3), CRF is not overfitting here and the proposed pivot features (Table 1) are powerful enough to learn the phrasal structure across domain.

6 Conclusion

This paper presented a novel hybrid framework for aspect specific opinion expression extraction. Two models PSM and PSM-GPU were proposed that employ CRF discriminative sequence modeling for phrase boundary extraction and generative modeling for grouping relevant terms under a topic. PSM-GPU further optimized the aspect coherence using the generalized Pólya urn sampling scheme. Experimental results showed that the proposed hybrid models can extract more coherent aspect specific opinion expressions significantly outperforming all competitors across all domains and are robust in cross-domain knowledge transfer.

Abstract

The advent of social media and its prosperity enable users to share their opinions and views. Understanding users' emotional states might provide the potential to create new business opportunities. Automatically identifying users' emotional states from their texts and classifying emotions into finite categories such as *joy*, *anger*, *disgust*, etc., can be considered as a text classification problem. However, it introduces a challenging learning scenario where multiple emotions with different intensities are often found in a single sentence. Moreover, some emotions co-occur more often while other emotions rarely coexist. In this paper, we propose a novel approach based on emotion distribution learning in order to address the aforementioned issues. The key idea is to learn a mapping function from sentences to their emotion distributions describing multiple emotions and their respective intensities. Moreover, the relations of emotions are captured based on the Plutchik's wheel of emotions and are subsequently incorporated into the learning algorithm in order to improve the accuracy of emotion detection. Experimental results show that the proposed approach can effectively deal with the emotion distribution detection problem and perform remarkably better than both the state-of-the-art emotion detection method and multi-label learning methods.

1 Introduction

The advent of social media and its prosperity enable the creation of massive online user-generated content including opinions and product reviews. Analyzing such user-generated content allows the detection of users' emotional states, which might be potentially useful for downstream applications such as brand watching, product recommendation, and detection of health-related issues, etc. Based on the way emotions are represented, computational models for emotion analysis can be categorized into dimensional models and categorical models (Calvo and D'Mello, 2010). Dimensional approaches (Russell, 2003) emphasize the fundamental dimensions of valence and arousal in understanding emotional experience, which have long been studied by emotion theorists. Categorical models (Gupta et al., 2013) involve the use of a categorical representation, in which emotions are represented by a number of labels. For example, Ekman's basic emotion set (Ekman, 1992) consists of anger, disgust, fear, happiness, sadness and surprise. An example of a sentence and the annotated emotions can be found in Table 1.

Sentence	Trains crash near Thai resort town					
Emotions	anger	disgust	fear	joy	sadness	surprise
	2	0	62	0	90	10

Table 1: An example of a sentence containing emotions selected from SemEval 2007 Task#14, Affective Text, where each of the six emotions are indicated using a score of [0, 100].

Considering each basic emotion as class label for the sentence, emotion detection can be treated as a classification problem. There is a large body of prior work on emotion classification (Mishne and de Rijke, 2006; Lin and He, 2009; Quan et al., 2015; Wang and Pal, 2015). By choosing the strongest emotion as the emotion label for the sentence, most of

*Corresponding author

Austin, Texas, November 1-5, 2016.

classification approaches are based on single-label learning. However, as shown in Table 1, a sentence might contain multiple emotions with varying intensities. Although, some lexicon-based approach such as (Wang and Pal, 2015) can output multiple emotions with intensities using non-negative matrix factorization. It can only guarantee convergence to a local minimum, which is prohibitive on the large, realistically-sized emotion detection problem.

Machine learning methods such as multi-label learning (MLL) can be employed to identify multiple emotions for each sentence (Zhang and Zhou, 2014). MLL usually selects a threshold, then labels emotions with scores higher than the threshold as relevant and the others as irrelevant. However, these methods are not able to learn the intensity of each emotion. To address this problem, a new machine learning paradigm called Label Distribution Learning (LDL) (Geng, 2016) was proposed in recently years. Similarly, in this paper, we propose an emotion distribution learning (EDL) algorithm. Different from the previous approaches, EDL assumes that each sentence contains a mixture of basic emotions with different intensities. Using categorical model, we can label each sentence with an emotion vector where each element corresponds to one basic emotion and the value of each element indicates the intensity of the emotion. We require that each vector element has a value between 0 and 1 and they sum up to 1. By doing so, the emotion vectors can be considered as emotion distributions and the proposed EDL algorithm aims to learn the mapping from sentences to their corresponding emotion distributions by minimizing the differences between the true distributions and the predicted distributions. Both the single-label learning and MLL can be considered as special cases of EDL in emotion detection. Moreover, as some emotions co-occur more often while others rarely co-exist, the relations between basic emotions are captured according to the Plutchik's wheel of emotions theory (Plutchik, 1980) and are incorporated in the learning framework as constraints in order to improve the accuracy of emotion detection.

Our work makes the following contributions:

- We propose a novel approach based on emotion distribution learning to identify multiple emotions with their intensities from texts. To the best of our knowledge, it is the first attempt to identify both emotions and intensities in the distribution learning framework.
- The relations between basic emotions are incorporated into the learning framework as constraints to improve the emotion detection accuracy. To avoid the incorporation of noisy information from the training data, the relation constraint is set based on the Plutchik's wheel of emotions theory.
- Experimental results show that the proposed approach can effectively deal with the emotion distribution detection problem and perform remarkably better than the state-of-the-art multi-label learning methods and emotion detection method.

2 Related Work

In general, emotion classification can be approached by two types of methods, lexicon-based or corpus-based. Lexicon-based approaches rely on emotion lexicons consisting of words and their corresponding emotion labels for detecting emotions from text. For example, WordNetAffect (Strapparava and Valitutti, 2004) was constructed by extending Wordnet, a lexical database of English terms, with information on affective terms. EmoSenticNet assigns six WordNetAffect emotion labels to SenticNet concepts (Poria et al., 2013), which can be thought of as an expansion of WordNetAffect emotion labels to a larger vocabulary. Many approaches were proposed based on emotion lexicons. For example, (Aman and Szpakowicz, 2007) classified emotional and non-emotional sentences using the constructed emotion lexicon. (Choudhury et al., 2012) employed a classifier to detect human affective states in social media. (Wang and Pal, 2015) proposed a model with several constraints based on an emotion lexicon for emotion classification.

Corpus-based methods aim to train supervised classifiers from annotated training data where each sentence or document is labelled with an emotion class. (Mishne and de Rijke, 2006) constructed models to predict the levels of various moods according to the language used by bloggers at a giv-

en time. (Aman and Szpakowicz, 2007) described an emotion annotation task of identifying emotion category, emotion intensity and the words/phrases that indicate emotions in text. Emotion classification was conducted using trained support vector machines. (Agrawal and An, 2012) proposed an unsupervised context-based approach to detect emotions from text at the sentence level. They computed an emotion vector for each potential affect bearing word based on the semantic relatedness between words and various emotion concepts. The scores are then tuned using the syntactic dependencies within the sentence structure. (Bao et al., 2009) proposed an emotion topic model by augmenting latent Dirichlet allocation with an intermediate emotion layer. (Quan et al., 2015) proposed a logistic regression model for social emotion detection. Intermediate hidden variables were also introduced to model the latent structure of input text corpora.

Our work is partly inspired by (Quan et al., 2015). However, our proposed approach differs from (Quan et al., 2015) in two aspects: 1) by introducing the emotion distribution learning framework, many different criteria can be used to measure the distance between the true distribution and the predicted distribution, such as squared $\mathcal{X}^2$, Euclidean, Jeffery's divergence apart from Kullback-Leibler divergence employed in logistic regression model. 2) the relations between basic emotions are captured based on the Plutchik's wheel of emotions theory to avoid the incorporation of any noisy information from the training data.

3 Emotion Distribution Learning

3.1 Problem Setting

As have discussed in section 1, one sentence might contain one or more emotions, and each emotion has its own intensity. We use d_x^y to indicate the intensity of emotion y for sentence x, where $x \in \mathcal{X}$ and $y \in \mathcal{Y}$. The emotion intensity is normalized to make $d_x^y \in [0,1]$ and $\sum_y d_x^y = 1$ to constitute the emotion distribution.

Note that d_x^y denotes the proportion that y accounts for in a full emotion distribution of x. It is different from the probability of y being a correct emotion label for x. Probability distribution implies that only one emotion label is correct for each sentence, while emotion distribution allows multiple emotions in one sentence. The goal of EDL is to learn a mapping from sentences $\mathcal{X} = \mathbb{R}^m$ to the distributions over a finite set of labels $\mathcal{Y} = \{y_1, y_2, ...y_c\}$. Each label represents one of the basic emotions.

3.2 Learning

Given a training set $P = \{(x_1, E_1), (x_2, E_2), ..., (x_n, E_n)\}$, where $x_i \in \mathcal{X}$ is a sentence and $E_i = \{d_{x_i}^{y_1}, d_{x_i}^{y_2}, ..., d_{x_i}^{y_c}\}$ is the emotion distribution associated with x_i. The goal of EDL is to learn a conditional probability mass function $p(y|x)$ from P, where $x \in \mathcal{X}$ and $y \in \mathcal{Y}$. Assuming that $p(y|x)$ is a parametric model $p(y|x;\theta)$, where θ are model parameters, many different criteria can be used to measure the distance between two distributions, such as Squared $\mathcal{X}^2$, Euclidean, Jeffery's divergence, Kullback-Leibler (K-L) divergence and so on. Here we use Divergence defined by

$$D_J(Q_a||Q_b) = 2\sum_j \frac{(Q_a^j - Q_b^j)^2}{(Q_a^j + Q_b^j)^2}$$

, where Q_a^j and Q_b^j are the j-th element of the two distributions Q_a and Q_b, respectively. Divergence is balanced, which makes $D_J(Q_a||Q_b)$ equal to $D_J(Q_b||Q_a)$. The formula above calculates the sum of all the distances between emotion intensities in the same position.

Then the optimal model parameters θ^* is determined by

$$\begin{aligned}
\theta^* &= \arg\min_\theta \left\{ \sum_i D_J(E_i||\hat{E}_i) + \frac{\xi_1}{n}\sum_{k,r}|\theta_{k,r}|_1 \right. \\
&\left. + \frac{\xi_2}{n}\sum_u\sum_{j,k}\omega_{jk}\|\theta_{u,j} - \theta_{u,k}\|_2^2 \right\} \\
&= \arg\min_\theta \left\{ 2\sum_{i,j}\frac{(d_{x_i}^{y_j} - p(y_j|x_i,\theta))^2}{(d_{x_i}^{y_j} + p(y_j|x_i,\theta))^2} \right. \\
&+ \frac{\xi_1}{n}\sum_{k,r}|\theta_{k,r}|_1 \\
&\left. + \frac{\xi_2}{n}\sum_u\sum_{j,k}\omega_{jk}\|\theta_{u,j} - \theta_{u,k}\|_2^2 \right\}
\end{aligned} \tag{1}$$

, where E_i is the ground truth emotion distribution of the i-th sentence and the $\hat{E}_i$ is the predicted one by $p(y|x_i;\theta)$. The second term is a regularizer to make the predicted emotion distribution sparse, and the third term considers the relationship between different emotions. As mentioned in section 1, some emotions often co-occur such as joy and love, and some rarely co-exist such as joy and anger. Therefore, the third term is employed to incorporate such prior knowledge. The weight ω_{jk} models the relationship between the *j*-th emotion and the *k*-th emotion in the distribution. In this paper, we capture the relationships between different emotions based on Plutchik's wheel of emotions (Plutchik, 1980) which is produced in psychology view. Plutchik's wheel of emotions includes several typical emotions and its eight sectors indicate eight primary emotion dimensions arranged as four pairs of opposites. We re-produce a wheel of eight emotions' relationships according to Plutchik's theory, which is shown in Figure 1.

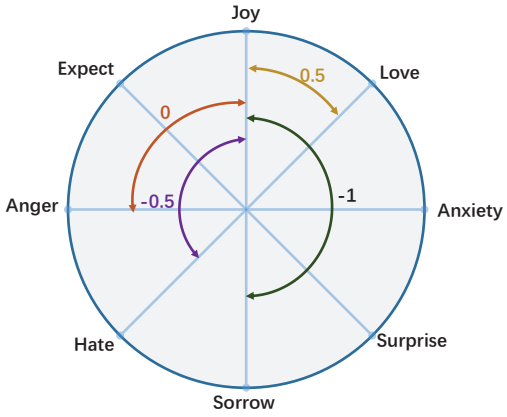

Figure 1: Plutchik's wheel of emotions.

In the emotion wheel, emotions sat at opposite end have an opposite relationship, while emotions next to each other are more closely related. We quantify the relations between each pair of emotions based on the angle between them in wheel of emotions (Plutchik, 2001). For example, emotion pairs with 180 degrees are opposite to each other, which are described by -1, while emotion pairs with 90 degrees are described by 0, meaning no relationship between them. Emotion pairs with 45 degrees have the relationship value of 0.5, while emotion pairs with 135 degrees have the relationship value of -0.5. Figure 2 shows the gray-scale image of the pair-wise relationships of emotions presented in Figure 1. In each cell, the darker the color is, the more similar the two emotions are.

As for $p(y|x;\theta)$, similar to (Geng, 2016), we assume it takes a maximum entropy model, i.e.,

$$p(y_k|x_i;\theta) = \frac{1}{\mathcal{Z}_i}\exp(\sum_r \theta_{kr}x_i^r) \tag{2}$$

, where $\mathcal{Z}_i = \sum_k \exp(\sum_r \theta_{kr}x_i^r)$ is the normalization factor, x_i^r is the *r*-th feature of x_i, and θ_{kr} is an element in θ. Substituting Equation 2 into Equation 1 yields the target function,

$$\begin{aligned} T(\theta) = 2\sum_{i,j}\left(1 - \frac{4\mathcal{Z}_i d_{x_i}^{y_j}\exp\left(\sum_r \theta_{jr}x_i^r\right)}{\left(\mathcal{Z}_i d_{x_i}^{y_j} + \exp\left(\sum_r \theta_{jr}x_i^r\right)\right)^2}\right) \\ + \frac{\xi_1}{n}\sum_{k,r}|\theta_{k,r}|_1 \\ + \frac{\xi_2}{n}\sum_u\sum_{j,k}\omega_{jk}\|\theta_{u,j} - \theta_{u,k}\|_2^2. \end{aligned} \tag{3}$$

The minimization of the function $T(\theta)$ can be effectively solved by the limited-memory quasi-Newton method (L-BFGS). The basic idea of L-BFGS is to avoid explicit calculation of the inverse Hessian matrix used in the Newton method. L-BFGS approximates the inverse Hessian matrix with an iteratively updated matrix instead of actually storing the full matrix. Here we follow the idea of an effective quasi-Newton method BFGS. Consider the second-order Taylor series of $T'(\theta) = -T(\theta)$ at the current estimate of the parameter vector $\theta^{(l)}$:

$$\begin{aligned} T'(\theta^{(l+1)}) \approx T'(\theta^{(l)}) + \nabla T'(\theta^{(l+1)})^T\Delta \\ + \frac{1}{2}\Delta^T H(\theta^{(l)})\Delta, \end{aligned} \tag{4}$$

where $\Delta = \theta^{(l+1)} - \theta^{(l)}$ is the update step, $\nabla T'(\theta^{(l)})$ and $h(\theta^{(l)})$ are the gradient and Hessian matrix of $T'(\theta^{(l)})$ at $\theta^{(l)}$, respectively. The minimizer of Equation 4 is

$$\Delta^l = -H^{-1}(\theta^{(l)})\nabla T'(\theta^{(l)}). \tag{5}$$

The line search Newton method uses $\Delta^{(l)}$ as the search direction $p^{(l)} = \Delta^{(l)}$ and updates model parameters by

$$\theta^{(l+1)} = \theta^{(l)} + \alpha^{(l)}p^{(l)}, \tag{6}$$

where the step length $\alpha^{(l)}$ is obtained from a line search procedure to satisfy the strong Wolfe conditions (Nocedal and Wright, 2006):

$$T'(\theta^{(l)}+\alpha^{(l)}p^{(l)}) \leq T'(\theta^{(l)})+c_1\alpha^{(l)}\nabla T'(\theta^{(l)})^T p^{(l)}$$
$$|\nabla T'(\theta^{(l)}+\alpha^{(l)}p^{(l)}| \leq c_2|\nabla T'(\theta^{(l)})^T p^{(l)}|,$$

where $0 < c_1 < c_2 < 1$. The idea of BFGS is to avoid explicit calculation of $H^{-1}(\theta^{(l)})$ by approximating it with an iteratively updated matrix B, i.e.

$$\begin{aligned} B^{(L+1)} &= (I-\rho^{(l)}s^{(l)}(u^{(l)})^T)\times B^{(l)} \\ &\quad \times(I-\rho^{(l)}u^{(l)}(s^{(l)})^T) \\ &\quad +\rho^{(l)}s^{(l)}(s^{(l)})^T \end{aligned}$$

where

$$\begin{aligned} s^{(l)} &= \theta^{(l+1)}-\theta^{(l)}, \\ u^{(l)} &= \nabla T'(\theta^{(l+1)})-\nabla T'(\theta^{(l)}), \\ \rho^{(l)} &= \frac{1}{s^{(l)}u^{(l)}}. \end{aligned}$$

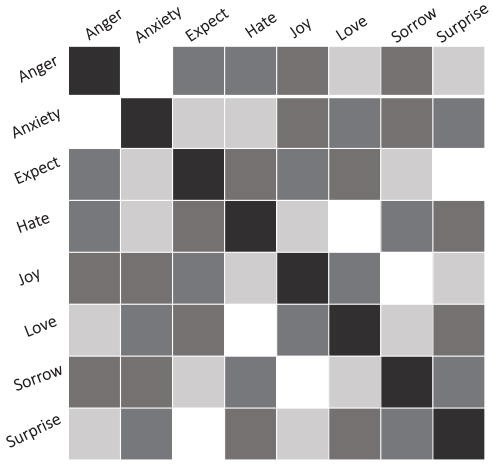

Figure 2: Gray-scale image of the pair-wise relationships of emotions shown in Figure 1.

As for the optimization of the target function $T(\theta)$, the computation of BFGS is mainly related to the first-order gradient of $T'(\theta)$, which can be achieved by

$$\begin{aligned} \frac{\partial T(\theta)}{\partial \theta_{jr}} &= \frac{4d_{x_i}^{y_j}p_{ij}(1-p_{ij})(d_{x_i}^{y_j}-p_{ij})}{(d_{x_i}^{y_j}+p_{ij})^3} \\ &\quad +\xi_1\sum_{k,r} sgn(\theta_{k,r}) \\ &\quad +\frac{1}{n}\xi_2\sum_k \omega_{jk}(\theta_j-2\theta_k), \end{aligned} \quad (7)$$

where $p_{ij} = \frac{1}{Z_i}\exp(\sum_r \theta_{jr}x_i^r)$. Thus it performs more efficiently than the standard line search Newton method.

In order to compare with the MLL methods, labels in the predicted distribution need to be divided into two sets, i.e, the relevant and irrelevant sets. For this purpose, an extra virtual label y_0 is added into the label set, i.e., the extended label set $\mathcal{Y}' = \mathcal{Y} \cup \{y_0\}$=$\{y_0, y_1, y_2 ... y_c\}$. Using the new extended label set in the training process, the optimal parameter vector θ^* is learned. As y_0 is the label that distinguishes the relevant and irrelevant emotions directly, it is initialized as the threshold used in MLL. Given a sentence x', its emotion distribution is predicted by $p(y|x';\theta^*)$. The intensity value of y_0 splits the predicted distribution into two sets. The emotions with the intensity value higher than y_0's are regarded as the relevant emotions, and the rest emotions are regarded as irrelevant ones. Therefore, EDL in fact implements the function of MLL without the need of setting the threshold manually.

4 Experiments

4.1 Setup

We evaluate the proposed approach on the RenCECps corpus (Quan and Ren, 2010). It contains $35,096$ sentences selected from blogs in Chinese. Each sentence is annotated with 8 basic emotions, such as *anger*, *anxiety*, *expect*, *hate*, *joy*, *love*, *sorrow* and *surprise*, together with their emotion scores. Higher score represents higher emotion intensity. We use $AS_i(j)$ to represent the score of emotion j in sentence i. Given a sentence x_i, the intensity of emotion j is calculated by $d_{x_i}^{y_j} = \frac{AS_i(j)}{\sum_k AS_i(k)}$. By doing so, each intensity value fulfills $d_{x_i}^{y_j} \in [0,1]$ and $\sum_y d_{x_i}^{y_j} = 1$.

For each sentence, features are extracted using recursive auto-encoders (RAEs) (Socher et al., 2011). RAEs are neural networks that represent meanings of fixed-size inputs in the reduced dimensional space. For example, each word in a sentence is represented using a vector $w \in \mathbb{R}^d$, and the RAE method reduces the entire sentence to a single vector of size $\mathbb{R}^d$. Sentences are sequences of words that can be represented by a binary tree structure. The words are the leaves of the tree and their combined grouping is used to get a notion of the meaning of the sentence.

The internal nodes of the tree correspond to the combined meaning of the nodes underneath them. Each internal node is also represented in the same manner as individual words in the form of a vector $\hat{w} \in \mathbb{R}^d$. These internal nodes are the hidden representations of the neural network. In the RAE model, the vocabulary is stored in an embedding matrix $V \in \mathbb{R}^d \times D$ where D is the cardinality of the vocabulary. Typically, each word $w \in V$ is initialized independently following a Gaussian distribution $w_i \sim N(0, \gamma^2)$. In our experiment, we set the dimension of each sentence representation to 100.

We build a gray-scale image shown in Figure 3 by computing the correlation coefficient of the emotions from the Ren-CECps corpus. It can be observed that Figure 3 is quite similar to Figure 2, which shows that our proposed way in capturing the relations between emotions is inline with what have been revealed by the emotion annotations in the Ren-CECps corpus.

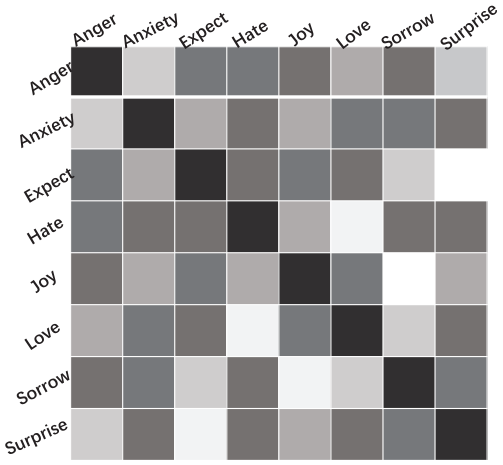

Figure 3: Gray-scale image of the pair-wise relations of the emotions in the Ren-CECps corpus.

4.2 Experimental Results

As the output of EDL is a distribution, a natural choice of criteria is the averaged similarity or distance between the actual emotion distribution and the predicted distribution. There are many metrics that can be applied to measure the distance between two distributions. In this paper six of them are used to evaluate the results of EDL, i.e, Euclidean, Sϕrensen, Squared $\mathcal{X}^2$, KL divergence, Intersection and Fidelity, as suggested in (Geng and Ji, 2013).

	Name	Formula
Distance	Euclidean	$Euclidean(P,Q) = \sqrt{\sum_{j=1}^{c}(P_j - Q_j)^2}$
	Sϕrensen	$S\phi rensen(P,Q) = \frac{\sum_{j=1}^{c}\lvert P_j - Q_j\rvert}{\sum_{j=1}^{c}(P_j + Q_j)}$
	Squared $\mathcal{X}^2$	$Squared\mathcal{X}^2(P,Q) = \sum_{j=1}^{c}\frac{(P_j - Q_j)^2}{P_j + Q_j}$
	Kullback-Leibler (KL)	$K\text{-}L(P,Q) = \sum_{j=1}^{c} P_j \ln \frac{P_j}{Q_j}$
Similarity	Intersection	$Intersection(P,Q) = \sum_{j=1}^{c}\min(P_j, Q_j)$
	Fidelity	$Fidelity(P,Q) = \sum_{j=1}^{c}\sqrt{P_j Q_j}$

Table 2: Evaluation criteria for the Label Distribution Learning (LDL) methods.

Name	Formula
Hamming Loss	$hloss(h) = \frac{1}{P}\sum_{i=1}^{P}\lvert h(x_i) \triangle Y_i\rvert$
One error	$one\text{-}error(f) = \frac{1}{P}\sum_{i=1}^{P}[\arg\max_{y \in Y} f(x_i, y)] \notin Y_i$
Coverage	$Coverage(f) = \frac{1}{P}\sum_{i=1}^{P}\max_{y \in Y_i} rank_f(x_i, y) - 1$
Ranking Loss	$rloss(f) = \frac{1}{P}\sum_{i=1}^{P}\frac{1}{\lvert Y_i\rvert\lvert\bar{Y}_i\rvert} \cdot \lvert R\rvert, Where$ $R = (y', y'')\lvert f(x_i, y') \leq f(x_i, y''), (y', y'') \in Y_i \times \bar{Y}_i$
Average Precision	$Average(f) = \frac{1}{P}\sum_{i=1}^{P}\frac{1}{\lvert Y_i\rvert}\sum_{y \in Y_i}\frac{\lvert P_i\rvert}{rank_f(x_i, y)}, where$ $P_i = y'\lvert rank_f(x_i, y') \leq rank_f(x_i, y), (y)' \in Y_i$

Table 3: Evaluation criteria for the MLL methods.

The formulae of the six criteria are summarized in Table 4.2. Note that the virtual label y_0 is removed before evaluation.

As EDL can output both the relevant emotions and their respective emotion intensities, MLL can be seen as a special case of EDL that it only outputs emotion labels but not their intensities. Several evaluation criteria typically used in MLL can also be used to measure EDL's ability of distinguishing relevant emotions from irrelevant ones, including hamming loss, one error, coverage, ranking loss, and average precision as suggested by (Zhang and Zhou, 2014), which are summarized in Table 4.2. Hamming loss evaluates how many times an emotion label is misclassified. One-error evaluates the fraction of sentences whose top-ranked emotion is not in the relevant emotion set. Coverage evaluates how many steps are needed to move down the ranked emotion list so as to cover all the relevant emotions of the example. Ranking loss evaluates the fraction of reversely ordered emotion pairs. Average precision evaluates the average fraction of the relevant emotions ranked higher than a particular emotion $y \in \mathcal{Y}$.

For each algorithm, ten-fold cross validation is conducted. EDL is first compared with four existing Label Distribution Learning (LDL) methods (Geng,

Table 5: Experimental results in comparison with the MLL methods.

2016), i.e., PT-Bayes, PT-SVM, AA-KNN, AA-BP. k in AA-KNN is set to 8. Linear kernel is used in PT-SVM. The number of hidden-layer neurons for AA-BP is set to 60. The evaluation results of our proposed approach in comparison to the LDL baselines are presented in Table 4.2. For all the measures, "↓" indicates "the smaller the better", while "↑" indicates "the larger the better". The best performance on each measure is highlighted by boldface. The two-tailed t-tests with 5% significance level are performed to see whether the differences between EDL and the baselines are statistically significant. We use • to indicate significance difference. As the state-of-the-art emotion detection method proposed in (Wang and Pal, 2015) can output the emotion distributions based on a dimensional reduction method, we present its experimental results on the Ren-CECps corpus in the last row of Table 4.2. It can be observed that EDL performs significantly better than all the baseline LDL methods and the state-of-the-art emotion detection approach on all criteria considered here.

Since EDL can be seen as an extension of MLL, EDL is compared with 7 widely used MLL methods using the virtual label y_0, namely ML-KNN (Zhang and Zhou, 2014), ECC (Read et al., 2011), MLLOC (Huang and Zhou, 2012), LIFT (Zhang, 2011), ML-RBF (Zhang, 2009), Rank-SVM (Zhang and Zhou, 2014), BP-MLL (Zhang and Zhou, 2006). Among the compared algorithms, ML-kNN is derived from the traditional k-nearest neighbor (kNN) algorithm. Maximum a posteriori (MAP) principle is used to determine which emotion set is related to the given sentence. CC (classifier chains method) overcomes the limitations of BR and performs better but requires more computations. ECC (ensemble classifier chains) applies classifier chains in an ensemble framework and obtains high predictive performances. MLLOC (Multi-label LOcal Correlation) tries to exploit emotion correlations in the expression data locally. The global discrimination fitting and local correlation sensitivity are incorporated into a unified framework, and solution for the optimization are developed. Rank-SVM provides a way of controlling the complexity of the overall learning system while having a small empirical error. The architectures of Rank-SVM is based on linear models of Support Vector Machines (SVM) (Boser et al., 1992). LIFT constructs features specific to each emotion by conducting clustering analysis on its positive or negative instances, and then performs training and testing by querying the clustering results (Zhang, 2011). BP-MLL is derived from the famous backpropagation algorithm through employing a novel error function capturing the characteristics of multi-label learning, i.e., the emotions belonging to a sentence should be ranked higher than those not belonging to that sentence (Zhang and

Zhou, 2006).

The virtual label y_0 used in EDL and the threshold value used in MLL are all set to 2.5. Besides, the ε, ξ_1 and ξ_2 are set as 0.25, 0.0001, 0.1 respectively. For the MLL methods, the value of k is set to 8 in ML-KNN, ratio is 0.02 and μ is 2 in ML-RBF. Linear kernel is used in LIFT. Rank-SVM uses the RBF kernel with the width σ equals to 1. The evaluation results of the proposed approach in comparison to all MLL baselines are presented in Table 4.2. EDL performs best on all evaluation measures. It verifies the advantage of EDL owing to the consideration of varying intensity of the basic emotions.

4.3 Further Analysis

To fully understand the emotion detection results, we use word cloud (Harris, 2011) to output the top 30 frequent words in the testing data for the emotion *love* and *anxiety* based on the annotation as shown in the left part of Figure 4. We also output the top 30 frequent words for the two emotions based on the prediction generated by EDL as shown in Figure 4 's right part. It can be observed that most words based on prediction indeed express their associated emotions. For example, word "like" delivers the emotion of *love* (right part of Figure 4(a)) and word "problem" tells *anxiety* (right part of Figure 4(b)). Moreover, the annotation and the prediction share 20 out of the top 30 most frequent words for the emotion *love* such as "friend", "joy", "happiness", etc as shown in the middle of Figure 4(a) and 19 out of 30 for the emotion of *anxiety* (the middle of Figure 4(b). It demonstrates that EDL can learn emotions from text precisely.

To investigate the emotion distributions generated by EDL, a sentence from the Ren-CECps corpus together with the emotion distribution output by EDL is illustrated in Figure 5. The ground truth emotion distribution is obtained by normalizing the scores and the virtual label y_0. As can be seen, the curve of the predicted emotion distribution is very similar as the ground truth distribution, which demonstrates that EDL can learn the varying intensities of all the basic emotions well.

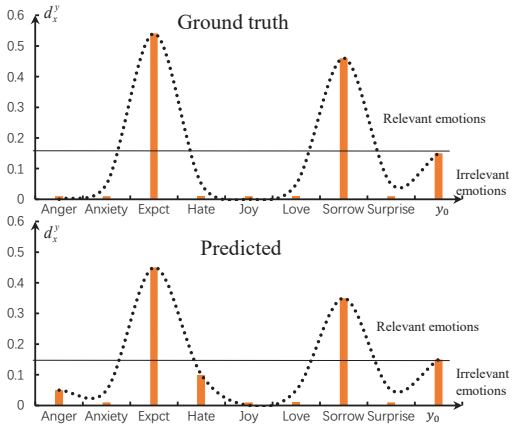

Figure 5: A sentence with the emotion distribution predicted by EDL.

5 Conclusions and Future Work

In this paper, we have proposed a novel approach based on EDL to identify multiple emotions with their intensities from texts. Moreover, the relations between basic emotions is incorporated in the learning framework as constraints to improve the learning accuracy. Experimental results show that the proposed approach can effectively deal with the emotion distribution detection problem and perform remarkably better than the state-of-the-art multi-label learning methods and the emotion detection method. In future work, we will investigate the efficiency of the proposed approach in other datasets and explore other methods in capturing the inter-relations of emotions.

Abstract

Evaluation of NLP methods requires testing against a previously vetted gold-standard test set and reporting standard metrics (accuracy/precision/recall/F1). The current assumption is that all items in a given test set are equal with regards to difficulty and discriminating power. We propose Item Response Theory (IRT) from psychometrics as an alternative means for gold-standard test-set generation and NLP system evaluation. IRT is able to describe characteristics of individual items - their difficulty and discriminating power - and can account for these characteristics in its estimation of human intelligence or ability for an NLP task. In this paper, we demonstrate IRT by generating a gold-standard test set for Recognizing Textual Entailment. By collecting a large number of human responses and fitting our IRT model, we show that our IRT model compares NLP systems with the performance in a human population and is able to provide more insight into system performance than standard evaluation metrics. We show that a high accuracy score does not always imply a high IRT score, which depends on the item characteristics and the response pattern.[1]

1 Introduction

Advances in artificial intelligence have made it possible to compare computer performance directly with human intelligence (Campbell et al., 2002; Ferrucci et al., 2010; Silver et al., 2016). In most cases, a common approach to evaluating the performance of a new system is to compare it against an unseen gold-standard test dataset (GS items). Accuracy, recall, precision and F1 scores are commonly used to evaluate NLP applications. These metrics assume that GS items have equal weight for evaluating performance. However, individual items are different: some may be so hard that most/all NLP systems answer incorrectly; others may be so easy that every NLP system answers correctly. Neither item type provides meaningful information about the performance of an NLP system. Items that are answered incorrectly by some systems and correctly by others are useful for differentiating systems according to their individual characteristics.

In this paper we introduce Item Response Theory (IRT) from psychometrics and demonstrate its application to evaluating NLP systems. IRT is a theory of evaluation for characterizing test items and estimating human ability from their performance on such tests. IRT assumes that individual test questions (referred to as "items" in IRT) have unique characteristics such as difficulty and discriminating power. These characteristics can be identified by fitting a joint model of human ability and item characteristics to human response patterns to the test items. Items that do not fit the model are removed and the remaining items can be considered a scale to evaluate performance. IRT assumes that the probability of a correct answer is associated with both item characteristics and individual ability, and therefore a collection of items of varying characteristics can determine an individual's overall ability.

Our aim is to build an intelligent evaluation metric to measure performance for NLP tasks. With IRT we

[1]Data and code will be made available for download at https://people.cs.umass.edu/lalor/irt.html

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 648–657,
Austin, Texas, November 1-5, 2016.

can identify an appropriate set of items to measure ability in relation to the overall human population as scored by an IRT model. This process serves two purposes: (i) to identify individual items appropriate for a test set that measures ability on a particular task, and (ii) to use the resulting set of items as an evaluation set in its own right, to measure the ability of future subjects (or NLP models) for the same task. These evaluation sets can measure the ability of an NLP system with a small number of items, leaving a larger percentage of a dataset for training.

Our contributions are as follows: First, we introduce IRT and describe its benefits and methodology. Second, we apply IRT to Recognizing Textual Entailment (RTE) and show that evaluation sets consisting of a small number of sampled items can provide meaningful information about the RTE task. Our IRT analyses show that different items exhibit varying degrees of difficulty and discrimination power and that high accuracy does not always translate to high scores in relation to human performance. By incorporating IRT, we can learn more about dataset items and move past treating each test case as equal. Using IRT as an evaluation metric allows us to compare NLP systems directly to the performance of humans.

2 Background and Related Work

2.1 Item Response Theory

IRT is one of the most widely used methodologies in psychometrics for scale construction and evaluation. It is typically used to analyze human responses (graded as right or wrong) to a set of questions (called "items"). With IRT individual ability and item characteristics are jointly modeled to predict performance (Baker and Kim, 2004). This statistical model makes the following assumptions: (a) Individuals differ from each other on an unobserved latent trait dimension (called "ability" or "factor"); (b) The probability of correctly answering an item is a function of the person's ability. This function is called the item characteristic curve (ICC) and involves item characteristics as parameters; (c) Responses to different items are independent of each other for a given ability level of the person ("local independence assumption"); (d) Responses from different individuals are independent of each other.

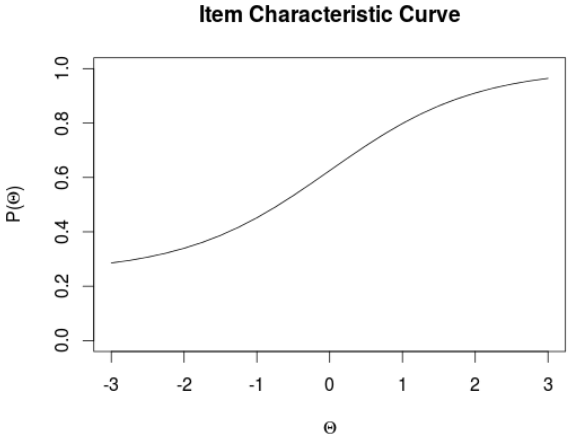

Figure 1: Example ICC for a 3PL model with the following parameters: $a = 1.0$, $b = 0.0$, $c = 0.25$.

More formally, if we let j be an individual, i be an item, and θ_j be the latent ability trait of individual j, then the probability that individual j answers item i correctly can be modeled as:

$$p_{ij}(\theta_j) = c_i + \frac{1 - c_i}{1 + e^{-a_i(\theta_j - b_i)}} \quad (1)$$

where a_i, b_i, and c_i are item parameters: a_i (the slope or discrimination parameter) is related to the steepness of the curve, b_i (the difficulty parameter) is the level of ability that produces a chance of correct response equal to the average of the upper and lower asymptotes, and c_i (the guessing parameter) is the lower asymptote of the ICC and the probability of guessing correctly. Equation 1 is referred to as the three-parameter logistic (3PL) IRT model. A two-parameter logistic (2PL) IRT model assumes that the guessing parameter c_i is 0.

Figure 1 shows an ICC of a 3PL model. The ICC for a good item will look like a sigmoid plot, and should exhibit a relatively steep increasing ICC between ability levels -3 and 3, where most people are located, in order to have appropriate power to differentiate different levels of ability. We have described a one factor IRT model where ability is uni-dimensional. Multi-factor IRT models would involve two or more latent trait dimensions and will not be elaborated here.

To identify the number of factors in an IRT model, the polychoric correlation matrix of the items is calculated and its ordered eigenvalues are plotted. The

number of factors is suggested by the number of large eigenvalues. It can be further established by fitting (see below) and comparing IRT models with different numbers of factors. Such comparison may use model selection indices such as Akaike Information Criterion (AIC) and Conditional Bayesian Information Criterion (CBIC) and should also take into account the interpretablility of the loading pattern that links items to factors.

An IRT model can be fit to data with the marginal maximum likelihood method through an EM algorithm (Bock and Aitkin, 1981). The marginal likelihood function is the probability to observe the current response patterns as a function of the item parameters with the persons' ability parameters integrated out as random effects. This function is maximized to produce estimates of the item parameters. For IRT models with more than one factor, the slope parameters (i.e. loadings) that relate items and factors must be properly rotated (Browne, 2001) before they can be interpreted. Given the estimated item parameters, Bayesian estimates of the individual person's ability parameters are obtained with the standard normal prior distribution.

After determining the number of factors and fitting the model, the local independence assumption can be checked using the residuals of marginal responses of item pairs (Chen and Thissen, 1997) and the fit of the ICC for each item can be checked with item fit statistics (Orlando and Thissen, 2000) to determine whether an item should be retained or removed. If both tests are passed and all items have proper discrimination power, then the set of items is considered a calibrated measurement scale and the estimated item parameters can be further used to estimate an individual person's ability level.

IRT accounts for differences among items when estimating a person's ability. In addition, ability estimates from IRT are on the ability scale of the population used to estimate item parameters. For example, an estimated ability of 1.2 can be interpreted as 1.2 standard deviations above the average ability in this population. The traditional total number of correct responses generally does not have such quantitative meaning.

IRT has been widely used in educational testing. For example, it plays an instrumental role in the construction, evaluation, or scoring of standardized tests such as the Test of English as a Foreign Language (TOEFL), Graduate Record Examinations (GRE) and the SAT college admissions standardized test.

2.1.1 IRT Terminology

Here we outline common IRT terminology in terms of RTE. An *item* refers to a pair of sentences to which humans or NLP systems assign a label (entailment, contradiction, or neutral). A set of responses to all items (each graded as correct or incorrect) is a *response pattern*. An *evaluation scale* is a test set of items to be administered to an NLP system and assigns an *ability score* (or *theta score*) to the system as its performance.

2.2 Recognizing Textual Entailment

RTE was introduced to standardize the challenge of accounting for semantic variation when building models for a number of NLP applications (Dagan et al., 2006). RTE defines a directional relationship between a pair of sentences, the text (T) and the hypothesis (H). T entails H if a human that has read T would infer that H is true. If a human would infer that H is false, then H contradicts T. If the two sentences are unrelated, then the pair are said to be neutral. Table 1 shows examples of T-H pairs and their respective classifications. Recent state-of-the-art systems for RTE require a large amount of feature engineering and specialization to achieve high performance (Beltagy et al., 2015; Lai and Hockenmaier, 2014; Jimenez et al., 2014).

A number of gold-standard datasets are available for RTE (Marelli et al., 2014; Young et al., 2014; Levy et al., 2014). We consider the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015). SNLI examples were obtained using only human-generated sentences with Amazon Mechanical Turk (AMT) to mitigate the problem of poor data that was being used to build models for RTE. In addition, SNLI included a quality control assessment of a sampled portion of the dataset (about 10%, 56,951 sentence pairs). This data was provided to 4 additional AMT users to provide labels (entailment, contradiction, neutral) for the sentence pairs. If at least 3 of the 5 annotators (the original annotator and 4 additional annotators) agreed on a label the item was retained. Most of the items (98%) received

Text	Hypothesis	Label
Retained - 4GS		
1. A toddler playing with a toy car next to a dog	A toddler plays with toy cars while his dog sleeps	Neutral
2. People were watching the tournament in the stadium	The people are sitting outside on the grass	Contradiction
Retained - 5GS		
3. A person is shoveling snow	It rained today	Contradiction
4 Two girls on a bridge dancing with the city skyline in the background	The girls are sisters.	Neutral
5. A woman is kneeling on the ground taking a photograph	A picture is being snapped	Entailment
Removed - 4GS		
6. Two men and one woman are dressed in costume hats	The people are swingers	Neutral
7. Man sweeping trash outside a large statue	A man is on vacation	Contradiction
8. A couple is back to back in formal attire	Two people are facing away from each other	Entailment
9. A man on stilts in a purple, yellow and white costume	A man is performing on stilts	Entailment
Removed - 5GS		
10. A group of soccer players are grabbing onto each other as they go for the ball	A group of football players are playing a game	Contradiction
11. Football players stand at the line of scrimmage	The players are in uniform	Neutral
12. Man in uniform waiting on a wall	Near a wall, a man in uniform is waiting	Entailment

Table 1: Examples of retained & removed sentence pairs. The selection is not based on right/wrong labels but based on IRT model fitting and item elimination process. Note that no 4GS entailment items were retained (Section 4.2)

a gold-standard label. Specifics of SNLI generation are at Bowman et al. (2015).

2.3 Related Work

To identify low-quality annotators (*spammers*), Hovy et al. (2013) modeled annotator responses, either answering correctly or guessing, as a random variable with a guessing parameter varying only across annotators. Passonneau and Carpenter (2014) used the model of Dawid and Skene (1979) in which an annotator's response depends on both the true label and the annotator. In both models an annotator's response depends on an item only through its correct label. In contrast, IRT assumes a more sophisticated response mechanism involving both annotator qualities and item characteristics. To our knowledge we are the first to introduce IRT to NLP and to create a gold standard with the intention of comparing NLP applications to human intelligence.

Bruce and Wiebe (1999) analyze patterns of agreement between annotators in a case-study sentence categorization task, and use a latent-trait model to identify true labels. That work uses 4 annotators at varying levels of expertise and does not consider the discriminating power of dataset items.

Current gold-standard dataset generation methods include web crawling (Guo et al., 2013), automatic and semi-automatic generation (An et al., 2003), and expert (Roller and Stevenson, 2015) and non-expert human annotation (Bowman et al., 2015; Wiebe et al., 1999). In each case validation is required to ensure that the data collected is appropriate and usable for the required task. Automatically generated data can be refined with visual inspection or post-collection processing. Human annotated data usually involves more than one annotator, so that comparison metrics such as Cohen's or Fleiss' κ can be used to determine how much they agree. Disagreements between annotators are resolved by researcher intervention or by majority vote.

3 Methods

We collected and evaluated a random selection from the SNLI RTE dataset (GS_{RTE}) to build our IRT models. We first randomly selected a subset of GS_{RTE}, and then used the sample in an AMT Human Intelligence Task (HIT) to collect more labels

for each text-hypothesis pair. We then applied IRT to evaluate the quality of the examples and used the final IRT models to create evaluation sets (GS_{IRT}) to measure ability for RTE.

3.1 Item Selection

For our evaluation we looked at two sets of data: sentence-pairs selected from SNLI where 4 out of 5 annotators agreed on the gold-standard label (referred to as 4GS), and sentence-pairs where 5 out of 5 annotators agreed on the gold-standard label (referred to as 5GS). We make the assumption for our analysis that the 4GS items are harder than the 5GS items due to the fact that there was not a unanimous decision regarding the gold-standard label.

We selected the subset of GS_{RTE} to use as an examination set in 4GS and 5GS according to the following steps: (1) Identify all "quality-control" items from GS_{RTE} (i.e. items where 5 annotators provided labels, see §2.2), (2) Identify items in this section of the data where 4 of the 5 annotators agreed on the eventual gold label (to be selected from for 4GS) and 5 of the 5 annotators agreed on the gold standard label (to be selected from for 5GS), (3) Randomly select 30 entailment sentence pairs, 30 neutral pairs, and 30 contradiction pairs from those items where 4 of 5 annotators agreed on the gold label (4GS) and those items where 5 of 5 annotators agreed on the gold label (5GS) to obtain two sets of 90 sentence pairs.

90 sentence pairs for 4GS and 5GS were sampled so that the annotation task (supplying 90 labels) could be completed in a reasonably short amount of time during which users remained engaged. We selected items from 4GS and 5GS because both groups are considered high quality for RTE. We evaluated the selected 180 sentence pairs using the model provided with the original dataset (Bowman et al., 2015) and found that accuracy scores were similar compared to performance on the SNLI test set.

3.2 AMT Annotation

For consistency we designed our AMT HIT to match the process used to validate the SNLI quality control items (Bowman et al., 2015) and to generate labels for the SICK RTE dataset (Marelli et al., 2014). Each AMT user was shown 90 premise-hypothesis pairs (either the full 5GS or 4GS set) one pair at a time, and was asked to choose the appropriate label for each. Each user was presented with the full set, as opposed to one-label subsets (e.g. just the entailment pairs) in order to avoid a user simply answering with the same label for each item.

For each 90 sentence-pair set (5GS and 4GS), we collected annotations from 1000 AMT users, resulting in 1000 label annotations for each of the 180 sentence pairs. While there is no set standard for sample sizes in IRT models, this sample size satisfies the standards based on the non-central χ^2 distribution (MacCallum et al., 1996) used when comparing two multidimensional IRT models. This sample size is also appropriate for tests of item fit and local dependence that are based on small contingency tables.

Only AMT users with approval ratings above 97% were used to ensure that users were of a high quality. The task was only available to users located in the United States, as a proxy for identifying English speakers. Attention check questions were included in the HIT, to ensure that users were paying attention and answering to the best of their ability. Responses where the attention-check questions were answered incorrectly were removed. After removing individuals that failed the attention-check, we retained 976 labels for each example in the 4GS set and 983 labels for each example in the 5GS set. Average time spent for each task was roughly 30 minutes, a reasonable amount for AMT users.

3.3 Statistical Analysis

Data collected for 4GS and 5GS were analyzed separately in order to evaluate the differences between "easier" items (5GS) and "harder" items (4GS), and to demonstrate the ability to show that theta score is consistent even if dataset difficulty varies. For both sets of items, the number of factors was identified by a plot of eigenvalues of the 90 x 90 tetrachoric correlation matrix and by a further comparison between IRT models with different number of factors. A target rotation (Browne, 2001) was used to identify a meaningful loading pattern that associates factors and items. Each factor could then be interpreted as the ability of a user to recognize the correct relationship between the sentence pairs associated with that factor (e.g. contradiction).

Once the different factors were associated with different sets of items, we built a unidimensional

	4GS	5GS	Overall
Pairs with majority agreement	95.6%	96.7%	96.1%
Pairs with supermajority agreement	61.1%	82.2%	71.7%

Table 2: Summary statistics from the AMT HITs.

Fleiss' κ	4GS	5GS	Bowman et al. 2015
Contradiction	0.37	0.59	0.77
Entailment	0.48	0.63	0.72
Neutral	0.41	0.54	0.6
Overall	0.43	0.6	0.7

Table 3: Comparison of Fleiss' κ scores with scores from SNLI quality control sentence pairs.

IRT model for each set of items associated with a single factor. We fit and compared one- and two-factor 3PL models to confirm our assumption and the unidimensional structure underlying these items, assuming the possible presence of guessing in people's responses. We further tested the guessing parameter of each item in the one factor 3PL model. If the guessing parameter was not significantly different from 0, a 2PL ICC was used for that particular item.

Once an appropriate model structure was determined, individual items were evaluated for goodness of fit within the model (§2.1). If an item was deemed to fit the ICC poorly or to give rise to local dependence, it was removed for violating model assumptions. Furthermore, if the ICC of an item was too flat, it was removed for low discriminating power between ability levels. The model was then refit with the remaining items. This iterative process continued until no item could be removed (2 to 6 iterations depending on how many items were removed from each set).

The remaining items make up our final test set (GS_{IRT}), which is a calibrated scale of ability to correctly identify the relationship between the two sentence pairs. Parameters of these items were estimated as part of the IRT model and the set of items can be used as an evaluation scale to estimate ability of test-takers or RTE systems. We used the *mirt* R package (Chalmers et al., 2015) for our analyses.

4 Results

4.1 Response Statistics

Table 2 lists key statistics from the AMT HITs. Most of the sampled sentence pairs resulted in a gold standard label being identified via a majority vote. Due to the large number of individuals providing labels during the HIT, we also wanted to see if a gold standard label could be determined via a two-thirds supermajority vote. We found that 28.3% of the sentence pairs did not have a supermajority gold label. This highlights the ambiguity associated with identifying entailment.

We believe that the items selected for analysis are appropriate for our task in that we chose high-quality items, where at least 4 annotators selected the same label, indicating a strong level of agreement (Section 3.1). We argue that our sample is a high-quality portion of the dataset, and further analysis of items where the gold-standard label was only selected by 3 annotators originally would result in lower levels of agreement.

Table 3 shows that the level of agreement as measured by the Fleiss' κ score is much lower when the number of annotators is increased, particularly for the 4GS set of sentence pairs, as compared to scores noted in Bowman et al. (2015). The decrease in agreement is particularly large with regard to contradiction. This could occur for a number of reasons. Recognizing entailment is an inherently difficult task, and classifying a correct label, particularly for contradiction and neutral, can be difficult due to an individual's interpretation of the sentences and assumptions that an individual makes about the key facts of each sentence (e.g. coreference). It may also be the case that the individuals tasked with creating the sentence pairs on AMT created sentences that appeared to contradict a premise text, but can be interpreted differently given a different context.

Before fitting the IRT models we performed a visual inspection of the 180 sentence pairs and removed items clearly not suitable for an evaluation scale due to syntactic or semantic discrepancies. For example item 10 in Table 1 was removed from the 5GS contradiction set for semantic reasons. While many people would agree that the statement is a contradiction due to the difference between football and soccer, individuals from outside the U.S. would possibly consider the two to be synonyms and classify this as entailment. Six such pairs were identified

and removed from the set of 180 items, leaving 174 items for IRT model-fitting.

4.2 IRT Evaluation

4.2.1 IRT Models

We used the methods described in Section 3.3 to build IRT models to scale performance according to the RTE task. For both 4GS and 5GS items three factors were identified, each related to items for the three GS_{RTE} labels (entailment, contradiction, neutral). This suggests that items with the same GS_{RTE} label within each set defines a separate ability. In the subsequent steps, items with different labels were analyzed separately. After analysis, we were left with a subset of the 180 originally selected items. Refer to Table 1 for examples of the retained and removed items based on the IRT analysis. We retained 124 of the 180 items (68.9%). We were able to retain more items from the 5GS datasets (76 out of 90 - 84%) than from the 4GS datasets (48 out of 90 - 53.5%). Items that measure contradiction were retained at the lowest rate for both 4GS and 5GS datasets (66% in both cases). For the 4GS entailment items, our analysis found that a one-factor model did not fit the data, and a two-factor model failed to yield an interpretable loading pattern after rotation. We were unable to build an IRT model that accurately modeled ability to recognize entailment with the obtained response patterns. As a result, no items from the 4GS entailment set were retained.

Figure 2 plots the empirical spline-smoothed ICC of one item (Table 1, item 9) with its estimated response curve. The ICC is not continuously increasing, and thus a logistic function is not appropriate. This item was spotted for poor item fit and removed. Figure 3 shows a comparison between the ICC plot of a retained item (Table 1, item 4) and the ICC of a removed item (Table 1, item 8). Note that the removed item has an ICC that is very flat between -3 and 3. This item cannot discriminate individuals at any common level of ability and thus is not useful.

The items retained for each factor can be considered as an evaluation scale that measures a single ability of an individual test-taker. As each factor is associated with a separate gold-standard label, each factor (θ) is a person's ability to correctly classify the relationship between the text and hypothesis for one such label (e.g. entailment).

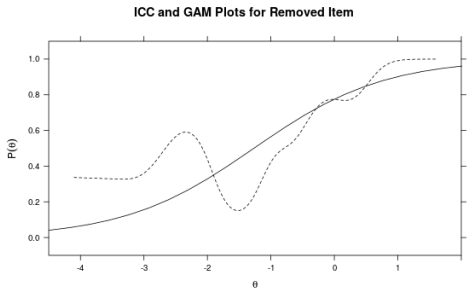

Figure 2: Estimated (solid) and actual (dotted) response curves for a removed item.

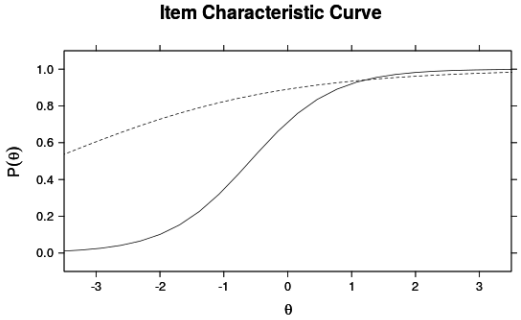

Figure 3: ICCs for retained (solid) and removed (dotted) items.

4.2.2 Item Parameter Estimation

Parameter estimates of retained items for each label are summarized in Table 4, and show that all parameters fall within reasonable ranges. All retained items have 2PL ICCs, suggesting no significant guessing. Difficulty parameters of most items are negative, suggesting that an average AMT user has at least 50% chance to answer these items correctly. Although some minimum difficulties are quite low for standard ranges for a human population, the low range of item difficulty is appropriate for the evaluation of NLP systems. Items in each scale have a wide range of difficulty and discrimination power.

With IRT we can use the heterogeneity of items to properly account for such differences in the estimation of a test-taker's ability. Figure 4 plots the estimated ability of each AMT user from IRT against their total number of correct responses to the retained items in the 4GS contradiction item set. The two estimates of ability differ in many aspects. First, test-takers with the same total score may differ in their IRT score because they have different response

Item Set	Min. Difficulty	Max. Difficulty	Min. Slope	Max. Slope
5GS				
Contradiction	-2.765	0.704	0.846	2.731
Entailment	-3.253	-1.898	0.78	2.61
Neutral	-2.082	-0.555	1.271	3.598
4GS				
Contradiction	-1.829	1.283	0.888	2.753
Neutral	-2.148	0.386	1.133	3.313

Table 4: Parameter estimates of the retained items

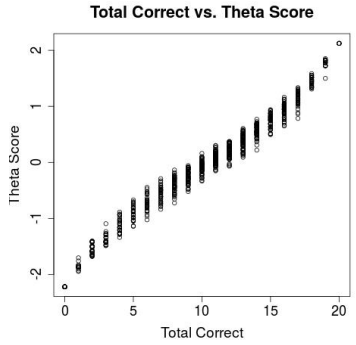

Figure 4: Plot of total correct answers vs. IRT scores.

patterns (i.e. they made mistakes on different items), showing that IRT is able to account for differences among items. Second, despite a rough monotonic trend between the two scores, people with a higher number of correct responses may have a lower ability estimate from IRT.

We can extend this analysis to the case of RTE systems, and use the newly constructed scales to evaluate RTE systems. A system could be trained on an existing dataset and then evaluated using the retained items from the IRT models to estimate a new ability score. This score would be a measurement of how well the system performed with respect to the human population used to fit the model. With this approach, larger sections of datasets can be devoted to training, with a small portion held out to build an IRT model that can be used for evaluation.

4.2.3 Application to an RTE System

As a demonstration, we evaluate the LSTM model presented in Bowman et al. (2015) with the items in our IRT evaluation scales. In addition to the theta scores, we calculate accuracy for the binary classification task of identifying the correct label for all

Item Set	Theta Score	Percentile	Test Acc.
5GS			
Entailment	-0.133	44.83%	96.5%
Contradiction	1.539	93.82%	87.9%
Neutral	0.423	66.28%	88%
4GS			
Contradiction	1.777	96.25%	78.9%
Neutral	0.441	67%	83%

Table 5: Theta scores and area under curve percentiles for LSTM trained on SNLI and tested on GS_{IRT}. We also report the accuracy for the same LSTM tested on all SNLI quality control items (see Section 3.1). All performance is based on binary classification for each label.

items eligible for each subset in Table 5 (e.g. all test items where 5 of 5 annotators labeled the item as *entailment* for 5GS). Note that these accuracy metrics are for subsets of the SNLI test set used for binary classifications and therefore do not compare with the standard SNLI test set accuracy measures.

The theta scores from IRT in Table 5 show that, compared to AMT users, the system performed well above average for contradiction items compared to human performance, and performed around the average for entailment and neutral items. For both the neutral and contradiction items, the theta scores are similar across the 4GS and 5GS sets, whereas the accuracy of the more difficult 4GS items is consistently lower. This shows the advantage of IRT to account for item characteristics in its ability estimates. A similar theta score across sets indicates that we can measure the "ability level" regardless of whether the test set is easy or hard. Theta score is a consistent measurement, compared to accuracy which varies with the difficulty of the dataset.

The theta score and accuracy for 5GS entailment show that high accuracy does not necessarily mean that performance is above average when compared to human performance. However, theta score is not meant to contradict accuracy score, but to provide a better idea of system performance compared against a human population. The theta scores are a result of the IRT model fit using human annotator responses and provide more context about the system performance than an accuracy score can alone. If accuracy is high and theta is close to 0 (as is the case with 5GS entailment), we know that the performance of RTE

is close to the average level of the AMT user population and that 5GS entailment test set was "easy" to both. Theta score and percentile are intrinsically in reference to human performance and independent of item difficulty, while accuracy is intrinsically in reference to a specific set of items.

5 Discussion and Future Work

As NLP systems have become more sophisticated, sophisticated methodologies are required to compare their performance. One approach to create an intelligent gold standard is to use IRT to build models to scale performance on a small section of items with respect to the tested population. IRT models can identify dataset items with different difficulty levels and discrimination powers based on human responses, and identify items that are not appropriate as scale items for evaluation. The resulting small set of items can be used as a scale to score an individual or NLP system. This leaves a higher percentage of a dataset to be used in the training of the system, while still having a valuable metric for testing.

IRT is not without its challenges. A large population is required to provide the initial responses in order to have enough data to fit the models; however, crowdsourcing allows for the inexpensive collection of large amounts of data. An alternative methodology is Classical Test Theory, which has its own limitations, in particular that it is test-centric, and cannot provide information for individual items.

We have introduced Item Response Theory from psychometrics as an alternative method for generating gold-standard evaluation datasets. Fitting IRT models allows us to identify a set of items that when taken together as a test set, can provide a meaningful evaluation of NLP systems with the different difficulty and discriminating characteristics of the items taken into account. We demonstrate the usefulness of the IRT-generated test set by showing that high accuracy does not necessarily indicate high performance when compared to a population of humans.

Future work can adapt this analysis to create evaluation mechanisms for other NLP tasks. The expectation is that systems that perform well using a standard accuracy measure can be stratified based on which types of items they perform well on. High quailty systems should also perform well when the models are used together as an overall test of ability. This new evaluation for NLP systems can lead to new and innovative methods that can be tested against a novel benchmark for performance, instead of gradually incrementing on a classification accuracy metric.

Abstract

Embedding words in a vector space has gained a lot of attention in recent years. While state-of-the-art methods provide efficient computation of word similarities via a low-dimensional matrix embedding, their motivation is often left unclear. In this paper, we argue that word embedding can be naturally viewed as a *ranking* problem due to the ranking nature of the evaluation metrics. Then, based on this insight, we propose a novel framework *WordRank* that efficiently estimates word representations via robust ranking, in which the attention mechanism and robustness to noise are readily achieved via the DCG-like ranking losses. The performance of *WordRank* is measured in word similarity and word analogy benchmarks, and the results are compared to the state-of-the-art word embedding techniques. Our algorithm is very competitive to the state-of-the- arts on large corpora, while outperforms them by a significant margin when the training set is limited (*i.e.*, sparse and noisy). With 17 million tokens, *WordRank* performs almost as well as existing methods using 7.2 billion tokens on a popular word similarity benchmark. Our multi-node distributed implementation of *WordRank* is publicly available for general usage.

1 Introduction

Embedding words into a vector space, such that *semantic* and *syntactic* regularities between words are preserved, is an important sub-task for many applications of natural language processing. Mikolov et al. (2013a) generated considerable excitement in the machine learning and natural language processing communities by introducing a neural network based model, which they call *word2vec*. It was shown that *word2vec* produces state-of-the-art performance on both word similarity as well as word analogy tasks. The word similarity task is to retrieve words that are similar to a given word. On the other hand, word analogy requires answering queries of the form *a:b;c:?*, where *a, b*, and *c* are words from the vocabulary, and the answer to the query must be semantically related to *c* in the same way as *b* is related to *a*. This is best illustrated with a concrete example: Given the query *king:queen;man:?* we expect the model to output *woman*.

The impressive performance of *word2vec* led to a flurry of papers, which tried to explain and improve the performance of *word2vec* both theoretically (Arora et al., 2015) and empirically (Levy and Goldberg, 2014). One interpretation of *word2vec* is that it is approximately maximizing the positive pointwise mutual information (PMI), and Levy and Goldberg (2014) showed that directly optimizing this gives good results. On the other hand, Pennington et al. (2014) showed performance comparable to *word2vec* by using a modified matrix factorization model, which optimizes a log loss.

Somewhat surprisingly, Levy et al. (2015) showed that much of the performance gains of these new word embedding methods are due to certain hyper-parameter optimizations and system-design choices. In other words, if one sets up careful experiments, then existing word embedding models more or less perform comparably to each other. We conjecture that this is because, at a high level, all these methods

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 658–668,
Austin, Texas, November 1-5, 2016.

are based on the following template: From a large text corpus eliminate infrequent words, and compute a $|\mathcal{W}| \times |\mathcal{C}|$ word-context co-occurrence count matrix; a context is a word which appears less than d distance away from a given word in the text, where d is a tunable parameter. Let $w \in \mathcal{W}$ be a word and $c \in \mathcal{C}$ be a context, and let $X_{w,c}$ be the (potentially normalized) co-occurrence count. One learns a function $f(w, c)$ which approximates a transformed version of $X_{w,c}$. Different methods differ essentially in the transformation function they use and the parametric form of f (Levy et al., 2015). For example, *GloVe* (Pennington et al., 2014) uses $f(w, c) = \langle \mathbf{u}_w, \mathbf{v}_c \rangle$ where $\mathbf{u}_w$ and $\mathbf{v}_c$ are k dimensional vectors, $\langle \cdot, \cdot \rangle$ denotes the Euclidean dot product, and one approximates $f(w, c) \approx \log X_{w,c}$. On the other hand, as Levy and Goldberg (2014) show, *word2vec* can be seen as using the same $f(w, c)$ as *GloVe* but trying to approximate $f(w, c) \approx \text{PMI}(X_{w,c}) - \log n$, where $\text{PMI}(\cdot)$ is the pairwise mutual information (Cover and Thomas, 1991) and n is the number of negative samples.

In this paper, we approach the word embedding task from a different perspective by formulating it as a *ranking* problem. That is, given a word w, we aim to output an ordered list $(c_1, c_2, \cdots)$ of context words from $\mathcal{C}$ such that words that co-occur with w appear at the top of the list. If $\text{rank}(w, c)$ denotes the rank of c in the list, then typical ranking losses optimize the following objective: $\sum_{(w,c)\in\Omega} \rho\left(\text{rank}(w, c)\right)$, where $\Omega \subset \mathcal{W} \times \mathcal{C}$ is the set of word-context pairs that co-occur in the corpus, and $\rho(\cdot)$ is a ranking loss function that is monotonically increasing and concave (see Sec. 2 for a justification).

Casting word embedding as ranking has two distinctive advantages. First, our method is *discriminative* rather than generative; in other words, instead of modeling (a transformation of) $X_{w,c}$ directly, we only aim to model the relative order of $X_{w,\cdot}$ values in each row. This formulation fits naturally to popular word embedding tasks such as word similarity/analogy since instead of the likelihood of each word, we are interested in finding the most relevant words in a given context[1]. Second, casting word embedding as a ranking problem enables us to design models robust to noise (Yun et al., 2014) and focusing more on differentiating top relevant words, a kind of attention mechanism that has been proved very useful in deep learning (Larochelle and Hinton, 2010; Mnih et al., 2014; Bahdanau et al., 2015). Both issues are very critical in the domain of word embedding since (1) the co-occurrence matrix might be noisy due to grammatical errors or unconventional use of language, *i.e.*, certain words might co-occur purely by chance, a phenomenon more acute in smaller document corpora collected from diverse sources; and (2) it's very challenging to sort out a few most relevant words from a very large vocabulary, thus some kind of attention mechanism that can trade off the resolution on most relevant words with the resolution on less relevant words is needed. We will show in the experiments that our method can mitigate some of these issues; with 17 million tokens our method performs almost as well as existing methods using 7.2 billion tokens on a popular word similarity benchmark.

2 Word Embedding via Ranking

2.1 Notation

We use w to denote a word and c to denote a context. The set of all words, that is, the vocabulary is denoted as $\mathcal{W}$ and the set of all context words is denoted $\mathcal{C}$. We will use $\Omega \subset \mathcal{W} \times \mathcal{C}$ to denote the set of all word-context pairs that were observed in the data, Ω_w to denote the set of contexts that co-occured with a given word w, and similarly Ω_c to denote the words that co-occurred with a given context c. The size of a set is denoted as $|\cdot|$. The inner product between vectors is denoted as $\langle \cdot, \cdot \rangle$.

2.2 Ranking Model

Let $\mathbf{u}_w$ denote the k-dimensional embedding of a word w, and $\mathbf{v}_c$ denote that of a context c. For convenience, we collect embedding parameters for words and contexts as $\mathbf{U} := \{\mathbf{u}_w\}_{w\in\mathcal{W}}$, and $\mathbf{V} := \{\mathbf{v}_c\}_{c\in\mathcal{C}}$.

We aim to capture the relevance of context c for word w by the inner product between their embedding vectors, $\langle \mathbf{u}_w, \mathbf{v}_c \rangle$; the more relevant a context is, the larger we want their inner product to be.

[1]Roughly speaking, this difference in viewpoint is analogous to the difference between pointwise loss function vs listwise loss function used in ranking (Lee and Lin, 2013).

We achieve this by learning a ranking model that is parametrized by $\mathbf{U}$ and $\mathbf{V}$. If we sort the set of contexts $\mathcal{C}$ for a given word w in terms of each context's inner product score with the word, the rank of a specific context c in this list can be written as (Usunier et al., 2009):

$$\begin{aligned}\text{rank}\,(w,c) &= \sum_{c'\in\mathcal{C}\setminus\{c\}} I\left(\langle \mathbf{u}_w, \mathbf{v}_c\rangle - \langle \mathbf{u}_w, \mathbf{v}_{c'}\rangle \leq 0\right) \\ &= \sum_{c'\in\mathcal{C}\setminus\{c\}} I\left(\langle \mathbf{u}_w, \mathbf{v}_c - \mathbf{v}_{c'}\rangle \leq 0\right), \quad (1)\end{aligned}$$

where $I(x \leq 0)$ is a 0-1 loss function which is 1 if $x \leq 0$ and 0 otherwise. Since $I(x \leq 0)$ is a discontinuous function, we follow the popular strategy in machine learning which replaces the 0-1 loss by its convex upper bound $\ell(\cdot)$, where $\ell(\cdot)$ can be any popular loss function for binary classification such as the hinge loss $\ell(x) = \max(0, 1-x)$ or the logistic loss $\ell(x) = \log_2(1+2^{-x})$ (Bartlett et al., 2006). This enables us to construct the following convex upper bound on the rank:

$$\text{rank}\,(w,c) \leq \overline{\text{rank}}\,(w,c) = \sum_{c'\in\mathcal{C}\setminus\{c\}} \ell(\langle \mathbf{u}_w, \mathbf{v}_c - \mathbf{v}_{c'}\rangle) \quad (2)$$

It is certainly desirable that the ranking model positions relevant contexts at the top of the list; this motivates us to write the objective function to minimize as:

$$J(\mathbf{U},\mathbf{V}) := \sum_{w\in\mathcal{W}} \sum_{c\in\Omega_w} r_{w,c} \cdot \rho\left(\frac{\overline{\text{rank}}\,(w,c)+\beta}{\alpha}\right) \quad (3)$$

where $r_{w,c}$ is the weight between word w and context c quantifying the association between them, $\rho(\cdot)$ is a monotonically increasing and concave ranking loss function that measures goodness of a rank, and $\alpha > 0$, $\beta > 0$ are the hyperparameters of the model whose role will be discussed later. Following Pennington et al. (2014), we use

$$r_{w,c} = \begin{cases} (X_{w,c}/x_{max})^{\epsilon} & \text{if } X_{w,c} < x_{max} \\ 1 & \text{otherwise,} \end{cases} \quad (4)$$

where we set $x_{max} = 100$ and $\epsilon = 0.75$ in our experiments. That is, we assign larger weights (with a saturation) to contexts that appear more often with the word of interest, and vice-versa. For the ranking loss function $\rho(\cdot)$, on the other hand, we consider the class of monotonically increasing and concave functions. While monotonicity is a natural requirement, we argue that concavity is also important so that the derivative of ρ is always non-increasing; this implies that the ranking loss to be the most sensitive at the top of the list (where the rank is small) and becomes less sensitive at the lower end of the list (where the rank is high). Intuitively this is desirable, because we are interested in a small number of relevant contexts which frequently co-occur with a given word, and thus are willing to tolerate errors on infrequent contexts[2]. Meanwhile, this insensitivity at the bottom of the list makes the model robust to noise in the data either due to grammatical errors or unconventional use of language. Therefore, a single ranking loss function $\rho(\cdot)$ serves two different purposes at two ends of the curve (see the example plots of ρ in Figure 1); while the left hand side of the curve encourages "high resolution" on most relevant words, the right hand side becomes less sensitive (with "low resolution") to infrequent and possibly noisy words[3]. As we will demonstrate in our experiments, this is a fundamental attribute (in addition to the ranking nature) of our method that contributes its superior performance as compared to the state-of-the-arts when the training set is limited (*i.e.*, sparse and noisy).

What are interesting loss functions that can be used for $\rho(\cdot)$? Here are four possible alternatives, all of which have a natural interpretation (see the plots of all four ρ functions in Figure 1(a) and the related work in Sec. 3 for a discussion).

$$\rho_0(x) := x \quad \text{(identity)} \quad (5)$$

$$\rho_1(x) := \log_2(1+x) \quad \text{(logarithm)} \quad (6)$$

$$\rho_2(x) := 1 - \frac{1}{\log_2(2+x)} \quad \text{(negative DCG)} \quad (7)$$

$$\rho_3(x) := \frac{x^{1-t}-1}{1-t} \quad (\log_t \text{ with } t \neq 1) \quad (8)$$

[2]This is similar to the attention mechanism found in human visual system that is able to focus on a certain region of an image with "high resolution" while perceiving the surrounding image in "low resolution" (Larochelle and Hinton, 2010; Mnih et al., 2014).

[3]Due to the linearity of $\rho_0(x) = x$, this ranking loss doesn't have the benefit of attention mechanism and robustness to noise since it treats all ranking errors uniformly.

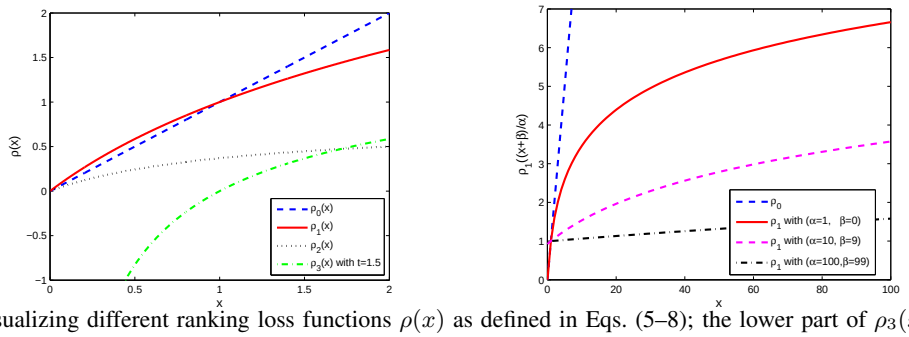

Figure 1: (a) Visualizing different ranking loss functions $\rho(x)$ as defined in Eqs. (5–8); the lower part of $\rho_3(x)$ is truncated in order to visualize the other functions better. (b) Visualizing $\rho_1((x+\beta)/\alpha)$ with different α and β; ρ_0 is included to illustrate the dramatic scale differences between ρ_0 and ρ_1.

We will explore the performance of each of these variants in our experiments. For now, we turn our attention to efficient stochastic optimization of the objective function (3).

2.3 Stochastic Optimization

Plugging (2) into (3), and replacing $\sum_{w\in\mathcal{W}}\sum_{c\in\Omega_w}$ by $\sum_{(w,c)\in\Omega}$, the objective function becomes:

$$J(\mathbf{U},\mathbf{V}) = \sum_{(w,c)\in\Omega} r_{w,c}\cdot \rho\left(\frac{\sum_{c'\in\mathcal{C}\setminus\{c\}}\ell\left(\langle\mathbf{u}_w,\mathbf{v}_c-\mathbf{v}_{c'}\rangle\right)+\beta}{\alpha}\right). \quad (9)$$

This function contains summations over Ω and $\mathcal{C}$, both of which are expensive to compute for a large corpus. Although stochastic gradient descent (SGD) (Bottou and Bousquet, 2011) can be used to replace the summation over Ω by random sampling, the summation over $\mathcal{C}$ cannot be avoided unless $\rho(\cdot)$ is a linear function. To work around this problem, we propose to optimize a linearized upper bound of the objective function obtained through a first-order Taylor approximation. Observe that due to the concavity of $\rho(\cdot)$, we have

$$\rho(x) \le \rho\left(\xi^{-1}\right) + \rho'\left(\xi^{-1}\right)\cdot\left(x-\xi^{-1}\right) \quad (10)$$

for any x and $\xi \neq 0$. Moreover, the bound is tight when $\xi = x^{-1}$. This motivates us to introduce a set of auxiliary parameters $\Xi := \{\xi_{w,c}\}_{(w,c)\in\Omega}$ and define the following upper bound of $J(\mathbf{U},\mathbf{V})$:

$$\overline{J}(\mathbf{U},\mathbf{V},\Xi) := \sum_{(w,c)\in\Omega} r_{w,c}\cdot\left\{\rho(\xi_{wc}^{-1}) + \rho'(\xi_{wc}^{-1})\cdot\left(\alpha^{-1}\beta+\alpha^{-1}\sum_{c'\in\mathcal{C}\setminus\{c\}}\ell\left(\langle\mathbf{u}_w,\mathbf{v}_c-\mathbf{v}_{c'}\rangle\right)-\xi_{w,c}^{-1}\right)\right\}. \quad (11)$$

Note that $J(\mathbf{U},\mathbf{V}) \le \overline{J}(\mathbf{U},\mathbf{V},\Xi)$ for any Ξ, due to (10)[4]. Also, minimizing (11) yields the same $\mathbf{U}$ and $\mathbf{V}$ as minimizing (9). To see this, suppose $\hat{\mathbf{U}} := \{\hat{\mathbf{u}}_w\}_{w\in\mathcal{W}}$ and $\hat{\mathbf{V}} := \{\hat{\mathbf{v}}_c\}_{c\in\mathcal{C}}$ minimizes (9). Then, by letting $\hat{\Xi} := \left\{\hat{\xi}_{w,c}\right\}_{(w,c)\in\Omega}$ where

$$\hat{\xi}_{w,c} = \frac{\alpha}{\sum_{c'\in\mathcal{C}\setminus\{c\}}\ell\left(\langle\hat{\mathbf{u}}_w,\hat{\mathbf{v}}_c-\hat{\mathbf{v}}_{c'}\rangle\right)+\beta}, \quad (12)$$

we have $\overline{J}\left(\hat{\mathbf{U}},\hat{\mathbf{V}},\hat{\Xi}\right) = J\left(\hat{\mathbf{U}},\hat{\mathbf{V}}\right)$. Therefore, it suffices to optimize (11). However, unlike (9), (11) admits an efficient SGD algorithm. To see this, rewrite (11) as

$$\overline{J}(\mathbf{U},\mathbf{V},\Xi) = \sum_{(w,c,c')} r_{w,c}\cdot\left(\frac{\rho(\xi_{w,c}^{-1})+\rho'(\xi_{w,c}^{-1})\cdot(\alpha^{-1}\beta-\xi_{w,c}^{-1})}{|\mathcal{C}|-1} + \frac{1}{\alpha}\rho'(\xi_{w,c}^{-1})\cdot\ell\left(\langle\mathbf{u}_w,\mathbf{v}_c-\mathbf{v}_{c'}\rangle\right)\right), \quad (13)$$

where $(w,c,c') \in \Omega\times(\mathcal{C}\setminus\{c\})$. Then, it can be seen that if we sample uniformly from $(w,c)\in\Omega$ and $c'\in\mathcal{C}\setminus\{c\}$, then $j(w,c,c') :=$

$$|\Omega|\cdot(|\mathcal{C}|-1)\cdot r_{w,c}\cdot\left(\frac{\rho(\xi_{w,c}^{-1})+\rho'(\xi_{w,c}^{-1})\cdot(\alpha^{-1}\beta-\xi_{w,c}^{-1})}{|\mathcal{C}|-1} + \frac{1}{\alpha}\rho'(\xi_{w,c}^{-1})\cdot\ell\left(\langle\mathbf{u}_w,\mathbf{v}_c-\mathbf{v}_{c'}\rangle\right)\right), \quad (14)$$

which does not contain any expensive summations and is an unbiased estimator of (13), i.e., $\mathbb{E}[j(w,c,c')] = \overline{J}(\mathbf{U},\mathbf{V},\Xi)$. On the other hand, one can optimize $\xi_{w,c}$ exactly by using (12). Putting

[4] When $\rho=\rho_0$, one can simply set the auxiliary variables $\xi_{w,c}=1$ because ρ_0 is already a linear function.

everything together yields a stochastic optimization algorithm *WordRank*, which can be specialized to a variety of ranking loss functions $\rho(\cdot)$ with weights $r_{w,c}$ (e.g., DCG (Discounted Cumulative Gain) (Manning et al., 2008) is one of many possible instantiations). Algorithm 1 contains detailed pseudo-code. It can be seen that the algorithm is divided into two stages: a stage that updates $(\mathbf{U}, \mathbf{V})$ and another that updates Ξ. Note that the time complexity of the first stage is $\mathcal{O}(|\Omega|)$ since the cost of each update in Lines 8–10 is independent of the size of the corpus. On the other hand, the time complexity of updating Ξ in Line 15 is $\mathcal{O}(|\Omega|\,|\mathcal{C}|)$, which can be expensive. To amortize this cost, we employ two tricks: we only update Ξ after a few iterations of $\mathbf{U}$ and $\mathbf{V}$ update, and we exploit the fact that the most computationally expensive operation in (12) involves a matrix and matrix multiplication which can be calculated efficiently via the SGEMM routine in BLAS (Dongarra et al., 1990).

17: **end for**
18: **until** $\mathbf{U}$, $\mathbf{V}$ and Ξ are converged

2.4 Parallelization

The updates in Lines 8–10 have one remarkable property: To update $\mathbf{u}_w$, $\mathbf{v}_c$ and $\mathbf{v}_{c'}$, we only need to *read* the variables $\mathbf{u}_w$, $\mathbf{v}_c$, $\mathbf{v}_{c'}$ and $\xi_{w,c}$. What this means is that updates to another triplet of variables $\mathbf{u}_{\hat{w}}$, $\mathbf{v}_{\hat{c}}$ and $\mathbf{v}_{\hat{c}'}$ can be performed independently. This observation is the key to developing a parallel optimization strategy, by distributing the computation of the updates among multiple processors. Due to lack of space, details including pseudo-code are relegated to the supplementary material.

2.5 Interpreting of α and β

The update (12) indicates that $\xi_{w,c}^{-1}$ is proportional to $\overline{\mathrm{rank}}\,(w, c)$. On the other hand, one can observe that the loss function $\ell\,(\cdot)$ in (14) is weighted by a $\rho'\left(\xi_{w,c}^{-1}\right)$ term. Since $\rho\,(\cdot)$ is concave, its gradient $\rho'\,(\cdot)$ is monotonically non-increasing (Rockafellar, 1970). Consequently, when $\overline{\mathrm{rank}}\,(w, c)$ and hence $\xi_{w,c}^{-1}$ is large, $\rho'\left(\xi_{w,c}^{-1}\right)$ is small. In other words, the loss function "gives up" on contexts with high ranks in order to focus its attention on top of the list. The rate at which the algorithm gives up is determined by the hyperparameters α and β. For the illustration of this effect, see the example plots of ρ_1 with different α and β in Figure 1(b). Intuitively, α can be viewed as a *scale* parameter while β can be viewed as an *offset* parameter. An equivalent interpretation is that by choosing different values of α and β one can modify the behavior of the ranking loss $\rho\,(\cdot)$ in a problem dependent fashion. In our experiments, we found that a common setting of $\alpha = 1$ and $\beta = 0$ often yields uncompetitive performance, while setting $\alpha = 100$ and $\beta = 99$ generally gives good results.

3 Related Work

Our work sits at the intersection of word embedding and ranking optimization. As we discussed in Sec. 2.2 and Sec. 2.5, it's also related to the attention mechanism widely used in deep learning. We therefore review the related work along these three axes.

Word Embedding. We already discussed some related work (*word2vec* and *GloVe*) on word embedding in the introduction. Essentially, *word2vec* and *GloVe* derive word representations by modeling a transformation (PMI or log) of $X_{w,c}$ directly, while

WordRank learns word representations via robust ranking. Besides these state-of-the-art techniques, a few ranking-based approaches have been proposed for word embedding recently, e.g., (Collobert and Weston, 2008; Vilnis and McCallum, 2015; Liu et al., 2015). However, all of them adopt a pair-wise binary classification approach with a linear ranking loss ρ_0. For example, (Collobert and Weston, 2008; Vilnis and McCallum, 2015) employ a hinge loss on positive/negative word pairs to learn word representations and ρ_0 is used *implicitly* to evaluate ranking losses. As we discussed in Sec. 2.2, ρ_0 has no benefit of the attention mechanism and robustness to noise since its linearity treats all the ranking errors uniformly; empirically, sub-optimal performances are often observed with ρ_0 in our experiments. More recently, by extending the Skip-Gram model of *word2vec*, Liu et al. (2015) incorporates additional pair-wise constraints induced from 3rd-party knowledge bases, such as WordNet, and learns word representations jointly. In contrast, *WordRank* is a fully ranking-based approach without using any additional data source for training.

Robust Ranking. The second line of work that is very relevant to *WordRank* is that of ranking objective (3). The use of score functions $\langle \mathbf{u}_w, \mathbf{v}_c \rangle$ for ranking is inspired by the latent collaborative retrieval framework of Weston et al. (2012). Writing the rank as a sum of indicator functions (1), and upper bounding it via a convex loss (2) is due to Usunier et al. (2009). Using $\rho_0(\cdot)$ (5) corresponds to the well-known pairwise ranking loss (see *e.g.*, (Lee and Lin, 2013)). On the other hand, Yun et al. (2014) observed that if they set $\rho = \rho_2$ as in (7), then $-J(\mathbf{U}, \mathbf{V})$ corresponds to the DCG (Discounted Cumulative Gain), one of the most popular ranking metrics used in web search ranking (Manning et al., 2008). In their RobiRank algorithm they proposed the use of $\rho = \rho_1$ (6), which they considered to be a special function for which one can derive an efficient stochastic optimization procedure. However, as we showed in this paper, the general class of monotonically increasing concave functions can be handled efficiently. Another important difference of our approach is the hyperparameters α and β, which we use to modify the behavior of ρ, and which we find are critical to achieve good empirical results. Ding and Vishwanathan (2010) proposed the use of $\rho = \log_t$ in the context of robust *binary* classification, while here we are concerned with ranking, and our formulation is very general and applies to a variety of ranking losses $\rho(\cdot)$ with weights $r_{w,c}$. Optimizing over $\mathbf{U}$ and $\mathbf{V}$ by distributing the computation across processors is inspired by work on distributed stochastic gradient for matrix factorization (Gemulla et al., 2011).

Attention. Attention is one of the most important advancements in deep learning in recent years (Larochelle and Hinton, 2010), and is now widely used in state-of-the-art image recognition and machine translation systems (Mnih et al., 2014; Bahdanau et al., 2015). Recently, attention has also been applied to the domain of word embedding. For example, under the intuition that not all contexts are created equal, Wang et al. (2015) assign an importance weight to each word type at each context position and learn an attention-based Continuous Bag-Of-Words (CBOW) model. Similarly, within a ranking framework, *WordRank* expresses the context importance by introducing the auxiliary variable $\xi_{w,c}$, which "gives up" on contexts with high ranks in order to focus its attention on top of the list.

4 Experiments

In our experiments, we first evaluate the impact of the weight $r_{w,c}$ and the ranking loss function $\rho(\cdot)$ on the test performance using a small dataset. We then pick the best performing model and compare it against *word2vec* (Mikolov et al., 2013b) and *GloVe* (Pennington et al., 2014). We closely follow the framework of Levy et al. (2015) to set up a careful and fair comparison of the three methods. Our code is publicly available at `https://bitbucket.org/shihaoji/wordrank`.

Training Corpus Models are trained on a combined corpus of 7.2 billion tokens, which consists of the 2015 Wikipedia dump with 1.6 billion tokens, the WMT14 News Crawl[5] with 1.7 billion tokens, the "One Billion Word Language Modeling Benchmark"[6] with almost 1 billion tokens, and UMBC

Analogy	22.7	24.9	31.9	34.3	<u>44.5</u>	32.3	40.4	33.6	42.9

Table 2: Performance of different ρ functions on Text8 dataset with 17M tokens.

webbase corpus[7] with around 3 billion tokens. The pre-processing pipeline breaks the paragraphs into sentences, tokenizes and lowercases each corpus with the Stanford tokenizer. We further clean up the dataset by removing non-ASCII characters and punctuation, and discard sentences that are shorter than 3 tokens or longer than 500 tokens. In the end, we obtain a dataset of 7.2 billion tokens, with the first 1.6 billion tokens from Wikipedia. When we want to experiment with a smaller corpus, we extract a subset which contains the specified number of tokens.

Co-occurrence matrix construction We use the *GloVe* code to construct the co-occurrence matrix X, and the same matrix is used to train *GloVe* and *WordRank* models. When constructing X, we must choose the size of the vocabulary, the context window and whether to distinguish left context from right context. We follow the findings and design choices of *GloVe* and use a symmetric window of size win with a decreasing weighting function, so that word pairs that are d words apart contribute $1/d$ to the total count. Specifically, when the corpus is small (*e.g.*, 17M, 32M, 64M) we let $win = 15$ and for larger corpora we let $win = 10$. The larger window size alleviates the data sparsity issue for small corpus at the expense of adding more noise to X. The parameter settings used in our experiments are summarized in Table 1.

Using the trained model It has been shown by Pennington et al. (2014) that combining the $\mathbf{u}_w$ and $\mathbf{v}_c$ vectors with equal weights gives a small boost in performance. This vector combination was originally motivated as an ensemble method (Pennington et al., 2014), and later Levy et al. (2015) provided a different interpretation of its effect on the cosine similarity function, and show that adding context vectors effectively adds first-order similarity terms to the second-order similarity function. In our experiments, we find that vector combination boosts the performance in word analogy task when training set is small, but when dataset is large enough (*e.g.*, 7.2 billion tokens), vector combination doesn't help anymore. More interestingly, for the word similarity task, we find that vector combination is detrimental in all the cases, sometimes even substantially[8]. Therefore, we will always use $\mathbf{u}_w$ on word similarity task, and use $\mathbf{u}_w + \mathbf{v}_c$ on word analogy task unless otherwise noted.

4.1 Evaluation

Word Similarity We use six datasets to evaluate word similarity: WS-353 (Finkelstein et al., 2002) partitioned into two subsets: WordSim Similarity and WordSim Relatedness (Agirre et al., 2009); MEN (Bruni et al., 2012); Mechanical Turk (Radinsky et al., 2011); Rare words (Luong et al., 2013); and SimLex-999 (Hill et al., 2014). They contain word pairs together with human-assigned similarity judgments. The word representations are evaluated by ranking the pairs according to their cosine similarities, and measuring the Spearman's rank correlation coefficient with the human judgments.

[7] `http://ebiquity.umbc.edu/resource/html/id/351`

[8] This is possible since we optimize a ranking loss: the absolute scores don't matter as long as they yield an ordered list correctly. Thus, *WordRank*'s $\mathbf{u}_w$ and $\mathbf{v}_c$ are less comparable to each other than those generated by *GloVe*, which employs a point-wise L_2 loss.

Word Analogies For this task, we use the Google analogy dataset (Mikolov et al., 2013a). It contains 19544 word analogy questions, partitioned into 8869 semantic and 10675 syntactic questions. A question is correctly answered only if the algorithm selects the word that is exactly the same as the correct word in the question: synonyms are thus counted as mistakes. There are two ways to answer these questions, namely, by using 3CosAdd or 3CosMul (see (Levy and Goldberg, 2014) for details). We will report scores by using 3CosAdd by default, and indicate when 3CosMul gives better performance.

4.2 The impact of $r_{w,c}$ and $\rho(\cdot)$

In Sec. 2.2 we argued the need for adding weight $r_{w,c}$ to ranking objective (3), and we also presented our framework which can deal with a variety of ranking loss functions ρ. We now study the utility of these two ideas. We report results on the 17 million token dataset in Table 2. For the similarity task, we use the WS-353 test set and for the analogy task we use the Google analogy test set. The best scores for each task are underlined. We set $t = 1.5$ for ρ_3. "Off" means that we used uniform weight $r_{w,c} = 1$, and "on" means that $r_{w,c}$ was set as in (4). For comparison, we also include the results using RobiRank (Yun et al., 2014)[9].

It can be seen from Table 2 that adding the weight $r_{w,c}$ improves performance in all the cases, especially on the word analogy task. Among the four ρ functions, ρ_0 performs the best on the word similarity task but suffers notably on the analogy task, while $\rho_1 = \log$ performs the best overall. Given these observations, which are consistent with the results on large scale datasets, in the experiments that follow we only report *WordRank* with the best configuration, *i.e.*, using ρ_1 with the weight $r_{w,c}$ as defined in (4).

4.3 Comparison to state-of-the-arts

In this section we compare the performance of *WordRank* with *word2vec*[10] and *GloVe*[11], by using the code provided by the respective authors. For a fair comparison, *GloVe* and *WordRank* are given as input the same co-occurrence matrix X; this eliminates differences in performance due to window size and other such artifacts, and the same parameters are used to *word2vec*. Moreover, the embedding dimensions used for each of the three methods is the same (see Table 1). With *word2vec*, we train the Skip-Gram with Negative Sampling (SGNS) model since it produces state-of-the-art performance, and is widely used in the NLP community (Mikolov et al., 2013b). For *GloVe*, we use the default parameters as suggested by (Pennington et al., 2014). The results are provided in Figure 2 (also see Table 4 in the supplementary material for additional details).

As can be seen, when the size of corpus increases, in general all three algorithms improve their prediction accuracy on both tasks. This is to be expected since a larger corpus typically produces better statistics and less noise in the co-occurrence matrix X. When the corpus size is small (*e.g.*, 17M, 32M, 64M, 128M), *WordRank* yields the best performance with significant margins among three, followed by *word2vec* and *GloVe*; when the size of corpus increases further, on the word analogy task *word2vec* and *GloVe* become very competitive to *WordRank*, and eventually perform neck-to-neck to each other (Figure 2(b)). This is consistent with the findings of (Levy et al., 2015) indicating that when the number of tokens is large even simple algorithms can perform well. On the other hand, *WordRank* is dominant on the word similarity task for all the cases (Figure 2(a)) since it optimizes a ranking loss *explicitly*, which aligns more naturally with the objective of word similarity than the other methods; with 17 million tokens our method performs almost as well as existing methods using 7.2 billion tokens on the word similarity benchmark.

To further evaluate the model performance on the word similarity/analogy tasks, we use the best performing models trained on the 7.2-billion-token corpus to predict on the six word similarity datasets described in Sec. 4.1. Moreover, we breakdown the performance of the models on the Google word analogy dataset into the semantic and syntactic subtasks. Results are listed in Table 3. As can be seen, *WordRank* outperforms *word2vec* and *GloVe* on 5 of 6 similarity tasks, and 1 of 2 Google analogy subtasks.

[9] We used the code provided by the authors at `https://bitbucket.org/d_ijk_stra/robirank`. Although related to RobiRank, we attribute the superior performance of *WordRank* to the use of weight $r_{w,c}$ (4), introduction of hyperparameters α and β, and many implementation details.

Table 3: Performance of the best *word2vec*, *GloVe* and *WordRank* models, learned from 7.2 billion tokens, on six similarity tasks and Google semantic and syntactic subtasks.

5 Visualizing the results

To understand whether *WordRank* produces *syntatically* and *semantically* meaningful vector space, we did the following experiment: we use the best performing model produced using 7.2 billion tokens, and compute the nearest neighbors of the word "cat". We then visualize the words in two dimensions by using t-SNE (Maaten and Hinton, 2008). As can be seen in Figure 3, our ranking-based model is indeed capable of capturing both semantic (*e.g.*, cat, feline, kitten, tabby) and syntactic (*e.g.*, leash, leashes, leashed) regularities of the English language.

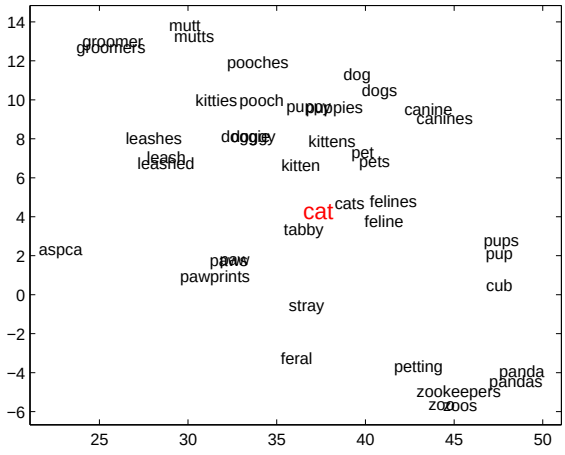

Figure 3: Nearest neighbors of "cat" found by projecting a 300d word embedding learned from *WordRank* onto a 2d space.

6 Conclusion

We proposed *WordRank*, a ranking-based approach, to learn word representations from large scale textual corpora. The most prominent difference between our method and the state-of-the-art techniques, such as *word2vec* and *GloVe*, is that *WordRank* learns word representations via a robust ranking model, while *word2vec* and *GloVe* typically model a transformation of co-occurrence count $X_{w,c}$ directly. Moreover, by a ranking loss function $\rho(\cdot)$, *WordRank* achieves its attention mechanism and robustness to noise naturally, which are usually lacking in other ranking-based approaches. These attributes significantly boost the performance of *WordRank* in the cases where training data are sparse and noisy. Our multi-node distributed implementation of *WordRank* is publicly available for general usage.

Acknowledgments

We'd like to thank Omer Levy for sharing his script for preprocessing the corpora used in the paper. We also thank the anonymous reviewers for their valuable comments and suggestions.

Abstract

In this paper, we utilize distributed word representations (i.e., word embeddings) to analyse the representation of semantics in brain activity. The brain activity data were recorded using functional magnetic resonance imaging (fMRI) when subjects were viewing words. First, we analysed the functional selectivity of different cortex areas by calculating the correlations between neural responses and several types of word representations, including skip-gram word embeddings, visual semantic vectors, and primary visual features. The results demonstrated consistency with existing neuroscientific knowledge. Second, we utilized behavioural data as the semantic ground truth to measure their relevance with brain activity. A method to estimate word embeddings under the constraints of brain activity similarities is further proposed based on the semantic word embedding (SWE) model. The experimental results show that the brain activity data are significantly correlated with the behavioural data of human judgements on semantic similarity. The correlations between the estimated word embeddings and the semantic ground truth can be effectively improved after integrating the brain activity data for learning, which implies that semantic patterns in neural representations may exist that have not been fully captured by state-of-the-art word embeddings derived from text corpora.

1 Introduction

Recently, the topic of exploring semantic representation in human brain has attracted the attention of researchers from both neuroscience and computational linguistics fields. In these studies, concepts are represented in terms of neural activation patterns in the brain that can be recorded by functional magnetic resonance imaging (fMRI) (Haxby et al., 2001). It has been found that the semantic space shared among different individuals is distributed continuously across the cortex (Huth et al., 2012). A recent study proposed an efficient way to measure and visualize the semantic selectivity of different cortex areas (Huth et al., 2016).

Similar to the distributed semantic representation in the brain, describing the meaning of a word using a dense low-dimensional and continuous vector (i.e., word embedding) is currently a popular approach in computational linguistics (Hinton et al., 1986; Turney et al., 2010). Word embeddings are commonly estimated from large text corpora utilizing statistics concerning the co-occurrences of words (Mikolov et al., 2013a; Mikolov et al., 2013b; Pennington et al., 2014). To investigate the correlation between word embeddings and the brain activity involved in viewing words, Mitchell et al. (2008) designed a computational model to predict brain responses using hand-tailored word embeddings as input. Further, Fyshe et al. (2014) proposed a joint non-negative sparse embedding (JNNSE) method to combine fMRI data and textual data to estimate word embeddings. This work improved the correlation between word embeddings and human behavioural data, which lends support to the view that fMRI data can provide additional semantic information that may not exist in textual data.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 669–679,
Austin, Texas, November 1-5, 2016.

The factors that can influence the activities of cortex areas are diverse. Recent studies show that visual semantic features such as bag-of-visual-words (BoVW) are significantly correlated with the fMRI data captured when viewing words (Anderson et al., 2013). The primary visual features derived using Gabor wavelets can be used to determine the images presented to the subjects from their recorded brain activity (Kay et al., 2008; Naselaris et al., 2009). Some other research work also indicates that visual experiences (Nishimoto et al., 2011) and speech information (Ryali et al., 2010) can affect neural responses in cortex areas.

In this paper, we first study the semantic representation of words in brain activity by correlation analysis (Anderson et al., 2013; Carlson et al., 2014). Then, we calculate the correlations between subjects' neural responses when viewing words and three types of word representations: skip-gram word embeddings, primary visual features, and visual semantic vectors. The goal of doing this is to investigate whether these representations can account for the brain data and the functional selectivity of different cortex areas. Then, we utilize behavioural data as the semantic ground truth to measure the semantic relevance of brain activity. A method of estimating word embeddings within the constraints of similar brain activities is proposed. This method is based on the semantic word embedding (SWE) model (Liu et al., 2015) which develops from the skip-gram model. It aims at verifying whether textual data and brain activity data can be complementary to derive word embeddings that are more consistent with human judgement.

The contributions of this study are twofold. First, this study involved a comprehensive correlation analysis on brain activity data and state-of-the-art skip-gram word embeddings at both whole-brain and brain lobe levels. Primary visual features and visual semantic vectors are also introduced as auxiliary representations to better understand the functional selectivity across the cortex. Some results of this analysis are interpretable using existing neuroscience knowledge. Second, to our knowledge, this study marks the first attempt to integrate brain activity data into the skip-gram model for estimating word embeddings. The experimental results show that the correlation between the estimated word embeddings and the behavioural measure of semantics can be effectively improved after integrating brain activity data for learning.

2 Related work

The correlation between brain data and word vectors has been studied in previous work. The experiments in Carlson et al. (2014) adopted brain activity data for correlation analysis from only the ventral temporal pathway, not from the whole brain. Anderson et al. (2013) performed correlation analysis using the voxels of the whole brain and compared the HAL-based textual semantic model (Lund and Burgess, 1996) with the BoVW-based visual semantic model (Sivic and Zisserman, 2003; Csurka et al., 2004) in terms of these two model's ability to account for the patterns found in the neural data. However, the experiments in Anderson et al. (2013) failed to detect differential interactions of semantic models with brain areas. In this paper, considering the popularity of word embedding estimation approaches based on neural networks in recent years, we adopt skip-gram word embeddings (Mikolov et al., 2013a) for correlation analysis. To our knowledge, this is the first time that the association between skip-gram word embeddings and brain activity data have been studied. Furthermore, our work improves on the voxel selection strategy used in Anderson et al. (2013), leading to more interpretable results when demonstrating the functional selectivity of brain areas.

To our knowledge, the first and only attempt to integrate brain activity data into the acquisition of textual word embedding is the JNNSE method (Fyshe et al., 2014). In this method, word embeddings were estimated as latent representations using matrix factorization. The objective functions contained additional constraints for reconstructing brain activity data. In this paper, we adopt the SWE model (Liu et al., 2015) to incorporate brain activity knowledge into word embedding estimation. The SWE model was developed from the skip-gram model. In SWE, semantically related knowledge is converted into inequality constraints for learning word embeddings. The experimental results show that our proposed method using SWE can improve

the semantic consistency between word embeddings and human judgements.

3 From Skip-Gram to SWE

3.1 Skip-gram model

The skip-gram model (Mikolov et al., 2013b) adopts a neural network structure to derive the distributed representation of words from textual corpus. The word vectors are learned based on the distributional hypothesis (Harris, 1954; Miller and Charles, 1991), which assumes that words with similar contexts tend to have similar semantic meanings. For a sequence of training data of T words, denoted as $\{w_1, w_2, w_3, \cdots, w_T\}$, the skip-gram model is trained to maximize the following objective function

$$Q = \frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c, j\neq 0}\log p(w_{t+j}|w_t), \quad (1)$$

where w_t and w_{w+j} are the central word and neighbouring words in a context window respectively, and c denotes the size of the context window. The conditional probability $p(w_{t+j}|w_t)$ in Eq.(1) is calculated as

$$p(w_{t+j}|w_t) = \frac{\exp(\mathbf{w}_{t+j}^{(2)} \cdot \mathbf{w}_t^{(1)})}{\sum_{k=1}^{V}\exp(\mathbf{w}_k^{(2)} \cdot \mathbf{w}_t^{(1)})}, \quad (2)$$

where $\mathbf{w}_t^{(1)}$ and $\mathbf{w}_k^{(2)}$ denote row vectors in the matrices $\mathbf{W}^{(1)}$ and $\mathbf{W}^{(2)}$ respectively, and V is the vocabulary size of the corpus. The matrix $\mathbf{W}^{(1)}$ stores the word vectors of input central words, and the matrix $\mathbf{W}^{(2)}$ stores the word vectors of predicted neighbouring words. The optimization of the objective function Q is solved by the stochastic gradient descent (SGD) method (Mikolov et al., 2013b). Finally, the learned matrix $\mathbf{W}^{(1)}$ is used as the estimated word embeddings of all words in the vocabulary.

3.2 Semantic word embedding (SWE)

The skip-gram model learns word embeddings based on the distributional hypothesis; however, this hypothesis still has some limitations. For example, antonyms often appear in similar contexts although they have opposite meanings. The semantic word embedding (SWE) model (Liu et al., 2015) has been proposed to address this issue by incorporating external semantic knowledge into the text-based learning process for word embeddings.

In this method, semantic knowledge is represented as a set of ranking inequalities. Each inequality contains a triplet (i, j, k) of three words $\{w_i, w_j, w_k\}$ with a similarity relation

$$similarity(w_i, w_j) > similarity(w_i, w_k), \quad (3)$$

which can be notated in simplified form as $s_{ij} > s_{ik}$. Then, the learning method of SWE is defined as the following constrained optimization problem

$$\{\mathbf{W}^{(1)}, \mathbf{W}^{(2)}\} = arg\max_{\mathbf{W}^{(1)},\mathbf{W}^{(2)}} Q(\mathbf{W}^{(1)}, \mathbf{W}^{(2)}),$$
$$s.t.\ s_{ij} > s_{ik}, \forall (i, j, k) \in S, \quad (4)$$

where function Q is defined in Eq. (1) and S denotes the inequality set. Then, the constrained optimization problem in Eq. (4) is simplified into an unconstrained problem by introducing a penalty term into the objective function of the skip-gram model. The penalty term is defined as

$$D = \sum_{(i,j,k)\in S} f(i, j, k), \quad (5)$$

where $f(i, j, k) = \max(0, s_{ik} - s_{ij})$ is a Hinge loss function. Finally, the object function to be maximized in SWE can be written as follows:

$$Q' = Q - \beta \cdot D, \quad (6)$$

where β is a parameter to control the contribution of the penalty term. Similar to the skip-gram model, the Q' function in the SWE model is optimized using SGD to estimate word embeddings. The detailed formulae can be found in Liu et al. (2015).

3.3 Integrating brain activity into SWE

In the implementation of the SWE model in Liu et al. (2015), the ranking inequalities were collected using hypernym-hyponym and synonym-antonym relationships extracted from WordNet (Fellbaum and others, 1998). In this paper, the SWE model is utilized as a tool to explore the semantic relevance of brain activity by examining the performance of the estimated word embeddings after integrating brain-activity-related knowledge. Therefore, we construct

the ranking inequalities in Eq. (3) using brain activity data. When a subject is viewing a word, the neural response in the cortex is captured using fMRI and further stored as a vector. After collecting the fMRI data for a set of words, the inequalities in Eq. (3) can be constructed by using a similarity measure on the neural response vectors of word pairs. Here, we adopt Pearson correlation as the similarity measure. The details will be introduced in Section 5.1.

4 Data

4.1 Brain data

The fMRI data used in our experiments was recorded and preprocessed by Mitchell et al. (2008). It includes the recorded data of 9 subjects. To record the data, each of 60 concrete nouns was presented visually to each subject with a textual label and a simple line drawing. The subjects were asked to think about the properties of the objects indicated by the words during fMRI scanning. This procedure repeated 6 times, and the stimuli of the 60 nouns were presented in a random order in each run. More details about the data acquisition and preprocessing procedures can be found in Mitchell et al. (2008) and its supplement materials. Finally, an fMRI vector measuring the neural response at all voxels across the cortex was created for each word and each subject.

4.2 Behavioural data

The behavioural data collects human judgements on the semantic similarity between word pairs. The approach to behavioural data collection in our experiment is similar to the one used in the WordSim-353 dataset (Finkelstein et al., 2001). For the 60 concrete nouns used in Section 4.1, we obtained $C_{60}^2 = 1,770$ word pairs. Then, we asked 15 participants to score the semantic similarity of each word pair on a scale from 0 to 10, in which "0" signified that the two words were totally unrelated and "10" signified that the two words were highly related or had identical meanings. This collection procedure was conducted on the Amazon Mechanical Turk[1] crowdsourcing platform. We tested the average Spearman correlation coefficient among the scores given by different annotators and found that it was approximately 0.4873 with a p-value of 1.1e-02. After gathering the scores for all the word pairs, the highest and lowest scores for each word pair were discarded, and the average of the remaining 13 scores was calculated as the similarity score for each word pair[2].

To verify the reliability of the above data collection process, we also added 15 word pairs from the WordSim-353 dataset into our 1,770 word pairs during score collection. Then, we calculated the similarity scores of these 15 word pairs using the collected scores and compared them with the scores in the WordSim-353 dataset using Spearman correlation analysis. The correlation coefficient was 0.8451 with a p-value of $2.7e-04$. This high correlation verifies the reliability of our behavioural data collection.

5 Experiments

5.1 Correlations between brain activity and word vectors

We calculated the correlations between the fMRI vectors and the different types of word representations to investigate whether these representations can account for the brain activity and the functional selectivity of different cortex areas. We adopted the method of representational similarity analysis (Kriegeskorte et al., 2008) in our experiments. For a specific word representation, we calculated the cosine similarity for each word pair in a set of n words, resulting in a similarity vector with a total length of C_n^2. For the fMRI data[3], we constructed a similarity vector for each subject using the Pearson correlation coefficients between pairs of fMRI vectors (Anderson et al., 2013). Then, the 9 vectors of the 9 subjects were averaged to obtain an overall similarity vector in the fMRI space (Anderson et al., 2013). Finally, the Spearman rank correlation coefficient between the similarity vectors given by the fMRI data and each word representation was calculated together with a p-value for significance

[1] http://www.mturk.com/

[2] The behavioural data are available at http://home.ustc.edu.cn/~ypruan/work/emnlp2016/behaviour_data/

[3] Before using the fMRI data, we first regularized its mean value to 0 and variance to 1.

analysis. The p-value was calculated using a permutation test under a positive hypothesis with the word pair labels randomly shuffled 10,000 times. Empirically, two similarity vectors are considered to be correlated when $p < 0.05$, and they are considered significantly correlated when $p < 0.01$.

5.1.1 Word vectors

Three types of word representations, i.e., skip-gram word embeddings, visual semantic vectors, and primary visual features, were used in the correlation analysis. Some details about the acquisitions of these three word representations will be introduced in the following paragraphs.

Skip-gram word embeddings The Wikipedia text corpus[4], containing 130 million words, was adopted to train our skip-gram word embeddings, and the hierarchical softmax scheme was followed. The dimension of word embedding was 200. The window size, learning rate, and negative sampling number were set to 8, 0.05, and 8, respectively. The model was trained for one iteration using a single execution thread.

Visual semantic vectors On one hand, distributed word representations are usually learnt from text corpora. On the other hand, visual perception also contributes to semantic cognition according to some neuroscience research (Louwerse, 2011), and it has been utilized to complement the semantic representation learned from texts (Bruni et al., 2012). One approach to constructing visual semantic vectors is to first extract the low-level visual features from images and then convert them into higher-level semantic representations using the bag-of-visual-words (BoVW) (Grauman and Leibe, 2011) model. In our experiments, we built the BoVW representations from ImageNet (Deng et al., 2009) using the VSEM[5] toolkit. Due to coverage limitations, only 57 of the 60 concrete nouns in the fMRI data could be found in ImageNet[6] and each noun has approximately 1000 image samples. Similar to Anderson et al. (2013), we adopted the Scale Invariant Feature Transform (SIFT) (Lowe, 2004) to extract lower-level visual features; however, we did not use the "object" box to discriminate "object" and "context" areas during the extraction. Then, we clustered the SIFT features into 1000 classes to construct the visual vocabulary, and each image was divided into 8 regions. Thus, the BoVW representation of an image was a vector of 8000 dimensions. The BoVW vectors of all images in ImageNet corresponding to the same word were averaged to obtain the BoVW representation of that word. Finally, we transformed the BoVW representation matrix of the 57 nouns to nonnegative point-wise mutual information (PMI) association scores (Church and Hanks, 1990) to obtain the final visual semantic vectors.

Primary visual features As introduced in Section 4.1, a line drawing of each word was presented to subjects together with the textual label when collecting the fMRI data (Mitchell et al., 2008). This presentation led to neural responses in visual cortices that may be irrelevant to semantic representation. Because the receptive fields of simple cells in the primary visual cortex of mammalian brains can be modelled by Gabor functions (Marĉelja, 1980; Daugman, 1985), we adopted Gabor wavelets to extract the primary visual features from the line drawings of the 60 nouns and further analysed their correlations with fMRI data. The original resolution of the image stimuli used in Mitchell et al. (2008) was 500 x 500 pixels. These images were converted to 64 x 64 pixels after trimming the black borders and downsampling. The Gabor wavelet filter bank was designed using an open source tool (Haghighat et al., 2015). The number of scales and orientations were set to 5 and 8, respectively. Thus, we represented the primary visual features of each noun as a vector of 163,840 dimensions. The singular value decomposition (SVD) technique was employed to reduce the dimension of each vector to 60.

5.1.2 Correlation analysis at the whole-brain level

The fMRI recording measures the neural responses of more than 20,000 voxels across the cortex. To perform dimensionality reduction, we selected 500 voxels from all voxels for each subject according to

[4] http://mattmahoney.net/dc/enwik9.zip

[6] The three missing words are *arm*, *eye* and *saw*.

word representation	rho (p-value)
skip-gram	0.0065 (4.0e-01)
BoVW	**0.3515** (0.0e-00)
Gabor	**0.3924** (0.0e-00)

Table 1: Spearman's rank correlation coefficients (**rho**) between different word representations and whole-brain fMRI data for 57 nouns and their corresponding p-values.

Lobe	Proportion (%)
frontal	5.89
temporal	6.96
parietal	10.13
occipital	58.40
other	18.62

Table 2: The proportions of the regional distributions of the 500 selected voxels.

the stability of the voxel responses across 6 runs of fMRI recordings. This selection strategy was the same as the one used in Mitchell et al. (2008) and Anderson et al. (2013). The correlation analysis followed the method described at the beginning of Section 5.1. Table 1 shows the results, where *skip-gram*, *BoVW*, and *Gabor* denote the skip-gram word embeddings, visual semantic vectors, and primary visual features introduced above, respectively.

As Table 1 shows, the visual semantic vectors and primary visual features are significantly correlated with the fMRI vectors at the whole-brain level; however, the skip-gram word embeddings are not correlated with the fMRI data. To investigate the reason for this lack of correlation, we analysed the distribution of the 500 selected voxels across the four brain lobes (i.e., frontal, temporal, parietal and occipital) using the automated anatomical labeling scheme (Tzourio-Mazoyer et al., 2002). From the results shown in Table 2, we can find that most of the selected voxels are located in the occipital lobe although it is the smallest of the four main lobes in the human brain. The occipital lobe occupies most of the anatomical area of the visual cortex and is considered to be the visual processing centre of the mammalian brain. This unbalanced distribution led to the conclusion that the semantic information related to skip-gram word embeddings is not well represented by the 500 selected voxels. Thus, an alternative strategy to select stable voxels at the brain lobe level for correlation analysis was necessary.

5.1.3 Correlation analysis at the brain lobe level

As an alternative approach, rather than selecting the 500 most stable voxels from the whole-brain data as in (Mitchell et al., 2008; Anderson et al., 2013), we selected the 100 most stable voxels at each of the four main brain lobes independently for this experiment. Then, the correlations between the fMRI vectors measuring different lobes and word representations were calculated and are shown in Table 3.

From this table, we can observe the association differences of different word representations with brain lobe level activities. First, the primary visual features (*Gabor*) are highly correlated with the occipital fMRI data and are uncorrelated with the other three lobes. This is reasonable considering that the primary visual cortex (V1) is located in the occipital lobe. Second, the skip-gram word embeddings are significantly correlated with the fMRI data of all brain lobes except the occipital lobe. Previous neuroscience research has revealed that the frontal, temporal, and parietal lobes all play important roles in semantic cognition, including high-level and abstract knowledge processing (Miller et al., 2002), integration of lexical information (Hagoort, 2005), speech comprehension (Hickok and Poeppel, 2007), and knowledge retrieval (Binder et al., 2009). This indicates that the skip-gram word embeddings can partly account for the semantic processing in the cortex and contain little visual information about words. Third, the visual sematic vectors (*BoVW*) are significantly correlated with all four brain lobes. It has been found that the temporal lobe plays a key role in both the formation of long-term visual memories (Smith and Kosslyn, 2007) and in the recognition of visual stimuli and objects (Chao et al., 1999; Kanwisher and Yovel, 2006). The parietal lobe is relevant to high-level vision and is part of the dorsal visual stream correlated with spatial cognition (Sack, 2009; Vannini et al., 2004). This indicates that the visual sematic vectors used in our experiment may contain not only low-level but also high-level and semantically related visual information.

	Frontal	Temporal	Parietal	Occipital
Skip-gram	**0.1450** (0.0e+00)	**0.1483** (0.0e+00)	**0.2317** (0.0e+00)	-0.0385 (9.4e-01)
BoVW	**0.0601** (8.2e-03)	**0.2053** (0.0e+00)	**0.2750** (0.0e+00)	**0.3120** (0.0e+00)
Gabor	-0.0823 (1.0e+00)	-0.0879 (1.0e+00)	0.0111 (3.4e-01)	**0.5116** (0.0e+00)

5.2 Correlations between brain activity and behavioural data

After analysing the correlation between brain activity and the three types of word vectors in the previous experiments, we further examined the correlations between brain activity and the behavioural data introduced in Section 4.2. Here, the behavioural data were used as the semantic ground truth to evaluate the semantic relevance of the brain activity and word embeddings. The results are shown in Table 4. In this subsection, the fMRI data at the whole-brain and brain lobe levels adopted the voxel selection strategies introduced in Sections 5.1.2 and 5.1.3, respectively. As Table 4 shows, the behavioural data are significantly correlated with the fMRI data of the whole brain and the occipital lobe, and they are also correlated with the fMRI data of the temporal and parietal lobes.

Furthermore, we utilized the SWE model introduced in Section 3.2 to explore the semantic relevance of brain activity by examining the performance of the estimated word embeddings after integrating brain activity related knowledge. The inequality set used in Eq. (3) was created using the fMRI data, where the similarity score s_{ij} was calculated as the Pearson correlation coefficient between the fMRI vectors of the i-th and the j-th words. For the 60 nouns (a total of 12 categories with 5 words in each category), we produced $12 \times 3 \times C_5^3 = 360$ intra-category inequalities and $3 \times C_{12}^3 = 660$ inter-category inequalities. To collect the inter-category inequalities, we first used the label words of each category and averaged the fMRI vectors of the 5 words belonging to each category to obtain the fMRI data for these label words. Then, the inter-category inequalities were produced from the triplets of these label words. The text corpus and parameter settings we used to train SWE were the same as those used for training the skip-gram word embeddings as described in Section 5.1.1. The penalty term β in Eq. (6) was tuned through experiments.

We evaluated the word embeddings estimated with brain activity constraints using the collected behavioural data for the 60 nouns and the WordSim-353 dataset. WordSim-353 is a behavioural dataset containing semantic similarity scores for 353 word-pairs (Finkelstein et al., 2001). We checked to ensure these word-pairs have no overlap with the 60 nouns used in our experiments. The purpose of using the WordSim-353 dataset is to explore the effects of utilizing the brain data of the 60 nouns on other words for which we had no brain data.

	60 nouns	WordSim353
skip-gram	0.2232	0.6876
SWE (whole brain)	0.3814	0.6878
SWE (frontal)	0.3173	0.6822
SWE (temporal)	0.3613	0.6890
SWE (parietal)	0.3516	0.6706
SWE (occipital)	0.3348	0.6803
JNNSE	0.3006	0.1795

Table 5: Spearman's rank correlation coefficients between different word embeddings and the behavioural data of the two datasets.

The performance of the word embeddings estimated using the SWE model and the whole-brain fMRI data are shown in Figure 1. In this figure, the SWE model becomes a conventional skip-gram model when $\beta = 0$. The correlation coefficient between the skip-gram word embeddings and the behavioural data of the 60 nouns was 0.2232. As β was increased, this correlation coefficient increased significantly. The maximum correlation efficient was 0.3814 when $\beta = 2.8$. This result implies that textual data and brain activity data can be used in a complementary fashion to derive word embeddings that are more consistent with human judgements. On one hand, semantic patterns may exist in neural representations that have not been fully captured by state-of-the-art word embeddings derived from text corpora. On the other hand, we can see that the variation of the correlation coefficients for the WordSim-353 dataset with different β values is small. This indicates that our SWE training didn't negatively affect the word embeddings without fMRI observations.

Furthermore, we produced ranking inequalities using the fMRI data measuring each brain lobe to estimate word embeddings under the SWE framework. The correlations between the learned word embeddings and the behavioural data of the two datasets were calculated and are shown in Table 5. For each SWE model in this table, the value of β was tuned to obtain the highest correlation on the 60 nouns. Comparing the correlation coefficients of the different models on the 60 nouns, we can see that the fMRI data at all brain lobes can contribute to learning more semantically related word embeddings using the SWE model. The improvement from using the fMRI data of the temporal lobe is the most significant among the four lobes, but the highest correlation coefficient is achieved when utilizing the fMRI data of whole brain.

Finally, we compared the performance of our SWE models with the JNNSE model proposed by Fyshe et al. (2014) on the two datasets. The word embeddings estimated by the JNNSE model utilized either fMRI or magnetoencephalography (MEG) measures of the 60 nouns. We adopted the best JNNSE word embeddings reported by the authors[7] for these comparisons, and the results are shown in the last row of Table 5[8]. As Table 5 shows, the performance of the JNNSE word embeddings on the WordSim-353 dataset is not as good as those of the skip-gram and SWE results. Examining the correlation coefficients on the 60 nouns with brain activity data, we can see that the JNNSE model achieves better performance than the skip-gram model, but is still below that of the SWE models. It should be noted that it is unfair to directly compare the SWE models and the JNNSE model because they used different training corpora and word embedding dimensions. Moreover, the β values of the SWE models were tuned to achieve the best performance on these 60 nouns. Here, the motivation behind introducing the JNNSE model as a reference is to help readers better understand the effects of integrating brain data into SWE training. These experimental results demonstrate that the SWE model is an effective model structure for integrating external knowledge into the estimation of word embeddings.

6 Conclusion

This study utilized word embeddings to investigate the semantic representations in brain activity as measured by fMRI. First, the functional selectivity of different cortex areas is explored by calculating the correlations between neural responses and three types of word vectors: skip-gram word embeddings, visual semantic vectors, and primary visual features.

[7] http://www.cs.cmu.edu/~afyshe/papers/acl2014/

[8] Because there were 32 word-pairs in the WordSim-353 dataset that were not covered by the vocabulary of the JNNSE word embeddings, the value 0.1795 in the last row of Table 5 was calculated using only 321 word-pairs.

Experimental results demonstrate the differences between the associations of different word vectors with brain-lobe-level brain activities. The skip-gram word embeddings are significantly correlated with the fMRI data of all brain lobes except the occipital lobe. Furthermore, we utilized behavioural data as the semantic ground truth to measure its relevance to brain activity. The SWE model was employed to explore the semantic relevance of brain activity by examining the performances of word embeddings after integrating brain-activity-related knowledge into their estimations. Experimental results show that whole-brain fMRI data are significantly correlated with human judgement with respect to semantic similarity. The correlations between the estimated word embeddings and the human-assigned similarity scores are effectively improved after integrating brain activity data into SWE training.

The experiments in this paper provide information about how semantic features correlate with brain activities, laying foundations for further investigations of higher-level semantic processing in the human brain. Furthermore, our experiments with SWE modelling show the potential of applying fMRI data to obtain better word embeddings. Although this approach is still far from being a practical engineering application due to issues such as the high costs and low signal-to-noise ratio of fMRI recordings and the diversity among individuals, it provides us with an alternative method for verifying the semantic relevance of brain activities and with evidence for recognizing the limitations of estimating word embeddings using only text corpora.

Abstract

To alleviate the error propagation in the traditional pipelined models for Abstract Meaning Representation (AMR) parsing, we formulate AMR parsing as a joint task that performs the two subtasks: concept identification and relation identification simultaneously. To this end, we first develop a novel component-wise beam search algorithm for relation identification in an incremental fashion, and then incorporate the decoder into a unified framework based on multiple-beam search, which allows for the bi-directional information flow between the two subtasks in a single incremental model. Experiments on the public datasets demonstrate that our joint model significantly outperforms the previous pipelined counterparts, and also achieves better or comparable performance than other approaches to AMR parsing, without utilizing external semantic resources.

1 Introduction

Producing semantic representations of text is motivated not only by theoretical considerations but also by the hypothesis that semantics can be used to improve many natural language tasks such as question answering, textual entailment and machine translation. Banarescu et al. (2013) described a semantics bank of English sentences paired with their logical meanings, written in Abstract Meaning Representation (AMR), which is rapidly emerging as an important practical form of structured sentence semantics. Recently, some literatures reported some promising applications of AMR. Pan et al. (2015) presented an unsupervised entity linking system with AMR, achieving the performance comparable to the supervised state-of-the-art. Liu et al. (2015) demonstrated a novel abstractive summarization framework driven by the AMR graph that shows promising results. Garg et al. (2016) showed that AMR can significantly improve the accuracy of a biomolecular interaction extraction system compared to only using surface- and syntax-based features. Mitra and Baral (2016) presented a question-answering system by exploiting the AMR representation, obtaining good performance.

Automatic AMR parsing is still in a nascent stage. Flanigan et al. (2014) built the first AMR parser, JAMR, based on a pipelined approach, which breaks down the whole task into two separate subtasks: concept identification and relation identification. Considering that node generation is an important limiting factor in AMR parsing, Werling et al. (2015) proposed an improved approach to the concept identification subtask by using a simple classifier over actions which generate these subgraphs. However, the overall architecture is still based on the pipelined model.

As a common drawback of the staged architecture, errors in upstream component are often compounded and propagated to the downstream prediction. The downstream components, however, cannot impact earlier decision. For example, for the verb "affect" in the example shown in Figure 1, there exist two possible concepts: "affect-01" and "affect-02". Comparatively, the first concept has more common use cases than the second one. But, when the verb "affect" is followed by the noun "ac-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 680–689,
Austin, Texas, November 1-5, 2016.

cent", it should evoke the concept "affect-02". Obviously, the correct concept choice for the verb "affect" should exploit a larger context, and even the whole semantic structure of the sentence, which is more probable to be unfolded at the downstream relation identification stage. This example indicates that it is necessary to allow for the interaction of information between the two stages.

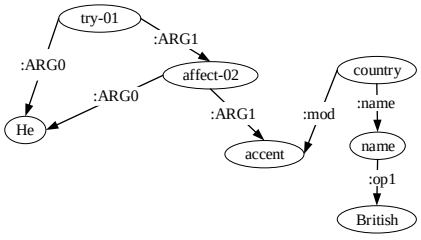

Figure 1: The AMR graph for the sentence "He tries to affect a British accent."

To address this problem, in this paper we reformulate this task as a joint parsing problem by exploiting an incremental parsing model. The underlying learning algorithm has shown the effectiveness on some other Natural Language Processing (NLP) tasks, such as dependency parsing and extraction of entity mentions and relations (Collins and Roark, 2004; Hatori et al., 2012; Li and Ji, 2014). However, compared to these NLP tasks, the AMR parsing is more challenging in that the AMR graph is more complicated. In addition, the nodes in the graph are latent.

One main challenge to search for concept fragments and relations incrementally is how to combine the two subtasks in a unified framework. To this end, we first develop a novel Component-Wise Beam Search (CWBS) algorithm for incremental relation identification to examine the accuracy loss in a fully incremental fashion compared to the global fashion in which a sequence of concept fragments derived from the whole sentence are required as input, as the MSCG algorithm in JAMR. Secondly, we adopt a segment-based decoder similar to the multiple-beam algorithm (Zhang and Clark, 2008b) for concept identification, and then incorporate the CWBS algorithm for relation identification into this framework, combining the two subtasks in a single incremental model. For parameter estimation, "violation-fixing" perceptron is adopted since it is designed specifically for inexact search in structured learning (Huang et al., 2012).

Experimental results show that the proposed joint framework significantly outperforms the pipelined counterparts, and also achieves better or comparable performance than other AMR parsers, even without employing external semantic resources.

2 Background

2.1 AMR Parsing Task

Nodes of an AMR graph are labeled with concepts, and edges are labeled with relations. Concepts can be English words ("He"), PropBank event predicates ("try-01", "affect-02"), or special keywords ("British"). For example, "affect-02" represents a PropBank roleset that corresponds to the first sense of "affect". According to (Banarescu et al., 2013), AMR uses approximately 100 relations. The rolesets and core semantic relations (e.g., ARG0 to ARG5) are adopted from the PropBank annotations in OntoNotes. Other semantic relations include "mode", "name", "time", "topic" and so on. The AMR guidelines provide more detailed descriptions.

2.2 The Pipelined Models for AMR Parsing

The AMR parser JAMR is a two-stage algorithm that first identifies concepts and then identifies the relations that obtain between these.

The concept identification stage maps spans of words in the input sentence to a sequence of concept graph fragments. Note that these graph fragments, in some cases, are subgraphs with multiple nodes and edges, not just one labeled concept node. The relation identification stage adds edges among the concept subgraph fragments identified in the first stage. JAMR requires the output subgraph $G =< V_G, E_G >$ should respect the following constraints:

(1) Simple: For any two vertices u and $v \in V_G$, E_G includes at most one edge between u and v.

(2) Connected: G must be weakly connected (every vertex reachable from every other vertex, ignoring the direction of edges).

(3) Deterministic: For each node $u \in V_G$, and for each label $l \in \{\text{ARG0}, \ldots, \text{ARG5}\}$, there is at

most one outgoing edge in E_G from u with label l.

To find a maximum spanning AMR graph, JAMR proposed a two-step approach[1] . First, a graph that ignores constraint (3) but respects the others was created, by searching for the maximum spanning connected subgraph from an edge-labeled, directed graph representing all possible relations between the identified concepts; Second, a Lagrangian relaxation was adopted to iteratively adjust the edge scores so as to enforce constraint (3).

In order to train the parser, JAMR built an automatic aligner that uses a set of rules to greedily align concepts to spans of words in the training data to generate an alignment table.

3 Algorithms

Based on the hypothesis that concept identification and relation identification are interrelated, we propose to jointly perform the two subtasks in a single model. To this end, we present an incremental model for AMR parsing. Evidence from psycholinguistic research also suggests that human language comprehension is incremental. Comprehenders do not wait until the end of the sentence before they build a syntactic or semantic representation for the sentence.

However, the challenges of successfully applying the incremental joint model to this problem formulation are: 1) how can we design an effective decoding algorithm for identifying the relations between the nodes in an incremental fashion, given a partial sequence of spans, i.e., a partial sequence of gold-standard concept fragments; 2) further, if given a sentence, how can we design an incremental framework to perform concept identification and relation identification simultaneously. In the following subsections we introduce our solutions to these challenges in detail.

3.1 An Incremental Decoding Algorithm for Relation Identification

We define the relation identification problem as finding the highest scoring graph y from all possible outputs given a sequence of concept fragments c:

$$F(c) = \arg\max_{Gen(c)} Score(y) \quad (1)$$

where $Gen(c)$ denotes the set of possible AMR graph for the input c. The score of an output parse y is defined to be decomposed by edges, and with a linear model:

$$Score(y) = \sum_{e \in E_y} w^T \cdot \varphi(e) \quad (2)$$

where $\varphi(e)$ is the feature vector over the edge e, and w is weight vector of the model.

The AMR graph is a directed graph that respects three constraints (see section 2.2) and has a node marked as the focus node. Obviously, finding such a maximum spanning graph in AMR parsing in fact carries more complexities than that of maximum spanning tree (MST) decoding for syntactic parsing. Especially, performing the task incrementally is substantially harder than doing it non-incrementally. In both cases, parsing is in general intractable and we provide an approximate inference algorithm to make these cases tractable.

Inspired by the graph-based dependency parser under the framework of beam-search, which yields a competitive performance compared to the exact-search-based counterpart (Zhang and Clark, 2008a), we develop a CWBS algorithm for the relation identification task.

Basically, the decoder works incrementally, building a state item (i.e. a partial AMR graph) fragment by fragment. When each concept fragment is processed, edges are added between the current concept fragment and its predecessors. However, how to treat its predecessors is a difficult problem. In our experiments, we found that if we consider every preceding concept fragment to the left of the current fragment in a right-to-left order in the search process, the decoder suffers from low efficiency and poor performance. Unlike the beam-search for dependency parsing, which can greatly reduce the search space by exploiting the projectivity property of the dependency tree (Covington, 2001; Zhang and Clark, 2008a), this naive search process in this context inevitably leads to huge search space, and furthermore is difficult to guarantee the connectivity of

[1] In this paper, we refer to this two-step approach for relation identification as MSCG algorithm.

output graph. Instead, we propose a component-wise beam search scheme, which can not only alleviate much noisy partial candidate, but also ensure that the final output graph is *connected*.

Algorithm 1 shows the pseudocode for the complete procedure of the decoder. In a nutshell, the algorithm builds the AMR graph in one left-to-right pass over the sequence of concept fragments. Beam search is applied by keeping the B-best[2] items in the agenda at each processing stage, according to the scores of partial graph up to the current concept fragment. Lets take an illustrative diagram to demonstrate the procedure (see Figure 2). When appending the current concept fragment to the left partial graph to extend it, we just need to consider the relations between current concept and each preceding connected component. However, even at this single step, picking B-best extended partial graphs is still a difficult task due to the large combination space. Here, we adopt an effective *nested beam search strategy* at this step. In other words, edges are added between the current concept fragment and its preceding connected components by iterating through these components in a right-to-left order[3] using an *inner beam-search*. When examining the edges between the current concept fragment and some preceding component, four elementary actions are used:

(1) **SHIFT** (lines 12-14): Add only current concept to the partial graph.

(2) **LEFT-ARC** (lines 16-19): Add current concept and a highest-scoring edge from a node in the current concept to a node in some preceding connected component to the partial graph.

(3) **RIGHT-ARC** (lines 21-24): Add current concept and a highest-scoring edge from a node in some preceding connected component to a node in current concept to the partial graph.

(4) **LEFT & RIGHT-ARCS** (lines 26-27): Add current concept and highest-scoring left arc and right arc to the partial graph.

The first three actions are similar in form to those in the Arc-Standard algorithm for transition-based dependency parsing (Nivre, 2008; Zhang and Clark, 2008a). The last one is defined to cope with the cases where there may be multiple parents for some nodes in an AMR graph. Note that the "SHIFT" action does not add any edges. This operation is particularly necessary because the partial graphs are not always connected during the search process. In our experiments, we also found that the number of connected components during search process is relatively small, which is generally less than 6. It is important to note that, in order to guarantee the output graph *connected*, when the last concept fragment is encountered, the "SHIFT" action is skipped (see line 10 in Algorithm 1), and the other three 'arc' actions will add edges to connect the last concept fragment with all preceding connected components to yield a connected graph.

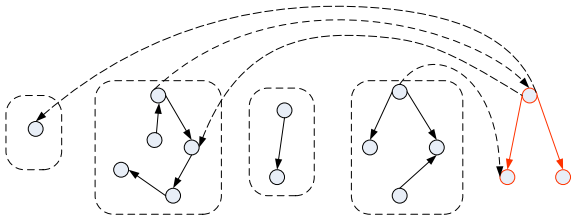

Figure 2: An illustrative diagram for CWBS algorithm. Each dotted box corresponds to a connected component in the partial graph, each of which consists one or multiple concept fragments. The rightmost subgraph corresponds to the current concept fragment.

For purpose of brevity, we introduce some functional symbols in Algorithm 1. Function CalEdgeScores($state, c_i$) calculates the scores of all candidate edges between the nodes in current concept fragment c_i and the nodes in the partial graph in state covering $(c_1, c_2, \ldots, c_{i-1})$. For computing the scores of edges, we use the same features as JAMR (refer to Flanigan et al. (2014) for more details). Function FindComponents($state$) returns all connected components $(p_1, p_2, \ldots, p_m)$ in the partial graph in $state$, sorted by the maximum end position of spans including in every component. The AddItem function adds the current concept fragment and left/right arc to the partial graph. Function AppendItem($buf, item$) inserts the partial graph $item$ into buf by its score. Functions GetMaxLeftEdge(c_i, p_j) and

[2]The constant B denotes the beam size.

[3]The right-to-left order reflects the principle of local priority.

Algorithm 1 The incremental decoding algorithm for relation identification.

Input: A sequence of concept fragments $(c_1, c_2, \ldots, c_n)$
Output: Best AMR graph including $(c_1, c_2, \ldots, c_n)$

$agenda \leftarrow$ {Empty-graph}
for $i \leftarrow 1 \ldots n$ **do**
  for $state$ in $agenda$ **do**
    CalEdgeScores($state$, c_i)
    $(p_1, p_2, \ldots, p_m) \leftarrow$ FindComponents($state$)
    $innerAgenda \leftarrow state$
    for $j \leftarrow m \ldots 1$ **do**
      $buf \leftarrow NULL$
      for $item$ in $innerAgenda$ **do**
        if $i < n$ **then**
          //Add only c_i to the item
          $newitem \leftarrow item$
          AddItem($newitem, c_i$)
          AppendAgenda($buf, newitem, i, n$)
        // Add a left arc from c_i to p_j to the $item$
        $newitem \leftarrow item$
        $le \leftarrow$ GetMaxLeftEdge(c_i, p_j)
        AddItem($newitem, c_i, le$)
        AppendAgenda($buf, newitem, i, n$)
        //Add a right arc from p_j to c_i the $item$
        $newitem \leftarrow item$
        $re \leftarrow$ GetMaxRightEdge(p_j, c_i)
        AddItem($newitem, c_i, le$)
        AppendAgenda($buf, newitem, i, n$)
        //Add both left and right arc to the $item$
        AddItem($item, c_i, le, re$)
        AppendAgenda($buf, item, i, n$)
      $innerAgenda \leftarrow B$-best(buf)
  $agenda \leftarrow innerAgenda$
return $agenda$[0]
function AppendAgenda($buf, item, i, n$)
  //parameter n represents the terminal position
  if $i = n$ **then**
    CalRootFeatures($item$)
  AppendItem($buf, item$)

GetMaxRightEdge(p_j, c_i) pick the highest-scoring left-arc and right-arc linking current fragment c_i and the connected component p_j by the scores returned from the CalEdgeScores function, respectively.

Finally, the function CalRootFeatures(g) first computes the scores for all nodes in the output graph g by treating them as the candidate root respectively, and then pick the node with the highest score as the focus node of the graph. When computing the score for each candidate node, similar to JAMR, two types of features were used: the concept of the node, and the shortest dependency path from a word in the span to the root of the dependency tree.

The time complexity of the above algorithm is $O(MB^2n)$, where M is the maximum number of connected components during search, B is beam size and n is the number of concept fragments. It is linear in the length of sequence of concept fragments. However, the constant in the O is relatively large. In practice, the search space contains a large number of invalid partial candidates. Therefore, we introduce three partial output pruning schemes which are helpful in reducing search space as well as making the input for parameter update less noisy.

Firstly, we limit the number of children and parents of every node. By observing the training data, we set the maximum numbers of children and parents of every node as 7 and 4, respectively. Secondly, due to the fact that all frame arguments ARG0-ARG5 are derived from the verb framesets, the edges with label $l \in \{ARG0, \ldots, ARG5\}$ that do not outgo from a verb node will be skipped.

Finally, consider the determinism constraint (as illustrated in section 2.2) that should be satisfied by an AMR representation. When one edge has the same label $l \in \{ARG0, \ldots, ARG5\}$ as one of edges outgoing from the same parent node, this edge will also be skipped. Obviously, this type of pruning can enforce the *determinism* constraint for every decoding output.

3.2 Joint Decoding for Concept Identifica-tion and Relation Identification

In this section, we further consider the joint decoding problem for a given sentence x, which maps the sentence x to an output AMR graph y. The objective function for the joint decoding is as follows:

$$\hat{y} = \arg\max_{y' \in Gen(x)} (w^T \cdot \phi(x, y') + w^T \cdot \mathbf{f}(y')) \quad (3)$$

where the first term is to calculate the score over all concept fragments derived from the words in the sentence x, and the second one is to calculate the score over all edges linking the concept fragments. Maximizing Equation (3) amounts to concurrently maximizing the score over the concept fragments and the score over the edges. Admittedly, the joint decoding problem is more intricate and in general

intractable. Therefore, we use a beam-search-based incremental decoder for approximate joint inference during training and testing.

In order to combine the two subtasks in a unified framework, we first relax the exact-search for concept identification in JAMR by beam search, resulting in a segment-based decoder similar to the multiple-beam algorithm in (Zhang and Clark, 2008b; Li and Ji, 2014), and then incorporate the CWBS algorithm for relation identification (as depicted in section 3.1) into this framework, which provides a natural formulation for combining the two subtasks in a single incremental model.

Algorithm 2 shows the joint decoding algorithm. In short, during performing joint decoding incrementally for the input sentence, for each word index i in the input sentence, it maintains a beam for the partial graphs whose last segments end at the i-th word, which is denoted as $agendas[i]$ in the algorithm. When the i-th word is processed, it either triggers concepts starting from this word by looking up the alignment table generated from the training data, or evokes no concept (we refer to this type of words as *function words*). If the current word triggers multiple concepts, we first append each candidate concept to the partial graphs in the beam $agendas[i-1]$, by using a component-wise beam search way (see section 3.1), and then pick B-best extended partial graphs by exploiting the features from *both the concept level* and *relation level* to compute the overall scores.

In particular, judging whether a word is a *function word* is an important and difficult task. For example, the word "*make*" corresponds to multiple candidate concepts in the alignment table, such as "*make-01*" and "*make-02*". However, it can also act as a functional word in some cases. To resolve the judgement problem, we view each word as a *function word* and a *non-function word* at the same time to allow them to compete against each other by their scores. For instance, for the i-th word, this is done by combining all partial graphs in the beam $agendas[i-1]$ with those in the beam $agendas[i]$ to select B-best items and then record them in $agendas[i]$, which is represented as the Union function in Algorithm 2.

After all words are processed, the highest-scoring graph in the beam corresponding to the terminal position of the sentence is selected as the output.

Algorithm 2 The joint decoding algorithm.

Input: Input sentence $x = (w_1, w_2, \ldots, w_n)$
Output: Best AMR graph derived from x

```
agendas[0] ← ∅
last ← Scan(x)
for i ← 1 ... n do
    list ← Lookup(x, i)
    if list.size > 0 then
        preAgenda ← agendas[i − 1]
        for cf ∈ list do
            end ← i + cf.size − 1
            if preAgenda.size = 0 then
                g ← Graph.empty
                CalConceptFeatures(g, cf)
                AppConcept(agendas, end, g, cf, last)
            else
                for item ∈ preAgenda do
                    g ← item
                    CalConceptFeatures(g, cf)
                    AppConcept(agendas, end, g, cf, last)
        Union(agendas, i, i − 1)
    else
        agendas[i] ← agendas[i − 1]
bestGraph ← agendas[last][0]
return bestGraph
```

In algorithm 2, function Scan(x) is used to search the terminal position corresponding to the last concept fragment in the sentence x, which will be passed as a parameter to the function AppConcept. The Scan function can be efficiently implemented by calling the function Lookup in a right-to-left order. Function Lookup(x, i) maps a sequence of words starting from the index i in sentence x to a set of candidate concept fragments, by looking up the alignment table that was generated from the training data. The alignments are accomplished using an aligner from JAMR. Motivated by Werling et al. (2015), we also adopt two additional actions to generate the candidate concept fragments: LEMMA and VERB. The action LEMMA is executed by using the lemma of the source token as the generated node title, and the action VERB is to find the most similar verb in PropBank based on Jaro-Winkler distance, and adopt its most frequent sense.

Function CalConceptFeatures(g, cf) calculates the feature vector for the candidate concept fragment cf and the partial graph g, using the features

defined in Table 1. Among them, features 1-4 are from JAMR. Additional features 5-16 aim to capture the association between the current concept and the context in which it appears. Function AppConcept($agendas, end, g, cf, last$) appends the current concept cf to the partial graph g, and then inserts the extended partial graph into $agendas[end]$. Note that when the parameter end equals to the parameter $last$, this function will call the function CalRootFeatures to select the focus node, as illustrated in Algorithm 1.

	Name	Description
1	Fragment given words	Relative frequency estimates of the probability of a concept fragment given the span of words.
2	Span length	The length of the span.
3	NER	1 if the span corresponds to a named entity, 0 otherwise.
4	Bias	1 for any concept fragment from the alignment table, 0 otherwise.
5	c	c represents the current concept label, w represents the current words, lem represents the current lemmas, pos represents the current POS tags. w_{-1} denotes the first word to the left of current word, w_{+1} denotes the first word to the right of current word, and so on.
6	$c + w$	
7	$c + lem$	
8	$c + pos$	
9	$c + w_{-1}$	
10	$c + w_{+1}$	
11	$c + pos_{-1}$	
12	$c + pos_{+1}$	
13	$c + w_{-2}$	
14	$c + w_{+2}$	
15	$c + pos_{-2}$	
16	$c + pos_{+2}$	

Table 1: Features associated with the concept fragments.

3.3 Violation-Fixing Perceptron for Training

Online learning is an attractive method for the structured learning since it quickly converges within a few iterations (Collins, 2002). Particularly, Huang et al. (2012) establish a theoretical framework called "violation-fixing perceptron" which is tailored for structured learning with inexact search and has provable convergence properties. Since our incremental decoding for AMR parsing is an approximate inference, it is very natural to employ violation-fixing perceptron here for AMR parsing training.

Specifically, we use an improved update method "max-violation" which updates at the worst mistake, and converges much faster than early update with similar or better accuracy. We adopt this idea here as follows: decode the whole sentence, and find the word index i^* where the difference between the candidate partial graph and gold-standard one is the biggest. Only part of the graph ending at the word index i^* is used to calculate the weight update, in order to account for search errors.

To reduce overfitting, we used averaged parameters after training to decode test instances in our experiments. The resulting model is called averaged perceptron (Collins, 2002).

Additionally, in our training algorithms, the implementation of the oracle function is rela-tively straightforward. Specifically, when the i-th span is processed in the incremental parsing process, the partial gold-standard AMR graph up to the i-th span consists of the edges and nodes that appear before the end position of the i-th span, over which the gold-standard feature vectors are calculated.

4 Experiments

4.1 Dataset and Evaluation Metric

Following previous studies on AMR parsing, our experiments were performed on the newswire sections of LDC2013E117 and LDC2014T12, and we also follow the official split for training, development and evaluation. Finally, we also show our parsers performance on the full LDC2014T12 dataset. We evaluate the performance of our parser using Smatch v2.0 (Cai and Knight, 2013), which counts the precision, recall and F1 of the concepts and relations together.

4.2 Development Results

Generally, larger beam size will increase the computational cost while smaller beam size may reduce the performance. As a tradeoff, we set the beam size as 4 throughout our experiments. Figure 3 shows the training curves of the averaged violation-fixing perceptron with respect to the performance on the both development sets. As we can see the curves converge very quickly, at around iteration 3.

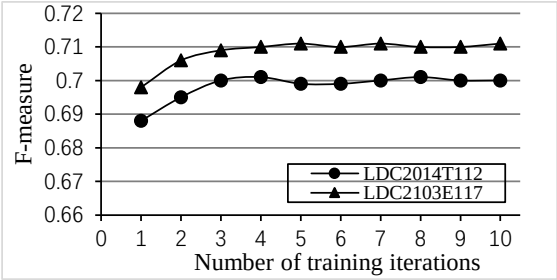

Figure 3: Learning curves on development sets.

Dataset	System	P	R	F1
LDC2013E117	MSCG	.85	.77	.81
	CWBS	.85	.78	.81
LDC2014T12	MSCG	.84	.77	.80
	CWBS	.84	.77	.80

Table 2: Results of two different relation identification algorithms.

4.3 Incremental Relation Identification Performance

Before performing joint decoding, we should first verify the effectiveness of our incremental algorithm CWBS. The first question about CWBS is whether the component-wise search is a valid scheme for deriving the gold-standard AMR graph given the sequence of gold-standard concepts. Therefore, we first implement an oracle function by performing the incremental component-wise search for each fragment sequence c to get a "pseudo-gold" graph $G_c^{'}$; Then we compare with gold-standard AMR graph G_c . On the training data of LDC2013E117 and LDC2014T12, we respectively got an overall 99.6% and 99.7% F-scores for all $< G_c^{'}, G_c >$ pairs, which indicates that our component-wise search is an effective incremental search scheme.

Further, we train a perceptron model using the max-violation update to approximate the oracle search procedure. As shown in Table 2, our incremental algorithm CWBS achieves almost the same performance as the non-incremental algorithm MSCG in JAMR, using the same features as MSCG. The results indicate that CWBS is a competitive alternative to MSCG.

4.4 Joint Model vs. Pipelined Model

In this section, we compare the overall performance of our joint model to the pipelined model, JAMR[4]. To give a fair comparison, we first implemented ***system 1*** only using the same features (i.e., features 1-4 in Table 1) as JAMR for concept fragments. Table 3 gives the results on the two datasets. In terms of F-measure, we gain a 6% absolute improvement, and a 5% absolute improvement over the results of JAMR on the two different experimental setups respectively.

Next, we implemented ***system 2*** by using more lexical features to capture the association between concept and the context (i.e., features 5-16 in Table 1). Intuitively, these lexical contextual features should be helpful in identifying concepts in parsing process. As expected, the results in Table 3 show that we gain 3% improvement over the two different datasets respectively, by adding only some additional lexical features.

Dataset	System	P	R	F1
LDC2013E117	JAMR(fixed)	.67	.58	.62
	System 1	.72	.65	.68
	System 2	.73	.69	.71
LDC2014T12	JAMR(fixed)	.68	.59	.63
	System 1	.74	.63	.68
	System 2	.73	.68	.71

Table 3: Comparison between our joint approaches and the pipelined counterparts.

Dataset	System	P	R	F1
LDC2013E117	CAMR*	.69	.67	.68
	CAMR	.71	.69	.70
	Our approach	**.73**	**.69**	**.71**
LDC2014T12	CAMR*	.70	.66	.68
	CAMR	.72	.67	.70
	CCG-based	.67	.66	.66
	Our approach	**.73**	**.68**	**.71**

Table 4: Final results of various methods.

4.5 Comparison with State-of-the-art

We give a comparison between our approach and other state-of-the-art AMR parsers, including CCG-based parser (Artzi et al., 2015) and dependency-based parser (Wang et al., 2015b). For comparison

[4]We use the latest, fixed version of JAMR, available at `https://tiny.cc/jamr`.

purposes, we give two results from two different versions of dependency-based AMR parser[5]: CAMR* and CAMR. Compared to the latter, the former denotes the system that does not use the extended features generated from the semantic role labeling system, word sense disambiguation system and so on, which is directly comparable to our system.

From Table 4 we can see that our parser achieves better performance than other approaches, even without utilizing any external semantic resources.

We also evaluate our parser on the full LDC2014T12 dataset. We use the training/development/test split recommended in the release: 10,312 sentences for training, 1,368 sentences for development and 1,371 sentences for testing. For comparison, we include the results of JAMR, CAMR*, CAMR and SMBT-based parser (Pust et al., 2015), which are also trained on the same dataset. The results in Table 5 show that our approach outperforms CAMR*, and obtains comparable performance with CAMR. However, our approach achieves slightly lower performance, compared to the SMBT-based parser, which adds data and features drawn from various external semantic resources.

Dataset	System	P	R	F1
LDC2014T12	JAMR(fixed)	.64	.53	.58
	CAMR*	.68	.60	.64
	CAMR	.70	.62	.66
	SMBT-based	-	-	**.67**
	Our approach	.70	.62	.66

Table 5: Final results on the full LDC2014T12 dataset.

5 Related Work

Our work is motivated by JAMR (Flanigan et al., 2014), which is based on a pipelined model, resulting in a large drop in overall performance when moving from gold concepts to system concepts.

Wang et al. (2015a) uses a two-stage approach; dependency parses are modified by executing a sequence of actions to resolve dis-crepancies between dependency tree and AMR structure. Goodman et al. (2016) improves the transition-based parser with the imitation learning algorithms, achieving almost the same performance as that of Wang et al. (2015b), which exploits the extended features from additional trained analysers, including co-reference and semantic role labelers. Artzi et al. (2015) introduces a new CCG grammar induction algorithm for AMR parsing, combined with a factor graph to model non-compositional phenomena. Pust et al. (2015) adapts the SBMT parsing framework to AMR parsing by designing an AMR transformation, and adding external semantic resources. More recently, Damonte et al. (2016) also presents an incremental AMR parser based on a simple transition system for dependency parsing. However, compared to our parser, their parser cannot parse non-projective graphs, resulting in a limited coverage.

Our work is also inspired by a new computational task of incremental semantic role labeling, in which semantic roles are assigned to incomplete input (Konstas et al., 2014).

6 Conclusions and Future Work

In this paper, we present a new approach to AMR parsing by using an incremental model for performing the concept identification and relation identification jointly, which alleviates the error propagation in the pipelined model.

In future work, we plan to improve the parsing performance by exploring more features from the coreference resolution, word sense disambiguation system and other external semantic resources. In addition, we are interested in further incorporating the incremental semantic role labeling into our incremental framework to allow bi-directional information flow between the two closely related tasks.

Identifying Dogmatism in Social Media: Signals and Models

Ethan Fast and **Eric Horvitz**
ethaen@stanford.edu, horvitz@microsoft.com

Abstract

We explore linguistic and behavioral features of dogmatism in social media and construct statistical models that can identify dogmatic comments. Our model is based on a corpus of Reddit posts, collected across a diverse set of conversational topics and annotated via paid crowdsourcing. We operationalize key aspects of dogmatism described by existing psychology theories (such as over-confidence), finding they have predictive power. We also find evidence for new signals of dogmatism, such as the tendency of dogmatic posts to refrain from signaling cognitive processes. When we use our predictive model to analyze millions of other Reddit posts, we find evidence that suggests dogmatism is a deeper personality trait, present for dogmatic users across many different domains, and that users who engage on dogmatic comments tend to show increases in dogmatic posts themselves.

1 Introduction

> "I'm supposed to trust the opinion of a MS minion? The people that produced Windows ME, Vista and 8? They don't even understand people, yet they think they can predict the behavior of new, self-guiding AI?" *–anonymous*
>
> "I think an AI would make it easier for Patients to confide their information because by nature, a robot cannot judge them. Win-win? :D"' *–anonymous*

Dogmatism describes the tendency to lay down opinions as incontrovertibly true, without respect for conflicting evidence or the opinions of others (Oxford Dictionary, 2016). Which user is more dogmatic in the examples above? This question is simple for humans. Phrases like "they think" and "they don't even understand," suggest an intractability of opinion, while "I think" and "win-win?" suggest the opposite. Can we train computers to draw similar distinctions? Work in psychology has called out many aspects of dogmatism that can be modeled computationally via natural language, such as over-confidence and strong emotions (Rokeach, 1954).

We present a statistical model of dogmatism that addresses two complementary goals. First, we validate psychological theories by examining the predictive power of feature sets that guide the model's predictions. For example, do linguistic signals of certainty help to predict a post is dogmatic, as theory would suggest? Second, we apply our model to answer four questions:

R1: What kinds of topics (e.g., guns, LGBT) attract the highest levels of dogmatism?

R2: How do dogmatic beliefs cluster?

R3: How does dogmatism influence a conversation on social media?

R4: How do other user behaviors (e.g., frequency and breadth of posts) relate to dogmatism?

We train a predictive model to classify dogmatic posts from Reddit, one of the most popular discussion communities on the web.[1] Posts on Reddit capture discussion and debate across a diverse set of domains and topics – users talk about everything from climate change and abortion, to world news and relationship advice, to the future of artificial intelligence. As a prerequisite to training our model, we have created a corpus of 5,000 Reddit posts annotated with levels of dogmatism, which we are releasing to share with other researchers.

[1] http://www.reddit.com

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 690–699,
Austin, Texas, November 1-5, 2016.

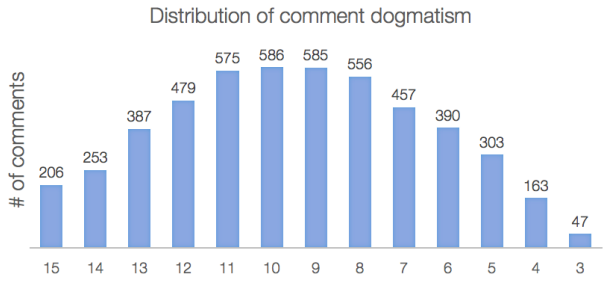

Figure 1: We crowdsourced dogmatism labels for 5000 comments. The distribution is slightly skewed towards higher levels of dogmatism. For example, crowdworkers unanimously labeled 206 comments as highly dogmatic ($5 \times 3 = 15$), but only 47 as minimally dogmatic ($1 \times 3 = 3$).

Using the model, we operationalize key domain-independent aspects of psychological theories of dogmatism drawn from the literature. We find these features have predictive power that largely supports the underlying theory. For example, posts that use less confident language tend to be less dogmatic. We also discover evidence for new attributes of dogmatism. For example, dogmatic posts tend not to verbalize cognition, through terms such as "I think," "possibly," or "might be."

Our model is trained on only 5,000 annotated posts, but once trained, we use it to analyze millions of other Reddit posts to answer our research questions. We find a diverse set of topics are colored by dogmatic language (e.g., people are dogmatic about religion, but also about LGBT issues). Further, we find some evidence for dogmatism as a deeper personality trait – people who are strongly dogmatic about one topic are more likely to express dogmatic views about others as well. Finally, in conversation, we discover that one user's dogmatism tends to bring out dogmatism in their conversational partner, forming a vicious cycle.

2 Dogmatism data

Posts on Reddit capture debate and discussion across a diverse set of topics, making them a natural starting point for untangling domain-independent linguistic features of dogmatism.

Data collection. Subreddits are sub-communities on Reddit oriented around specific interests or topics, such as *technology* or *politics*. Sampling from Reddit as a whole would bias the model towards the most commonly discussed content. But by sampling posts from individual subreddits, we can control the kinds of posts we use to train our model. To collect a diverse training dataset, we have randomly sampled 1000 posts each from the subreddits *politics*, *business*, *science*, and *AskReddit*, and 1000 additional posts from the Reddit frontpage. All posts in our sample appeared between January 2007 and March 2015, and to control for length effects, contain between 300 and 400 characters. This results in a total training dataset of 5000 posts.

Dogmatism annotations. Building a useful computational model requires labeled training data. We labeled the Reddit dataset using crowdworkers on Amazon Mechanical Turk (AMT), creating the first public corpus annotated with levels of dogmatism. We asked crowdworkers to rate levels of dogmatism on a 5-point Likert scale, as supported by similar annotation tasks in prior work (Danescu-Niculescu-Mizil et al., 2013). Concretely, we gave crowdworkers the following task:

> Given a comment, imagine you hold a well-informed, different opinion from the commenter in question. We'd like you to tell us how likely that commenter would be to engage you in a constructive conversation about your disagreement, where you each are able to explore the other's beliefs. The options are:
>
> **(5)**: It's unlikely you'll be able to engage in any substantive conversation. When you respectfully express your disagreement, they are likely to ignore you or insult you or otherwise lower the level of discourse.
>
> **(4)**: They are deeply rooted in their opinion, but you are able to exchange your views without the conversation degenerating too much.
>
> **(3)**: It's not likely you'll be able to change their mind, but you're easily able to talk and understand each other's point of view.
>
> **(2)**: They may have a clear opinion about the subject, but would likely be open to discussing alternative viewpoints.
>
> **(1)**: They are not set in their opinion, and it's possible you might change their mind. If the comment does not convey an opinion of any kind, you may also select this option.

To ensure quality work, we restricted the task to Masters workers and provided examples corresponding to each point on the scale. Including examples in a task has been shown to significantly increase the agreement and quality of crowdwork

(Doroudi et al., 2016). For instance, here is an example of a highly dogmatic *(5)* comment:

> I won't be happy until I see the executive suite of BofA, Wells, and all the others, frog-marched into waiting squad cars. It's ALREADY BEEN ESTABLISHED that...

And a minimally dogmatic *(1)* comment:

> I agree. I would like to compile a playlist for us trance yogi's, even if you just would like to experiment with it. Is there any preference on which platform to use?

Each comment has been annotated by three independent workers on AMT, which is enough to produce reliable results in most labeling tasks (Sheng et al., 2008). To compute an aggregate measure of dogmatism for each comment, we summed the scores of all three workers. We show the resulting distribution of annotations in Figure 1.

Inter-annotator agreement. To evaluate the reliability of annotations we compute Krippendorff's α, a measure of agreement designed for variable levels of measurement such as a Likert scale (Hayes and Krippendorff, 2007). An α of 0 indicates agreement indistinguishable from chance, while an α of 1 indicates perfect agreement. Across all annotations we find $\alpha = 0.44$. While workers agree much more than chance, clearly dogmatism is also subjective. In fact, when we examine only the middle two quartiles of the dogmatism annotations, we find agreement is no better than chance. Alternatively, when we measure agreement only among the top and bottom quartiles of annotations, we find agreement of $\alpha = 0.69$. This suggests comments with scores that are only slightly dogmatic are unreliable and often subject to human disagreement. For this reason, we use only the top and bottom quartiles of comments when training our model.

3 Approaches to Identifying Dogmatism

We now consider strategies for identifying dogmatism based on prior work in psychology. We start with the Linguistic Inquiry and Word Count (LIWC), a lexicon popular in the social sciences (Pennebaker et al., 2001). LIWC provides human validated lists of words that correspond to high-level psychological categories such as *certainty* or *perception*. In other studies, LIWC has uncovered linguistic signals relating to politeness (Danescu-Niculescu-Mizil et al., 2013), deception (Yoo and Gretzel, 2009), or authority in texts (Gilbert, 2012). Here, we examine how dogmatism relates to 17 of LIWC's categories (Table 1).

To compute the relationships between LIWC categories and dogmatism, we first count the relevant category terms that appear in each annotated Reddit comment, normalized by its word count. We then calculate odds ratios on the aggregate counts of each LIWC category over the top and bottom quartiles of dogmatic comments. As we have discussed, using the top and bottom quartiles of comments provides a more reliable signal of dogmatism. We check for significant differences in categories between dogmatic and non-dogmatic comments using the Mann-Whitney U test and apply Holmes method for correction. All odds we report in this section are significant after correction.

Dogmatic statements tend to express a high degree of certainty (Rokeach, 1954). Here we consider LIWC categories that express certainty both positively (*certainty*) and negatively (*tentativeness*). For example, the word "always" is certain, while "possibly" is tentative. Conforming to existing theory, *certainty* is more associated with dogmatic comments (1.52 odds), while *tentativeness* is more associated with the absence of dogmatism (0.88 odds).

Terms used to verbalize cognition can act as a hedge that often characterizes non-dogmatic language. LIWC's *insight* category captures this effect through words such as "think," "know," or "believe." These words add nuance to a statement (Pennebaker and Francis, 1996), signaling it is the product of someone's mind ("*I think* you should give this paper a good review") and not meant to be interpreted as an objective truth. Along these lines, we find the use of terms in the *insight* category is associated with non-dogmatic comments (0.83 odds).

Sensory language, with its focus on description and detail, often signals a lack of any kind of opinion, dogmatic or otherwise. LIWC's *perception* category captures this idea through words associated with hearing, feeling, or seeing. For example, these words might occur when recounting a personal experience ("I saw his incoming fist"), which even if emotionally charged or negative, is less likely to be dogmatic. We find perception is associated with

Strategy	Odds	Example
Certainty	1.33*	Be a hate monger **all** you want... Your life will **never** truly be happy though, and you will **never** know peace.
Tentativeness	0.88*	Most are **likely** to be more technically advanced and, **if** still using radio, **might** very well be emitting signals we could detect
Insight	0.83*	I **think** stating the obvious is a necessary function. Information like this is important to **consider**...
Perception	0.77*	I **saw** four crows on that same branch, **staring** at the deceased. The **silence** of the crows was **deafening**.
Relativity	0.82*	I've known a number to go **into** shock **during** the procedure
Comparison	0.91	This may be **more than** a coincidence.
I (pronouns)	0.68*	Like **I** said, **I** want to believe the former. **I'm** glad it worked out.
You (pronouns)	2.18*	I don't give a fuck what **you** do. **You** can get drink **yourself** to death, **you** can get **yourself** pregnant...
We (pronouns)	0.96	**We** need a bigger, better, colder fridge. **We** have worked hard...
They (pronouns)	1.63*	**They** want the ability to prosecute who they please.
Past	0.69*	I **was** walking past and **thought** about asking if they **needed** help.
Present	1.11*	Can I **steal** your organs and nutrients if I **need** them and you don't **want** to give them up?
Future	1.06	Trump's thugs **will** be pretending to be Bernie supporters and **will** set fire to Philadelphia.
Interrogatory	1.12*	Gee, **where** was the NY Times back in the day? **Why** didn't we hear of the Kennedys, LBJ and FDR?
Negation	1.35*	If you **didn't** know the woman well enough to know she **didn't** take BC regularly, you certainly **don't** know her well enough to know she **doesn't** have an std.
Negative emotion	2.32*	A prank?!? You **arrogant** son of a **bitch**
Positive emotion	0.96	They were **excellent** fishermen - they built **fine** boats.

Table 1: Linguistic features that capture high level psychological categories and their relationship with dogmatic comments. *Strategy* describes the psychological category. *Odds* describes the likelihood that a category will appear more often in a dogmatic comment (e.g., dogmatic comments are 2.18 times more likely to mention *you*-oriented phrases). *Example* illustrates a comment that matches the category. * indicates significance ($p < 0.05$) after correction with Holmes method.

non-dogmatic comments at 0.77 odds.

Drawing comparisons or qualifying something as relative to something else conveys a nuance that is absent from traditionally dogmatic language. The LIWC categories *comparison* and *relativity* capture these effects through comparison words such as "than" or "as" and qualifying words such as "during" or "when." For example, the statement "I hate politicians" is more dogmatic than "I hate politicians *when* they can't get anything done.' *Relativity* is associated with non-dogmatic comments at 0.80 odds, but *comparison* does not reach significance.

Pronouns can be surprisingly revealing indicators of language: for example, signaling one's gender or hierarchical status in a conversation (Pennebaker, 2011). We find first person singular pronouns are a useful negative signal for dogmatism (0.46 odds), while second person singular pronouns (2.18 odds) and third person plural (1.63 odds) are a useful positive signal. Looking across the corpus, we see *I* often used with a hedge ("I think" or "I know"), while *you* and *they* tend to characterize the beliefs of oth-

ers, often in a strongly opinionated way ("you are a moron" or "they are keeping us down"). Other pronoun types do not show significant relationships.

Like pronouns, verb tense can reveal subtle signals in language use, such as the tendency of medical inpatients to focus on the past (Wolf et al., 2007). On social media, comments written in the *present tense* are more likely to be oriented towards a user's current interaction ("this *is* all so stupid"), creating opportunities to signal dogmatism. Alternatively, comments in the *past tense* are more likely to refer to outside experiences ("it *was* an awful party"), speaking less to a user's stance towards an ongoing discussion. We find *present tense* is a positive signal for dogmatism (1.11 odds) and *past tense* is a negative signal (0.69 odds).

Dogmatic language can be either positively or negatively charged in sentiment: for example, consider the positive statement "*Trump is the SAVIOR of this country!!!*" or the negative statement "*Are you REALLY that stupid?? Education is the only way out of this horrible mess. It's hard to imagine how anyone could be so deluded.*" In diverse communities, where people hold many different kinds of opinions, dogmatic opinions will often tend to come into conflict with one another (McCluskey and Hmielowski, 2012), producing a greater likelihood of negative sentiment. Perhaps for this reason, *negative emotion* (2.09 odds) is a useful positive signal of dogmatism, while *positive emotion* shows no significant relationship.

Finally, we find that *interrogative* language (1.12 odds) and *negation* (1.35 odds) are two additional positive signals of dogmatism. While interrogative words like "how" or "what" have many benign uses, they disproportionately appear in our data in the form of rhetorical or emotionally charged questions, such as "how can anyone be that dumb?"

Many of these linguistic signals are correlated with each other, suggesting that dogmatism is the cumulative effect of many component relationships. For example, consider the relatively non-dogmatic statement: "I think the reviewers are wrong in this instance." Removing signals of *insight*, we have: "the reviewers are wrong in this instance," which is slightly more dogmatic. Then removing *relativity*, we have: "the reviewers are wrong." And finally, adding *certainty*, we have a dogmatic statement: "the reviewers are always wrong."

Classifier	In-domain	Cross-domain
BOW	0.853	0.776
SENT	0.677	0.646
LING	0.801	0.728
BOW + SENT	0.860	0.783
BOW + LING	0.881	0.791

Table 2: The AUC scores for dogmatism classifiers within and across domains. BOW (bag-of-words) and SENT (sentiment signals) are baselines, and LING uses the linguistic features from Table 1. We compute in-domain accuracy using 15-fold cross-validation on the Reddit dataset, and cross-domain accuracy by training on Reddit and evaluating on comments on articles from the New York Times. Chance AUC is 0.5.

4 Predicting dogmatism

We now show how we can use the linguistic feature sets we have described to build a classifier that predicts dogmatism in comments. A predictive model further validates our feature sets, and also allows us to analyze dogmatism in millions of other Reddit comments in a scalable way, with multiple uses in ongoing, downstream analyses.

Prediction task. Our goal is (1) to understand how well we can use the strategies in Section 3 to predict dogmatism, and (2) to test the *domain-independence* of these strategies. First, we test the performance of our model under cross-validation within the Reddit comment dataset. We then evaluate the Reddit-based model on a held out corpus of New York Times comments annotated using the technique in Section 2. We did not refer to this second dataset during feature construction.

For classification, we consider two classes of comments: *dogmatic* and *non-dogmatic*. As in the prior analysis, we draw these comments from the top and bottom quartiles of the dogmatism distribution. This means the classes are balanced, with 2,500 total comments in the Reddit training data and 500 total comments in the New York Times testing data.

We compare the predictions of logistic regression models based on unigram bag-of-words features (BOW), sentiment signals[2] (SENT), the linguistic

[2]For SENT, we use normalized word counts from LIWC's positive and negative emotional categories.

features from our earlier analyses (LING), and combinations of these features. BOW and SENT provide baselines for the task. We compute BOW features using term frequency-inverse document frequency (TF-IDF) and category-based features by normalizing counts for each category by the number of words in each document. The BOW classifiers are trained with regularization (L2 penalties of 1.5).

Classification results. We present classification accuracy in Table 2. BOW shows an AUC of 0.853 within Reddit and 0.776 on the held out New York Times comments. The linguistic features boost classification results within Reddit (0.881) and on the held out New York Times comments (0.791). While linguistic signals by themselves provide strong predictive power (0.801 AUC within domain), sentiment signals are much less predictive.

These results suggest that linguistic features inspired by prior efforts in psychology are useful for predicting dogmatism in practice and generalize across new domains.

5 Dogmatism in the Reddit Community

We now apply our dogmatism classifier to a larger dataset of posts, examining how dogmatic language shapes the Reddit community. Concretely, we apply the BOW+LING model trained on the full Reddit dataset to millions of new unannotated posts, labeling these posts with a probability of dogmatism according to the classifier (0=non-dogmatic, 1=dogmatic). We then use these dogmatism annotations to address four research questions.

5.1 What subreddits have the highest and lowest levels of dogmatism? (R1)

A natural starting point for analyzing dogmatism on Reddit is to examine how it characterizes the site's sub-communities. For example, we might expect to see that subreddits oriented around topics such as abortion or climate change are more dogmatic, and subreddits about cooking are less so.

To answer this question, we randomly sample 1.6 million posts from the entire Reddit community between 2007 and 2015. We then annotate each of these posts with dogmatism using our classifier, and compute the average dogmatism level for each subreddit in the sample with at least 100 posts.

Highest	Score	Lowest	Score
cringepics	0.553	photography	0.399
DebateAChristian	0.551	DIY	0.399
DebateReligion	0.540	homebrewing	0.401
politics	0.536	cigars	0.402
ukpolitics	0.533	wicked_edge	0.404
atheism	0.529	guitar	0.406
lgbt	0.527	gamedeals	0.406
TumblrInAction	0.524	buildapc	0.407
islam	0.523	techsupport	0.410
SubredditDrama	0.520	travel	0.410

Table 3: Subreddits with the highest and lowest dogmatism scores. Politics and religion are common themes among the most dogmatic subreddits, while hobbies (e.g., photography, homebrewing, buildapc) show the least dogmatism.

We present the results of this analysis in Table 3. The subreddits with the highest levels of dogmatism tend to be oriented around politics and religion (*DebateAChristian* or *ukpolitics*), while those with the lowest levels tend to focus on hobbies (*photography* or *homebrewing*). The subreddit with the highest average dogmatism level, *cringepics*, is a place to make fun of socially awkward messages, often from would-be romantic partners. Dogmatism here tends to take the form of "how could someone be that stupid" and is directed at the subject of the post, as opposed to other members of the community.

Similarly, *SubredditDrama* is a community where people come to talk about fights on the internet or social media. These fights are often then extended in discussion, for example: *"If the best you can come up with is that something you did was legal, it's probably time to own up to being an ass."* The presence of this subreddit in our analysis provides a further sanity check that our model is capturing a robust signal of dogmatism.

5.2 How do dogmatic beliefs cluster? (R2)

Dogmatism is widely considered to be a domain-specific attitude (for example, oriented towards religion or politics) as opposed to a deeper personality trait (Rokeach, 1954). Here we use Reddit as a lens to examine this idea more closely. Are users who are dogmatic about one topic likely to be dogmatic about others? Do clusters of dogmatism exist around particular topics? To find out, we examine the re-

Libertarianism	business	conspiracy	science	Christianity	lgbt
Anarcho_Capitalism	Bitcoin	Republican	Christianity	DebateAChristian	feminisms
Bitcoin	economy	conspiritard	relationship_advice	DebateReligion	Equality
ronpaul	entertainment	ronpaul	worldpolitics	science	SubredditDrama
Conservative	TrueReddit	collapse	MensRights	videos	TwoXChromosomes
Android	socialism	guns	IAmA	news	MensRights
ukpolitics	bestof	worldpolitics	TwoXChromosomes	Libertarianism	offbeat
Equality	philosophy	occupywallstreet	WTF	atheism	fffffffuuuuuuuuuuu

Table 4: Clusters of subreddits that share dogmatic users. For example, users who are dogmatic on the *conspiracy* subreddit (a place to discuss conspiracy theories) are also likely to be dogmatic on *guns* or *occupywallstreet*.

lationships between subreddits over which individual users are dogmatic. For example, if many users often post dogmatic comments on both the *politics* and *Christianity* subreddits, but less often on *worldnews*, that would suggest *politics* and *Christianity* are linked per a boost in likelihood of individuals being dogmatic in both.

We sample 1000 Reddit users who posted at least once a year between 2007 and 2015 to construct a corpus of 10 million posts that constitute their entire post history. We then annotate these posts using the classifier and compute the average dogmatism score per subreddit per user. For example, one user might have an average dogmatism level of 0.55 for the *politics* subreddit and 0.45 for the *economics* subreddit. Most users do not post in all subreddits, so we track only subreddits for which a user had posted at least 10 times. Any subreddits with an average dogmatism score higher than 0.50 we consider to be a user's dogmatic subreddits. We then count all pairs of these dogmatic subreddits. For example, 45 users have *politics* and *technology* among their dogmatic subreddits, so we consider *politics* and *technology* as linked 45 times. We compute the mutual information (Church and Hanks, 1990) between these links, which gives us a measure of the subreddits that are most related through dogmatism.

We present the results of this analysis in Table 4, choosing clusters that represent a diverse set of topics. For example, *Libertarianism* is linked through dogmatism to other political communities like *Anarcho_Capitalism*, *ronpaul*, or *ukpolitics*, as well as other topical subreddits like *guns* or *economy*. Similarly, people who are dogmatic in the *business* subreddit also tend to be dogmatic in subreddits for *Bitcoin*, *socialism*, and *technology*. Notably, when we apply the same mutual information analysis to links defined by subreddits posted in by the same user, we see dramatically different results. For example, the subreddits most linked to *science* through user posts are *UpliftingNews*, *photoshopbattles*, and *firstworldanarchist*, and *millionairemakers*.

Feature	Direction
total user posts	↑
proportion of posts in most active subreddit	↑
number of subreddits posted in	↓
average number of posts in active articles	↓

Table 5: User behavioral features that are positively and negatively associated with dogmatism. ↑ means the feature is positively predictive with dogmatism, and ↓ means the feature is negatively predictive. For example, the more subreddits a user posts in, the less likely they are to be dogmatic. All features are statistically significant ($p < 0.001$).

Finally, we see less obvious connections between subreddits that suggest some people may be dogmatic by nature. For example, among the users who are dogmatic on *politics*, they are also disproportionately dogmatic on unrelated subreddits such as *science* ($p < 0.001$), *technology* ($p < 0.001$), *IAmA* ($p < 0.001$), and *AskReddit* ($p < 0.05$), with p-values computed under a binomial test.

5.3 What user behaviors are predictive of dogmatism? (R3)

We have shown dogmatism is captured by many linguistic features, but can we discover other high-level user behaviors that are similarly predictive?

To find out, we compute metrics of user behavior using the data sample of 1000 users and 10 million posts described in Section 5.2. Specifically, we calculate (1) *activity*: a user's total number of posts, (2) *breadth*: the number of subreddits a user has posted in, (3) *focus*: the proportion of a user's posts that appear in the subreddit where they are most active, and (4) *engagement*: the average number of posts a user contributes to each discussion they engage in.

We then fit these behavioral features to a linear regression model where we predict each user's average dogmatism level. Positive coefficients in this model are positively predictive of dogmatism, while negative coefficients are negatively predictive.

We find this model is significantly predicitive of dogmatism ($R^2 = 0.1$, $p < 0.001$), with all features reaching statistical significance ($p < 0.001$). *Activity* and *focus* are positively associated with dogmatism, while *breadth* and *engagement* are negatively associated (Table 5). Together, these results suggest dogmatic users tend to post frequently and in specific communities, but are not as inclined to continue to engage with a discussion, once it has begun.

5.4 How does dogmatism impact a conversation? (R4)

How does interacting with a dogmatic comment impact a conversation? Are users able to shrug it off? Or do otherwise non-dogmatic users become more dogmatic themselves?

To answer this question, we sample 600,000 conversations triples from Reddit. These conversations consist of two people (A and B) talking, with the structure: A1 $\rightarrow$ B $\rightarrow$ A2. This allows us to measure the impact of B's dogmatism on A's response, while also controlling for the dogmatism level initially set by A. Concretely, we model the impact of dogmatism on these conversations through a linear regression. This model takes two features, the dogmatism levels of A1 and B, and predicts the dogmatism response of A2. If B's dogmatism has no effect on A's response, the coefficient that corresponds to B will not be significant in the model. Alternatively, if B's dogmatism does have some effect, it will be captured by the model's coefficient.

We find the coefficient of the B feature in the model is positively associated with dogmatism ($p < 0.001$). In other words, engagement with a dogmatic comment tends to make a user more dogmatic themselves. This effect holds when we run the same model on data subsets consisting only of dogmatic or non-dogmatic users, and also when we conservatively remove all words used by B from A's response (i.e., controlling for quoting effects).

6 Related Work

In contrast to the computational models we have presented, dogmatism is usually measured in psychology through survey scales, in which study participants answer questions designed to reveal underlying personality attributes (Rokeach, 1954). Over time, these surveys have been updated (Shearman and Levine, 2006) and improved to meet standards of psychometric validity (Crowson, 2009).

These surveys are often used to study the relationship between dogmatism and other psychological phenomena. For example, dogmatic people tend to show an increased tendency for confrontation (El-Nawawy and Powers, 2010) or moral conviction and religiosity (Swink, 2011), and less likelihood of cognitive flexibility (Martin et al., 2011), even among stereotypically non-dogmatic groups like atheists (Gurney et al., 2013). From a behavioral standpoint, dogmatic people solve problems differently, spending less time framing a problem and expressing more certainty in their solution (Lohman, 2010). Here we similarly examine how user behaviors on Reddit relate to a language model of dogmatism.

Ertel sought to capture dogmatism linguistically, though a small lexicon of words that correspond with high-level concepts like certainty and compromise (1985). McKenny then used this dictionary to relate dogmatism to argument quality in student essays (2005). Our work expands on this approach, applying supervised models based on a broader set of linguistic categories to identify dogmatism in text.

Other researchers have studied topics similar to dogmatism, such as signals of cognitive style in right-wing political thought (Van Hiel et al., 2010), the language used by trolls on social media (Cheng et al., 2015), or what makes for impartial language on twitter (Zafar et al., 2016). A similar flavor of work has examined linguistic models that capture politeness (Danescu-Niculescu-Mizil et al., 2013), deception (Ott et al., 2011), and authority (Gilbert, 2012). We took inspiration from these models when constructing the feature sets in our work.

Finally, while we examine what makes an opinion dogmatic, other work has pushed further into the structure of arguments, for example classifying their justifications (Hasan and Ng, 2014), or what makes an argument likely to win (Tan et al., 2016). Our

model may allow future researchers to probe these questions more deeply.

7 Conclusion

We have constructed the first corpus of social media posts annotated with dogmatism scores, allowing us to explore linguistic features of dogmatism and build a predictive model that analyzes new content. We apply this model to Reddit, where we discover behavioral predictors of dogmatism and topical patterns in the comments of dogmatic users.

Could we use this computational model to help users shed their dogmatic beliefs? Looking forward, our work makes possible new avenues for encouraging pro-social behavior in online communities.

Abstract

Search personalization that considers the social dimension of the web has attracted a significant volume of research in recent years. A user profile is usually needed to represent a user's interests in order to tailor future searches. Previous research has typically constructed a profile solely from a user's usage information. When the user has only limited activities in the system, the effect of the user profile on search is also constrained. This research addresses the setting where a user has only a limited amount of usage information. We build enhanced user profiles from a set of annotations and resources that users have marked, together with an external knowledge base constructed according to usage histories. We present two probabilistic latent topic models to simultaneously incorporate social annotations, documents and the external knowledge base. Our web search strategy is achieved using personalized social query expansion. We introduce a topical query expansion model to enhance the search by utilizing individual user profiles. The proposed approaches have been intensively evaluated on a large public social annotation dataset. Results show that our models significantly outperformed existing personalized query expansion methods which use user profiles solely built from past usage information in personalized search.

1 Introduction

On today's social web, users can enrich the social context of web pages. The most notable fact is that users can often freely tag web pages with annotations (Gupta et al., 2011). These tags could be high quality descriptors of the web pages' topics and a good indicator of web users' interests. However, the uncontrolled manner of social tagging results in the use of an unrestricted vocabulary. This makes searching through the collection difficult and generally less accurate. Thus the social annotation or bookmarking system demonstrates an extreme example of the vocabulary mismatch problem encountered in personalized web search. To tackle the problem, various personalized query expansion (QE) and results reranking techniques have been proposed and evaluated (Bouadjenek et al., 2016).

There have been some attempts to achieve personalized QE using social data. For example, Researchers have considered selecting the most related tags from a user's profile to expand queries (Bender et al., 2008; Bertier et al., 2009; Bouadjenek et al., 2011). Local analysis and co-occurrence based user profile representation have also been adopted to expand the query (Chirita et al., 2007; Biancalana et al., 2013). Recently, Zhou et al. proposed a query expansion framework based on individual user profiles (Zhou et al., 2012a). In their work, terms in the user profile are modeled according to their associations, which can be defined by co-occurrence statistics or defined by a tag-topic model.

All of the previously mentioned systems are dependent upon historical usage information being available in an individual user profile (Sugiyama et al., 2004; Teevan et al., 2005; Bennett et al., 2012; Zhou et al., 2014; Guha et al., 2015; Zhou et al., 2016). This information is pivotal when tailoring search results to the preferences of specific individuals. However, in some

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 700–710,
Austin, Texas, November 1-5, 2016.

cases a user may have very limited previous interactions with the system. With little usage information to hand, the personalized search experience is poor. Furthermore, using only historical usage information to personalize search may not be enough.

In this paper, we extend personalized search using social data in two directions. First, we exploit external knowledge bases to enhance the user profile built from a user's historical usage information. We build queries from the user tags and annotated web pages. Subsequently, we fetch the relevant documents from an external corpus to be included in the user profile. We then propose to incorporate the user's annotations, web page content information and external documents through two statistical models, which we have named Mixture Enhanced User Profiling (MEUP) Model and Separated Enhanced User Profiling (SEUP) Model. Both models infer latent topics, their probabilities of being relevant and a multinomial distribution of topics of the documents being considered. MEUP mixed the tags, annotated documents and external documents together to infer unified latent topics, while SEUP is an extension of MEUP which learns topics that are shared between the two groups of document-aligned pairs.

Second, we propose a topical query expansion model to personalize web search by utilizing the user profiles. In the topical QE model, profile terms are calculated based on their topical relevance to the query terms to expand the query.

Experimental results show that the Enhanced User Profiling models together with the topic QE can significantly improve retrieval performance over user profiles solely built from a user's historical information. Improvements were observed for users with both a rich amount of usage information and a small amount of information. We also demonstrate that the approach proposed in the paper outperforms existing QE methods proposed for personalized search using social data.

The contribution of this paper can be summarized as follows:

i. *We tackle the challenge of personalized web search using social data in a novel way by enhancing user profiles that are built solely from users' historical usage information.*

ii. *We propose and systematically evaluate two novel generative models to construct enriched user profiles with the help of external corpora in the context of personalized search using social data.*

iii. *We suggest and evaluate a novel query expansion method. Instead of relying on lexical relevance information between query terms and profile terms, we also consider the topical relevance between them to expand the query.*

2.1 Personalized Search Using Social Media

In personalized search using social media (Jamali and Ester, 2010; Lin et al., 2013), the search process is either performed over "social" data gathered from Web 2.0 applications such as social bookmarking systems, wikis, blogs etc., or it re-adapts the web search results produced by search engines by using social data (Carman et al., 2008; Bouadjenek et al., 2016). For example, the authors in (Vallet et al., 2010) investigated how the ranking of search engine results can be improved with respect to users if the users' social information is taken into consideration. A similar approach was also explored in (Noll and Meinel, 2007) where the system performed re-ranking of Google search results based on social bookmarks and tags harvested from *del.icio.us*[1]. However, the data sparsity problem poses a challenge to this approach as not all Web pages returned by search engines are tagged in the *del.icio.us* dataset.

2.2 Personalized Results Re-Ranking

Because of this problem, researchers started to use social data as a test collection to develop personalized techniques. In this way, personalization usually involves two general approaches. The first approach submits a query into the collection but re-ranks the returned results based on an individual user profile. In (Xu et al., 2008) the authors re-rank the results according to the topical relevance of documents and users' interests. Carmel et al. (Carmel et al., 2009) investigated personalized results re-ranking based on the user's social relations. Wang and Jin (Wang and Jin, 2010) explored gathering data from multiple online social systems for adaptive search personalization. Bouadjenek et al. (Bouadjenek et al., 2013a; Bouadjenek et al., 2013b) propose to use social data and user relationships to enhance document

Notation	Meaning
$\mathcal{U}$	finite sets of users
$\mathcal{D}$	finite sets of web pages/documents
$\mathcal{T}$	finite sets of tags
$\mathcal{A}$	a ternary relation, elements are tags
$\mathcal{A}^u$	the set of annotations of a user
$\mathcal{T}^u$	the tag vocabulary of a user
$\mathcal{D}^u$	a user's set of documents
t	a tag
d	a document
u	a user
w	a word/term
$docTerm^u$	the vocabulary extracted from the documents that a user has tagged
$exterTerm^u$	the full set of terms extracted from a user's external documents
$\mathcal{D}_{exter}$	an external corpus
$\mathcal{D}^u_{exter}$	a user's set of external documents
q	a source query
$q^{\mathcal{T}^u}$	a query concatenated by tags of a user
$Q^{\mathcal{D}^u}$	queries extracted from a user's set of documents
Q_{exter}	queries to be sent to an external corpus
$s_{x,y}$	retrieval score of a query q_y to retrieve a document d_x
K	number of topics
μ_z	mean of Log-normal distribution of retrieval scores for topic z
σ_z	deviation of Log-normal distribution of retrieval scores for topic z
N_{d_j}	number of `words` in document d_j
$z_{j,i}$	topic associated with the i-th word in the document d_j
$w_{j,i}$	i-th word in document d_j
$n_{j,k}$	the number of times that topic k sampled w.r.t. document d_j
$v_{k,w_{j,i}}$	the number of times $w_{j,i}$ has been generated by topic k
θ	multinomial distribution of topics
φ	multinomial distribution of words
ϕ	multinomial distribution of words (used in SEUP)
α	the parameter of topic Dirichlet prior
β	the parameter of word Dirichlet prior

Table 1. Basic notations used in the paper

representation for re-ranking purposes. Though this group of work is attractive, if relevant items cannot be fetched in the first place, regardless of the complex re-ranking process, the results still tend to be unsatisfactory.

2.3 Personalized Query Expansion

Another group of work modifies or augments a user's original query. This approach is termed query expansion (Zhou et al., 2015). Researchers have considered tag-tag relationships for personalized query expansion, by selecting the most related tags from a user's profile (Bender et al., 2008; Bertier et al., 2009). However, tags cannot be relied upon to consistently provide precise descriptions of resources for use when searching. Local analysis and co-occurrence based user profile representation have also been adopted to expand the query (Chirita et al., 2007; Biancalana and Micarelli, 2009). However, the expansion terms are solely based on lexical matching between the query and the terms which exist in the user profile. Zhou et al. proposed a query expansion framework based on individual user profiles (Zhou et al., 2012a; Zhou et al., 2012b). In their work, terms in the user profile are modeled according to their associations, which can be defined by co-occurrence statistics or defined by a tag-topic model. The method simultaneously incorporates annotations and web documents in a latent graph, regularized by terms extracted from the top-ranked documents.

However, all of the previously mentioned systems consider constructing user profiles solely from past usage information. In contrast, in this paper we extend personalized web search using social data by exploiting an external knowledge base to enhance the user profile.

3 Problem Definition and Solution Overview

In social annotation and bookmarking systems such as *del.icio.us* or *CiteUlike*[2], users can label interesting web resources with primarily short and unstructured *annotations* in natural language called *tags*. These web resources are denoted as a URL in the *del.icio.us* website. Textual content can be crawled by following a URL that refers to a *document* or *web page*. Please refer to Table 1 for the basic notations used in this paper.

Formally, social tagging data can be represented by a tuple $\mathcal{P} := (\mathcal{U}, \mathcal{D}, \mathcal{T}, \mathcal{A})$. $\mathcal{A} \subseteq \mathcal{U} \times \mathcal{D} \times \mathcal{T}$ is a ternary relation, whose elements are called tag assignments or annotations (or bookmarks). The

Table 2. Procedure for personalized search using social data

set of annotations of a user is defined as: $\mathcal{A}^u \coloneqq \{(t, d)|u, d, t \in \mathcal{A}\}$. The tag vocabulary of a user, is given as $\mathcal{T}^u \coloneqq \{t|(t, d) \in \mathcal{A}^u\}$. A user's set of documents is $\mathcal{D}^u \coloneqq \{d|(t, d) \in \mathcal{A}^u\}$. We define terms extracted from a user's set of documents as $docTerm^u \coloneqq \{w|w \in \mathcal{D}^u\}$, where w denotes a word/term in the annotated documents. Similarly, we define terms extracted from a user's set of external documents as $exterTerm^u \coloneqq \{w|w \in \mathcal{D}^u_{exter}\}$, where $\mathcal{D}^u_{exter}$ denotes a user's set of external documents from an external corpus $\mathcal{D}_{exter}$.

In a typical personalized search scenario, given a source query q and a set of words in the user profile $\{w_1, w_2 \dots w_n\}$ the goal is to return a ranked list of profile terms to be added to the query, for a second round retrieval of results.

Our personalization approach consists of three main steps (see Table 2): Fetching external documents; User profile modelling; and Personalized query expansion. We enhance a user's historical usage information in step one. We firstly concatenate all tags t in $\mathcal{T}^u$ into a query $q^{\mathcal{T}^u}$ (line 1). Then for each document d in $\mathcal{D}^u$, we extract terms with the highest inverted document frequency (*idf*) scores as queries $Q^{\mathcal{D}^u}$ (lines 2-3, with the *EXTRACTTOP* function returns top λ terms). Next we send queries in Q_{exter} ($q^{\mathcal{T}^u} \cup Q^{\mathcal{D}^u}$) to an external corpus $\mathcal{D}_{exter}$ to fetch $\mathcal{D}^u_{exter}$ together with their retrieval scores $s_{x,y}$ (lines 5-7, the number of documents retrieved by each query is controlled by the parameter γ). Step two integrates $\mathcal{T}^u$ (here all tags are concatenated and viewed as a single document), $\mathcal{D}^u$, $\mathcal{D}^u_{exter}$ and their retrieval scores $s_{x,y}$ into a topic model such that a multinomial distribution of topics specific to each document can be inferred (lines 8-14, we eliminate the procedure for the SEUP model because its similarity to the simpler model, see the next section). In the last step, the algorithm uses the output of step two to build a topical query expansion model in order to expand the original query (lines 15-18). Note that step one and step two could be executed off-line so as to improve the efficiency of the algorithm.

4 Enhanced User Profiling Models

In this section we describe how to model user profiles (i.e. step two in Table 2). We present two Enhanced User Profiling (EUP) models for this purpose.

4.1 Mixture Enhanced User Profiling

Topic discovery in the EUP models is influenced not only by term co-occurrences, but also by the retrieval scores of documents. To avoid normalization, we employ a log-normal distribution for retrieval scores to infer latent topics via the documents and their relevance probabilities.

The MEUP model developed here is a generative model of retrieval scores and the words in the documents. The generative process is as follows:

Generative process of the MEUP model

1. **for** each topic $k \in [1, K]$ **do**
sample the mixture of words $\varphi \sim Dirichlet(\beta)$
2. **for** each document $d_j \in \mathcal{T}^u \cup \mathcal{D}^u \cup \mathcal{D}^u_{exter}$ **do**
sample the mixture of topics $\theta_j \sim Dirichlet(\alpha)$
for each word w_i indexed by $i = 1, \dots, N_{d_j}$ **do**
sample the topic index topic $z_{j,i} \sim Mult(\theta_{d_j})$
sample the weight of word $w_{j,i} \sim Mult(\varphi_{z_{j,i}})$
sample the retrieval score $s_{,i} \sim \mathcal{N}(\mu_{z_{j,i}}, \sigma_{z_{j,i}})$

In the above process, the retrieval scores of terms in the same document are the same and calculated by a language model retrieval function (Manning et al., 2008) for retrieved documents in $\mathcal{D}^u_{exter}$. The retrieval scores for $\mathcal{T}^u$ (here all tags are concatenated and viewed as a single document) and documents in $\mathcal{D}^u$ are set to one. We normalize the scores by the max score in the retrieval list. We used a fixed number of latent topics K. The posterior distribution of topics depends on two sets of information, both the terms and retrieval scores of the documents.

In this model, inference is intractable. We use Gibbs Sampling (Heck and Thomas, 2015) to perform approximate inference. We employ a conjugate prior for the multinomial distributions, and integrate out θ and φ. In the sampling procedure, we need to calculate the conditional distribution $p(z_{j,i} = k)$ (line 12 in Table 2). By using Gibbs Sampling, for each word the topic is sampled from:

$$p(z_{j,i} = k) \propto \frac{n_{j,k,\neg i} + \alpha}{n_{j,\cdot,\neg i} + K \cdot \alpha} \times \frac{v_{k,w_{j,i},\neg} + \beta}{v_{k,\cdot,\neg} + V \cdot \beta} \times \frac{1}{s_{j,i}\sigma_{z_{j,i}}\sqrt{2\pi}} \exp\left(-\frac{\left(\ln s_{j,i} - \mu_{z_{j,i}}\right)^2}{2\sigma^2_{z_{j,i}}}\right)$$

where $n_{j,k,\neg i}$ counts the number of times that topic with index k has been sampled from the multinomial distribution specific to document d_j with the current $z_{j,i}$ not counted. Another counter variable $v_{k,w_{j,i},\neg}$ counts the number of times $w_{j,i}$ has been generated by topic k, but not counting the current $w_{j,i}$. A dot denotes summation over all values of the variable whose index that dot takes. $\mu_{z_{j,i}}$ and $\sigma_{z_{j,i}}$ are elements from μ_z and σ_z, respectively. After that we can calculate the posterior estimate of θ and φ (line 14 in Table 2).

4.2 Separated Enhanced User Profiling

In the MEUP model, $\mathcal{T}^u$, $\mathcal{D}^u$ and $\mathcal{D}^u_{exter}$ are mixed together to infer unified latent topics. However, the MEUP model may miss important information when the topics are learned. Our SEUP model extends the MEUP model by learning topics which are shared between document-aligned pairs. In order to do this, we create pseudo-aligned documents between $\mathcal{T}^u$, $\mathcal{D}^u$ and $\mathcal{D}^u_{exter}$. This procedure works as follows. For each external document in $\mathcal{D}^u_{exter}$ retrieved by a query from Q_{exter}, which is formed through step one of our approach, we treat the document (from $\mathcal{D}^u_{exter}$) and the query (from Q_{exter}) as pseudo-aligned documents in two groups. The first group we named source group C, the other group we named target group E. By using the aligned documents, we propose a model to learn the latent topics between the two groups.

Note that in this case, there is a comparable document set aligned at the document-level. Therefore, θ can be viewed as a group independent factor, and shared among comparable aligned documents. Henceforth, the generation process for the SEUP model is slightly different from the MEUP model. The generative process is summarized below:

Generative process of the SEUP model

1. **for** each of topics $k \in [1, K]$ **do**
   sample the mixture of words $\varphi \sim Dirichlet(\beta)$
   sample the mixture of words $\phi \sim Dirichlet(\beta)$
2. **for** each document pair $d_j = \{d^C_j \in \mathcal{T}^u \cup \mathcal{D}^u, d^E_j \in \mathcal{D}^u_{exter}\}$ **do**
   sample the mixture of topics $\theta_j \sim Dirichlet(\alpha)$
   for each word w^C_i indexed by $i = 1, \ldots, N_{d^C_j}$ **do**
   sample the topic index topic $z^C_{j,i} \sim Mult(\theta_{d_j})$
   sample the weight of word $w^C_{j,i} \sim Mult(\varphi_{z^C_{j,i}})$
   sample the retrieval score $s^C_{j,i} \sim \mathcal{N}(\mu^C_{z_{j,i}}, \sigma^C_{z_{j,i}})$
   for each word w^E_i indexed by $i = 1, \ldots, N_{d^E_j}$ **do**
   sample the topic index topic $z^E_{j,i} \sim Mult\left(\theta_{d_j}\right)$
   sample the weight of word $w^E_{j,i} \sim Mult(\phi_{z^E_{j,i}})$
   sample the retrieval score $s^E_{j,i} \sim \mathcal{N}(\mu^E_{z_{j,i}}, \sigma^E_{z_{j,i}})$

Similar to the MEUP model, the updated formulas for Gibbs sampling for the SEUP model are:

$$p(z^C_{j,i} = k) \propto \frac{n^C_{j,k,\neg i} + n^E_{j,k} + \alpha}{n^C_{j,\cdot,\neg i} + n^E_{j,\cdot} + K \cdot \alpha} \times \frac{v^C_{k,w^C_{j,i},\neg} + \beta}{v^C_{k,\cdot,\neg} + V^C \cdot \beta} \times \frac{1}{s^C_{j,i}\sigma^C_{z_{j,i}}\sqrt{2\pi}} \exp\left(-\frac{\left(\ln s^C_{j,i} - \mu^C_{z_{j,i}}\right)^2}{2\sigma^{C\,2}_{z_{j,i}}}\right)$$

$$p(z^E_{j,i} = k) \propto \frac{n^E_{j,k,\neg i} + n^C_{j,k} + \alpha}{n^E_{j,\cdot,\neg i} + n^C_{j,\cdot} + K \cdot \alpha} \times \frac{v^E_{k,w^E_{j,i},\neg} + \beta}{v^E_{k,\cdot,\neg} + V^E \cdot \beta} \times \frac{1}{s^E_{j,i}\sigma^E_{z_{j,i}}\sqrt{2\pi}} \exp\left(-\frac{\left(\ln s^E_{j,i} - \mu^E_{z_{j,i}}\right)^2}{2\sigma^{E\,2}_{z_{j,i}}}\right)$$

The meaning of the symbols used in the SEUP model is the same as in the MEUP model, except this time for two groups *E* and *C*. In the two EUP models, the multinomial distribution of topics is specific to each document and each word can be easily inferred.

5 Topical Query Expansion

In step three of our approach to personalization, we use the output from step two to build a QE model that calculates the weights of the profile terms to be added to the initial query. In this section we detail this process.

Given the query $q = \{w_a^q\}_{a=1}^n$ of n independent query terms, the probability of the query generating a word w is defined as (see also (Lavrenko and Croft, 2001; Ganguly et al., 2012)):

$$P(w|q) = P(w|w_1^q, \dots, w_n^q) \propto \prod_{a=1}^{n} P(w|w_a^q)$$

We further assume that there are a set of relevant documents $\{d_b\}_{b=1}^N$ related to the query and the word being considered, where N is the number of documents. Incorporating this set of documents into the above equation leads to:

$$P(w|w_a^q) = \sum_{b=1}^{N} P(w|d_b)P(d_b|w_a^q) \propto \frac{1}{N}\sum_{b=1}^{N} P(w|d_b)P(w_a^q|d_b)$$

The calculation discards the uniform prior for $P(w_a^q)$, and takes the uniform prior of documents outside the summation.

As we already have outputs from step two, the documents inside the user profile can be used as a set of relevant documents in the above calculation. In addition, because we now have latent topics related to each document and each word, there is no longer a direct dependency of w on d_b and q. In this case, in order to estimate $P(w|d_b)$, we can marginalize the probability over the latent topic variables z_k, then we have:

$$P(w|d_b) = \sum_{k=1}^{K} P(w|z_k)P(z_k|d_b)$$

Similarly, the probability $P(w_a^q|d_b)$ becomes:

$$P(w_a^q|d_b) = \sum_{k=1}^{K} P(w_a^q|z_k)P(z_k|d_b)$$

So that the probability of the query generating a word w can be re-defined as:

$$P(w|w_a^q) \propto \frac{1}{N}\sum_{b=1}^{N}(\sum_{k=1}^{K} P(w|z_k)P(z_k|d_b))\times(\sum_{k=1}^{K} P(w_a^q|z_k)P(z_k|d_b))$$

In the SEUP Model, we use one side of the word-topic distributions from the group that contains tags and annotated documents to calculate the weighting. All the profile terms $\{w_1, w_2 \dots w_n\} = exterTerm^u \cup docTerm^u \cup \mathcal{T}^u$ are ranked by their probability of being generated by the given query $P(w|q)$ (line 16-17 in Table 2), and the top δ terms are chosen to expand the query.

6 Evaluation

In the following section we describe experiments which have been designed to evaluate the proposed method. We start the section by discussing the experimental settings, and then we present and analyze the results.

6.1 Experimental Setup

In order to evaluate the above proposed methods on real-world data, we selected two delicious datasets: *socialbm0311* and *deliciousT140*, which are public, described and analyzed in (Zubiaga et al., 2009; Zubiaga et al., 2013). The *deliciousT140* dataset is made up by 144,574 unique URLs, all of them with their corresponding social tags retrieved from *del.icio.us*. However, this dataset does not contain the actual web pages (i.e. documents). So we used another *socialbm0311* dataset. It contains the complete bookmarking activity for almost 2 million users. After matching the documents in *deliciousT140 wi*th the bookmark activities in *socialbm0311*, we obtained a total of 5,153,720 bookmark activities, 259,511 users, 131,283 web pages and 137,870 tags. We used a public parser[3] to parse the web pages in order to get their textual content.

We constructed two corpora from different external knowledge bases. The first corpus was obtained from the largest encyclopedia – Wikipedia[4]. A Wikipedia snapshot was obtained on the 14/08/2014, which contained a collection of 4,634,369 articles. The second corpus consists of English news documents from the Glasgow Herald 1995, Los Angeles Times 1994 and Los Angeles Times 2002, a collection made available by the CLEF AdHoc-News Test Suites (2004-2008)[5], which we refer to as CLEF. This collection contains 304,630 documents.

To investigate the effects of enhanced user profiles, we selected two groups of users as test users. One group contains 1,000 randomly selected users with no more than 50 bookmarks (refer to as **User-SMALL**) and another group contains 1,000 randomly selected users with more than 200 bookmarks (refer to as **User-LARGE**). These two groups of users represent users with small amount

[3] http://htmlparser.sourceforge.net/
[4] http://www.wikipedia.org
[5] http://catalog.elra.info/

of and rich amount of past usage information respectively. The English terms were processed by down-casing the alphabetic characters, removing the stop words and stemming words using the Por ter stemmer. For each user, 75% of his/her tags with annotated web pages were used to create the user profile and the other 25% were used as a test collection.

The evaluation method used by previous researchers in personalized social search (Xu et al., 2008; Wang and Jin, 2010; Zhou et al., 2012a) is employed. The main assumption is as follows: Any documents tagged by u with t are considered relevant for the personalized query (u, t) (u submits the query t).

The following evaluation metrics were chosen to measure the effectiveness of the various approaches: the normalized discounted cumulative gain (NDCG), mean reciprocal rank (MRR) and mean average precision (MAP) (Voorhees, 1999; Järvelin and Kekäläinen, 2000). The average performance over all users is calculated. Statistically significant differences were determined using a paired t-test at a confidence level of 95%.

6.2 Experimental Runs

The proposed approach is applied to social search personalization through the means of query expansion. We evaluate our proposed models and compare with several state-of-the-art methods as follows.

LM A popular and quite robust language model retrieval method which has previously demonstrated good results (Zhai and Lafferty, 2001). We compute the Kullback-Leibler divergence between the query and document language model as described in (Zhai and Lafferty, 2001).

LMRM A relevance model involves pseudo-relevance feedback in the language model as in (Lavrenko and Croft, 2001). We include this model as a competitive non-personalized query expansion baseline.

LMRM-external This is a modified version of the relevance model as described in (Diaz and Metzler, 2006). Instead of using the top-ranked documents as pseudo-relevance documents, this model uses external corpora to obtain the relevance documents. We include this model as a strong non-personalized baseline as we also used external corpora in our models. In the experiments, this method will acquire external documents from the Wikipedia corpus and CLEF.

Co-occur This method has been used by several researchers. In this method the selection of expansion terms is based on their co-occurrence statistics with the query terms and other terms inside the user model. We used this approach as previously it demonstrated satisfactory performance as in (Chirita et al., 2007).

Co-tag Pure tag-tag relationships are also favored by many researchers. This method is based on the co-tagging activities a user performed (Bender et al., 2008; Bertier et al., 2009; Bouadjenek et al., 2011). In this case, the user profiles contain training tags with their co-tagging statistics computed using the Jaccard coefficient.

Tag-topic-regu Zhou et al. (Zhou et al., 2012a) proposed a query expansion framework based on regularizing the smoothness of word associations over a connected graph using terms extracted from top-ranked documents. The user profiles are built according to a Tag-Topic model in a latent graph. We include the highest performing method from their work for comparison.

MEUP From our proposed methods, the MEUP method using the MEUP model and the topical query expansion method for social web search.

SEUP This is our alternative proposed method, by using the SEUP model and the topical query expansion method to personalize search.

The number of documents retrieved by each query in step one is set to $\gamma = 5$ empirically. Parameter λ used in the *EXTRACTTOP* function is set to 10. For the EUP modeling, α and β were set to $50/K$ and 0.01. In the expansion method, the number of expansion terms δ are set to 5. All the parameters in the other baseline models are set according to their tuning procedures in the original papers

6.3 Results

Firstly we examine the experimental results that describe the performance of the proposed methods in this paper together with three non-personalized baselines on the overall test users, which are shown in Table 3. The statistically significant differences are marked as *l* and *w* with respect to the **LMRM** and **LMRM-external** baselines as these two methods work better than the simpler **LM**

Table 3. Overall results, statistically significant differences between our methods and LMRM, LMRM-External, Co-occur, Co-tag, Tag-topic-regu are indicated by *l, w, o, t, r* respectively.

method. As illustrated by the results, the **LM** model was the lowest performer for all evaluation metrics for two groups of users. This result shows that merely borrowing common lexical-matching techniques from traditional information retrieval will not solve the personalized search problem. With the help of pseudo-relevance feedback, the **LMRM** and **LMRM-external** methods work consistently better than the **LM** baseline. This demonstrates the power of query expansion. Specifically, the technique that explores external corpora to obtain the relevant documents works better than the method which simply uses top-ranked documents. The results are consistent with previous research (Diaz and Metzler, 2006). The improvements are more noticeable when using Wikipedia as the external corpus. However, all the non-personalized baselines are outperformed by the personalized approaches including our proposed methods **MEUP** and **SEUP**, all with statistically significant results. This illustrates that non-personalized query expansion methods can only bring limited improvements while methods with additional terms from the user profiles can greatly improve retrieval effectiveness.

Next we evaluate the performance of the proposed methods compared to several personalized baselines that use only the users' past information for query expansion, i.e. **Co-occur**, **Co-tag** and **Tag-topic-regu** methods.

As seen from Table 3, three conclusions emerge. First, **MEUP** and **SEUP** both outperform all personalization methods previously proposed, in all metrics measured with two external corpora for both groups of users. Moreover, the difference between our proposed methods and the baseline runs is always significant. We believe that the strong performance of our methods is due to the fact that our methods do not only consider a user's past usage information, but also uses an external knowledge base to enhance the user profiling process. Secondly, the **SEUP** method works consistently better than the **MEUP** method. This result confirms that merely mixing the documents from the historical evidence and external knowledge bases will miss some important information. By treating the documents as a pseudo-aligned corpus, we obtain much better performance. The highest improvement over the best performing run reaches 54.95% (in terms of the **SEUP** method with the MRR metric when compared to **Tag-topic-regu** by using Wikipedia as the external corpus in the **User-SMALL** group). Third, further improvements are achieved by us-

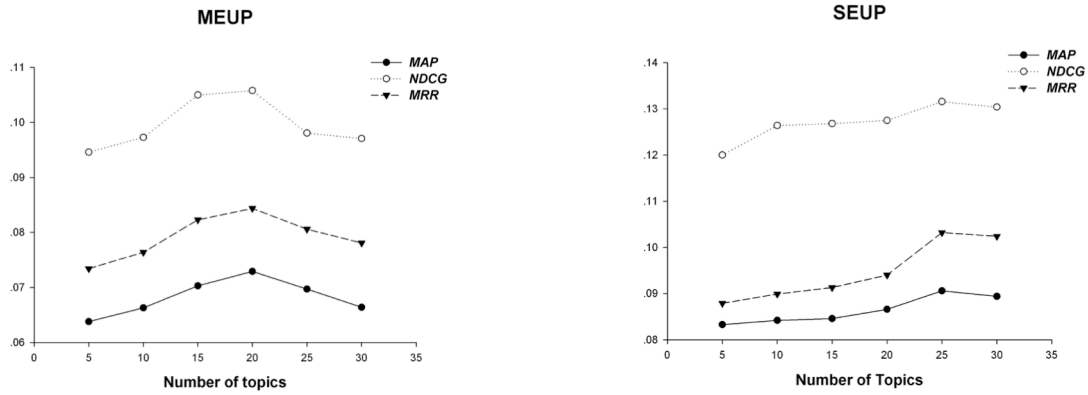

Fig. 1. Performance with different number of topics by using Wikipedia as external corpus in the user-SMALL group

ing Wikipedia as the external corpus rather than using the CLEF collection. The possible reason, as pointed out by Diaz and Metzler (Diaz and Metzler, 2006), is that an external corpus is likely to be a better source of expansion terms if it has better topic coverage over the target corpus. The results also show that the improvements over baseline models in the **User-SMALL** group are more noticeable than in the **User-LARGE** group. However, the differences are small. This result confirms that our methods work well both for users with small amounts, and those with rich amounts of past usage information.

We now examine the effect of the performance of the number of latent topics used in **MEUP** and **SEUP**. We vary the number of topics in both methods from 5 to 30, the results are shown in Figure 1, using Wikipedia as the external corpus in the **user-SMALL** group (we eliminated other results as they gave similar results). As can be seen from the figure, the highest performance is reached when the number of latent topics is 20 in **MEUP** and 25 in **SEUP**. When the number of topics continues to grow, the performance starts to degrade. However, even the lowest scored run still outperformed the strongest baseline. By varying the topic numbers, **SEUP** still outperforms **MEUP**.

7 Conclusion and Future Work

In this paper, we tackle the challenge of personalized web search using social data in a novel way by building enhanced user profiles from the annotations and resources the user has marked, together with an external knowledge base. We present two probabilistic latent models to simultaneously incorporate social annotations, documents and the external knowledge base. In addition, we introduce a topical query expansion model to enhance the search by utilizing individual user profiles. The proposed methods performed well on the social data crawled from the web, delivering statistically significant improvements over non-personalized and personalized representative baseline systems by constructing user profiles from a user's historical usage information only. It is also confirmed that our proposed methods work well for both active and less active users. In future research, we aim to automatically estimate the number of topics to be used in the EUP models. We also plan to explore the use of more external resources and novel latent semantic models to enhance performance.

Effective Greedy Inference for Graph-based Non-Projective Dependency Parsing

Ilan Tchernowitz **Liron Yedidsion** **Roi Reichart**
Faculty of Industrial Engineering and Management, Technion, IIT
{ilantc@campus|lirony@ie|roiri@ie}.technion.ac.il

Abstract

Exact inference in high-order graph-based non-projective dependency parsing is intractable. Hence, sophisticated approximation techniques based on algorithms such as belief propagation and dual decomposition have been employed. In contrast, we propose a simple greedy search approximation for this problem which is very intuitive and easy to implement. We implement the algorithm within the second-order TurboParser and experiment with the datasets of the CoNLL 2006 and 2007 shared task on multilingual dependency parsing. Our algorithm improves the run time of the parser by a factor of 1.43 while losing 1% in UAS on average across languages. Moreover, an ensemble method exploiting the joint power of the parsers, achieves an average UAS 0.27% higher than the TurboParser.

1 Introduction

Dependency parsing is instrumental in NLP applications, with recent examples in information extraction (Wu and Weld, 2010), word embeddings (Levy and Goldberg, 2014), and opinion mining (Almeida et al., 2015). The two main approaches for this task are graph based (McDonald et al., 2005) and transition based (Nivre et al., 2007).

The graph based approach aims to optimize a global objective function. While exact polynomial inference algorithms exist for projective parsing (Eisner, 1996; McDonald et al., 2005; Carreras, 2007; Koo and Collins, 2010, inter alia), high order non-projective parsing is NP-hard (McDonald and Pereira, 2006). The current remedy for this comes in the form of advanced optimization techniques such as dual decomposition (Martins et al., 2013), LP relaxations (Riedel et al., 2012), belief propagation (Smith and Eisner, 2008; Gormley et al., 2015) and sampling (Zhang et al., 2014b; Zhang et al., 2014a).

The transition based approach (Zhang and Nivre, 2011; Bohnet and Nivre, 2012; Honnibal et al., 2013; Choi and McCallum, 2013a, inter alia), and the easy first approach (Goldberg and Elhadad, 2010) which extends it by training non-directional parsers that consider structural information from both sides of their decision points, lack a global objective function. Yet, their sequential greedy solvers are fast and accurate in practice.

We propose a greedy search algorithm for high-order, non-projective graph-based dependency parsing. Our algorithm is a simple iterative graph-based method that does not rely on advanced optimization techniques. Moreover, we factorize the graph-based objective into a sum of terms and show that our basic greedy algorithm relaxes the global objective by sequentially optimizing these terms instead of globally optimizing their sum.

Unlike previous greedy approaches to dependency parsing, transition based and non-directional, our algorithm does not require a specialized feature set or a training method that specializes in local decisions. In contrast, it supports global parameter training based on the comparison between an induced tree and the gold tree. Hence, it can be integrated into any graph-based parser.

We first present a basic greedy algorithm that relaxes the global graph-based objective (Section 3). However, as this simple algorithm does not provide a

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 711–720,
Austin, Texas, November 1-5, 2016.

realistic estimation of the impact of an arc selection on uncompleted high-order structures in the partial parse forest, it is not competitive with state of the art approximations. We hence present an advanced version of our algorithm with an improved arc score formulation and show that this simple algorithm provides high quality solutions to the graph-based inference problem (Section 4).

Particularly, we implement the algorithm within the TurboParser (Martins et al., 2013) and experiment (Sections 8 and 9) with the datasets of the CoNLL 2006-2007 shared tasks on multilingual dependency parsing (Buchholz and Marsi, 2006; Nilsson et al., 2007). On average across languages our parser achieves UAS scores of 87.78% and 89.25% for first and second order parsing respectively, compared to respective UAS of 87.98% and 90.26% achieved by the original TurboParser.

We further implement (Section 6) an ensemble method that integrates information from the output tree of the original TurboParser and the arc weights learned by our variant of the parser into our search algorithm to generate a new tree. This yields an improvement: average UAS of 88.03% and 90.53% for first and second parsing, respectively.

Despite being greedy, the theoretical runtime complexity of our advanced algorithm is not better than the best previously proposed approximations for our problem ($O(n^{k+1})$, for n word sentences and k order parsing, Section 5). In experiments, our algorithms improve the runtime of the TurboParser by a factor of up to 2.41.

The main contribution of this paper is hence in providing a simple, intuitive and easy to implement solution for a long standing problem that has been addressed in past with advanced optimization techniques. Besides the intellectual contribution, we believe this will make high-order graph-based dependency parsing accessible to a much broader research and engineering community as it substantially relaxes the coding and algorithmic proficiency required for the implementation and understanding of parsing algorithms.

2 Problem Formulation

We start with a brief definition of the high order graph-based dependency parsing problem. Given an n word input sentence, an input graph $G = (V, E)$ is defined. The set of vertices is $V = \{0, ..., n\}$, with the $\{1, \ldots, n\}$ vertices representing the words of the sentence, in their order of appearance, and the 0 vertex is a specialized *root* vertex. The set of arcs is $E = \{(u, v) : u \in \{0, ..., n\}, v \in \{1, ..., n\}, u \neq v\}$, that is, the root vertex has no incoming arcs.

We further define a part of order k to be a subset of E of size k, and denote the set of all parts with *parts*. For the special case of $k = 1$ a part is an arc. Different works employed different $parts$ sets (e.g. (Martins et al., 2013; McDonald et al., 2005; Koo and Collins, 2010)). Generally, most *parts* sets consist of arcs connecting vertices either vertically (e.g. $\{(u, v), (v, z)\}$ for $k = 2$) or horizontally (e.g. $\{(u, v), (u, z)\}$, for $k = 2$). In this paper we focus on the parts employed by (Martins et al., 2013), a state-of-the-art parser, but our algorithms are generally applicable for any *parts* set consistent with this general definition.[1]

In graph-based dependency parsing, each part p is given a score $W_p \in \mathcal{R}$. A Dependency Tree (*DT*) T is a subset of arcs for which the following conditions hold: (1) Every vertex, except for the root, has an incoming arc: $\forall v \in V \setminus \{0\} : \exists u \in V s.t. (u, v) \in T$; (2) No vertex has multiple incoming arcs: $\forall (u, u', v) \in V, (u, v) \in T \rightarrow (u', v) \notin T$; and (3) There are no cycles in T. The score of a DT T is finally defined by:

$$score(T) = \sum_{part \subseteq T} W_{part}$$

The inference problem in this model is to find the highest scoring DT in the input weighted graph.

3 Basic Greedy Inference

We start with a basic greedy algorithm (Algorithm 1), analyze the approximation it provides for the graph-based objective and its inherent limitations.

[1] More generally, a part is defined by two arc subsets, A and B, such that a part p belongs to a tree T if $\forall e \in A : e \in T$ and $\forall e \in B : e \notin T$. In this paper we assume $B = \phi$. Hence, we cannot experiment with the third order TurboParser as in all its third order parts $B \neq \phi$. Also, when we integrate our algorithms into the second order TurboParser we omit the nextSibling part for which $B \neq \phi$. For the original TurboParser to which we compare our results, we do not omit this part as it improves the parser's performance.

Algorithm 1 maintains a *partial tree* data structure, T^i, to which it iteratively adds arcs from the input graph G, one in each iteration, until a dependency tree T^n is completed. For this end, in every iteration, i, a value, v_e^i, composed of $loss_e^i$ and $gain_e^i$ terms, is computed for every arc $e \in E$ and the arc with the lowest v_e^i value is added to T^{i-1} to create the extended partial tree T^i.

Due to the aforementioned conditions on the induced dependency tree, every arc that is added to T^{i-1} yields a set of *lostArcs* and *lostParts* that cannot be added to the partial tree in subsequent iterations. The loss value is defined to be:

$$loss_e^i := \sum_{part \in lostParts} W_{part}$$

That is, every part that contains one or more arcs that violate the dependency tree conditions for a tree that extends the partial tree $T^{i-1} \cup \{e\}$ is considered a *lost part* as it will not be included in any tree extending $T^{i-1} \cup \{e\}$. The loss value sums the weights of these parts.

Likewise, the gain value is the sum of the weights of all the parts that are added to T^{i-1} when we add e to it. Denote this set of parts with $P_e := \{part : part \subseteq T^{i-1} \cup \{e\}, part \notin T^{i-1}\}$, then:

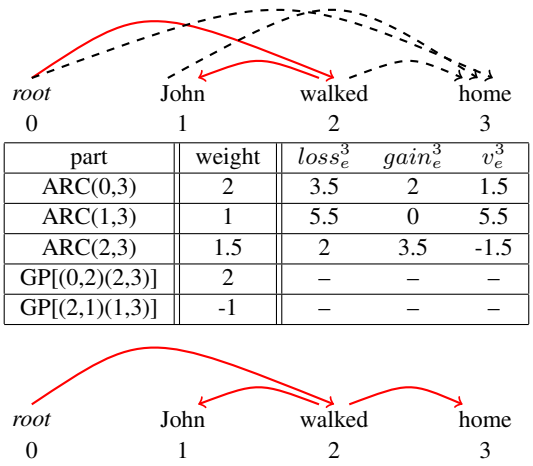
$$gain_e^i := \sum_{part \in P_e} W_{part}$$

Finally, v_e^i is given by:

$$v_e^i = loss_e^i - gain_e^i$$

After the arc with the minimal value v_e^i is added to T^{i-1}, the arcs that violate the structural constraints on dependency trees are removed from G.

An example of an update iteration of the algorithm (lines 3-16) is given in Figure 1. In this example we consider two types of parts: first-order, arc, parts (ARC) and second-order grandparent parts (GP), consisting of arc pairs, $\{(g,u),(u,v)\}$. The upper graph shows the partial tree T^2 (solid arcs) as well as the rest of the graph G (dashed arcs). The parts included in T^2 are ARC(0,2), ARC(2,1) and GP[(0,2),(2,1)]. The table contains the weights of the parts and the values computed for the arcs during the third iteration. The arc that is chosen is (2,3), as it has the minimal v_e^3 value. Thus, in the bottom



part	weight	$loss_e^3$	$gain_e^3$	v_e^3
ARC(0,3)	2	3.5	2	1.5
ARC(1,3)	1	5.5	0	5.5
ARC(2,3)	1.5	2	3.5	-1.5
GP[(0,2)(2,3)]	2	–	–	–
GP[(2,1)(1,3)]	-1	–	–	–

Figure 1: An example of an iteration of Algorithm 1 (lines 3-16)). See description in text.

graph that corresponds to T^3 all other incoming arcs to vertex 3 are removed. (in this instance there are no cycle forming arcs).

Analysis We now turn to an analysis of the relaxation that Algorithm 1 provides for the global graph-based objective. Recall that our objective in iteration i is: $v_{e^i}^i = min\{v_e^i\}$. For the inferred tree T^n it holds that:

$$\sum_{e^i \in T^n} v_{e^i}^i - \sum_{part \subseteq G} W_{part} =$$

$$\sum_{part \nsubseteq T^n} W_{part} - \sum_{part \subseteq T^n} W_{part} - \sum_{part \subseteq G} W_{part} =$$

$$-2 \times \sum_{part \subseteq T^n} W_{part} + \sum_{part \nsubseteq T^n} W_{part} - \sum_{part \nsubseteq T^n} W_{part} =$$

$$-2 \times \sum_{part \subseteq T^n} W_{part}$$

The first equation holds since $\sum_{e^i \in T^n} v_{e^i}^i$ is the sum of all lost parts (parts that are not in T^n) minus all the gained parts (parts in T^n). Each of these parts was counted exactly once: when the part was added to the partial tree or when one of its arcs was removed from G. The second equation splits the term of $\sum_{part \subseteq G} W_{part}$ to two sums, one over parts in T^n and the other over the rest. Since $\sum_{part \subseteq G} W_{part}$ and 2 are constants, we get:

$$\arg\min_{T^n}(-\sum_{part \subseteq T^n} W_{part}) = \arg\min_{T^n} \sum_{e^i \in T^n} v_{e^i}^i$$

From this argument it follows that our inference algorithm performs sequential greedy optimization over the presented factorization of the graph-based

objective instead of optimizing the sum of terms, and hence the objective, globally.

The main limitation of Algorithm 1 is that it does not take into account high order parts contribution until the part is actually added to T. For example, in Figure 1, when the arc $(2,1)$ is added, the part GP[(2,1),(1,3)] is getting closer to completion. Yet, this is not taken into account when considering whether $(2,1)$ should be added to the tree or not. Including this information in the gain and loss values of an arc can improve the accuracy of the algorithm, especially in high-order parsing.

Algorithm 1 Basic Greedy Inference

1: $T^0 = \{\}$
2: **for** $i \in 1..n$ **do**
3: **for** $e = (u, v) \in E$ **do**
4: $P_e := \{part \in parts : part \subseteq T^{i-1} \cup \{e\}, part \nsubseteq T^{i-1}\}$
5: $gain_e^i := \sum_{part \in P_e} W_{part}$
6: $incomingSet := \{(u', v) \in E : u' \neq u\}$
7: $cycleSet := \{(u', v') \in E : T^{i-1} \cup \{e\} \cup (u', v')\ contains\ a\ cycle\}$
8: $lostArcs = (incomingSet \cup cycleSet)$
9: $lostParts = \{part : \exists e \in lostArcs \cap part\}$
10: $loss_e^i := \sum_{part \in lostParts} W_{part}$
11: $v_e^i := loss_e^i - gain_e^i$
12: **end for**
13: $e^i = (u^i, v^i) = \arg\min_{e'}\{v_{e'}^i\}$
14: $T^i = T^{i-1} \cup \{e^i\}$
15: remove from G all incoming arcs to v^i
16: remove from G all cycle forming arcs w.r.t T^i
17: **end for**

4 Greedy Inference with Partial Part Predictions

In order for the algorithm to account for information about partial high order parts, we estimate the probability that such parts would be eventually included in T^n. Our way to do this (Algorithm 2) is by estimating these probabilities for arcs and from these derive parts probabilities.

Particularly, for the set of incoming arcs of a vertex v, $E_v = \{e = (u, v) : e \in E\}$, a probability measure p_e is computed according to:

$$p_{e=(u,v)} = \frac{exp^{\alpha \times W_e}}{\sum_{e'=(u',v)} exp^{\alpha \times W_{e'}}}$$

Where α is a hyper parameter of the model. For $\alpha = 0$ we get a uniform distribution over all possible heads of a vertex v, and for large α values arcs with larger weights get higher probabilities.

Algorithm 2 Greedy Inference with Partial Part Predictions

1: $T^0 = \{\}$
2: **for** $i \in 1..n$ **do**
3: **for** $e = (u, v) \in E$ **do**
4: $P_e := \{part \in parts : e \in part\}$
5: $gain_e^i := \sum_{part \in P_e} W_{part} \times p_{part}|(T^{i-1} \cup \{e\})$
6: $incomingSet := \{(u', v) \in E : u' \neq u\}$
7: $cycleSet := \{(u', v') \in E : T^{i-1} \cup \{e\} \cup (u', v')\ contains\ a\ cycle\}$
8: $lostArcs = (incomingSet \cup cycleSet)$
9: $lostParts = \{part : \exists e \in lostArcs \cap part\}$
10: $loss_e^i := \sum_{part \in lostParts} W_{part} \times p_{part}|T^{i-1}$
11: $v_e^i := \beta \times loss_e^i - (1 - \beta) \times gain_e^i$
12: **end for**
13: $e^i = (u^i, v^i) = \arg\min_{e'}\{v_{e'}^i\}$
14: $T^i = T^{i-1} \cup \{e^i\}$
15: remove from G all incoming arcs to v^i
16: remove from G all cycle forming arcs w.r.t T^i
17: **end for**

The intuition behind this measure is that arcs mostly compete with other arcs that have the same target vertex and hence their weight should be normalized accordingly. Using this measure, we define the arc-factored probability of a part to be:

$$p_{part} = \prod_{e \in part} p_e$$

And the residual probability of a part given an existing partial tree T:

$$p_{part}|T = \frac{p_{part}}{\prod_{e \in (part \bigcap T)} p_e}$$

These probability measures are used in both the gain and the loss computations (lines 5 and 10 in Algorithm 2) as follows:

$$gain_e^i := \sum_{part: e \in part} W_{part} \times p_{part}|(T^{i-1} \cup \{e\})$$

$$loss_e^i := \sum_{part \in lostParts} W_{part} \times p_{part}|T^{i-1}$$

Finally, as adding an arc to the dependency subtree results in an exclusion of several arcs, the number of lost parts is also likely to be much higher than the number of gained parts. In order to compensate for this effect, we introduce a balancing

hyper-parameter, $\beta \in [0,1]$, and change the computation of v_e^i (line 10 in Algorithm 2) to be: $v_e^i := \beta \times loss_e^i - (1-\beta) \times gain_e^i$.

5 Runtime Complexity Analysis

In this section we provide a sketch of the runtime complexity analysis of the algorithm. Full details are in appendix A. In what follows, we denote the maximal indegree of a vertex with n_{in}.

Algorithm 1 Algorithm 1 consists of two nested loops (lines 2-3) and hence lines 4-11 are repeated $O(n \times |E|) = O(n \times n \times n_{in})$ times. At each repetition, loss (lines 6-10) and gain (lines 4-5) values are computed. Afterwards the graph's data structures are updated (lines 13-16). We define data structures (DSs) that keep our computations efficient. With these DSs the total runtime of lines 4-11 is $O(n_{in} + min\{n_{in}^{k-1}, n_{in}^2\})$. The DSs are initialized in $O(|parts| \times k)$ time and their total update time is $O(k \times |parts|) = O(n_{in}^{k+1})$. Thus algorithm 1 runs in $O(|parts| \times k + n^2 \times n_{in} \times (n_{in} + min\{n_{in}^{k-1}, n_{in}^2\}))$ time.

Algorithm 2 Algorithm 2 is similar in structure to Algorithm 1. The enhanced loss and gain computations take $O(n_{in} + min\{n_{in}^{k-1}, n_{in}^2\})$ time. The initialization of the DSs takes $O(|parts| \times k)$ time and their update time is $O(n_{in}^k \times k^2)$. The total runtime of Algorithm 2 is $O(n_{in}^{k+1} \times k + n \times (n \times n_{in} \times (n_{in} + min\{n_{in}^2, n_{in}^{k-1}\}) + n_{in}^k \times k^2))$. For unpruned graphs and $k \geq 2$ this is equivalent to $O(n^{k+1})$, the theoretical runtime of the TurboParser's dual decomposition inference algorithm.

6 Error Propagation

Unlike modern approximation algorithms for our problem, our algorithm is greedy and deterministic. That is, in each iteration it selects an arc to be included in its final dependency tree and this decision cannot be changed in subsequent iterations. Hence, our algorithm is likely to suffer from error-propagation. We propose two solutions to this problem described within Algorithm 2.

Beam search In each iteration (lines 3-16) the algorithm outputs its $|B|$ best solutions to be subsequently considered in the next iteration. That is, lines 4-10 are performed $|B|$ times for each edge $e \in E$, one for each of the $|B|$ partial solutions in the beam, $b^j \in B$. For each such solution, we denote its weight, as calculated by the previous iteration of the algorithm with $beamVal_{b^j}$. When evaluating v_e^i for an arc e with respect to b^j (line 11), we set $v_e^{i,j} = beamVal_{b^j} + \beta \times loss_e^i - (1-\beta) \times gain_e^i$.

Post-search improvements After Algorithm 2 is executed, we perform s iterations of local greedy arc swaps. That is, for every vertex v, s.t. $(u,v) \in T^n$, we try to switch the arc (u,v) with the arc (u',v) as follows. Let T_v^n be the sub tree that is rooted at v, we distinguish between two cases:
(1) If $u' \notin T_v^n$ then $T^n = T^n \setminus \{(u,v)\} \cup \{(u',v)\}$.
(2) If $u' \in T_v^n$ then let w be the first vertex on the path from v to u' (if $(v,u') \in T$ then $w = u'$): $T^n = T^n \setminus \{(u,v),(v,w)\} \cup \{(u',v),(u,w)\}$.

After inspecting all possible substitutions, we choose the one that yields the best increase in the tree score (if such a substitution exists) and perform the substitution.

7 Parser Combination

In our experiments (see below), we implemented our algorithms within the TurboParser so that each of them, in turn, serves as its inference algorithm. In development data experiments with Algorithm 2 we found that for first order parsing, both our algorithm and the TurboParser predict on average over all languages around 1% of the gold arcs that are not included in the output of the other algorithm. For second order parsing, the corresponding numbers are 1.75% (for gold arcs in the output of our algorithm but not of the original TurboParser) and 4.3% (for the other way around). This suggests that an ensemble method may improve upon both parsers.

We hence introduce a variation of Algorithm 2 that accepts a dependency tree T_o as an input, and biases its output towards that tree. As different parsers usually generate weights on different scales, we do not directly integrate part weights. Instead, we change the weight of each part $part \subseteq T_o$ of order j, to be $W_{part} = W_{part} + \gamma_j$, where γ_j is an hyperparameter reflecting our belief in the prediction of the other parser on parts of order j. The change is applied only at test time, thus integrating two pre-trained parsers.

8 Experimental Setup

We implemented our algorithms within the TurboParser (Martins et al., 2013)[2]. That is, every other aspect of the parser – feature set, pruning algorithm, cost-augmented MIRA training (Crammer et al., 2006) etc., is kept fixed but our algorithms replace the inference algorithms: Chu-Liu-Edmonds ((Edmonds, 1967), first order) and dual-decomposition (higher order). We implemented two variants, for algorithm 1 and 2 respectively, and compare their results to those of the original TurboParser.

We experiment with the datasets of the CoNLL 2006 and 2007 shared task on multilingual dependency parsing (Buchholz and Marsi, 2006; Nilsson et al., 2007), for a total of 17 languages. When a language is represented in both sets, we used the 2006 version. We followed the standard train/test split of these datasets and, for the 8 languages with a training set of at least 10000 sentences, we randomly sampled 1000 sentences from the training set to serve as a development set. For these languages, we first trained the parser on the training set and then used the development set for hyperparameter tuning ($|B|$, s, α, β, and $\gamma_1, \ldots, \gamma_k$ for k order parsing).[3][4]

We employ four evaluation measures, where every measure is computed per language, and we report the average across all languages: (1) Unlabeled Attachment Score (UAS); (2) Undirected UAS (U-UAS) - for error analysis purposes; (3) Shared arcs (SARC) - the percentage of arcs shared by the predictions of each of our algorithms and of the original TurboParser; and (4) Tokens per second (TPS) - for ensemble models this measure includes the TurboParser's inference time.[5] We also report a *gold(x,y) = (a,b)* measure: where a is the percentage of gold standard arcs included in trees produced by algorithm x but not by y, and b is the corresponding number for y and x. We consider two setups.

Fully Supervised Training In this setup we only consider the 8 languages with a development set. For each language, the parser is trained on the training set and then the hyperparameters are tuned. First we set the beam size ($|B|$) and number of improvement iterations (s) to 0, and tune the other hyperparameters on the language-specific development set. Then, we tune $|B|$ and s, using the optimal parameters of the first step, on the English dev. set.

Minimally Supervised Training Here we consider all 17 languages. For each language we randomly sampled 20 training sets of 500 sentences from the original training set, trained a parser on each set and tested on the original test set. Results for each language were calculated as the average over these 20 folds. The hyper parameters for all languages were tuned once on the English development set to the values that yielded the best average results across the 20 training samples.

9 Results

Fully Supervised Training Average results for this setup are presented in table 1 (top). Unsurprisingly, UAS for second order parsing with basic greedy inference (Algorithm 1, BGI) is very low, as this model does not take information about partial high order parts into account in its edge scores. We hence do not report more results for this algorithm.

The table further reflects the accuracy/runtime tradeoff provided by Algorithm 2 (basic greedy inference with partial part predictions, BGI-PP): a UAS degradation of 0.34% and 2.58% for first and second order parsing respectively, with a runtime improvement by factors of 1.01 and 2.4, respectively. Employing beam search and post search improvements (BGI-PP+i+b) to compensate for error propagation improves UAS but harms the runtime gain: for example, the UAS gap in second order parsing is 1.01% while the speedup factor is 1.43.

As discussed in footnote 1 and Section 11, our algorithm does not support the third-order parts of the TurboParser. However, the average UAS of the third-order TurboParser is 90.62% (only 0.36% above second order TurboParser) and its TPS is 72.12 (almost 5 times slower).

The accuracy gaps according to UAS and undirected UAS are similar, indicating that the source

(b) The minimally supervised setup.

Table 1: Results for the fully supervised (top table) and minimally supervised (bottom table) setups. The left column section of each table is for individual models while the right column section is for ensemble models (Section 7). BGI-PP is the basic greedy inference algorithm with partial part predictions, +i indicates post-search improvements and +b indicates beam search (Section 6). The Tokens per Second (TPS) measure for the ensemble models reports the additional inference time over the TurboParser inference. All scores are averaged across individual languages.

of differences between the parsers is not arc directionality. The percentage of arcs shared between the parsers increases with model complexity but is still as low as 94.79% for BGI-PP+i+b in second order parsing. In this setup, gold(BGI-PP+i+b, TurboParser) = (1.6%,2.6%) which supports the development data pattern reported in Section 6 and further justifies an ensemble approach.

The right column section of the table indeed shows consistent improvements of the ensemble models over the TurboParser for second order parsing: the ensemble models achieve UAS of 90.5-90.53% compared to 90.26% of the TurboParser. Naturally, running the TurboParser alone is faster by a factor of 1.67. Like for the individual inference algorithms, the undirected UAS measure indicates that the gain does not come from arc directionality improvements. The ensemble methods share almost all of their arcs with the TurboParser, but in cases of disagreement ensembles tend to be more accurate.

Table 2 complements our results, providing UAS values for each of the 8 languages participating in this setup. The UAS difference between BGI+PP+i+b and the TurboParser are (+0.24)-(-0.71) in first order parsing and (+0.18)-(-2.46) in second order parsing. In the latter case, combining these two models (BGI+PP+i+b+e) yields improvements over the TurboParser in 6 out of 8 languages.

Minimally Supervised Training Results for this setup are in table 1 (bottom). While result patterns are very similar to the fully supervised case, two observations are worth mentioning. First, the percentage of arcs shared by our algorithms and the original parser is much lower than in the fully supervised case. This is true also for shared gold arcs: gold(BGI-PP+b+i,TurboParser) = (4.86%,5.92%) for second order parsing. This suggests that more sophisticated ensemble techniques may be useful in this setup.

Second, ensemble modeling improves UAS over the TurboParser also for first order parsing, leading to a gain of 0.3% in UAS for the BGI+i+b ensemble (79.29% vs. 78.99%). As the percentage of shared arcs between the ensemble models and the TurboParser is particularly low in first order parsing, as well as the shared gold arcs

Table 2: Per language UAS for the fully supervised setup. Model names are as in Table 1, 'e' stands for ensemble. Best results for each language and parsing model order are highlighted in bold.

(gold(BGI+i+b,TurboParser) = (4.98%,5.5%)), improving the ensemble techniques is a promising future research direction.

10 Related Work

Our work brings together ideas that have been considered in past, although in different forms.

Greedy Inference Goldberg and Elhadad (2010) introduced an easy-first, greedy, approach to dependency parsing. Their algorithm adds at each iteration the best candidate arc, in contrast to the left to right ordering of standard transition based parsers. This work is extended at (Tratz and Hovy, 2011; Goldberg and Nivre, ; Goldberg and Nivre, 2013).

The easy-first parser consists of a feature set and a specialized variant of the structured perceptron training algorithm, both dedicated to greedy inference. In contrast, we show that a variant of the TurboParser that employs Algorithm 2 for inference and is trained with its standard global training algorithm, performs very similarly to the same parser that employs dual decomposition inference.

Error Propagation in Deterministic Parsing Since deterministic algorithms are standard in transition-based parsing, the error-propagation problem has been dealt with in that context. Various methods were employed, with beam search being a prominent idea (Sagae and Lavie, 2006; Titov and Henderson, 2007; Zhang and Clark, 2008; Huang et al., 2009; Zhang and Nivre, 2011; Bohnet and Nivre, 2012; Choi and McCallum, 2013b, inter alia).

Post Search Improvements Several previous works employed post-search improvements techniques. Like in our case, these techniques improve the tree induced by an initial, possibly more principled, search technique through local, greedy steps.

McDonald and Pereira (2006) proposed to approximate high-order graph-based non-projective parsing, by arc-swap iterations over a previously induced projective tree. Levi et al. (2016) proposed a post-search improvements method, different than ours, to compensate for errors of their graph-based, undirected inference algorithm. Finally, Zhang et al. (2014a) demonstrated that multiple random initialization followed by local improvements with respect to a high-order parsing objective result in excellent parsing performance. Their algorithm, however, shouldbhhb employ hundreds of random initializations in order to provide state-of-the-art results.

Ensemble Approaches Finally, several previous works combined dependency parsers. These include Nivre and McDonald (2008) who used the output of one parser to provide features for another, Zhang and Clark (2008) that proposed a beam-search based parser that combines two parsers into a single system for training and inference, and Martins et al. (2008) that employed stacked learning, in which a second predictor is trained to improve the performance of the first. Our work complements these works by integrating information from a pre-trained TurboParser in our algorithm at test time only.

11 Discussion

We presented a greedy inference approach for graph-based, high-order, non-projective dependency parsing. Our experiments with 17 languages show that our simple and easy to implement algorithm is a decent alternative for dual-decomposition inference.

A major limitation of our algorithm is in-

cluding information from parts that require a given set of arcs *not* to be included in the dependency tree (footnote 1). For example, the $nextSibling((1,2),(1,5))$ part of the TurboParser would fire *iff* the tree includes the arcs $(1,2)$ and $(1,5)$ but not the arcs $(1,3)$ and $(1,4)$.

In order to account for such parts, we should decide how to compute their probabilities and, additionally, at which point they are considered part of the tree. We explored several approaches, but failed to improve our results. Hence, we did not experiment with the third-order TurboParser as all of its third-order parts contain "non-included" arcs. This is left for future work.

A Runtime Complexity Analysis

Here we analyze the complexity of our algorithms, denoting the maximal indegree of a vertex with n_{in}.

Algorithm 1 Algorithm 1 consists of two nested loops (lines 2-k3) and hence lines 4-11 are repeated $O(n \times |E|) = O(n \times n \times n_{in})$ times. At each repetition, loss (lines 6-10) and gain (lines 4-5) values are computed. Afterwards the graph's data structures are updated (lines 13-16).

For every arc that we examine (line 3), there are $O(n_{in})$ *lost* arcs, as there are $O(n_{in})$ incoming arcs (set 1) and $O(n_{in})$ cycles to break (set 2). Since every lost arc translates to a set of *lost parts*, we can avoid repeating computations by storing the partial loss of every arc in a data structure (DS): $e \rightarrow \sum_{part:e \in part} w_{part}$. Now, instead of summing all the lost parts, (every edge participates in $O(n_{in}^{k-1})$ parts,[6] thus there are $O(n_{in}^{k})$ lost parts per added arc), we can sum only $O(n_{in})$ partial loss values. However, since some lost parts may contain an arc from set 1 and an arc from set 2, we need to subtract the values that were summed twice, this can be done in $O(min\{n_{in}^{k-1}, n_{in}^{2}\})$ time by holding a second DS: $e_1 \times e_2 \rightarrow \sum_{part:e_1 \in part \wedge e_2 \in part} w_{part}$.[7]

In order to efficiently compute the gain values, we hold a mapping from arcs to the sum of weights of parts that can be completed in the current iteration by adding the arc to the tree. With this DS, gain values can be computed in constant time. In total, the runtime of lines 4-11 is $O(n_{in} + min\{n_{in}^{k-1}, n_{in}^{2}\})$.

The DSs are initialized in $O(|parts| \times k)$ time. Since every part is deleted at most once, and gets updated (its arcs are added to the tree) at most k times, the total DS update time is $O(k \times |parts|) = O(n_{in}^{k+1})$. Thus algorithm 1 runs in $O(|parts| \times k + n^2 \times n_{in} \times (n_{in} + min\{n_{in}^{k-1}, n_{in}^{2}\}))$ time.

Algorithm 2 Algorithm 2 is similar in structure to Algorithm 1 but the loss and gain computations are more complex. To facilitate efficiency, we hold two DSs: (a) a mapping from arcs to the sum of *lost parts* values, which are now $w_{part} \times P_{part}$ for $part \in parts$; and (b) a mapping from arc pairs to the sum of part values for parts that contain both arcs. The loss and gain values can be computed, as above, in $O(n_{in} + min\{n_{in}^{k-1}, n_{in}^{2}\})$ time.

The initialization of the DSs takes $O(|parts| \times k)$ time. In the i-th iteration we add $e = (u, v)$ to T^i, and remove the $lostArcs$ from E. Every lost arc participates in $O(n_{in}^{k-1})$ parts, and we need to update $O(k)$ entries for each lost part in DS(a) (as the value of the other arcs of that part should no longer account for that part's weight) and $O(k^2)$ entries in DS (b). Thus, the total update time of the DSs is $O(n_{in}^{k} \times k^2)$ and the total runtime of Algorithm 2 is $O(n_{in}^{k+1} \times k + n \times (n \times n_{in} \times (n_{in} + min\{n_{in}^{2}, n_{in}^{k-1}\}) + n_{in}^{k} \times k^2))$. For unpruned graphs and $k \geq 2$ this is equivalent to $O(n^{k+1})$, the theoretical runtime of the TurboParser's dual decomposition inference algorithm.

Generating Abbreviations for Chinese Named Entities Using Recurrent Neural Network with Dynamic Dictionary

Abstract

Chinese named entities occur frequently in formal and informal environments. Various approaches have been formalized the problem as a sequence labelling task and utilize a character-based methodology, in which character is treated as the basic classification unit. One of the main drawbacks of these methods is that some of the generated abbreviations may not follow the conventional wisdom of Chinese. To address this problem, we propose a novel neural network architecture to perform task. It combines recurrent neural network (RNN) with an architecture determining whether a given sequence of characters can be a word or not. For demonstrating the effectiveness of the proposed method, we evaluate it on Chinese named entity generation and opinion target extraction tasks. Experimental results show that the proposed method can achieve better performance than state-of-the-art methods.

1 Introduction

Abbreviations of Chinese named entities are frequently used on different kinds of environments. Along with the development of social media, this kinds of circumstance occurs more frequently. Unlike western languages such as English, Chinese does not insert spaces between words or word forms that undergo morphological alternations. Hence, most of the Chinese natural language processing methods assume a Chinese word segmenter is used in a pre-processing step to produce word-segmented Chinese sentences as input. However, if the Chinese word segmenter produces erroneous output, the quality of these methods will be degraded as a direct result. Moreover, since the word segmenter may split the targets into two individual words, many methods adopted character-based methodologies, such as methods for named entity recognition (Wu et al., 2005), aspect-based opinion mining (Xu et al., 2014), and so on.

Through character-based methodology, most of the previous abbreviation generation approaches have been formalized as sequence labelling problem. Chinese characters are treated as the basic classification unit and are classified one by one. In these methods, dictionaries play important effect in constructing features and avoiding meaningless outputs. Various previous works have demonstrated the significant positive effectiveness of the external dictionary (Zhang et al., 2010). However, because these external dictionaries are usually static and pre-constructed, one of the main drawbacks of these methods is that the words which are not included in the dictionaries cannot be well processed. This issue has also been mentioned by numerous previous works (Peng et al., 2004; Liu et al., 2012).

Hence, understanding how Chinese words are constructed can benefit a variety of Chinese NLP tasks to avoid meaningless output. For example, to generate the abbreviation for a named entity, we can use a binary classifier to determine whether a character should be removed or retained. Both "国航" and "中国国航" are appropriate abbreviations for "中国国际航空公司(Air China)". However "国航司" is not a Chinese word and cannot be understood by humans.

Austin, Texas, November 1-5, 2016.

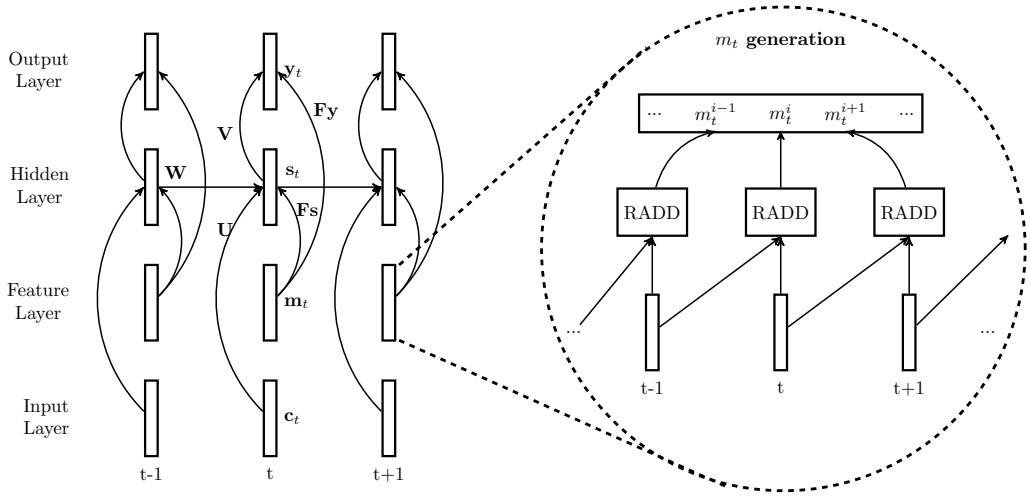

Figure 1: The architecture of RNN with dynamic dictionary.

Thus we are motivated to study the task of "*dynamic dictionary*" and integrating it with sequence labelling model to perform the abbreviation generation task. Dynamic dictionary denotes a binary classification problem which tries to determine whether or not a given sequence of characters is a word. Although human can use implicit knowledge to easily recognize whether an unseen text segment is a word or not at first glance, the task is not as easy as it may seem. First, Chinese has a different morphological system from English. Each Chinese character represents both a syllable and a morpheme (McBride-Chang et al., 2003). Hence, Chinese script is sometimes described as being morphosyllabic. Second, there are many homophones in Chinese. This means that characters that have very different written forms may sound identical. Third, there are a huge number of Chinese words. Without taking the implicit knowledge of morphology into consideration, an arbitrary sequence of characters can be used as a name. In Mandarin, there are approximately 7,000 characters in daily use. Hence, determining whether a given sequence of characters is a word or not is an challenging task.

Since the length of Chinese words is variable, in this paper, we propose a modified recurrent architecture to model the dynamic dictionary construction task. For processing sequence labelling tasks, we also combine the proposed method with RNN. Since the proposed dynamic dictionary model can be pre-trained independently with extensive domain independent dictionaries, the combined model can be easily used in different domains. The proposed model can take advantage of both the sequence-level discrimination ability of RNN and the ability of external dictionary.

The main contributions of this work can be summarized as follows:

- We define the dynamic dictionary problem and construct a large dataset, which consists of more than 20 million words for training and evaluation.
- We integrate RNN with a deep feedforward network based dynamic dictionary learning method for processing Chinese NLP tasks which are formalized as sequence labelling tasks.
- Experimental results demonstrate that the accuracy of the proposed method can achieve better results than current state-of-the-arts methods on two different tasks.

2 Model Architecture

2.1 Dynamic Dictionary

The task of dynamic dictionary is to predict whether a given sequence of characters can be a word or not. The input is a text segment, which contains a variable number of characters. The output is an

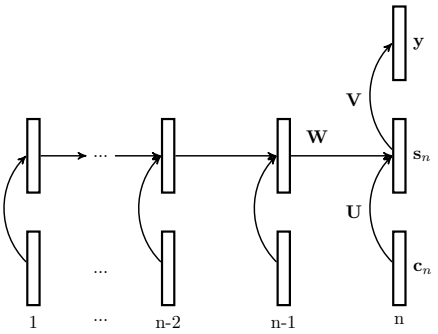

Figure 2: The recurrent architecture used in this work for modelling dynamic dictionary (RADD).

binary value. It is different from the traditional sequence classification tasks, whose the number of outputs are usually same as the input. However, the information of the whole sequence is an important factor and should be incorporated. Hence, in this work, we use a modified recurrent architecture (RADD is used to represent the network in the following literature for short), which is shown in Fig.2.

In Fig.2, n represents the number of characters of the input text segment. c_k represents input character at time k encoded using embeddings of characters through table lookup. The hidden layer s_k maintains the past and current information. The hidden activations of the last step s_n could be considered as the representation of the whole text segment. s_n is used as the input to the classification layer. y produces a probability distribution over the binary labels. Each layer is also represents a set of neurons. Layers are also connected with weights denoted by the matrices $\mathbf{U}$, $\mathbf{W}$, and $\mathbf{V}$. The values in the hidden and output layers are calculated as follows:

$$\begin{aligned} \mathbf{s}_k &= f(\mathbf{U}c_k + \mathbf{W}s_{k-1}) \\ \mathbf{y} &= f(\mathbf{V}s_n) \end{aligned} \tag{1}$$

where $f(\cdot)$ is sigmoid activation function $f(z) = \frac{1}{1+exp^{-z}}$. The architecture can be unfolded as a deep feedforward network.

We define all the parameters for the stage of modelling dynamic dictionary to be trained as $\theta = (W, U, V)$. Given an input text segment, the network with parameter θ outputs the probability, $p(1|x, \theta)$, of the given text segment can be a word or not. Cross entropy criterion is used as the loss function O of the binary classification problem. The network is trained by stochastic gradient descent using *backpropagation through time* (BPTT) (Werbos, 1990). The hidden layer activation of position i at time t, $\mathbf{s}_t^i$, is:

$$\mathbf{s}_t^i = f(a_t^i), \tag{2}$$

$$a_t^i = \sum_j u_{ij} c_t^j + \sum_l w_{il} s_{t-1}^l. \tag{3}$$

The error firstly propagates from output layer to hidden layer of last time step N. The derivatives with respect to the hidden active of position i at the last time step N can be calculated as follows:

$$\delta_N^i = f'(a_N^i) \frac{\partial O}{y} v^i, \tag{4}$$

where v^i represents the weight of hidden-output connection and the activation of the output layer y. The gradients of hidden layer of previous time steps can be recursively computed as:

$$\delta_t^i = f'(a_t^i) \sum_j \delta_{t+1}^j w_{ij}. \tag{5}$$

Given all (suppose the number is T) the training examples (x_i, y_i), we can then define the objective function as follows:

$$J(\theta) = \sum_{i=1}^{T} logp(y^{(i)}|x^{(i)}, \theta). \tag{6}$$

To compute the network parameter θ, we maximize the log likelihood $J(\theta)$ through stochastic gradient decent over shuffled mini-batches with the Adadelta(Zeiler, 2012) update rule.

2.2 RNN-RADD

As mentioned in the previous section, features extracted from external dictionary have been empirically proved to be useful for Chinese NLP various tasks. However, since these external dictionaries are usually pre-constructed, the out-of-vocabulary problem may impact the performance. Hence, we in this work propose to use RNN to determine whether a given sequence of characters is a word or not. Then the proposed RADD is incorporated into RNN (RNN-RADD is used as the abbreviation of the combined model).

2-gram	$c_{t-2}c_{t-1},\ c_{t-2}c_{t-1},\ c_{t-1}c_t$ $c_tc_{t+i},\ c_{t+1}c_{t+2}$
3-gram	$c_{t-2}c_{t-1}c_t,\ c_{t-1}c_tc_{t+1},\ c_tc_{t+1}c_{t+2}$
4-gram	$c_{t-2}c_{t-1}c_tc_{t+1},\ c_{t-1}c_tc_{t+1}c_{t+2}$

Table 1: Illustration of the templates used to generate m_t.

RNN-RADD also follows the character based methodology. Hence, the basic units of RNN-RADD are Chinese characters. The architecture is illustrated in Fig. 1, where c_t denotes the input character at time t encoded using dense distributed representation. The hidden layer s_t also maintains the history of the character sequence. y_t denotes the probability distribution over labels. m_t represents the features generated through RADD. Following previous works, we construct a number of text segments from the contexts of the character based on pre-defined templates. The templates used in this work is shown in the Table. For an input text segment, RADD generates a binary value to indicate whether or not the text segment is a word a not. m_{tj} represents the value of the output corresponding to the jth template for the tth character. Each layer represents a set of neurons. Layers are connected with weights denoted by the matrices $\mathbf{U}$, $\mathbf{W}$, $\mathbf{V}$, $\mathbf{F}_s$, and $\mathbf{F}_y$.

The values in the hidden and output layers in the RNN-RADD can be expressed as follows:

$$\begin{aligned}\mathbf{s}_t &= f(\mathbf{U}c_t + \mathbf{F_s}m_t + \mathbf{W}s_{t-1}), \\ \mathbf{y}_t &= g(\mathbf{V}s_t + \mathbf{F_y}m_t).\end{aligned} \quad (7)$$

Since RAD is trained separately with large scale domain independent dictionaries. In this work, the weight matrices of the RNN-RADD are updated with the similar way as RNN. The error loss function is computed via cross entropy criterion. The parameters are trained by stochastic gradient descent using BPTT. In order to speed up training process, the m_t and character embeddings are keep statistic, during the training procedure.

2.3 Learning Method

Based on the Eq.(3) and Eq.(4), Log-scale objective functions $Q(\theta)$ of RNN-RADD can be calculated as:

$$Q(\theta) = \sum_{t=1}^{T}(\eta a_{y^*_{t-1}y^*_t} + z_t^{y^*_t} - logZ_{R-CRF}).$$

To update the label transition weights, we compute gradients as follows:

$$\begin{aligned}\frac{\partial Q(\theta)}{\partial a_{ji}} &= \eta \sum_t \delta(y_{t-1} = j, y_t = i) \\ &- \eta \sum_t (\frac{\alpha^j_{t-1}\beta^i_t exp(\eta a_{ji} + z^t_i)}{\sum_j \alpha^j_t \beta^j_t}),\end{aligned}$$

where α^i_{t-1} is the sum of partial path scores ending at position $t-1$, with label i, which can be computed as follows:

$$\alpha^i_{t-1} = exp(z^i_{t-1}) \sum_j \alpha^j_{t-2} exp(\eta a_{ji}).$$

β^j_t is the sum of partial path scores starting at position t, with label j and exclusive of observation t, which can be computed as follows:

$$\beta^j_t = \sum_q \beta^q_{t+1} exp(\eta a_{jq} + z^j_{t+1}).$$

The model parameters θ are updated using stochastic gradient ascent (SGA) over the training data multiple passes.

3 Experiments

To demonstrate the effectiveness of the proposed method, we first compared the proposed RNN-based dynamic dictionary construction method against several baseline methods on the task. Then, we evaluated the performance of the proposed method on two Chinese natural language processing tasks: Chinese word segmentation, and opinion target extraction.

3.1 Experimental Settings

To generate the distributed representations for Chinese characters, we use the method similar to Skip-ngram (Mikolov et al., 2013), which has been successfully employed in comparable tasks. However,

in this work, characters were considered the basic units of data, and the toolkit was provided by the authors[1]. We used Sogou news corpus (SogouCA[2]), which consists of news articles belonging to 18 different domains published from June 2012 to July 2012, as the training data to optimize the distributed representations of Chinese characters. After several experiments on development, we decided to set the dimension of the character embedding to 200. Through several evaluations on the validation set, in both RNN-RAD and RAD, the hidden layer size is set to 50.

3.2 Learning Chinese Dynamic Dictionary

For training and testing the proposed dynamic dictionary method, we constructed a dataset by collecting words and names from publicly available resources belonging to different domains, including a Chinese dictionary[3], an English-Chinese bilingual wordlist[4], Baidu Baike[5], the Chinese Domain Dictionary[6], and the Chinese person names list[7]. After removing duplicates, the dataset contains 11,406,995 words in total. Based on the statics of the dictionary we used, about 80.6% of Chinese person names are three characters, and words with two characters comprise the majority of the normal Chinese dictionary. Since some sources contain corporation and organization names, there are also a number of words whose lengths are longer than ten characters. However, in all sources, most of the words are less than five characters.

We randomly selected 50,000 items for use as test data and an additional 50,000 items for use as development data for tuning parameters. In addition to these positive examples, for training and testing, we also needed negative examples, so we extracted bigrams, trigrams, 4-grams, and 5-grams from the SogouCA Then, we randomly extracted a number of n-grams which were not included in the collected word lists described above as negative training data. We treat these n-grams as negative results. For training, testing, and development, we randomly selected 20 million, 50,000, and 50,000 n-grams respectively.

Besides the proposed RADD method, we also evaluated some state-of-the-art supervised methods, including:

Support Vector Machine (SVM) is one of the most common supervised methods and has been successfully used for various tasks (Hearst et al., 1998). Hence, in this work, we also evaluated its performance on the same task. We used the characters as features to construct the vector representation. Since the number of Chinese characters is limited, we used all of the characters existing in the training data. We used LIBSVM to implement (Chang and Lin, 2011).

Conditional Random Fields (CRFs) were proposed by Lafferty et al. (2001) to model sequence labeling tasks. According to the description given in §2.2, an NLP task can be converted into a sequence labeling problem. Hence, we used CRF to model characters as basic features and several combination templates of them. Compared to SVM, CRF takes both richer features and the labeling sequence into consideration. CRF++ 0.58[8] was used to do the experiments.

Dynamic Convolutional Neural Network (DCNN), defined by Kalchbrenner et al. (2014), is used to model sentence semantics. The proposed method can handle input sequences of varying length, so we adopted their method by using the embeddings of characters as input. The toolkit we used in this work is provided by the authors[9].

Recursive Autoencoder (RAE) (Socher et al., 2011), is a machine learning framework for representing variable sized words with a fixed length vector. In this work, we used greedy unsupervised RAE for modeling sequences of Chinese characters. The toolkit was provided by the authors [10]. Then, SVM was used to do the binary classification based on the generated vectors.

Table 3.2 illustrates the results of the different methods on this task. From the results, we see that the proposed method obtains the best perfor-

RADD	**89.74%**	**91.00%**	**90.39%**

Table 2: Comparison of different methods on the dynamic dictionary construction task.

mance among all of the approaches. DCNN, RAE, and RADD outperform SVM and CRF, which use characters as features. One possible reason is that the character representations are more powerful in capturing morphology than characters only. Another advantage of the deep learning framework is that it can be easily trained and makes feature engineering efforts unnecessary.

We also note that although DCNN can capture word relations of varying size in modelling sentences, RADD achieves better performance on the task of learning the morphology of Chinese. One possible interpretation is that although the relations between words in a given sentence can be well captured by DCNN, relations usually exist between nearby characters hence the recurrent network is more appropriate for the task. Moreover, RADD is much easier to implement and is more efficient than DCNN.

Fig. 3 shows the performance of RADD with different character embedding dimensions and hidden layer sizes. From the figure, we see that RADD achieves the best result when the hidden layer size is larger than 200. We also observe that RNN can achieve the highest performance with many different parameters. This means that we can easily find optimal hyper parameters.

3.3 Experimental Results

3.3.1 Abbreviation Generation

The task of generating entity abbreviations involves producing abbreviated equivalents of the original entities. For example, 北大 is an abbreviation of 北京大学 (Peking University). Previous methods usually formulate the task as a sequence labeling problem and model it using character features (Yang et al., 2009; Xie et al., 2011). Although Chen et al. (2013) proposed to use Markov logic networks (MLN) (Richardson and Domingos, 2006) to combine local and global constraints, the morphology of Chinese was rarely considered.

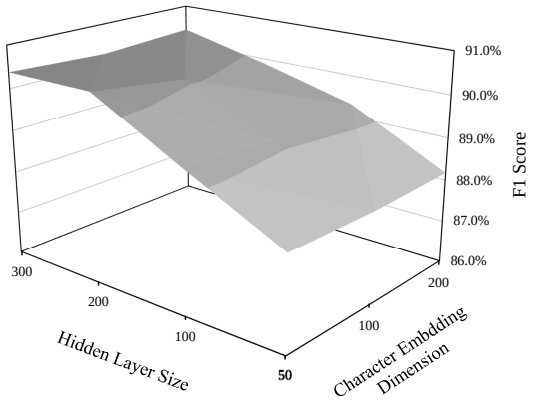

Figure 3: The results of RAD with different character embedding dimension and hidden layer size.

In this work, we report the performance of "RNN-RADD", which takes the dynamic Chinese dictionary into consideration, on the dataset constructed by Chen et al. (2013). The dataset contains 50,232 entity abbreviation pairs. They also reported the performance achieved by their method on the dataset. We follow the strategy used by Chen et al. (2013) to generate training and test data. 75% of randomly selected pairs are used for training data, 5% for development, and the other 20% are used for testing purposes.

For comparison, we also report results achieved by the state-of-the-art methods. Yang et al. (2009) transferred the abbreviation generation method into a sequence labeling problem and proposed to use CRF to model it with several linguistic features. Chen et al. (2013) introduced local and position features and proposed to use MLN to achieve the task. We directly reference and report the results achieved by these methods on the dataset.

Table 3.3.1 shows the relative performances of the different methods. "SVM" and "RNN" denote the results of SVM and RNN on the sequence labeling problem, respectively. From the results, we see that RNN-RADD achieves the best result among all the methods. The relative improvement

Methods	Accuracy
CRFs-Yang (Yang et al., 2009)	39.70%
CRFs-LF+DPF (Chen et al., 2013)	40.60%
MLN (Chen et al., 2013)	56.80%
SVM	40.00%
RNN	60.65%
RNN-RADD	**65.98%**

Table 3: Performance of different methods on abbreviation generation task. CRFs-Yang represents the method and feature sets proposed by Yang et al. (2009). CRF-LF+DPF denotes the local and position features introduced by Chen et al. (2013). MLN represents the method incorporating local and global constraints with MLN.

of it over the previous best result achieved by MLN is about 16.2%. Comparing the performance of RNN-RADD with RNN, we also observe that the dynamic dictionary of Chinese can benefit the abbreviation generation task. The relative improvement is approximately 7.3%.

Fig. 4 shows the values of log-scale objective function of RNN and RNN-RADD during training on the data set. From this figure, we can conclude that the RNN based dynamic dictionary can benefit the task. Although additional feature vector m_i is included, the absolutely value of objective function is lower than its of RNN. It can in some degree demonstrate the effectiveness of the proposed method.

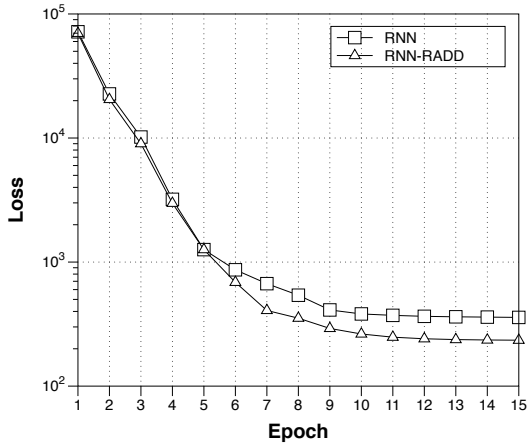

Figure 4: Comparison of RNN and RNN-RADD during training on the abbreviation data set. The vertical axis is the value of log-scale objective functions. Horizontal axis is the number of epochs during training.

	Sentences	Targets
Training	59,786	40,227
Test	11,829	8,034
Development	4,061	2,673

Table 4: Statistics of the dataset used for the opinion target extraction task.

3.3.2 Opinion Target Extraction

Opinion target extraction is a key subtask in the fine-grained opinion mining problem. The goal of it is to identify the items which opinions are expressed on from the given sentences. For example:

The *image quality* of the camera is amazing.

The "*image quality*" is the opinion target of the sentence. Previous methods studied the problem from different perspectives using supervised and unsupervised methods. Syntactic structure constituent is one of the most common assumptions used by previous works (Popescu and Etzioni, 2007; Qiu et al., 2009; Wu et al., 2009; Xu et al., 2014). Since these works usually use character level features, meaningless text segments are one of the major error types. Therefore, we integrate the dynamic Chinese dictionary into this method to detect and discard meaningless text segments.

To evaluate the proposed method, we used a dataset containing more than 6,000 reviews, which contains 75,676 sentences, about vehicles. The opinion target and opinion words were manually labeled. About 80% of the whole dataset is randomly selected for training. 15% and 5% reviews are selected as the test and development datasets respectively. Details of the data are listed in Table 3.3.2.

The task can also be modelled by sequence labelling problem. Hence, besides the proposed RNN-RADD method, we also evaluated some state-of-the-art supervised methods, including: CRF, SVM, and RNN. We used SVM and CRF under the character-based methodology for comparison. RNN is based on the character level embeddings. Table 3.3.2 shows the results of the different methods on the opinion target extraction task. From the results, we can see that, the proposed method RNN-RADD achieve the best performance in F1 score. Comparing the results of RNN with RNN-RADD, we see that the proposed dynamic dictionary

Methods	P	R	F1
CRF	71.1%	77.5%	74.2%
CRF+D	72.5%	74.3%	73.4%
SVM	77.2%	74.9%	76.0%
SVM+D	78.1%	74.3%	76.2%
RNN	79.5%	**81.7%**	80.6%
RNN-RADD	**85.5%**	81.5%	**83.4%**

Table 5: Results of different methods on the opinion target extraction task.

method can benefit the RNN based method. The error reduction achieved by its incorporation is about 11.4%. From the results of CRF and CRF+D, we can observe that dictionary is not always usefulness. We think that the main reason that the dictionary may bring too much conflict. From the results of CRF and RNN, we can see that similar to the Chinese word segmentation task, methods using character dense representations can usually achieve better performance than character based methods.

4 Related Work

Although dictionary can be manually constructed, it is a time-consuming work. Moreover, these manually constructed dictionaries are usually updated only occasionally. It would take months before it could be updated. Hence, automatic dictionary construction methods have also been investigated in recent years. Chang and Su (1997) proposed an unsupervised iterative approach for extracting out-of-vocabulary words from Chinese text corpora. Khoo (Khoo et al., 2002) introduced a method based on stepwise logistic regression to identify two-and three-character words in Chinese text. Jin and Wong (2002) incorporated local statistical information, global statistical information and contextual constraints to identify Chinese words. For collecting Thai unknown words, Haruechaiyasak et al. (2006) proposes a collaborative framework for achieving the task based on Web pages over the Internet.

Except these unsupervised methods, there have been other approaches requiring additional information or selective input. Yarowsky and Wicentowski (2000) proposed to use labeled corpus to train a supervised method for transforming past-tense in English. Rogati et al. (2003) introduced a stemming model based on statistical machine translation for Arabic. They used a parallel corpus to train the model. Luong et al. (2013) studied the problem of word representations for rare and complex words. They proposed to combine recursive neural networks and neural language models to build representations for morphologically complex words from their morphemes. Since English is usually considered limited in terms of morphology, their method can handle unseen words, whose representations could be constructed from vectors of known morphemes.

However, most of the existing Chinese dictionary construction methods focused on find out-of-vocabulary words from corpus. In this paper, we propose to transfer the dictionary construction problem to classification task and use a modified recurrent neutral network to directly model whether a given sequences of characters is a word or not.

5 Conclusion

In this work, we studied the problem of dynamic dictionary which tries to determine whether a sequence of Chinese characters is a word or not. We proposed a deep feed forward network architecture (RADD) to model the problem and integrated it into RNN method. To train the model and evaluate the effectiveness of the proposed method, we constructed a dataset containing more than 11 million words. By applying the proposed combined method to two different Chinese NLP tasks, we can see that it can achieve better performance than state-of-the-art methods. Comparing to the previous methods, the number of hyper parameters of the proposed method RNN-RADD is small and less feature engineering works are needed. In the future, we plan to integrate the dynamic dictionary into the term construction model in information retrieval.

Abstract

Multiple treebanks annotated under heterogeneous standards give rise to the research question of best utilizing multiple resources for improving statistical models. Prior research has focused on discrete models, leveraging stacking and multi-view learning to address the problem. In this paper, we empirically investigate heterogeneous annotations using neural network models, building a neural network counterpart to discrete stacking and multi-view learning, respectively, finding that neural models have their unique advantages thanks to the freedom from manual feature engineering. Neural model achieves not only better accuracy improvements, but also an order of magnitude faster speed compared to its discrete baseline, adding little time cost compared to a neural model trained on a single treebank.

1 Introduction

For many languages, multiple treebanks have been annotated according to different guidelines. For example, several linguistic theories have been used for defining English dependency treebanks, including Yamada and Matsumoto (2003), LTH (Johansson and Nugues, 2007) and Stanford dependencies (De Marneffe et al., 2006). For German, there exist TIGER (Brants et al., 2002) and TüBa-D/Z (Telljohann et al., 2006). For Chinese, treebanks have been made available under various segmentation granularities (Sproat and Emerson, 2003; Emerson, 2005; Xue, 2003). These give rise to the research problem of effectively making use of multiple treebanks under heterogeneous annotations for improving output accuracies (Jiang et al., 2015; Johansson, 2013; Li et al., 2015).

The task has been tackled using two typical approaches. The first is based on *stacking* (Wolpert, 1992; Breiman, 1996; Wu et al., 2003). As shown in Figure 1(a), the main idea is to have a model trained using a source treebank, which is then used to guide a target treebank model by offering source-style features. This method has been used for leveraging two different treebanks for word segmentation (Jiang et al., 2009; Sun and Wan, 2012) and dependency parsing (Nivre and McDonald, 2008; Johansson, 2013).

The second approach is based on *multi-view learning* (Johansson, 2013; Li et al., 2015). The idea is to address both annotation styles simultaneously by sharing common feature representations. In particular, Johansson (2013) trained dependency parsers using the domain adaptation method of Daumé III (2007), keeping a copy of shared features and a separate copy of features for each treebank. Li et al. (2015) trained POS taggers by coupling the labelsets from two different treebanks into a single combined labelset. A summary of such multi-view methods is shown in Figure 1(b), which demonstrates their main differences compared to stacking (Figure 1(a)).

Recently, neural network has gained increasing research attention, with highly competitive results being reported for numerous NLP tasks, including word segmentation (Zheng et al., 2013; Pei et al., 2014; Chen et al., 2015), POS-tagging (Ma et al., 2014; Plank et al., 2016), and parsing (Chen and

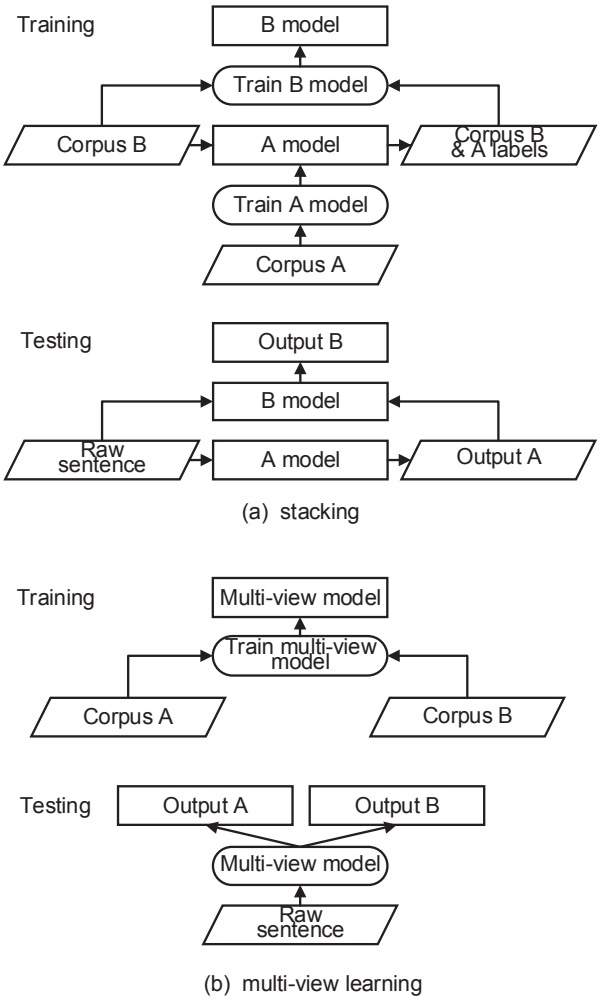

Figure 1: Two main approaches to utilizing heterogeneous annotations.

Manning, 2014; Dyer et al., 2015; Weiss et al., 2015; Zhou et al., 2015). On the other hand, the aforementioned methods on heterogeneous annotations are investigated mainly for discrete models. It remains an interesting research question how effective multiple treebanks can be utilized by neural NLP models, and we aim to investigate this empirically.

We follow Li et al. (2015), taking POS-tagging for case study, using the methods of Jiang et al. (2009) and Li et al. (2015) as the discrete stacking and multi-view training baselines, respectively, and building neural network counterparts to their models for empirical comparison. The base tagger is a neural CRF model (Huang et al., 2015; Lample et al., 2016), which gives competitive accuracies to discrete CRF taggers.

Results show that *neural stacking* allows deeper integration of the source model beyond one-best outputs, and further the fine-tuning of the source model during the target model training. In addition, the advantage of *neural multi-view learning* over its discrete counterpart are many-fold. First, it is free from the necessity of manual cross-labelset interactive feature engineering, which is far from trivial for representing annotation correspondence (Li et al., 2015). Second, compared to discrete model, parameter sharing in deep neural network eliminates the issue of exponential growth of search space, and allows separated training of each label type, in the same way as multi-task learning (Collobert et al., 2011).

Our neural multi-view learning model achieves not only better accuracy improvements, but also an order of magnitude faster speed compared to its discrete baseline, adding little time cost compared to a neural model trained on a single treebank. The C++ implementations of our neural network stacking and multi-view learning models are available under GPL, at `https://github.com/chenhongshen/NNHetSeq`.

2 Baseline Neural Network Tagger

We adopt a neural CRF with a Long-Short-Term-Memory (LSTM) (Hochreiter and Schmidhuber, 1997) feature layer for baseline POS tagger. As shown in Figure 2, the model consists of three main neural layers: the **input layer** calculates dense representation of input words using attention model on character embeddings; the **feature layer** employs a bi-directional LSTM model to extract non-local features from input vectors; the **output layer** uses a CRF structure to infer the most likely label for each input word.

2.1 Input Layer

Given a sentence $w^{(1:n)}$, the input layer builds a vector representation $\vec{r}_w^i$ for each word w^i based on both word and character embeddings. In particular, an embedding lookup table is used to convert vocabulary words into their embedding forms directly. To obtain a character based embedding of w^i, we denote the character sequence of w^i with $c^{(1:n)}$, where c^j is the jth character in w^i.

A character lookup table is used to map each char-

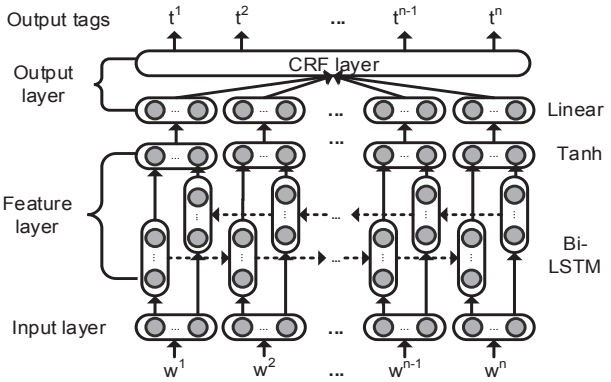

Figure 2: Baseline neural network tagger.

acter c^j into a character embedding $\vec{e}_c^j$. The character embeddings $\vec{e}_c^1, \vec{e}_c^2, ..., \vec{e}_c^m$ are combined using an attention model(Bahdanau et al., 2015): $\vec{w}_c^i = \sum_{j=1}^m a_c^j \odot \vec{e}_c^j$, where a_c^j is the weight for $\vec{e}_c^j$, $\odot$ is the Hadamard product function, and $\sum_{j=1}^m a_c^j = 1$.

Each a_c^j is computed according to both the word embedding vector and 5-character embedding window with the current character $\vec{e}_c^j$ in the middle:

$$
\begin{aligned}
a_c^j =& \frac{t_c^j}{\sum_1^m t_c^j} \\
t_c^j =& \exp(\mathbf{W}^t \vec{h}_c^j + \mathbf{U}^t \vec{e}_w^i + \vec{b}^t) \\
\vec{h}_c^i =& \tanh\big(\mathbf{W}^c(\vec{e}_c^{j-2} \oplus \vec{e}_c^{j-1} \oplus \vec{e}_c^j \oplus \vec{e}_c^{j+1} \\
& \oplus \vec{e}_c^{j+2}) + \vec{b}^c\big)
\end{aligned}
$$

Here $\oplus$ denotes vector concatenation and $\vec{e}_w^i$ is the embedding of current word w^i. $\mathbf{W}^t$, $\mathbf{U}^t$, $\mathbf{W}^c$ and $\vec{b}^t$, $\vec{b}^c$ are model parameters. Finally, $\vec{w}_c^i$ is concatenated with word embedding to form final word representation $\vec{r}_w^i$: $\vec{r}_w^i = \vec{e}_w^i \oplus \vec{w}_c^i$

2.2 Feature Layer

Recently, bi-directional LSTM has been successfully applied in various NLP tasks (Liu et al., 2015; Zhou and Xu, 2015; Klerke et al., 2016; Plank et al., 2016). The feature layer uses a bi-directional LSTM to extract a feature vector $\vec{h}^i$ for each word w^i, respectively. An input vector $\vec{x}^i = (\vec{r}_w^{i-2} \oplus \vec{r}_w^{i-1} \oplus \vec{r}_w^i \oplus \vec{r}_w^{i+1} \oplus \vec{r}_w^{i+2})$ is used to represent each word w^i.

We use a LSTM variation with peephole connections (Graves and Schmidhuber, 2005) to extract features based on $\vec{x}^{(1:n)}$. The model computes a hidden vector $\vec{h}^i$ for each input $\vec{x}^i$, passing information from $\vec{h}^1, ..., \vec{h}^{i-1}$ to $\vec{h}^n$ via a sequence of cell states $\vec{c}^1, \vec{c}^2, ..., \vec{c}^n$. Information flow is controlled using an input gate $\vec{g}^i$, a forget gate $\vec{f}^i$, and an output gate $\vec{o}^i$:

$$
\begin{aligned}
\vec{g}^i =& \sigma(\mathbf{W}^{(g)}\vec{x}^i + \mathbf{U}^{(g)}\vec{h}^{i-1} + \mathbf{V}^{(g)}\vec{c}^{i-1} + \vec{b}^{(g)}) \\
\vec{f}^i =& \sigma(\mathbf{W}^{(f)}\vec{x}^i + \mathbf{U}^{(f)}\vec{h}^{i-1} + \mathbf{V}^{(f)}\vec{c}^{i-1} + \vec{b}^{(f)}) \\
\vec{c}^i =& \vec{f}^i \odot \vec{c}^{i-1} + \\
& \vec{g}^i \odot \tanh(\mathbf{W}^{(u)}\vec{x}^i + \mathbf{U}^{(u)}\vec{h}^{i-1} + \vec{b}^{(u)}) \\
\vec{o}^i =& \sigma(\mathbf{W}^{(o)}\vec{x}^i + \mathbf{U}^{(o)}\vec{h}^{i-1} + \mathbf{V}^{(o)}\vec{c}^i + \vec{b}^{(o)}) \\
\vec{h}^i =& \vec{o}^i \odot \tanh(\vec{c}^i),
\end{aligned}
$$

where σ denotes the component-wise sigmoid function. $\mathbf{W}^{(g)}$, $\mathbf{W}^{(f)}$, $\mathbf{W}^{(u)}$, $\mathbf{W}^{(o)}$, $\mathbf{U}^{(g)}$, $\mathbf{U}^{(f)}$, $\mathbf{U}^{(u)}$, $\mathbf{U}^{(o)}$, $\mathbf{V}^{(g)}$, $\mathbf{V}^{(f)}$, $\mathbf{V}^{(o)}$, $\vec{b}^{(g)}$, $\vec{b}^{(f)}$, $\vec{b}^{(u)}$, $\vec{b}^{(o)}$ are model parameters.

Bi-directional extension of the above LSTM structure is applied in both the left-to-right direction and the right-to-left direction, resulting in two hidden vector sequences $h_l^{(1:n)}, h_r^{(1:n)}$, respectively. Each $\vec{h}_l^i$ is combined with its corresponding $\vec{h}_r^i$ for final feature vector $\vec{h}_f^i$:

$$
\vec{h}_f^i = \tanh(\mathbf{W}^l \vec{h}_l^i + \mathbf{W}^r \vec{h}_r^i + \vec{b}),
$$

where $\mathbf{W}^l$, $\mathbf{W}^r$ and $\vec{b}$ are model parameters.

2.3 Output Layer

The output layer employs a conditional random field (CRF) to infer the POS t^i of each word w^i based on the feature layer outputs. The conditional probability of a tag sequence given an input sentence is:

$$
p(\vec{y}|\vec{x}) = \frac{\prod_{i=1}^n \Psi(\vec{x}, \vec{y}^i) \prod_{i=1}^n \Phi(\vec{x}, \vec{y}^i, \vec{y}^{i-1})}{Z(\vec{x})},
$$

where $Z(\vec{x})$ is the partition function:

$$
Z(\vec{x}) = \sum_{\vec{y}} \prod_{i=1}^n \Psi(\vec{x}, \vec{y}^i) \prod_{i=1}^n \Phi(\vec{x}, \vec{y}^i, \vec{y}^{i-1})
$$

In particular, the output clique potential $\Psi(\vec{x}, \vec{y}^i)$ shows the correlation between inputs and output labels: $\Psi(\vec{x}, \vec{y}^i) = \exp(\vec{s}^i)$, with the emission vector $\vec{s}^i$ being defined as:

$$
\vec{s}^i = \vec{\theta}_0 \vec{h}_f^i, \tag{1}
$$

where $\vec{\theta}_0$ is the model parameter.

The edge clique potential shows the correlation between consecutive output labels using a single transition weight $\tau(\vec{y}^i, \vec{y}^{i-1})$.

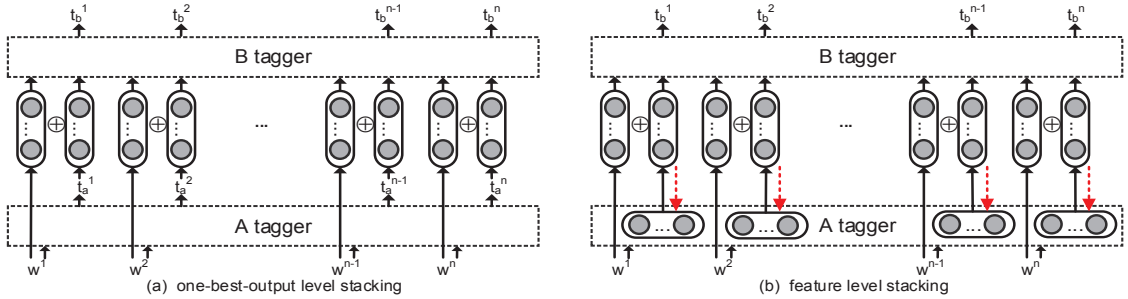

Figure 3: Neural stacking.

3 Stacking

3.1 Discrete Stacking

Stacking integrates corpora A and B by first training a tagger on corpus A, and then using the A tagger to provide additional features to a corpus B model. Figure 1(a) shows the training and testing of discrete stacking models, where the B tagger extracts features from both the raw sentence and A tagger output. This method achieves feature combination at the one-best-output level.

3.2 Neural Stacking

Figure 3(a) and (b) shows the two neural stacking methods of this paper, respectively.

Shallow Integration. Figure 3(a) is a variation of discrete stacking, with the output tags from tagger A being converted to a low-dimensional dense embedding features, and concatenated to the word embedding inputs to tagger B. Formally, for each word w^i, denote the tagger A output as t_a^i, we concatenate the embedding form of t_a^i, denoted as $\vec{e}_a^i$, to the word representation $\vec{r}_w^i$.

$$\vec{r}_w^{i\prime} = \vec{r}_w^i \oplus \vec{e}_a^i = \vec{e}_w^i \oplus \vec{w}_c^i \oplus \vec{e}_a^i \quad (2)$$

Deep Integration. Figure 3(b) offers deeper integration between the A and B models, which is feasible only with neural network features. We call this method feature-level stacking. For feature-level integration, the emission vector $\vec{s}^i$ in Eq.(1) is taken for input to tagger B via a projection:

$$\vec{w}_a^i = \tanh(\mathbf{W}^s \vec{s}^i)$$
$$\vec{r}_w^i = \vec{e}_w^i \oplus \vec{w}_c^i \oplus \vec{w}_a^i,$$

where $\mathbf{W}^s$ is a model parameter.

Fine-tuning. Feature-level stacking further allows tagger A to be fine-tuned during the training of tagger B, with the loss function being back propagated to tagger A via the $\vec{w}_a^i$ layer (shown in the red dotted lines in Figure 3(b)). This is a further benefit of neural stacking compared with discrete stacking.

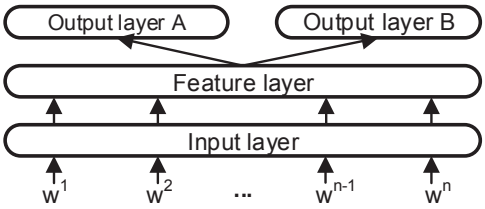

Figure 4: Neural multi-view model.

4 Multi-view Learning

4.1 Discrete Label Coupling

As shown in Figure 1(b), multi-view learning (Li et al., 2015) utilizes corpus A and corpus B simultaneously for training. The coupled tagger directly learns the logistic correspondences between both corpora, therefore can lead a more comprehensive usage of corpus A compared with stacking. In order to better capture such correlation, specifically designed feature templates between two tag sets are essential.

For each training instances, both A and B labels are needed. However, one type of tag is missing. Li et al. (2015) used a mapping function to supplement the missing annotations with the help of the annotated tag. The result is a set of sentence with bundled tags in both annotations, but with ambiguities on one side, due to one-to-many mappings. Li et al. (2015) showed that speed can be significantly improved by manually restricting possible mappings between the labelsets, but a full mapping without restriction yields the highest accuracies.

4.2 Neural Multi-task Learning

Neural multi-task learning is free from manual feature engineering, and avoids manual mapping func-

tions between tag sets by establishing two separate output layers, one for each type of label, with shared low-level parameters. The general structure of a neural multi-view model is shown in Figure 4, which can be regarded as a variation of the parameter sharing model of Caruana (1993) and Collobert et al. (2011). Leveraging heterogeneous annotations for the same task, compared to parameter sharing between different NLP tasks (Collobert et al., 2011), can benefit from tighter integration of information, and hence allows deeper parameter sharing. These are verified empirically in the experiments.

In training and testing, sentences from both corpora go through the same input layer and feature layer. The outputs of each type of tag is then computed separately according to the shared parameters. The conditional probability of a tag sequence given an input sentence and its corpus type is:

$$p(\vec{y}|\vec{x},T) = \frac{\prod_{i=1}^{n} \Psi_T(\vec{x},\vec{y}^{\,i}) \prod_{i=1}^{n} \Phi_T(\vec{x},\vec{y}^{\,i},\vec{y}^{\,i-1})}{Z_T(\vec{x})},$$

where T is the corpus type, $T \in \{A, B\}$. $\Psi_T(\vec{x},\vec{y}^{\,i})$ and $\Phi_T(\vec{x},\vec{y}^{\,i},\vec{y}^{\,i-1})$ are the corresponding output clique potential and edge clique potential, respectively. $Z_T(\vec{x})$ is the partition function:

$$Z_T(\vec{x}) = \sum_{\vec{y}} \prod_{i=1}^{n} \Psi_T(\vec{x},\vec{y}^{\,i}) \prod_{i=1}^{n} \Phi_T(\vec{x},\vec{y}^{\,i},\vec{y}^{\,i-1})$$

This indicates that each time only one output layer is activated according to the corpus type of input sentences.

5 Training

A max-margin objective is used to train the full set of model parameters Θ:

$$L(\Theta) = \frac{1}{D} \sum_{d=1}^{D} l(\vec{x_d},\vec{y_d},\Theta) + \frac{\lambda}{2} \|\Theta\|^2,$$

where $\vec{x}_d, \vec{y}_d|_{d=1}^{D}$ are the training examples, λ is a regularization parameter, and $l(\vec{x}_d,\vec{y}_d,\Theta)$ is the max-margin loss function towards one example $(\vec{x}_d, \vec{y_d})$.

The max-margin loss function is defined as:

$$l(\vec{x}_d,\vec{y_d},\Theta) = \max_{y} \left(s(\vec{y}|\vec{x}_d,\Theta) + \delta(\vec{y},\vec{y}_d)\right) - s(\vec{y}_d|\vec{x}_d,\Theta),$$

Algorithm 1 Neural multi-view training

Input: Two training datasets: $D^{(1)} = (x_n^{(1)}, y_n^{(1)})|_{n=1}^{N}$, $D^{(2)} = (x_m^{(2)}, y_m^{(2)})|_{m=2}^{M}$; Parameters: E, A, R

Output: Θ

	dev	18875	958026

Table 1: Data statistics.

where $\vec{y}$ is the model output, $s(\vec{y}|\vec{x}) = logP(\vec{y}|\vec{x})$ is the log probability of $\vec{y}$ and $\delta(\vec{y},\vec{y}_d)$ is the Hamming distance between $\vec{y}$ and $\vec{y}_d$.

We adopt online learning, updating parameters using AdaGrad (Duchi et al., 2011). To train the neural stacking model, we first train a base tagger using corpus A. Then, we train the stacked tagger with corpus B, where the parameters of the A tagger has been pretrained from corpus A and the B tagger is randomly initialized.

For neural multi-view model, we follow Li et al. (2015) and take a the corpus-weighting strategy to sample a number of training instances from both corpora for each training iteration, as shown in Algorithm 1. At each epoch, we randomly sample from the two datasets according to a *corpus weights ratio*, namely the ratio between the number of sentences in each dataset used for training, to form a training set for the epoch.

6 Experiments

6.1 Experimental Settings

We adopt the Penn Chinese Treebank version 5.0 (*CTB5*) (Xue et al., 2005) as our main corpus, with the standard data split following previous work (Zhang and Clark, 2008; Li et al., 2015). People's Daily (*PD*) is used as second corpus with a different scheme. We filter out *PD* sentences longer than 200 words. Details of the datasets are listed in Table 1. The standard token-wise POS tagging accuracy is used as the evaluation metric. The systems are implemented with LibN3L (Zhang et al., 2016).

For all the neural models, we set the hidden layer size to 100, the initial learning rate for Adagrad to 0.01 and the regularization parameter λ to 10^{-8}. *word2vec*[1] is used to pretrain word embeddings. The Chinese Giga-word corpus version 5 (Graff and Chen, 2005), segmented by *zpar*[2] (Zhang and Clark, 2011), is used for the training corpus for word embeddings. The size of word embedding is 50.

6.2 Development Experiments

We use the development dataset for two main purposes. First, under each setting, we tune the model parameters, such as the number of training epochs. Second, we study the influence of several important hyper-parameters using the development dataset. For example, for the NN multi-view learning model, the *corpus weights ratio* (section 5) plays an important role for the performance. We determine the parameters of the model by studying the accuracy along with the increasing epochs.

Effect of batch size and dropout. The batch size affects the speed of training convergence and the final accuracies of the neural models, and the dropout rate has been shown to significantly influence the performance (Chen et al., 2015). We investigate the effects of these two hyper-parameters by adopting a corpus weight ratio of $1:1$ (All the *CTB* training data is used, while the same amount of *PD* is sampled randomly), drawing the accuracies of the neural multi-view learning model against the number of training epochs with various combinations of the dropout rate d and batch size b. The results are shown for the multi-view learning model. For the stacking model, we use b=100 for the *PD* sub model.

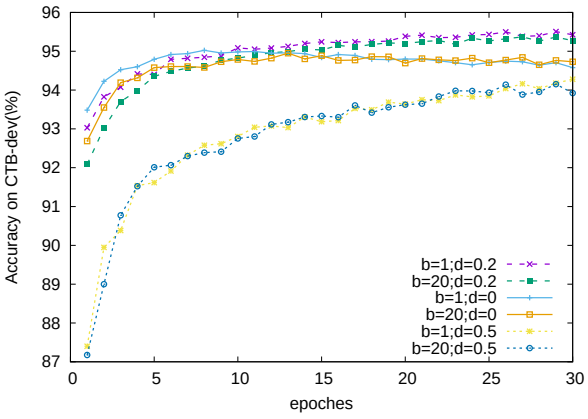

Figure 5: Accuracy on *CTB-dev* with different batch sizes and dropout rates for a multi-view learning model. b represents batch size, d denotes dropout rate.

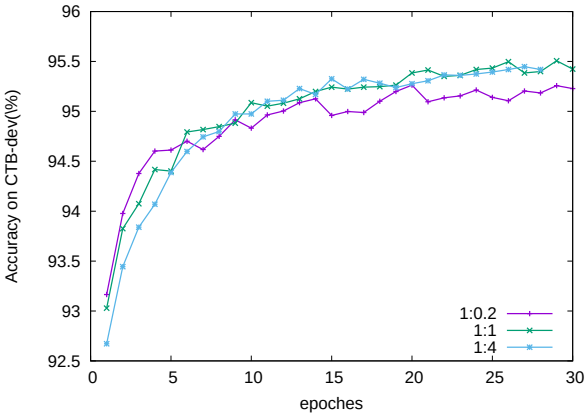

Figure 6: Accuracy on *CTB-dev* with different corpus weights ratio.

The results are shown in Figure 5, where the two dashed lines on the top at epoch 30 represent the dropout rate of 20%, the two solid lines in the middle represent zero dropout rate, and the two dotted lines in the bottom represent a dropout rate 50%. Without using dropout, the performance increases in the beginning, but then decreases as the number of training epochs increases beyond 10. This indicates that the NN models can overfit the training data without dropout. However, when a 50% dropout rate is used, the initial performances are significantly worse, which implies that the 50% dropout rate can be too large and leads to underfitting. As a result, we choose a dropout rate of 20% for the remaining experiments, which strikes the balance between over-

System	Accuracy
CRF Baseline (Li et al., 2015)	94.10
CRF Stacking (Li et al., 2015)	94.81
CRF Multi-view (Li et al., 2015)	95.00
NN Baseline	94.24
NN Stacking	94.74
NN Feature Stacking	95.01
NN Feature Stacking & Fine-tuning	95.32
NN Multi-view	95.40
Integrated NN Multi-view & Stacking	**95.53**

Table 2: Accuracies on *CTB-test*.

fitting and underfitting.

Figure 5 also shows that the batch size has a relative small influence on the accuracies, which varies according to the dropout rate. We simply choose a batch size of 1 for the remaining experiments according to the performance at the dropout rate 20%.

Effect of corpus weights ratio. Figure 6 shows the effects of different corpus weights ratios. In particular, a corpus weights ratio of 1:0.2 yields relative low accuracies. This is likely because it makes use of the least amount of *PD* data. The ratios of 1:1 and 1:4 give comparable performances. We choose the former for our final tests because it is a much faster choice.

6.3 Final Results

Table 2 shows the final results on the *CTB* test data. We lists the results of stacking method of Jiang et al. (2009) re-implemented by Li et al. (2015), and CRF multi-view method reported by Li et al. (2015). We adopt pair-wise significance test (Collins et al., 2005) when comparing the results between two different models.

Stacking. For baseline tagging using only *CTB*, NN model achieves a result of 94.24, slightly higher than CRF baseline (94.10). NN stacking model integrating *PD* data achieves comparable performance (94.74) compared with CRF stacking model (94.81). Compared with NN baseline, NN stacking model boosts the performance from 94.24 to 94.74, which is significant at the confidence level $p < 10^{-5}$. This demonstrates that neural network model can utilize one-best prediction of the *PD* model for the *CTB* task as effectively as the discrete stacking method of Jiang et al. (2009).

One advantage of NN stacking as compared with discrete stacking method is that it can directly leverage features of *PD* model for *CTB* tagging. Comparison between feature-level stacking and one-best-output level stacking of the NN stacking model shows that the former gives significantly higher results, namely 95.01 vs 94.74 at the confidence level $p < 10^{-3}$.

One further advantage of NN stacking is that it allows the *PD* model to be fine-tuned as an integral sub-model during *CTB* training. This is not possible for the discrete stacking model, because the output of the *PD* model are used as atomic feature in the stacking *CTB* model rather than a gradient admissive neural layer. By fine-tuning the *PD* sub-model, the performance is further improved from 95.01 to 95.32 at the confidence level $p < 10^{-3}$. The final NN stacking model improves over the NN baseline model from 94.24 to 95.32. The improvement is significantly higher compared to that by using discrete stacking which improves over the discrete baseline from 94.01 to 94.74. The final accuracy of the NN stacking model is higher than that of the CRF stacking model, namely 94.81 vs 95.32 at the confidence level $p < 10^{-3}$. This shows that neural stacking is a preferred choice for stacking.

Multi-view training. With respect of the multi-view training method, the NN model improves over the NN baseline from 94.24 to 95.40, by a margin of +1.16, which is higher than that of 0.90 brought by discrete method of Li et al. (2015) over its baseline, from 94.10 to 95.00. NN multi-view training method gives relatively higher improvements compared with NN stacking method. This is consistent with the observation of Li et al. (2015), who showed that discrete label coupling training gives slightly better improvement compared with discrete stacking. The final accuracies of NN multi-view training is also higher than that of its CRF counterpart, namely 95.00 vs 95.40 at the confidence level $p < 10^{-3}$. The difference between the final NN multi-view training result of 95.40 and the final NN stacking results is not significant.[3]

Integration. The flexibility of the NN models further allows both stacking (on the input) and multi-viewing (on the output) to be integrated. When

[3]Note, however, NN stacking method with one-best *PD* output gives significantly lower accuracies (94.74). It is the fine-tuning strategy that allows stacking to give comparable results compared to multi-view training for the NN models.

System	Time Cost(s)
CRF Baseline	176.925
CRF Multi-view (Li et al., 2015)	3992.27
NN Baseline	416.338
NN Multi-view	418.484

Table 3: Time for testing *CTB* training data.

NN multi-view training is combined with a fine-tuned NN feature stacking model, the performance further increases from 95.40 to 95.53. This is the best results we are aware of on this dataset. The improvement is significant at the confidence level $p < 10^{-2}$ compared with fine-tuned NN stacking model (95.32). This indicates that NN multi-view training and stacking model each provide unique advantages for heterogeneous annotations.

6.4 Speed Test

We compare the efficiencies of neural and discrete multi-view training by running our models and the model of Li et al. (2015)[4] with default configurations on the *CTB5* training data. The CRF baseline is adapted from Li et al. (2015). All the systems are implemented in C++ running on an Intel E5-1620 CPU. The results are shown in Table 3.

The NN baseline model is slower than the CRF baseline model. This is due to the higher computation cost of a deep neural network on a CPU. Compared with the CRF baseline, the CRF multi-view model is significantly slower because of its large feature set and the multi-label search space. However, the NN multi-view model achieves almost the same time cost with the NN baseline, and is much more efficient than the CRF counterpart. This shows the efficiency advantage of the NN multi-view model by parameter sharing and output splitting.

7 Related Work

Early research on heterogeneous annotations focuses on annotation conversion. For example, Gao et al. (2004) proposed a transformation-based method to convert the annotation style of a word segmentation corpus to that of another. Manually designed transformation templates are used, which makes it difficult to generalize the method to other tasks and treebanks.

Jiang et al. (2009) described a stacking-based model for heterogeneous annotations, using a pipeline to integrate the knowledge from one corpus to another. Sun and Wan (2012) proposed a structure-based stacking model, which makes use of structured features such as sub-words for model combination. These feature integration is stronger compared to those of Jiang et al. (2009). Johansson (2013) introduced path-based feature templates in using one parser to guide another. In contrast to the above discrete methods, our neural stacking method offers further feature integration by directly connecting the feature layer of the source tagger with the input layer of the target tagger. It also allows the fine-tuning of the source tagger. As one of the reviewers mentioned, two extensions of CRFs, dynamic CRFs (Sutton et al., 2004) and hidden-state CRFs (Quattoni et al., 2004), can also perform similar deep integration and fine-tuning.

For multi-view training, Johansson (2013) used a shared feature representation along with separate individual feature representation for each treebank. Qiu et al. (2013) proposed a multi-task learning model to jointly predict two labelsets given an input sentences. The joint model uses the union of baseline features for each labelset, without considering additional features to capture the interaction between the two labelsets. Li et al. (2015) improves upon this method by using a tighter integration between the two labelsets, treating the Cartesian product of the base labels as a single combined labelset, and exploiting joint features from two labelsets. Though capturing label interaction, their method suffers speed penalty from the sharply increased search space. In contrast to their methods, our neural approach enables parameter sharing in the hidden layers, thereby modeling label interaction without directly combining the two output labelsets. This leads to a lean model with almost the same time efficiency as a single-label baseline.

Recently, Zhang and Weiss (2016) proposed a stack-propagation model for learning a stacked pipeline of POS tagging and dependency parsing. Their method is similar to our neural stacking in fine-tuning the stacked module which yields features for the target model. While their multi-task learning is on heterogenous tasks, our multi-task learning is

[4]http://hlt.suda.edu.cn/zhli/resources/zhenghua-acl2015-resources.zip

defined on heterogenous treebanks.

8 Conclusion

We investigated two methods for utilizing heterogeneous annotations for neural network models, showing that they have respective advantages compared to their discrete counterparts. In particular, neural stacking allows tighter feature integration compared to discrete stacking, and neural multi-view training is free from the feature and efficiency constraints of discrete one. On a standard *CTB* test, the neural method gives the best integration effect, with a multi-view training model enjoying the same speed as its single treebank baseline.

LAMB: A Good Shepherd of Morphologically Rich Languages

Sebastian Ebert and **Thomas Müller** and **Hinrich Schütze**
Center for Information and Language Processing
LMU Munich, Germany
ebert@cis.lmu.de

Abstract

This paper introduces STEM and LAMB, embeddings trained for stems and lemmata instead of for surface forms. For morphologically rich languages, they perform significantly better than standard embeddings on word similarity and polarity evaluations. On a new WordNet-based evaluation, STEM and LAMB are up to 50% better than standard embeddings. We show that both embeddings have high quality even for small dimensionality and training corpora.

1 Introduction

Despite their power and prevalence, embeddings, i.e., (low-dimensional) word representations in vector space, have serious practical problems. First, large text corpora are necessary to train high-quality embeddings. Such corpora are not available for underresourced languages. Second, morphologically rich languages (MRLs) are a challenge for standard embedding models because many inflectional forms are rare or absent even in a large corpus. For example, a Spanish verb has more than 50 forms, many of which are rarely used. This leads to missing or low quality embeddings for such inflectional forms, even for otherwise frequent verbs, i.e., sparsity is a problem. Therefore, we propose to compute normalized embeddings instead of embeddings for surface/inflectional forms (referred to as *forms* throughout the rest of the paper): STem EMbeddings (STEM) for word stems and LemmA eMBeddings (LAMB) for lemmata.

Stemming is a heuristic approach to reducing form-related sparsity issues. Based on simple rules, forms are converted into their stem.[1] However, often the forms of one word are converted into several different stems. For example, present indicative forms of the German verb "brechen" (to break) are mapped to four different stems ("brech", "brich", "bricht", "brecht"). A more principled solution is lemmatization. Lemmatization unites many individual forms, many of which are rare, in one equivalence class, represented by a single lemma. Stems and equivalence classes are more frequent than each individual form. As we will show, this successfully addresses the sparsity issue.

Both methods can learn high-quality semantic representations for rare forms and thus are most beneficial for MRLs as we show below. Moreover, less training data is required to train lemma embeddings of the same quality as form embeddings. Alternatively, we can train lemma embeddings that have the same quality but fewer dimensions than form embeddings, resulting in more efficient applications.

If an application such as parsing requires inflectional information, then stem and lemma embeddings may not be a good choice since they do not contain such information. However, NLP applications such as similarity benchmarks (e.g., MEN (Bruni et al., 2014)) and (as we show below) polarity classification are semantic and are largely

[1] In this paper, we use the term "stem" not in its linguistic meaning, but to refer to the character string that is produced when a stemming algorithm like SNOWBALL is applied to a word form. The stem is usually a prefix of the word form, but some orthographic normalization (e.g., "possibly" → "possible" or "possibli") is often also performed.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 742–752,
Austin, Texas, November 1-5, 2016.

independent of inflectional morphology.

Our contributions are the following. (i) We introduce the normalized embeddings STEM and LAMB and show their usefulness on different tasks for five languages. This paper is the first study that comprehensively compares stem/lemma-based with form-based embeddings for MRLs. (ii) We show the advantage of normalization on word similarity benchmarks. Normalized embeddings yield better performance for MRL languages on most datasets (6 out of 7 datasets for German and 2 out of 2 datasets for Spanish). (iii) We propose a new intrinsic relatedness evaluation based on WordNet graphs and publish datasets for five languages. On this new evaluation, LAMB outperforms form-based baselines by a big margin. (iv) STEM and LAMB outperform baselines on polarity classification for Czech and English. (v) We show that LAMB embeddings are efficient in that they are high-quality for small training corpora and small dimensionalities.

2 Related Work

There have been a large number of studies on English, a morphologically simple language, that show that the effect of normalization, in particular stemming, is different for different applications. For instance, Karlgren and Sahlgren (2001) analyze the impact of morphological analysis on creating word representations for synonymy detection. They compare several stemming methods. Bullinaria and Levy (2012) use stemming and lemmatization before training word representations. The improvement of morphological normalization in both studies is moderate in the best case. Melamud et al. (2014) compute lemma embeddings to predict related words given a query word. They do not compare form and lemma representations.

A finding about English morphology does not provide insight into what happens with the morphology of an MRL. In this paper we use English to provide a data point for morphologically poor languages. Although we show that normalization for embeddings increases performance significantly on some applications – a novel finding to the best of our knowledge – morphologically simple languages (for which normalization is expected to be less important) are not the main focus of the paper. Instead, MRLs are the main focus. For these, we show large improvements on several tasks.

Recently, Köper et al. (2015) compared form and lemma embeddings on English and German focusing on morpho-syntactic and semantic relation tasks. Generally, they found that lemmatization has limited impact. We extensively study MRLs and find a strong improvement on MRLs when using normalization, on intrinsic as well as extrinsic evaluations.

Synonymy detection is a well studied problem in the NLP community (Turney, 2001; Turney et al., 2003; Baroni and Bisi, 2004; Ruiz-Casado et al., 2005; Grigonytė et al., 2010). Rei and Briscoe (2014) classify hyponomy relationships through embedding similarity. Our premise is that semantic similarity comprises all of these relations and more. Our ranking-based word relation evaluation addresses this issue. Similar to Melamud et al. (2014), our motivation is that, in contrast to standard word similarity benchmarks, large resources can be automatically generated for any language with a WordNet. This is also exploited by Tsvetkov et al. (2015). Their intrinsic evaluation method requires an annotated corpus, e.g., annotated with WordNet supersenses. Our approach requires only the WordNet.

An alternative strategy of dealing with data sparsity is presented by Soricut and Och (2015). They compute morphological features in an unsupervised fashion in order to construct a form embedding by the combination of the word's morphemes. We address scenarios (such as polarity classification) in which morphological information is less important, thus morpheme embeddings are not needed.

3 Stem/Lemma Creation

The main hypothesis of this work is that normalization addresses sparsity issues, especially for MRLs, because although a particular word form might not have been seen in the text, its stem or lemma is more likely to be known. For all stemming experiments we use SNOWBALL,[2] a widely used stemmer. It normalizes a form based on deterministic rules, such as *replace the suffix 'tional' by 'tion'* for English.

For lemmatization we use the pipeline version of the freely available, high-quality lemmatizer LEM-

[2] snowball.tartarus.org

MING (Müller et al., 2015). Since it is a language-independent token-based lemmatizer it is especially suited for our multi-lingual experiments. Moreover, it reaches state-of-the-art performance for the five languages that we study. We train the pipeline using the Penn Treebank (Marcus et al., 1993) for English, SPMRL 2013 shared task data (Seddah et al., 2013) for German and Hungarian, and CoNLL 2009 (Hajič et al., 2009) datasets for Spanish and Czech. We additionally use a unigram list extracted from Wikipedia datasets and the ASPELL dictionary of each language.[3]

4 Experiments

4.1 Word Similarity

Our first experiment evaluates how well STEM/LAMB embeddings predict human word similarity judgments. Given a pair of words (m, n) with a human-generated similarity value and a set of embeddings E we compute their similarity as cosine similarity. For form embeddings E^F, we directly use the embeddings of the word pairs' forms (E^F_m and E^F_n) and compute their similarity. For STEM we use $E^S_{stem(w)}$, where $stem(w)$ is the stem of w. For LAMB we use $E^L_{lemma(w)}$, where $lemma(w)$ is the lemma of w; we randomly select one of w's lemmata if there are several. We conduct experiments on English (en), German (de) and Spanish (es). Table 1 gives dataset statistics.

For good performance, high-quality embeddings trained on large corpora are required. Hence, the training corpora for German and Spanish are web corpora taken from COW14 (Schäfer, 2015). Preprocessing includes removal of XML, conversion of HTML characters, lowercasing, stemming using SNOWBALL and lemmatization using LEMMING. We use the entire Spanish corpus (3.7 billion tokens), but cut the German corpus to approximately 8 billion tokens to be comparable to Köper et al. (2015). We train CBOW models (Mikolov et al., 2013) for forms, stems and lemmata using WORD2VEC[4] with the following settings: 400 dimensions, symmetric context of size 2 (no dynamic window), 1 training iteration, negative sampling with 15 samples, a learning rate of 0.025, minimum count of words of 50, and a sampling parameter of 10^{-5}. CBOW is chosen, because it trains much faster than skip-gram, which is beneficial on these large corpora.

Since the morphology of English is rather simple we do not expect STEM and LAMB to reach or even surpass highly optimized systems on any word similarity dataset (e.g., Bruni et al. (2014)). Therefore, for practical reasons we use a smaller training corpus, namely the preprocessed and tokenized Wikipedia dataset of Müller and Schütze (2015).[5] Embeddings are trained with the same settings (using 5 iterations instead of only 1, due to the smaller size of the corpus: 1.8 billion tokens).

Table 1 shows results. We also report the Spearman correlation on the vocabulary intersection, i.e., only those word pairs that are covered by the vocabularies of all models.

Results. Although English has a simple morphology, LAMB improves over form performance on MEN and SL. A tie is achieved on RW. These are the three largest English datasets, giving a more reliable result. Both models perform comparably on WS. Here, STEM is ahead by 1 point. Forms are better on the small datasets MC and RG, where a single word pair can have a large influence on the result. Additionally, these are datasets with high frequency forms, where form embeddings can be well trained. Because of the simple morphology of English, STEM/LAMB do not outperform forms or only by a small margin and thus they cannot compete with highly optimized state-of-the-art systems.[6]

On German, both STEM and LAMB perform better on all datasets except WS. We set the new state-of-the-art of 0.79 on Gur350 (compared to 0.77 (Szarvas et al., 2011)) and 0.39 on ZG (compared to 0.25 (Botha and Blunsom, 2014)); 0.83 on Gur65 (compared to 0.79 (Köper et al., 2015)) is the best performance of a system that does not need additional knowledge bases (cf. Navigli and Ponzetto (2012), Szarvas et al. (2011)).

LAMB's results on Spanish are equally good. 0.82 on MC and 0.58 on WS are again the best per-

formances of a system not requiring an additional knowledge base (cf. Navigli and Ponzetto (2012)). The best performance before was 0.64 for MC and 0.50 for WS (both Hassan and Mihalcea (2009)). STEM cannot improve over form embeddings, showing the difficulty of Spanish morphology.

4.2 Word Relations

Word similarity benchmarks are not available for many languages and are expensive to create. To remedy this situation, we create word similarity benchmarks that leverage WordNets, which are available for a great number of languages.

Generally, a representation is deemed good if words related by a lexical relation in WordNet – synonymy, hyponymy etc. – have high cosine similarity with this representation. Since the gold standard necessary for measuring this property of a representation can be automatically derived from a WordNet, we can create very large similarity benchmarks with up to 50k lemmata for the five languages we investigate: Czech, English, German, Hungarian and Spanish.

We view each WordNet as a graph whose edges are the lexical relations encoded by the WordNet, e.g., synonymy, antonymy and hyponymy. We then define $\mathcal{L}$ as the set of lemmata in a WordNet and the distance $d(l, l')$ between two lemmata l and l' as the length of the *shortest path* connecting them in the graph. The k-neighborhood $N^k(l)$ of l is the set of lemmata l' that have distance k or less, excluding l: $N^k(l) := \{l' | d(l, l') \leq k, l \neq l'\}$. The rank of l for an embedding set E is defined as:

$$\text{rank}_E^k(l) := \underset{i}{\text{argmin}}\, l_i \in N^k(l) \quad (1)$$

where l_i is the lemma at position i in the list of all lemmata in the WordNet, ordered according to cosine similarity to l in descending order. We restrict $i \in [1, 10]$ and set $k = 2$ for all experiments in this paper. We omit the indexes k and E when they are clear from context.

To measure the quality of a set of embeddings we compute the mean reciprocal rank (MRR) on the rank results of all lemmata:

$$\text{MRR}_E = \frac{1}{|\mathcal{L}|} \sum_{l \in \mathcal{L}} \frac{1}{\text{rank}_E(l)} \quad (2)$$

We create large similarity datasets for five languages: Czech (cz), English (en), German (de), Hungarian (hu) and Spanish (es) by extracting all lemmata from the WordNet version of the respective language. For English and Spanish we use the preprocessed WordNets from the Open Multilingual WordNet (Bond and Paik, 2012). We use the Czech and Hungarian WordNets (PALA and SMRZ, 2004; Miháltz et al., 2008) and GermaNet (Hamp and Feldweg, 1997) for German. We keep all lemmata that have a known form in the form embeddings and that exist in the lemma embeddings. Moreover, we filter out all synsets that contain only one lemma and discard all multiword phrases. The split into development and test sets is done in a way that the distribution of synset sizes (i.e., the number of lemmata per synset) is nearly equal in both sets.

The number of lemmata in our evaluation sets can be found in Table 2. For more insight, we report results on all parts-of-speech (POS), as well as separately for nouns (n), verbs (v) and adjectives (a).[7] The data is provided as supplementary material.[8]

We propose the following models for the embedding evaluation. For form embeddings we compare three different strategies, a realistic one, an optimistic one and a lemma approximation strategy. In the realistic strategy (*form real*), given a query lemma we randomly sample a form, for which we then compute the k-neighborhood. If the neighbors contain multiple forms of the same equivalence class, we exclude the repetitions and use the next neighbors instead. For instance, if *house* is already a neighbor, then *houses* will be skipped. The optimistic strategy (*form opt*) works similarly, but uses the embedding of the most frequent surface form of a lemma. This is the most likely form to perform best in the form model. This strategy presupposes the availability of information about lemma and surface form counts. As a baseline lemma approximation strategy, we sum up all surface form embeddings that belong to one equivalence class (*form sum*). For STEM we repeat the same experiments as described for forms, leading to *stem real*, *stem opt* and *stem sum*.

For embedding training, Wikipedia comes as a

[7] The all-POS setting includes all POS, not just n, v, a.

Table 2: Number of lemmata in WordNet datasets

natural choice as corpus, because it is available for many languages. Therefore, we use the preprocessed and tokenized Wikipedia datasets of Müller and Schütze (2015). We train 50-dimensional skip-gram embeddings (Mikolov et al., 2013) with WORD2VEC on the original, the stemmed and the lemmatized corpus, respectively. Embeddings are trained for all tokens, because we need high coverage; the context size is set to 5, all remaining parameters are left at their default value.[9]

[9]We train smaller embeddings than before, because we have more models to train and training corpora are smaller.

Results. The MRR results in the left half of Table 3 ("unfiltered") show that for all languages and for all POS, *form real* has the worst performance among the form models. This comes at no surprise since this model does barely know anything about word forms and lemmata. The *form opt* model improves these results based on the additional information it has access to (the mapping from lemma to its most frequent form). *form sum* performs similar to *form opt*. For Czech, Hungarian and Spanish it is slightly better (or equally good), whereas for English and German there is no clear trend. There is a large difference between these two models on German nouns, with *form sum* performing considerably worse. We attribute this to the fact that many German noun forms are rare compounds and therefore lead to badly trained form embeddings, which summed up do not lead to high quality embeddings either.

Among the stemming models, *stem real* also is the worst performing model. We can further see that for all languages and almost all POS, *stem sum* performs worse than *stem opt*. That indicates that stemming leads to many low-frequency stems or many words sharing the same stem. This is especially apparent in Spanish verbs. There, the stemming models are clearly inferior to form models.

Overall, LAMB performs best for all languages and POS types. Most improvements of LAMB are

significant. The improvement over the best form-model reaches up to 6 points (e.g., Czech nouns). In contrast to *form sum*, LAMB improves over *form opt* on German nouns. This indicates that the sparsity issue is successfully addressed by LAMB.

In general, morphological normalization in terms of stemming or lemmatization improves the result on all languages, leading to an especially substantial improvement on MRLs. For the morphologically very rich languages Czech and Hungarian, the relative improvement of STEM or LAMB to form-based models is especially high, e.g., Hungarian all: 50%. Moreover, we find that MRLs yield lower absolute performance. This confirms the findings of Köper et al. (2015). Surprisingly, LAMB yields better performance on English despite its simple morphology.

The low absolute results – especially for Hungarian – show that we address a challenging task and that our new evaluation methodology is a good evaluation for new types of word representations.

For further insight, we restrict the nearest neighbor search space to those lemmata that have the same POS as the query lemma. The general findings in the right half of Table 3 ("filtered") are similar to the unrestricted experiment: Normalization leads to superior results. The *form real* and *stem real* models yield the lowest performance. *Form opt* improves the performance and *form sum* is better on average than *form opt*. *Stem sum* can rarely improve on *stem opt*. The best stemming model most often is better than the best form model. LAMB can benefit more from the POS type restriction than the form models. The distance to the best form model generally increases, especially on German adjectives and Spanish verbs. In all cases except on English adjectives, LAMB yields the best performance. Again, in almost all cases LAMB's improvement over the form-models is significant.

4.3 Polarity Classification

Our first two evaluations were intrinsic. We now show the benefit of normalization on an extrinsic task. The task is classification of Czech movie reviews (CSFD, Habernal et al. (2013)) into positive, negative or neutral (Table 4). We reimplement lingCNN (Ebert et al., 2015), a Convolutional Neural Network that uses linguistic information to improve polarity classification. This model reaches close to state-of-the-art performance on data of the SemEval 2015 Task 10B (message level polarity). LingCNN takes several features as input: (i) embedding features, (ii) linguistic features at word level and (iii) linguistic features at review level.

We reuse the 50-dimensional Wikipedia embeddings from Section 4.2 and compare three experimental conditions: using forms, STEM and LAMB.

Linguistic word level features are: (i) SubLex 1.0 sentiment lexicon (Veselovská and Bojar, 2013) (two binary indicators that word is marked positive/negative); (ii) SentiStrength[10] (three binary indicators that word is an emoticon marked as positive/negative/neutral); (iii) prefix "ne" (binary negation indicator in Czech).[11]

All word level features are concatenated to form a single word representation of the review's input words. The concatenation of these representations is the input to a convolution layer, which has several filters spanning the whole representation height and several representations (i.e., several words) in width. The output of the convolution layer is input to a k-max pooling layer (Kalchbrenner et al., 2014). The max values are concatenated with the following linguistic review level features: (i) the count of elongated words, such as "cooool"; (ii) three count features for the number of positive/negative/neutral emoticons using the SentiStrength list; (iii) a count feature for punctuation sequences, such as "!!!"; (iv) and a feature that counts the number of negated words. (v) A final feature type comprises one count feature each for the number of sentiment words in a review, the sum of sentiment values of these words as provided by the sentiment lexicon, the maximum sentiment value and the sentiment value of the last word (Mohammad et al., 2013). The concatenation of max values and review level features is then forwarded into a fully-connected three-class (positive, negative, neutral) softmax layer. We train lingCNN with AdaGrad (Duchi et al., 2011) and early stopping, batch size = 100, 200 filters per width of 3-6; k-max pooling with $k = 5$; learning rate 0.01; and ℓ_2 regularization ($\lambda = 5 \cdot 10^{-5}$).

We also perform this experiment for English on

[10] sentistrength.wlv.ac.uk/

[11] We disregard words with the prefix "nej", because they indicate superlatives. Exceptions are common negated words with this prefix, such as "nejsi" (engl. "you are not").

Table 3: Word relation results. MRR per language and POS type for all models. *unfiltered* is the unfiltered nearest neighbor search space; *filtered* is the nearest neighbor search space that contains only one POS. ‡ (resp. †): significantly worse than LAMB (sign test, $p < .01$, resp. $p < .05$). Best unfiltered/filtered result per row is in bold.

the SemEval 2015 Task 10B dataset (cf. Table 4). We reimplement Ebert et al. (2015)'s lexicon features. They exploit the fact that there are many more sentiment lexicons available in English. Other word level features are the same as above. Sentiment count features at review level are computed separately for the entire tweet, for all hashtag words and for each POS type (Ebert et al., 2015).

Considering the much smaller dataset size and shorter sentences of the SemEval data we chose the following hyperparameters: 100k most frequent word types, 100 filters per filter width of 2-5; and k-max pooling with $k = 1$.

Results. Table 5 lists the 10-fold cross-validation results (accuracy and macro F_1) on the CSFD dataset. LAMB/STEM results are consistently better than form results.

In our analysis, we found the following example for the benefit of normalization: "popis a název zajmavý a film je taková filmařská prasárna" (engl. "description and title are interesting, but it is bad film-making"). This example is correctly classified as negative by the LAMB model because it has an embedding for "prasárna" (bad, smut) whereas the form model does not.

The out-of-vocabulary counts for form and LAMB on the first fold of the CSFD experiment are 26.3k and 25.5k, respectively. The similarity of these two numbers suggests that the quality of word embeddings (form vs. LAMB) are responsible for the performance gain.

On the SemEval data, LAMB improves the results over form and stem (cf. Table 5).[12] Hence, LAMB can still pick up additional information despite the simple morphology of English. This is probably due to better embeddings for rare words. The SemEval 2015 winner (Hagen et al., 2015) is a highly domain-dependent and specialized system that we do not outperform.

In the introduction, we discussed that normalization removes inflectional information that is necessary for NLP tasks like parsing. For polarity classification, comparatives and superlatives can be important. Further analysis is necessary to deter-

[12] To be comparable with published results we report the macro F_1 of positive and negative classes.

mine whether their normalization hurts in our experiments. However, note that we evaluate on polarity only, not on valence.

5 Analysis

Normalized embeddings deal better with sparsity than form embeddings. In this section, we demonstrate two additional benefits of LAMB based on its robustness against sparsity.

Embedding Size. We now show that LAMB can train embeddings with fewer dimensions on the same amount of data and still reach the same performance as larger form embeddings. We repeat the word relation experiments of Section 4.2 (all POS) and train all models with embedding sizes 10, 20, 30 and 40 for Spanish. We choose Spanish because it has richer morphology than English and more training data than Czech and Hungarian.

Figure 1 depicts the MRR results of all models with respect to embedding size. The relative ranking of form models is *real* $<$ *opt* $<$ *sum*. That comes from the additional information the more complex models have access to. All stemming models reach lower performance than their form counterparts (similar to results in Table 3). That suggests that stemming is not a proper alternative to correctly dealing with Spanish morphology. LAMB reaches higher performance than *form real* with already 20 dimensions. The 30 dimensional LAMB model is better than all other models. Thus, we can create lower-dimensional lemma embeddings that are as good as higher-dimensional form embeddings; this has the benefits of reducing the number of parameters in models using these embeddings and of reducing training times and memory consumption.

Corpus Size. Our second hypothesis is that less training data is necessary to train good embeddings. We create 10 training corpora consisting of the first k percent, $k \in \{10, 20, \ldots, 100\}$, of the randomized Spanish Wikipedia corpus. With these 10 subcorpora we repeat the word relation experiments of Section 4.2 (all POS). As query lemmata, we use the lemmata from before that exist in all subcorpora.

Figure 2 shows that the relative ranking among the models is the same as before. This time however, *form sum* yields slightly better performance than *form opt*, especially when little training data is available. The stemming models again are inferior to their form counterparts. Only *stem opt* is able to reach performance similar to *form opt*. LAMB always reaches higher performance than *form real*, even when only 10% of the training corpus is used. With 30% of the training corpus, LAMB surpasses the performance of the other models.[13] Again, by requiring less than 30% of the training data, embedding training becomes much more efficient. Furthermore, in low-resource languages that lack the availability of a large homogeneous corpus, LAMB can still be trained successfully.

6 Conclusion

We have presented STEM and LAMB, embeddings based on stems and lemmata. In three experiments we have shown the superiority compared to commonly used form embeddings. Especially (but not only) on MRLs, where data sparsity is a problem, both normalized embeddings perform better than form embeddings by a large margin. In a new challenging WordNet-based experiment we have shown four methods of adding morphological information

[13] Recall that *form opt* is similar to an approach that is used in most systems that have embeddings, which just use the available surface forms.

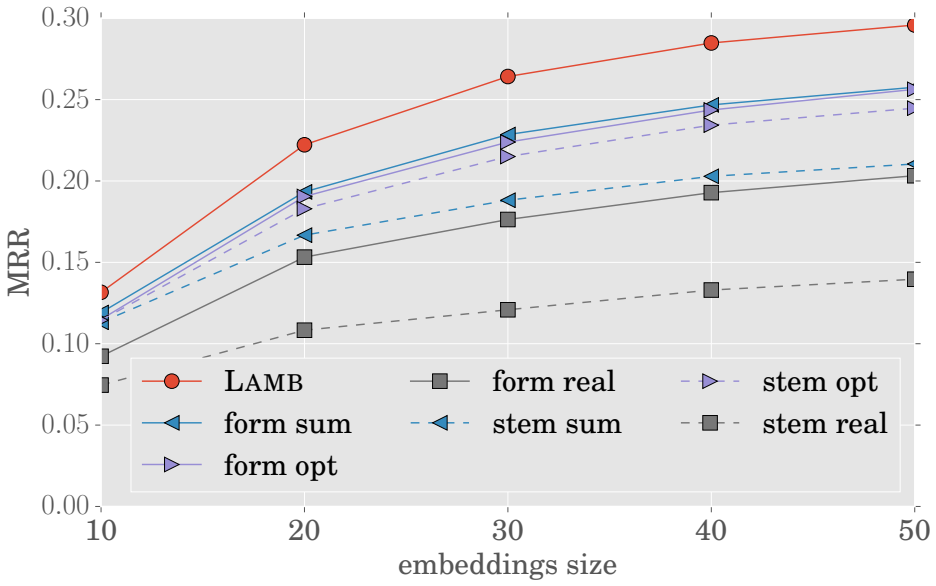

Figure 1: Embedding size analysis

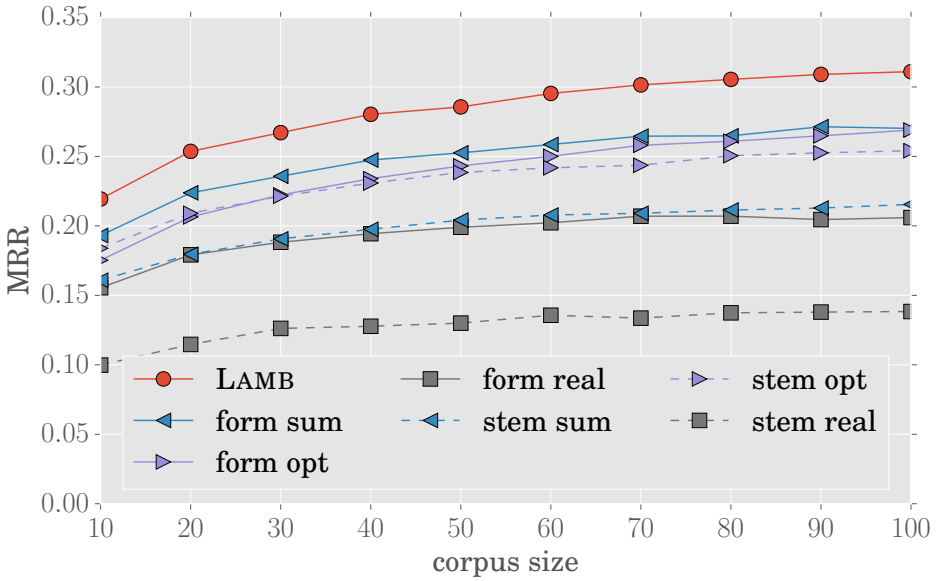

Figure 2: Corpus size analysis

(*opt*, *sum*, STEM, LAMB). Here, LAMB is the best of the proposed ways of using morphological information, consistently reaching higher performance, often by a large margin. STEM methods are not consistently better, indicating that the more principled way of normalization as done by LAMB is to be preferred. The datasets are available as supplementary material at `www.cis.uni-muenchen.de/ebert/`.

Our analysis shows that LAMB needs fewer embedding dimensions and less embedding training data to reach the same performance as form embeddings, making LAMB appealing for underresourced languages.

As morphological analyzers are becoming more widely available, our method – which is easy to implement, only requiring running the analyzer – should become applicable to more and more languages.

Fast Coupled Sequence Labeling on Heterogeneous Annotations via Context-aware Pruning

Zhenghua Li, Jiayuan Chao, Min Zhang*, Jiwen Yang
Soochow University, Suzhou, China

Abstract

The recently proposed coupled sequence labeling is shown to be able to effectively exploit multiple labeled data with heterogeneous annotations but suffer from severe inefficiency problem due to the large bundled tag space (Li et al., 2015). In their case study of part-of-speech (POS) tagging, Li et al. (2015) manually design context-free tag-to-tag mapping rules with a lot of effort to reduce the tag space.

This paper proposes a context-aware pruning approach that performs token-wise constraints on the tag space based on contextual evidences, making the coupled approach efficient enough to be applied to the more complex task of joint word segmentation (WS) and POS tagging for the first time. Experiments show that using the large-scale People Daily as auxiliary heterogeneous data, the coupled approach can improve F-score by $95.55 - 94.88 = 0.67\%$ on WS, and by $90.58 - 89.49 = 1.09\%$ on joint WS&POS on Penn Chinese Treebank. All codes are released at http://hlt.suda.edu.cn/~zhli.

1 Introduction

In statistical natural language processing, manually labeled data is inevitable for model supervision, but is also very expensive to build. However, due to the long-debated differences in underlying linguistic theories or emphasis of application, there often exist multiple labeled corpora for the same or similar tasks following different annotation guidelines (Jiang et al., 2009). For instance, in Chinese language processing, Penn Chinese Treebank version 5 (CTB5) is a widely used benchmark data and contains about 20 thousand sentences annotated with word boundaries, part-of-speech (POS) tags, and syntactic structures (Xue et al., 2005; Xia, 2000), whereas People's Daily corpus (PD)[1] is a large-scale corpus annotated with words and POS tags, containing about 300 thousand sentences from the first half of 1998 of People's Daily newspaper (Yu et al., 2003). Table 1 gives an example with both CTB and PD annotations. We can see that CTB and PD differ in both word boundary standards and POS tag sets.

	Especially		our	nation	economy	declines	.
CTB	特别是/AD		我/PN	国/NN	经济/NN	下滑/VV	。/PU
PD	特别/d	是/v	我国/n		经济/n	下滑/v	。/w

Table 1: An example of heterogeneous annotations.

Previous work on exploiting heterogeneous data mainly focuses on indirect guide-feature methods. The basic idea is to use one resource to generate extra guide features on another resource (Jiang et al., 2009; Sun and Wan, 2012), which is similar to stacked learning (Nivre and McDonald, 2008). Li et al. (2015) propose a coupled sequence labeling approach that can directly learn and predict two heterogeneous annotations simultaneously. The basic idea is to transform a single-side tag into a set of bundled tags for weak supervision based on the idea of ambiguous labeling. Due to the huge size of the bundled tag space, their coupled model is extremely inefficient. They then carefully design tag-to-tag

mapping rules to constrain the search space. Their case study on POS tagging shows that the coupled model outperforms the guide-feature method. However, the requirement of manually designed mapping rules makes their approach less attractive, since such mapping rules may be very difficult to construct for more complex tasks such as joint word segmentation (WS) and POS tagging.

This paper proposes a context-aware pruning approach that can effectively solve the inefficiency problem of the coupled model, making coupled sequence labeling more generally applicable. Specifically, this work makes the following contributions:

(1) We propose and systematically compare two ways for realizing context-aware pruning, i.e., online and offline pruning. Experiments on POS tagging show that both online and offline pruning can greatly improve the model efficiency with little accuracy loss.

(2) We for the first time apply coupled sequence labeling to the more complex task of joint WS&POS tagging. Experiments show that online pruning works badly due to the much larger tag set while offline pruning works well. Further analysis gives a clear explanation and leads to more insights in learning from ambiguous labeling.

(3) Experiments on joint WS&POS tagging show that our coupled approach with offline pruning improves F-score by $95.55 - 94.88 = 0.67\%$ on WS, and by $90.58 - 89.49 = 1.09\%$ on joint WS&POS on CTB5-test over the baseline, and is also consistently better than the guide-feature method.

2 Coupled Sequence Labeling

Given an input sequence of n tokens, denoted by $\mathbf{x} = w_1...w_n$, coupled sequence tagging aims to simultaneously predict two tag sequences $\mathbf{t}^a = t_1^a...t_n^a$ and $\mathbf{t}^b = t_1^b...t_n^b$, where $t_i^a \in \mathcal{T}^a$ and $t_i^b \in \mathcal{T}^b$ $(1 \leq i \leq n)$, and $\mathcal{T}^a$ and $\mathcal{T}^b$ are two different predefined tag sets. Alternatively, we can view the two tag sequences as one bundled tag sequence $\mathbf{t} = [\mathbf{t}^a, \mathbf{t}^b] = [t_1^a, t_1^b]...[t_n^a, t_n^b]$, where $[t_i^a, t_i^b] \in \mathcal{T}^a \times \mathcal{T}^b$ is called a *bundled tag*.

In this work, we treat CTB as the first-side annotation and PD as the second-side. For POS tagging, $\mathcal{T}^a$ is the set of POS tags in CTB, and $\mathcal{T}^b$ is the set of POS tags in PD, and we ignore the word boundary differences in the two datasets, following Li et al. (2015). We have $|\mathcal{T}^a| = 33$ and $|\mathcal{T}^b| = 38$.

For joint WS&POS tagging, we employ the standard four-tag label set to mark word boundaries, among which `B`, `I`, `E` respectively represent that the concerned character situates at the *begining, inside, end* position of a word, and *S* represents a single-character word. Then, we concatenate word boundary labels with POS tags. For instance, the first three characters in Table 1 correspond to "特/`B@AD` 别/`I@AD` 是/`E@AD`" in CTB, and to "特/`B@d` 别/`E@d` 是/`S@v`" in PD. We have $|\mathcal{T}^a| = 99$ and $|\mathcal{T}^b| = 128$.

2.1 Coupled Conditional Random Field (CRF)

Following Li et al. (2015), we build the coupled sequence labeling model based on a bigram linear-chain CRF (Lafferty et al., 2001). The conditional probability of a bundled tag sequence $\mathbf{t}$ is:

$$p(\mathbf{t}|\mathbf{x}, \tilde{\mathcal{S}}; \theta) = \frac{e^{Score(\mathbf{x},\mathbf{t};\theta)}}{Z(\mathbf{x}, \tilde{\mathcal{S}}; \theta)}$$
$$Z(\mathbf{x}, \tilde{\mathcal{S}}; \theta) = \sum\nolimits_{\mathbf{t} \in \tilde{\mathcal{S}}} e^{Score(\mathbf{x},\mathbf{t};\theta)} \quad (1)$$

where θ is the feature weights; $Z(\mathbf{x}, \tilde{\mathcal{S}}; \theta)$ is the normalization factor; $\tilde{\mathcal{S}}$ is the search space including all legal tag sequences for $\mathbf{x}$. We use $\tilde{\mathcal{T}}_i \subseteq \mathcal{T}^a \times \mathcal{T}^b$ to denote the set of all legal tags for token w_i, so $\tilde{\mathcal{S}} = \tilde{\mathcal{T}}_1 \times \cdots \times \tilde{\mathcal{T}}_n$.

According to the linear-chain Markovian assumption, the score of a bundled tag sequence is:

$$Score(\mathbf{x}, \mathbf{t}; \theta) = \theta \cdot \mathbf{f}(\mathbf{x}, [\mathbf{t}^a, \mathbf{t}^b])$$
$$\sum_{i=1}^{n+1} \theta \cdot \begin{bmatrix} \mathbf{f}_{joint}(\mathbf{x}, i, [t_{i-1}^a, t_{i-1}^b], [t_i^a, t_i^b]) \\ \mathbf{f}_{sep\_a}(\mathbf{x}, i, t_{i-1}^a, t_i^a) \\ \mathbf{f}_{sep\_b}(\mathbf{x}, i, t_{i-1}^b, t_i^b) \end{bmatrix} \quad (2)$$

where $\mathbf{f}(\mathbf{x}, [\mathbf{t}^a, \mathbf{t}^b])$ is the accumulated sparse feature vector; $\mathbf{f}_{joint/sep\_a/sep\_b}(\mathbf{x}, i, t', t)$ share the same list of feature templates, and return local feature vectors for tagging w_{i-1} as t' and w_i as t.

Traditional single-side tagging models can only exploit a single set of separate features $\mathbf{f}_{sep\_a}(.)$ or $\mathbf{f}_{sep\_b}(.)$. In contrast, the coupled model makes

use of all three sets of features. Li et al. (2015) demonstrate that the joint features $\mathbf{f}_{joint}(.)$ capture the implicit mappings between heterogeneous annotations, and the separate features function as back-off features for alleviating the data sparseness problem of the joint features.

For the feature templates, we follow Li et al. (2015) and adopt those described in Zhang and Clark (2008) for POS tagging, and use those described in Zhang et al. (2014b) for joint WS&POS tagging.

2.2 Learn from Incomplete Data

The key challenge for coupled sequence labeling is that both CTB and PD are non-overlapping and each contains only one-side annotations. Based on the idea of ambiguous labeling, Li et al. (2015) first concatenate a single-side tag with many possible second-side tags, and then use the set of bundled tags as possibly-correct references during training.

Suppose $\mathbf{x} = w_1...w_n$ is a training sentence from CTB, and $\mathbf{t}^a = \check{t}_1^a...\check{t}_n^a$ is the manually labeled tag sequence. Then we define $\mathcal{T}_i = \{\check{t}_i^a\} \times \mathcal{T}^b$ as the set of possibly-correct bundled tags, and $\mathcal{S} = \mathcal{T}_1 \times \cdots \times \mathcal{T}_n$ as a exponential-size set of possibly-correct bundled tag sequences used for model supervision.

Given $\mathbf{x}$ and the whole legal search space $\tilde{\mathcal{S}}$, the probability of the possibly-correct space $\mathcal{S} \subseteq \tilde{\mathcal{S}}$ is:

$$p(\mathcal{S}|\mathbf{x}, \tilde{\mathcal{S}}; \theta) = \sum_{\mathbf{t} \in \mathcal{V}} p(\mathbf{t}|\mathbf{x}, \tilde{\mathcal{S}}; \theta) = \frac{Z(\mathbf{x}, \mathcal{S}; \theta)}{Z(\mathbf{x}, \tilde{\mathcal{S}}; \theta)} \quad (3)$$

where $Z(\mathbf{x}, \mathcal{S}; \theta)$ is analogous to $Z(\mathbf{x}, \tilde{\mathcal{S}}; \theta)$ in Eq. (3) but only sums over $\mathcal{S}$.

Given $\mathcal{D} = \{(\mathbf{x}_j, \mathcal{S}_j, \tilde{\mathcal{S}}_j)\}_{j=1}^N$, the gradient of the log likelihood is:

$$\begin{aligned}
&\frac{\partial \mathcal{LL}(\mathcal{D}; \theta)}{\partial \theta} = \frac{\partial \log \sum_j p(\mathcal{S}_j|\mathbf{x}_j, \tilde{\mathcal{S}}_j; \theta)}{\partial \theta} \\
=&\sum\nolimits_j \left(\frac{\partial \log Z(\mathbf{x}_j, \mathcal{S}_j; \theta)}{\partial \theta} - \frac{\partial \log Z(\mathbf{x}_j, \tilde{\mathcal{S}}_j; \theta)}{\partial \theta} \right) \\
=&\sum\nolimits_j \left(E_{\mathbf{t}|\mathbf{x}_j, \mathcal{S}_j; \theta}[\mathbf{f}(\mathbf{x}_j, \mathbf{t})] - E_{\mathbf{t}|\mathbf{x}_j, \tilde{\mathcal{S}}_j; \theta}[\mathbf{f}(\mathbf{x}_j, \mathbf{t})] \right)
\end{aligned} \quad (4)$$

where the two terms are the feature expectations under $\mathcal{S}_j$ and $\tilde{\mathcal{S}}_j$ respectively. And the detailed derivations are as follows:

$$\begin{aligned}
&\frac{\partial \log Z(\mathbf{x}, \mathcal{S}; \theta)}{\partial \theta} \\
=&\frac{1}{Z(\mathbf{x}, \mathcal{S}; \theta)} \times \frac{\partial \sum_{\mathbf{t} \in \mathcal{S}} e^{Score(\mathbf{x}, \mathbf{t}; \theta)}}{\partial \theta} \\
=&\sum_{\mathbf{t} \in \mathcal{S}} \left(\frac{e^{Score(\mathbf{x}, \mathbf{t}; \theta)}}{Z(\mathbf{x}, \mathcal{S}; \theta)} \times \frac{\partial Score(\mathbf{x}, \mathbf{t}; \theta)}{\partial \theta} \right) \\
=&\sum_{\mathbf{t} \in \mathcal{S}} p(\mathbf{t}|\mathbf{x}, \mathcal{S}; \theta) \times \mathbf{f}(\mathbf{x}, \mathbf{t}) \\
=&E_{\mathbf{t}|\mathbf{x}, \mathcal{S}; \theta}[\mathbf{f}(\mathbf{x}, \mathbf{t})]
\end{aligned} \quad (5)$$

Please notice that $\mathbf{t} = [\mathbf{t}^a, \mathbf{t}^b]$ denotes a bundled tag sequence in this context of coupled sequence labeling.

2.3 Efficiency Issue

Under *complete mapping*, each one-side tag is mapped to all the-other-side tags for constructing bundled tags, producing a very huge set of legal bundled tags $\tilde{\mathcal{T}}_i = \mathcal{T}^a \times \mathcal{T}^b$. Using the classic Forward-Backward algorithm, we still need $O(n \times |\mathcal{T}^a|^2 \times |\mathcal{T}^b|^2)$ time complexity to compute $E_{\mathbf{t}|\mathbf{x}, \tilde{\mathcal{S}}; \theta}[\mathbf{f}(\mathbf{x}, \mathbf{t})]$, which is prohibitively expensive.[2]

In order to improve efficiency, Li et al. (2015) propose to use a set of context-free tag-to-tag mapping rules for reducing the search space. For example, we may specify that the CTB POS tag "NN" can only be concatenated with a set of PD tags like "{n, vn, ns}".[3] With much effort, they propose a set of *relaxed mapping* rules that greatly reduces the number of bundled tags from $|\mathcal{T}^a| \times |\mathcal{T}^b| = 33 \times 38 = 1,254$ to 179 for POS tagging.

3 Context-aware Pruning

Using manually designed context-free tag-to-tag mapping rules to constrain the search space has two major drawbacks. On the one hand, for more complex problems such as joint WS&POS tagging, it becomes very difficult to design proper mapping rules due to the much larger tag set. On the other hand, the experimental results in Li et al. (2015)

[2] In contrast, computing $E_{\mathbf{t}|\mathbf{x}, \mathcal{S}; \theta}[\mathbf{f}(\mathbf{x}, \mathbf{t})]$ is not the bottleneck, since $|\mathcal{T}_i| = |\mathcal{T}^b|$ for CTB or $|\mathcal{T}_i| = |\mathcal{T}^a|$ for PD.

[3] Please refer to http://hlt.suda.edu.cn/~zhli/resources/pos-mapping-CTB-PD.html for their detailed mapping rules.

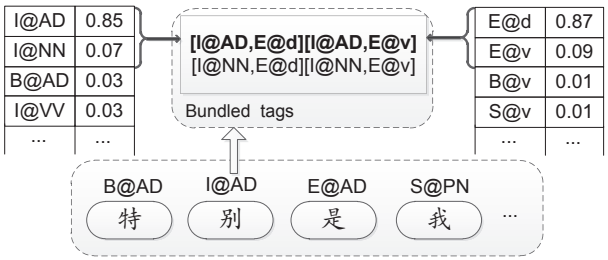

Figure 1: Illustration of context-aware pruning with $r = 2$ on a CTB training sentence.

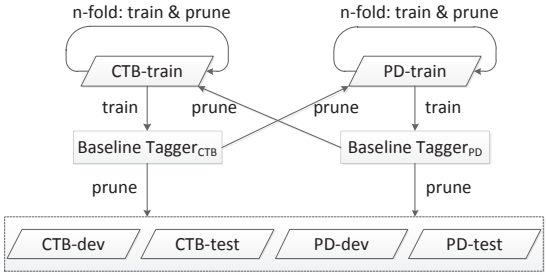

Figure 2: Workflow of offline pruning.

suggest that the coupled model can best learn the implicit context-sensitive mapping relationships between annotations under complete mapping, and imposing strict tag-to-tag mapping constraints usually hurts tagging accuracy.

In this work, our intuition is that the mapping relationships between heterogeneous annotations are highly context-sensitive. Therefore, we propose a context-aware pruning approach to more accurately capture such mappings, thus solving the efficiency issue. The basic idea is to consider only a small set of most likely bundled tags, instead of the whole bundled tag space $\mathcal{T}^a \times \mathcal{T}^b$, based on evidences of surrounding contexts. Specifically, for each token w_i, we only keep r one-side tags according to separate features $\mathbf{f}_{sep\_a/b}(.)$ for each side, and then use the remaining single-side tags to construct $\tilde{\mathcal{T}}_i$ and $\mathcal{T}_i$.

We use the second character "别/I@AD" in Fig. 1 as an example. We list the single-side tags in the descending order of their marginal probabilities according to $\mathbf{f}_{sep\_a/b}(.)$. Then we only keep $r = 2$ single-side tags, used as $\mathcal{T}_i^a$ and $\mathcal{T}_i^b$. Then $\tilde{\mathcal{T}}_i = \mathcal{T}^a \times \mathcal{T}^b$ contains the four bundled tags shown in the upper box, known as the whole possible tag set for searching. And $\mathcal{T}_i = \{\check{t}^a\} \times \mathcal{T}^b$ contains two bundled tags, as marked in bold, knowns as the possibly-correct tag set, since $\check{t}^a$ is the manually labeled tag. The case when the word has the second-side manually-labeled tag $\{\check{t}^b\}$ can be similarly handled.

Beside r, we use another hyper-parameter λ to further reduce the number of one-side tag candidates. The intuition is that in many cases, we may only need to use a smaller number $r' < r$ of possible candidates, since the remaining tags are very unlikely ones according to the marginal probabilities. Therefore, for each item w_i, we define r' as the smallest number of most likely candidate tags whose accumulative probability is larger than λ. Then, we only keep the $\min(r', r)$ most likely candidate tags.

We have $|\tilde{\mathcal{T}}_i| = r^2$ without considering the accumulated probability threshold λ. Thus, it requires $O(nr^4)$ time complexity to compute $E_{\mathbf{t}|\mathbf{x},\tilde{\mathcal{S}};\theta}[\mathbf{f}(\mathbf{x}, \mathbf{t})]$ using the Forward-Backward algorithm.

In the following, we propose two ways for realizing context-aware pruning, i.e., online and offline pruning. Their comparison and analysis are given in the experiment parts.

3.1 Online Pruning

The online pruning approach directly uses the coupled model to perform pruning. Given a sentence, we first use a subset of features $\mathbf{f}_{sep\_a}(.)$ and corresponding feature weights trained so far to compute marginal probabilities of first-side tags, and then analogously process the second-side tags based on $\mathbf{f}_{sep\_b}(.)$. This requires roughly the same time complexity as two baseline models. Then the marginal probabilities are used for pruning.

3.2 Offline Pruning

The offline pruning approach is a little bit more complex, and uses many additional single-side tagging models for pruning. Fig. 2 shows the workflow. Particularly, n-fold jack-knifing is adopted to perform pruning on the same-side training data. Finally, all training/dev/test datasets of CTB and PD are preprocessed in an offline way, so that each word in a sentence has a set of most likely CTB tags ($\mathcal{T}_i^a$) and another set of most likely PD tags ($\mathcal{T}_i^b$).

4 Experiment Settings

Data. Following Li et al. (2015), we use CTB5 and PD for the heterogeneous data. Under the standard

data split of CTB5, the training/dev/test datasets contain $16,091/803/1,910$ sentences respectively. For PD, we use the $46,815$ sentences in January 1998 as the training data, the first $2,000$ sentences in February as the development data, and the first $5,000$ sentences in June as the test data.

Evaluation Metrics. We use the standard token-wise tagging accuracy for POS tagging. For joint WS&POS tagging, besides character-wise tagging accuracy, we also use the standard precision (P), recall (R), and F-score of only words (WS) or POS-tagged words (WS&POS).

Parameter settings. Stochastic gradient descent (SGD) is adopted to train the baseline single-side tagging models, the guide-feature models, and the coupled models.[4]

For the coupled models, we directly follow the simple corpus-weighting strategy proposed in Li et al. (2015) to balance the contribution of the two datasets. We randomly sample $5,000$ CTB-train sentences and $5,000$ PD-train sentences, which are then merged and shuffled for one-iteration training. After each iteration, the coupled model is evaluated on both CTB-dev and PD-dev, providing us two single-side tag accuracies, one on CTB-side tags, and the other on PD-dev tags. Another advantage of using a subset of training data in one iteration is to monitor the training progress in smaller steps. For fair comparison, when building the baseline and guide-feature models, we also randomly sample $5,000$ training sentences from the whole training data for one-iteration training, and then report an tagging accuracy on development data. For all models, the training terminates if peak accuracies stop improving within 30 consecutive iterations, and we use the model that performs the best on development data for final evaluation on test data.

5 Experiments on POS Tagging

5.1 Parameter Tuning

For both online and offline pruning, we need to decide the maximum number of single-side tag candidates r and the accumulative probability threshold λ for further truncating the candidates. Table 2 shows the tagging accuracies and the averaged numbers of single-side tags for each token after pruning.

r	λ	Accuracy (%)		#Tags (pruned)	
		CTB5-dev	PD-dev	CTB-side	PD-side
Online Pruning					
2	0.98	94.25	95.03	2.0	2.0
4	0.98	95.06	95.66	3.9	4.0
8	**0.98**	**95.14**	**95.83**	6.3	7.4
16	0.98	95.12	95.81	7.8	14.1
8	0.90	**95.15**	95.79	3.7	6.3
8	0.95	95.13	**95.82**	5.1	7.1
8	0.99	**95.15**	95.74	7.4	7.9
8	1.00	**95.15**	95.76	8.0	8.0
Offline Pruning					
8	0.9999	94.95	96.05	4.1	5.1
16	**0.9999**	**95.15**	**96.09**	5.2	7.6
32	0.9999	95.13	96.09	5.5	9.3
16	0.99	94.42	95.77	1.6	2.2
16	0.999	95.02	**96.10**	2.6	4.0
16	0.99999	**95.10**	96.09	6.8	8.9

Table 2: POS tagging performance of online and offline pruning with different r and λ on CTB5 and PD.

The first major row tunes the two hyper-parameters for online pruning. We first fix $\lambda = 0.98$ and increase r from 2 to 8, leading to consistently improved accuracies on both CTB5-dev and PD-dev. No further improvement is gained with $r = 16$, indicating that tags below the top-8 are mostly very unlikely ones and thus insignificant for computing feature expectations. Then we fix $r = 8$ and try different λ. We find that λ has little effect on tagging accuracies but influences the numbers of remaining single-side tags. We choose $r = 8$ and $\lambda = 0.98$ for final evaluation.

The second major row tunes r and λ for offline pruning. Different from online pruning, λ has much greater effect on the number of remaining single-side tags. Under $\lambda = 0.9999$, increasing r from 8 to 16 leads to 0.20% accuracy improvement on CTB5-dev, but using $r = 32$ has no further gain. Then we fix $r = 16$ and vary λ from 0.99 to 0.99999. We choose $r = 16$ and $\lambda = 0.9999$ for offline pruning for final evaluation, which leaves each word with about 5.2 CTB-tags and 7.6 PD-tags on average.

[4] We use the implementation of SGD in CRFsuite (`http://www.chokkan.org/software/crfsuite/`), and set $b = 30$ as the batch-size and $C = 0.1$ as the regularization factor.

	Accuracy (%)		Speed
	CTB5-test	PD-test	Toks/Sec
Coupled (Offline)	**94.83**	95.90	246
Coupled (Online)	94.74	**95.95**	365
Coupled (No Prune)	94.58	95.79	3
Coupled (Relaxed)	94.63	95.87	127
Guide-feature	94.35	95.63	584
Baseline	94.07	95.82	1573
Li et al. (2012b)	94.60	—	—

Table 3: POS tagging performance of difference approaches on CTB5 and PD.

5.2 Main Results

Table 3 summarizes the accuracies on the test data and the tagging speed during the test phase. "Coupled (No Prune)" refers to the coupled model with complete mapping in Li et al. (2015), which maps each one-side tag to all the-other-side tags. "Coupled (Relaxed)" refers the coupled model with relaxed mapping in Li et al. (2015), which maps a one-side tag to a manually-designed small set of the-other-side tags. Li et al. (2012b) report the state-of-the-art accuracy on this CTB data, with a joint model of Chinese POS tagging and dependency parsing.

It is clear that both online and offline pruning greatly improve the efficiency of the coupled model by about two magnitudes, without the need of a carefully predefined set of tag-to-tag mapping rules.[5] Moreover, the coupled model with offline pruning achieves 0.76% accuracy improvement on CTB5-test over the baseline model, and 0.48% over our reimplemented guide-feature approach of Jiang et al. (2009). The gains on PD-test are marginal, possibly due to the large size of PD-train, similar to the results in Li et al. (2015).

6 Experiments on Joint WS&POS Tagging

6.1 Parameter Tuning

Table 4 shows results for tuning r and λ. From the results in the first major row, we can see that in the online pruning method, λ seems useless and r becomes the only threshold for pruning unlikely single-side tags. The accuracies are much inferior to those from the offline pruning approach. We believe that the accuracies can be further improved with larger r, which would nevertheless lead to severe inefficiency issue. Based on the results, we choose $r = 16$ and $\lambda = 1.00$ for final evaluation.

r	λ	Accuracy (%)		#Tags (pruned)	
		CTB5-dev	PD-dev	CTB-side	PD-side
Online Pruning					
8	1.00	90.41	89.91	8.0	8.0
16	0.95	90.65	90.22	15.9	16.0
16	0.99	90.77	**90.49**	16.0	16.0
16	**1.00**	**90.79**	**90.49**	16.0	16.0
Offline Pruning					
8	0.995	91.22	91.62	2.6	3.1
16	**0.995**	91.66	91.85	3.2	4.3
32	0.995	**91.67**	**91.87**	3.5	5.6
16	0.95	90.69	91.30	1.6	2.1
16	0.99	**91.64**	**91.92**	2.5	3.5
16	0.999	91.62	91.75	5.1	6.4

Table 4: WS&POS tagging performance of online and offline pruning with different r and λ on CTB5 and PD.

The second major row tries to decide r and λ for the offline pruning approach. Under $\lambda = 0.995$, increasing r from 8 to 16 improves accuracies both on CTB5-dev and PD-dev, but further using $r = 32$ leads to little gain. Then we fix $r = 16$ and vary λ from 0.95 to 0.999. Using $\lambda = 0.95$ leaves only 1.6 CTB tags and 2.1 PD tags for each character, but has a large accuracy drop. We choose $r = 16$ and $\lambda = 0.995$ for offline pruning for final evaluation, which leaves each character with 3.2 CTB-tags and 4.3 PD-tags on average.

6.2 Main Results

Table 5 summarizes the accuracies on the test data and the tagging speed (characters per second) during the test phase. "Coupled (No Prune)" is not tried due to the prohibitive tag set size in joint WS&POS tagging, and "Coupled (Relaxed)" is also skipped since it seems impossible to manually design reasonable tag-to-tag mapping rules in this case.

In terms of efficiency, the coupled model with offline pruning is on par with the baseline single-side tagging model.[6]

[5] Due to the model complexity of "Coupled (No Prune)", we discard all low-frequency (< 3) features in the training data to speed up training. This explains why "Coupled (No Prune)" has slightly lower accuracies than "Coupled (Relaxed)".

[6] The time estimation does not include the two separate processes of pruning single-side tags, which is approximately

	P/R/F (%) on CTB5-test		P/R/F (%) on PD-test		Speed
	Only WS	Joint WS&POS	Only WS	Joint WS&POS	Char/Sec
Coupled (Offline)	**95.65/95.46/95.55**	**90.68/90.49/90.58**	96.39/95.86/96.12	92.70/92.19/92.44	115
Coupled (Online)	95.17/94.71/94.94	89.80/89.37/89.58	95.76/95.45/95.60	91.71/91.41/91.56	26

Baseline	95.00/94.77/94.88	89.60/89.38/89.49	**96.56/96.00/96.28**	**92.74/92.20/92.47**	119

Table 5: WS&POS tagging performance of difference approaches on CTB5 and PD.

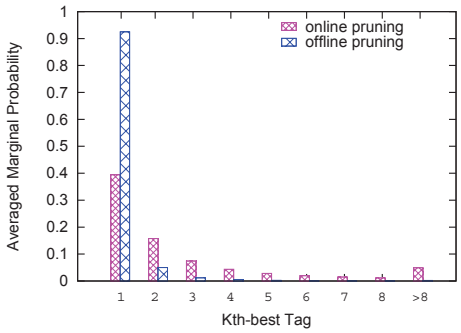

Figure 3: Probability distribution with online/offline pruning for the task of joint WS&POS.

In terms of F-score, the coupled model with offline pruning achieves 0.67% (WS) and 1.09% (WS&POS) gains on CTB5-test over the baseline model, and 0.48% (WS) and 0.79% (WS&POS) over our reimplemented guide-feature approach of Jiang et al. (2009). Similar to the case of POS tagging, the baseline model is very competitive on PD-test due to the large scale of PD-train.

6.3 Analysis

Online vs. offline pruning. The averaged numbers of single-side tags after pruning in Table 4 and 2), suggest that the online pruning approach works badly in assigning proper marginal probabilities to different tags. Our first guess is that in online pruning, the weights of separate features are optimized as a part of the coupled model, and thus producing somewhat flawed probabilities. However, our further analysis gives a more convincing explanation.

Fig. 3 compares the distribution of averaged probabilities of k^{th}-best CTB-side tags after online and offline pruning. The statistics are gathered on CTB5-test. Under online pruning, the averaged probability of the best tag is only about 0.4, which is surprisingly low and cannot be explained with the aforementioned improper optimization issue. Please note that both the online and offline models uses the best choices of r and λ based on Table 4, and are trained until convergence.

After a few trials of reducing the size of PD-train for training the coupled model, we realize that the underlying reason is that ambiguous labeling makes the probability mass more uniformly distributed, since for a PD-train sentence, the characters only have the gold-standard PD-side tags, and the model basically uses all CTB-side tags as gold-standard answers. Thanks to the CTB-train sentences, the model may be able to choose the correct tag, but inevitably becomes more indecisive at the same time due to the PD-train sentences.

In contrast, the offline pruning approach directly uses two baseline models for pruning, which is a job perfectly suitable for the baseline models. The entropy of the probability distribution for online pruning is about 1.524 while that for offline pruning is only 0.355.

Error distributions. To better understand the gains from the coupled approach, we show the F-score of specific POS tags for both the baseline and coupled models in Fig. 4, in the descending order of absolute F-score improvements. The largest improvement is from words tagged as "LB" (mostly for the word "被", marking a certain type of passive construction), and the F-score increases by $65.22 - 54.55 = 10.67\%$. Nearly all POS tags have more or less F-score improvement. Due to the space limit, we only show the tags with more than 2.0% improvement. The most noticeable exception is that F-score drops by $84.80 - 86.49 = -1.69\%$ for words tagged as "OD" (ordinal numbers, as opposed to cardinal numbers).

In terms of words, we find the largest gain is from "卢森博格/NR" (Luxemburgo, place name), which appears 11 times in CTB5-test, with an absolute

equal to the time of two baseline models.

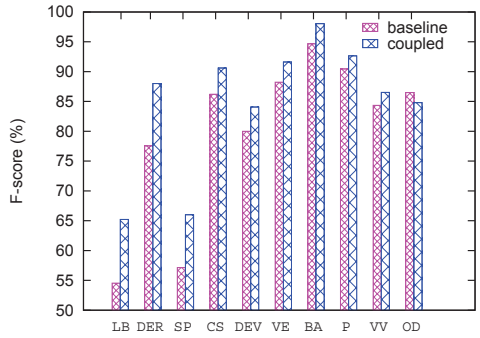

Figure 4: F-score comparison between the baseline and coupled WS&POS tagging models on different CTB POS tags.

	F (%) on CTB5X-test	
	Only WS	Joint WS&POS
Coupled (Offline)	**98.01**	**94.39**
Guide-feature	97.96	94.06
Baseline	97.37	93.23
Sun and Wan (2012)	—	94.36
Jiang et al. (2009)	98.23	94.03

Table 6: WS&POS tagging performance of difference approaches on CTB5X and PD.

improvement of $90.00 - 16.67 = 73.33\%$ in recall ratio. The reason is that PD-train contains a lot of related words such as "卢森堡" (Luxembourg, place name) and "克拉泽博格" (Krayzelburg, person name) while CTB5-train has none.

6.4 Comparison with Previous Work

In order to compare with previous work, we also run our models on CTB5X and PD, where CTB5X adopts a different data split of CTB5 and is widely used in previous research on joint WS&POS tagging (Jiang et al., 2009; Sun and Wan, 2012). CTB5X-dev/test only contain $352/348$ sentences respectively. Table 6 presents the F scores on CTB5X-test. We can see that the coupled model with offline pruning achieves 0.64% (WS) and 1.16% (WS&POS) F-score improvements over the baseline model, and 0.05% (WS) and 0.33% (WS&POS) over the guide-feature approach.

The original guide-feature method in Jiang et al. (2009) achieves 98.23% and 94.03% F-score, which is very close to the results of our reimplemented model. The sub-word stacking approach of Sun and Wan (2012) can be understood as a more complex variant of the basic guide-feature method.[7]

The results on both the larger CTB5-test (in Table 5) and CTB5X-test suggest that the coupled approach is more consistent and robust than the guide-feature method. The reason may be two-fold. First, in the coupled approach, the model is able to actively learn the implicit mappings between two sets of annotations, whereas the guide-feature model can only passively learn when to trust the automatically produced tags. Second, the coupled approach can directly learn from both heterogeneous training datasets, thus covering more phenomena of language usage.

7 Related Work

A lot of research has been devoted to design an effective way to exploit non-overlapping heterogeneous labeled data, especially in Chinese language processing, where such heterogeneous resources are ubiquitous due to historical reasons. Jiang et al. (2009) first propose the guide-feature approach, which is similar to stacked learning (Nivre and McDonald, 2008), for joint WS&POS tagging on CTB and PD. Sun and Wan (2012) further extend the guide-feature method and propose a more complex sub-word stacking approach. Qiu et al. (2013) propose a linear coupled model similar to that of Li et al. (2015). The key difference is that the model of Qiu et al. (2013) only uses separate features, while Li et al. (2015) and this work explore joint features as well.

Li et al. (2012a) apply the guide-feature idea to dependency parsing on CTB and PD. Zhang et al. (2014a) extend a shift-reduce dependency parsing model in order to simultaneously learn and produce two heterogeneous parse trees, which however assumes the existence of training data with both-side annotations.

Our context-aware pruning approach is similar to coarse-to-fine pruning in parsing community (Koo and Collins, 2010; Rush and Petrov, 2012), which is a useful technique that allows us to use very complex parsing models without too much efficiency cost. The idea is first to use a simple and basic off-shelf model to prune the search space and only keep highly likely dependency links, and then let the complex

[7] Sun and Wan (2012) achieve 94.68% F-score on CTB5X-test by further employing a re-training strategy.

model infer in the remaining search space. Weiss and Taskar (2010) propose structured prediction cascades: a sequence of increasingly complex models that progressively filter the space of possible outputs, and provide theoretical generalization bounds on a novel convex loss function that balances pruning error with pruning efficiency.

This work is also closely related with multi-task learning, which aims to jointly learn multiple related tasks with the benefit of using interactive features under a share representation (Ben-David and Schuller, 2003; Ando and Zhang, 2005; Parameswaran and Weinberger, 2010). However, as far as we know, multi-task learning usually assumes the existence of data with labels for multiple tasks at the same time, which is unavailable in our scenario, making our problem more particularly difficult.

Our coupled CRF model is similar to a factorial CRF (Sutton et al., 2004), in the sense that the bundled tags can be factorized into two connected latent variables. Initially, factorial CRFs are designed to jointly model two related (and typically hierarchical) sequential labeling tasks, such as POS tagging and chunking. In this work, our coupled CRF model jointly handles two same tasks with different annotation schemes. Moreover, this work provides a natural way to learn from incomplete annotations where one sentence only contains one-side labels.

Learning with ambiguous labeling is previously explored for classification (Jin and Ghahramani, 2002), sequence labeling (Dredze et al., 2009), parsing (Riezler et al., 2002; Täckström et al., 2013). Recently, researchers propose to derive natural annotations from web data to supervise Chinese word segmentation models in the form of ambiguous labeling (Jiang et al., 2013; Liu et al., 2014; Yang and Vozila, 2014).

8 Conclusion

This paper proposes a context-aware pruning approach for the coupled sequence labeling model of Li et al. (2015). The basic idea is to more accurately constrain the bundled tag space of a token according to its contexts in the sentence, instead of using heuristic context-free tag-to-tag mapping rules in the original work. We propose and compare two different ways of realizing pruning, i.e., online and offline pruning. In summary, extensive experiments leads to the following findings.

(1) Offline pruning works well on both POS tagging and joint WS&POS tagging, whereas online pruning only works well on POS tagging but fails on joint WS&POS tagging due to the much larger tag set. Further analysis shows that the reason is that under online pruning, ambiguous labeling during training makes the probabilities of single-side tags more evenly distributed.

(2) In terms of tagging accuracy and F-score, the coupled approach with offline pruning outperforms the baseline single-side tagging model by large margin, and is also consistently better than the mainstream guide-feature method on both POS tagging and joint WS&POS tagging.

Acknowledgments

The authors would like to thank the anonymous reviewers for the helpful comments. We are very grateful to Meishan Zhang for inspiring us to use online pruning to improve the efficiency of the coupled approach. We also thank Wenliang Chen for the helpful discussions. Unsupervised Neural Dependency Parsing*

Yong Jiang, Wenjuan Han and **Kewei Tu**

Abstract

Unsupervised dependency parsing aims to learn a dependency grammar from text annotated with only POS tags. Various features and inductive biases are often used to incorporate prior knowledge into learning. One useful type of prior information is that there exist correlations between the parameters of grammar rules involving different POS tags. Previous work employed manually designed features or special prior distributions to encode such information. In this paper, we propose a novel approach to unsupervised dependency parsing that uses a neural model to predict grammar rule probabilities based on distributed representation of POS tags. The distributed representation is automatically learned from data and captures the correlations between POS tags. Our experiments show that our approach outperforms previous approaches utilizing POS correlations and is competitive with recent state-of-the-art approaches on nine different languages.

1 Introduction

Unsupervised structured prediction from data is an important problem in natural language processing, with applications in grammar induction, POS tag induction, word alignment and so on. Because the training data is unannotated in unsupervised structured prediction, learning is very hard. In this paper, we focus on unsupervised dependency parsing, which aims to identify the dependency trees of sentences in an unsupervised manner.

*This work was supported by the National Natural Science Foundation of China (61503248).

Previous work on unsupervised dependency parsing is mainly based on the dependency model with valence (DMV) (Klein and Manning, 2004) and its extension (Headden III et al., 2009; Gillenwater et al., 2010). To effectively learn the DMV model for better parsing accuracy, a variety of inductive biases and handcrafted features have been proposed to incorporate prior information into learning. One useful type of prior information is that there exist correlations between the parameters of grammar rules involving different POS tags. Cohen and Smith (2009; 2010) employed special prior distributions to encourage learning of correlations between POS tags. Berg-Kirkpatrick et al. (2010) encoded the relations between POS tags using manually designed features.

In this work, we propose a neural based approach to unsupervised dependency parsing. We incorporate a neural model into the DMV model to predict grammar rule probabilities based on distributed representation of POS tags. We learn the neural network parameters as well as the distributed representations from data using the expectation-maximization algorithm. The correlations between POS tags are automatically captured in the learned POS embeddings and contribute to the improvement of parsing accuracy. In particular, probabilities of grammar rules involving correlated POS tags are automatically smoothed in our approach without the need for manual features or additional smoothing procedures.

Our experiments show that on the Wall Street Journal corpus our approach outperforms the previous approaches that also utilize POS tag correla-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 763–771,
Austin, Texas, November 1-5, 2016.

tions, and achieves a comparable result with recent state-of-the-art grammar induction systems. On the datasets of eight additional languages, our approach is able to achieve better performance than the baseline methods without any parameter tuning.

2 Related work

2.1 Dependency Model with Valence

The dependency model with valence (DMV) (Klein and Manning, 2004) is the first model to outperform the left-branching baseline in unsupervised dependency parsing of English. The DMV model is a generative model of a sentence and its parse tree. It generates a dependency parse from the root in a recursive top-down manner. At each step, a decision is first made as to whether a new child POS tag shall be generated from the current head tag; if the decision is yes, then a new child POS tag is sampled; otherwise, the existing child tags are recursively visited. There are three types of grammar rules in the model: `CHILD, DECISION` and `ROOT`, each with a set of multinomial parameters $\mathrm{P}_{CHILD}(c|h, dir, val)$, $\mathrm{P}_{DECISION}(dec|h, dir, val)$ and $\mathrm{P}_{ROOT}(c|root)$, where dir is a binary variable indicating the generation direction (left or right), val is a boolean variable indicating whether the current head POS tag already has a child in the current direction or not, c indicates the child POS tag, h indicates the head POS tag, and dec indicates the decision of either STOP or CONTINUE. A `CHILD` rule indicates the probability of generating child c given head h on direction dir and valence val. A `DECISION` rule indicates the probability of STOP or CONTINUE given the head, direction and valence. A `ROOT` rule is the probability of a child c generated by the root. The probability of a dependency tree is the product of probabilities of all the grammar rules used in generating the dependency tree. The probability of a sentence is the sum of probabilities of all the dependency trees consistent with the sentence.

The basic DMV model has the limitation of being oversimplified and unable to capture certain linguistic structures. Headden et al. (2009) incorporated more types of valence and lexicalized information in the DMV model to increase its representation power and achieved better parsing accuracy than the basic DMV model.

2.2 DMV-based Learning Algorithms for Unsupervised Dependency Parsing

To learn a DMV model from text, the Expectation Maximization (EM) algorithm (Klein and Manning, 2004) can be used. In the E step, the model calculates the expected number of times each grammar rule is used in parsing the training text by using the inside-outside algorithm. In the M-step, these expected counts are normalized to become the probabilities of the grammar rules.

There have been many more advanced learning algorithms of the DMV model beyond the basic EM algorithm. In the work of Cohen and Smith (2008), a logistic normal prior was used in the DMV model to capture the similarity between POS tags. In the work of Berg-Kirkpatrick et al. (2010), features that group various morphological variants of nouns and verbs are used to predict the `DECISION` and `CHILD` parameters. These two approaches both utilize the correlations between POS tags to obtain better probability estimation of grammar rules involving such correlated POS tags. In the work of Tu and Honavar (2012), unambiguity of parse trees is incorporated into the training objective function of DMV to obtain a better performance.

2.3 Other Approaches to Unsupervised Dependency Parsing

There are many other approaches to unsupervised dependency parsing that are not based on DMV. Daumé III (2009) proposed a stochastic search based method to do unsupervised Shift-Reduce transition parsing. Rasooli and Faili (2012) proposed a transition based unsupervised dependency parser together with "baby-step" training (Spitkovsky et al., 2010) to improve parsing accuracy. Le and Zuidema (2015) proposed a complicated reranking based unsupervised dependency parsing system and achieved the state-of-the-art performance on the Penn Treebank dataset.

2.4 Neural based Supervised Dependency Parser

There exist several previous approaches on using neural networks for supervised dependency parsing. Garg and Henderson (2011) proposed a Temporal Restricted Boltzmann Machine to do transition

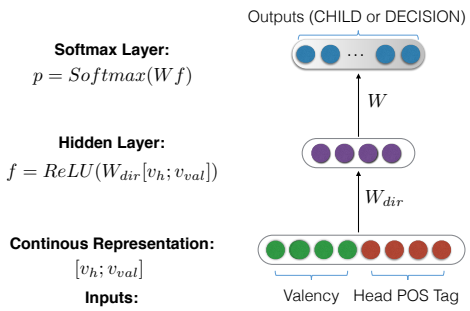

Figure 1: Structure of the neural network. Both CHILD and DECISION use the same architecture for the calculation of distributions.

based dependency parsing. Stenetorp (2013) applied recursive neural networks to transitional based dependency parsing. Chen and Manning (2014) built a neural network based parser with dense features instead of sparse indicator features. Dyer et al. (2015) proposed a stack long short-term memory approach to supervised dependency parsing. To our knowledge, our work is the first attempt to incorporate neural networks into a generative grammar for unsupervised dependency parsing.

3 Neural DMV

In this section, we introduce our neural based grammar induction approach. We describe the model in section 3.1 and the learning method in section 3.2.

3.1 Model

Our model is based on the DMV model (section 2.1), except that the CHILD and DECISION probabilities are calculated through two neural networks. We do not compute the ROOT probabilities using a neural network because doing that complicates the model while leads to no significant improvement in the parsing accuracy. Parsing a sentence using our model can be done in the same way as using DMV.

Below we show how the CHILD rule probabilities are computed in our neural based DMV model. Denote the set of all possible POS tags by T. We build a neural network to compute the probabilities of producing child tag $c \in T$ conditioned on the head, direction and valence (h, dir, val).

The full architecture of the neural network is shown in Figure 1. First, we represent each head tag h as a d dimensional vector $v_h \in \mathbb{R}^d$, represent each value of valence val as a d' dimensional vector $v_{val} \in \mathbb{R}^{d'}$. We concatenate v_h and v_{val} as the input embedding vector. Then we map the input layer to a hidden layer with weight matrix W_{dir} through a ReLU activation function. We have two versions of weight matrix W_{dir} for the direction dir being left and right respectively.

$$f(h, dir, val) = \mathrm{ReLU}(W_{dir}[v_h; v_{val}])$$

We then take the inner product of f and all the child POS tag vectors and apply a softmax function to obtain the rule probabilities:

$$[p_{c_1}, p_{c_2}, ..., p_{c_{\|T\|}}] = \mathrm{Softmax}(W^{\mathrm{T}} f)$$

where $W = [v_{c_1}, v_{c_2}, ..., v_{c_{\|T\|}}]$ is an embedding matrix composed of all the child POS tag vectors.

We use the same neural architecture to predict the probabilities of DECISION rules. The difference is that the neural network for DECISION has only two outputs (STOP and CONTINUE). Note that the two networks share parameters such as head POS tag embeddings and direction weight matrices W_{left} and W_{right}. Valence embeddings are either shared or distinct between the two networks depending on the variant of DMV we use (i.e., whether the maximal valences for CHILD and DECISION are the same).

The parameters of our neural based model include the weights of the neural network and all the POS and valence embeddings, denoted by a set $\Theta = \{v_h, v_c, v_{val}, v_{dec}, W_{dir}; h, c \in T, val \in \{0, 1, ...\}, dir \in \{left, right\}, dec \in \{\mathrm{STOP}, \mathrm{CONTINUE}\}\}$.

3.2 Learning

In this section, we describe an approach based on the EM algorithm to learn our neural DMV model. To learn the parameters, given a set of unannotated sentences $x_1, x_2, ..., x_N$, our objective function is the log-likelihood function.

$$L(\Theta) = \sum_{\alpha=1}^{N} \log \mathrm{P}(x_\alpha; \Theta)$$

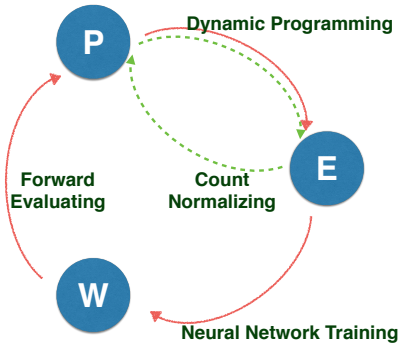

Figure 2: Learning procedure of our neural based DMV model. Green dashed lines represent the EM algorithm for learning traditional DMV. Red solid lines represent the learning procedure of our model. P represents the rule probabilities of DMV, E represents the expected counts of rules, and W represents the parameters of the neural networks. In the traditional EM algorithm, the expected counts are directly used to re-estimate the rule probabilities. In our approach, parameter re-estimation is divided into two steps: training the neural networks from the expected counts and forward evaluation of the neural networks to produce the rule probabilities.

The approach is visualized in the Figure 2. The E-step computes the expected number of times each grammar rule used in parsing each training sentence x_i, denoted by $e_c(x_i)$ for CHILD rule c, $e_d(x_i)$ for DECISION rule d, and $e_r(x_i)$ for ROOT rule r. In the M-step of traditional DMV learning, these expected counts are normalized to re-estimate the parameters of DMV. This maximizes the expected log likelihood (ELL) with respect to the DMV model parameters.

$$ELL(\Theta) = \sum_{\alpha=1}^{N} \left(\sum_{c} e_c(x_i) \log p_c + \sum_{d} e_d(x_i) \log p_d + \sum_{r} e_r(x_i) \log p_r \right)$$

In our model, however, we do not directly assign the optimal rule probabilities of CHILD and DECISION; instead, we train the neural networks to output rule probabilities that optimize ELL, which is equivalent to a weighted cross-entropy loss function for each neural network. Note that while the traditional M-step produces the global optimum of ELL, our neural-based M-step does not. This is because a neural network tends to produce similar outputs for correlated inputs. In our case, the neural network is able to capture the correlations between different POS tags as well as different valence values and smooth the probabilities involving correlated tags and valences. In other words, our M-step can be seen as optimizing the ELL with a regularization term taking into account the input correlations. We use momentum based batch stochastic gradient descent algorithm to train the neural network and learn all the embeddings and weight matrices.

In addition to standard EM, we can also learn our neural based DMV model based on the Viterbi EM algorithm. The difference from standard EM is that in the E-step, we compute the number of times each grammar rule is used in the best parse of a training sentence instead of considering all possible parses.

4 Experiments

4.1 Setup

We used the Wall Street Journal corpus (with section 2-21 for training, section 22 for validation and section 23 for testing) in section 4.2 and 4.3. Then we reported the results on eight additional languages in section 4.4. In each experiment, we trained our model on gold POS tags with sentences of length less than 10 after punctuation has been stripped off. As the EM algorithm is very sensitive to initializations, we used the informed initialization method proposed in (Klein and Manning, 2004).

The length of embeddings is set to 10 for both POS tags and valence. We trained the neural networks with batch size 10 and used the change of the validation set loss function as the stop criteria. We ran our model for five times and reported the averaged directed dependency accuracy (DDA) of the learned grammars on the test sentences with length less than 10 and all sentences.

4.2 Comparisons of Approaches based on POS Correlations

We first evaluated our approach in learning the basic DMV model and compared the results against (Cohen and Smith, 2009) and (Berg-Kirkpatrick et al., 2010), both of which have very similar motivation as ours in that they also utilize the correlation between POS tags to learn the basic DMV model. Table 1

Methods	WSJ10	WSJ
Standard EM	46.2	34.9
Viterbi EM	58.3	39.4
LN (Cohen et al., 2008)	59.4	40.5
Shared LN (Cohen and Smith, 2009)	61.3	41.4
Feature DMV (Berg-Kirkpatrick et al., 2010)	63.0	-
Neural DMV (Standard EM)	51.3	37.1
Neural DMV (Viterbi EM)	**65.9**	**47.0**

Table 1: Comparisons of Approaches based on POS Correlations

shows the results. It can be seen that our approach with Viterbi EM significantly outperforms the EM and viterbi EM baselines and also outperforms the two previous approaches.

4.3 Results on the extended DMV model

We directly apply our neural approach to learning the extended DMV model (Headden III et al., 2009; Gillenwater et al., 2010) (with the maximum valence value set to 2 for both CHILD and DECISION rules). As shown in Table 2, we achieve comparable accuracy with recent state-of-the-art systems. If we initialize our model with the grammar learned by Tu and Honavar (2012), the accuracy of our approach can be further improved.

Most of the recent state-of-the-art systems employ more complicated models and learning algorithms. For example, Spitkovsky et al. (2013) take several grammar induction techniques as modules and connect them in various ways; Le and Zuidema (2015) use a neural-based supervised parser and reranker that make use of high-order features and lexical information. We expect that the performance of our approach can be further improved when these more advanced techniques are incorporated.

4.4 Results on other languages

We also applied our approach on datasets of eight additional languages from the PASCAL Challenge on Grammar Induction (Gelling et al., 2012). We ran our approach using the hyper-parameters from experiment 4.2 on the new datasets without any further tuning. We tested three versions of our approach based on standard EM, softmax EM (Tu and Honavar, 2012) and Viterbi EM respectively. The results are shown in Table 3 for test sentence length no longer than ten and Table 4 for all test sentences.

Methods	WSJ10	WSJ
Systems with Basic Setup		
EVG (Headden III et al., 2009)	65.0	-
TSG-DMV (Blunsom and Cohn, 2010)	65.9	53.1
PR-S (Gillenwater et al., 2010)	64.3	53.3
UR-A E-DMV (Tu and Honavar, 2012)	71.4	57.0
Neural E-DMV	69.7	52.5
Neural E-DMV (Good Init)	**72.5**	**57.6**
Systems Using Extra Info		
LexTSG-DMV (Blunsom and Cohn, 2010)	67.7	55.7
L-EVG (Headden III et al., 2009)	68.8	-
CS (Spitkovsky et al., 2013)	72.0	64.4
MaxEnc (Le and Zuidema, 2015)	73.2	65.8

Table 2: Comparison of recent unsupervised dependency parsing systems. Basic setup means learning from POS tags with sentences of length $\leq$ 10 and punctuation stripped off. Extra information may contain punctuations, longer sentences, lexical information, etc. For Neural E-DMV, "Good Init" means using the learned DMV model from Tu and Honavar (2012) as our initialization.

Our neural based methods achieve better results than their corresponding baselines in 75.0% of the cases for test sentences no longer than 10 and 77.5% for all test sentences. The good performance of our approach without data-specific hyper-parameter tuning demonstrates the robustness of our approach. Carefully tuned hyper-parameters on validation datasets, in our experience, can further improve the performance of our approach, in some cases by a large margin.

4.5 Effects of Hyper-parameters

We examine the influence of hyper-parameters on the performance of our approach with the same experimental setup as in section 4.3.

Activation function We compare different linear and non-linear functions: ReLU, Leaky ReLU, Tanh, Sigmoid. The results are shown in Table 5. Non-linear activation functions can be seen to significantly outperform linear activation functions.

Length of the embedding vectors The dimension of the embedding space is an important hyper-parameter in our system. As Figure 3 illustrates, when the dimension is too low (such as $dim = 5$), the performance is bad probably because the embedding vectors cannot effectively discriminate between

different POS tags. On the other hand, when the dimension is too high (such as $dim = 30$), since we have only 35 POS tags, the neural network is prone to overfitting.

Shared parameters An alternative to our neural network architecture is to have two separate neural networks to compute `CHILD` and `DECISION` rule probabilities respectively. The embeddings of the head POS tag and the valence are not shared between the two networks. As can be seen in Table 6, sharing POS tags embeddings attribute to better performance.

5 Model Analysis

In this section, we investigate what information our neural based DMV model captures and analyze how it contributes to better parsing performance.

5.1 Correlation of POS Tags Encoded in Embeddings

A main motivation of our approach is to encode correlation between POS tags in their embeddings so as to smooth the probabilities of grammar rules involving correlated POS tags. Here we want to examine whether the POS embeddings learned by our approach successfully capture such correlation.

We collected the POS embeddings learned in the experiment described in section 4.3 and visualized them on a 2D plane using the t-SNE algorithm (Van der Maaten and Hinton, 2008). t-SNE is a dimensionality reduction algorithm that maps data from a high dimensional space to a low dimensional one (2 or 3) while maintaining the distances between

the data points in the high dimensional space. The "perplexity" hyper-parameter of the algorithm was set to 20.0 and the distance metric we used is the Euclidean distance.

Figure 4 shows the visualization result. It can be seen that in most cases, nearby POS tags in the figure are indeed similar. For example, VBP (Verb, non-3rd person singular present), VBD (Verb, past tense) and VBZ (Verb, 3rd person singular present) can be seen to be close to each other, and they indeed have very similar syntactic behavior. Similar observation can be made to NN (Noun, singular or mass), NNPS (Proper noun, plural) and NNS (Noun, plural).

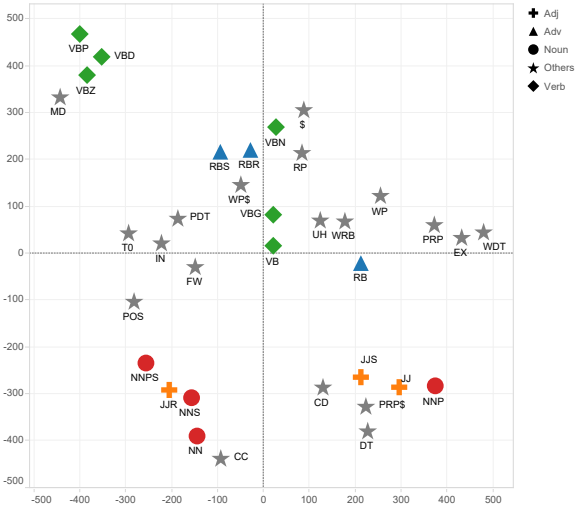

Figure 4: A visualization of the distances between embeddings of different POS tags.

5.2 Smoothing of Grammar Rule Probabilities

By using similar embeddings to represent correlated POS tags, we hope to smooth the probabilities of rules involving correlated POS tags. Here we analyze whether our neural networks indeed predict more similar probabilities for rules with correlated POS tags.

We conducted a case study on all types of verbs: VBP (Verb, non-3rd person singular present), VBZ (Verb, 3rd person singular present), VBD (Verb, past tense), VBN (Verb, past participle), VB (Verb, base form), VBG (Verb, gerund or present participle). We used the neural networks in our N-DMV model learned in the experiment described in section 4.2 to predict the probabilities of all the CHILD rules headed by a verb. For each pair of verb tags, we computed the total variation distance between the multinomial distributions of CHILD rules headed by the two verb tags. We also computed the total variation distances between CHILD rules of verb tags in the baseline DMV model learned by EM.

In Figure 5, We report the differences between the total variation distances computed from our model and from the baseline. A positive value means the distance is reduced in our model compared with that in the baseline. It can be seen that overall the distances between CHILD rules of different verb tags

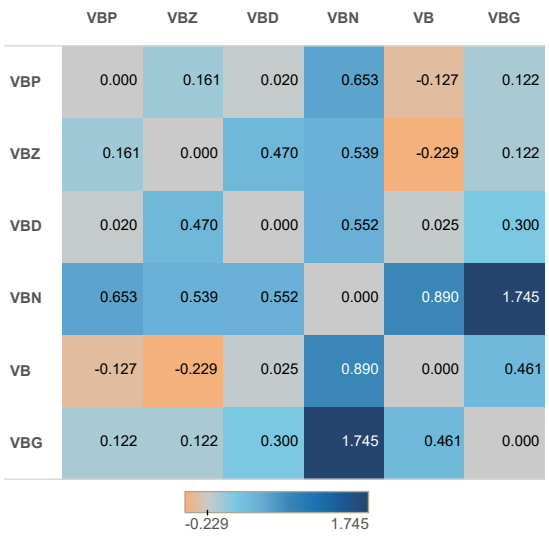

Figure 5: The change of the total variation distances between probabilities of CHILD rules headed by different verb tags in our model vs. the baseline. A positive value means the distance is reduced in our model compared with that in the baseline.

become smaller in our model. This verifies that our approach smooths the probabilities of rules involving correlated POS tags. From the figure one can see that the distance that reduces the most is between VBG and VBN. These two verb tags indeed have very similar syntactic behaviors and thus have similar embeddings as shown in figure 4. One the other hand, the distances between VB and VBZ/VBP become larger. This is reasonable since VB is syntactically different from VBZ/VBP in that it is very likely to generate a child tag TO to the left while VBZ/VBP always generate a subject (e.g., a noun or a pronoun) to the left.

6 Conclusion

We propose a neural based DMV model to do unsupervised dependency parsing. Our approach learns neural networks with continuous representations of POS tags to predict the probabilities of grammar rules, thus automatically taking into account the correlations between POS tags. Our experiments show that our approach outperforms previous approaches utilizing POS correlations and is competitive with recent state-of-the-art approaches on nine different languages.

For future work, we plan to extend our approach in learning lexicalized DMV models. In addition, we plan to apply our approach to other unsupervised tasks such as word alignment and sentence clustering.

Generating Coherent Summaries of Scientific Articles Using Coherence Patterns

{daraksha.parveen|mohsen.mesgar|michael.strube}@h-its.org

Abstract

Previous work on automatic summarization does not thoroughly consider coherence while generating the summary. We introduce a graph-based approach to summarize scientific articles. We employ coherence patterns to ensure that the generated summaries are coherent. The novelty of our model is twofold: we mine coherence patterns in a corpus of abstracts, and we propose a method to combine coherence, importance and non-redundancy to generate the summary. We optimize these factors simultaneously using Mixed Integer Programming. Our approach significantly outperforms baseline and state-of-the-art systems in terms of coherence (summary coherence assessment) and relevance (ROUGE scores).

1 Introduction

The growth in the scientific output of many different fields makes the task of automatic summarization imperative. Automatic summarizers assist researchers to have an informative and coherent gist of long scientific articles. An automatic summarizer produces summaries considering three properties:
Importance: The summary should contain the important information of the input document.
Non-redundancy: The summary should contain non-redundant information. The information should be diverse in the summary.
Coherence: Though the summary should comprise diverse and important information of the input document, its sentences should be connected to one another such that it becomes coherent and easy to read.

If we do not ensure that a summary is coherent, its sentences may not be properly connected. This results in an obscure summary. In previous work coherence has not been thoroughly considered. Parveen and Strube (2015) use single sentence connectivity in the input document as a coherence measure. They measure coherence by calculating the outdegree of a sentence in a graph representation of an input document. This has two disadvantages: first, since it is computed only based on one sentence, it is not sufficient to generate coherent summaries; second, it is obtained based on sentence connectivity in the input document rather than in the summary.

In this work, we focus on the coherence aspect of summarization. We use discourse entities as the unit of information that relate sentences. Here, discourse entities are referred to as head nouns of noun phrases (see Section 2). The main goal is to extract sentences which refer to those entities which are important and unique, and also to entities which connect the extracted sentences in a coherent manner. Entities in connected sentences can be used to create linguistically motivated coherence patterns (Daneš, 1974). Recently, Mesgar and Strube (2015) modeled these coherence patterns by subgraphs of the graph representation (nodes represent sentences and edges represent entity connections among sentences) of documents. They show that the frequency of coherence patterns can be used as features for coherence.

The key idea of this paper is to apply coherence patterns to long scientific articles to extract (possibly) non-adjacent sentences which, however, are already coherent. Based on the assumption that ab-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 772–783,
Austin, Texas, November 1-5, 2016.

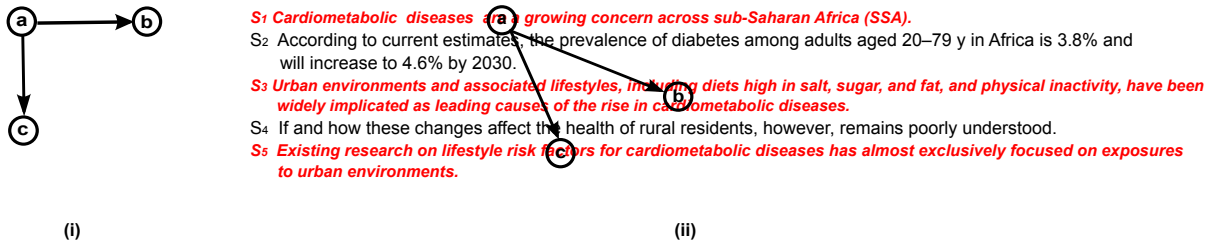

Figure 1: (i) A sample of mined coherence patterns from abstracts; nodes are sentences and edges are entity connections; (ii) Sentences S_1, S_3 and S_5 constitute the pattern in an input document.

stracts of scientific articles are similar in style to coherent summaries, we obtain coherence patterns by analyzing a corpus of abstracts of articles from bio-medicine (*PubMed* corpus). Then we apply the most frequent coherence patterns to input documents, i.e. long scientific articles from bio-medicine (*PLOS Medicine* dataset), extract corresponding sentences to generate coherent summaries, and evaluate them by comparing with summaries written by a *PLOS Medicine* editor. Figure 1 illustrates the extraction of sentences from an input document (Figure 1, (ii)) which constitute a coherence pattern (Figure 1, (i)). If we overlay the input document with coherence patterns and extract the sentences which constitute those patterns, then the extracted sentences are already coherent. We also take into account importance and non-redundancy. We capture all three factors in an objective function maximized by Mixed Integer Programming (MIP) (Section 2).

We evaluate our method on two different datasets: *PLOS Medicine* (Parveen and Strube, 2015) and *DUC 2002*. We extract frequent coherence patterns from all abstracts in the *PubMed* corpus, and generate summaries of unseen scientific articles of the *PLOS Medicine* dataset (Section 3.1). For DUC 2002 we extract coherence patterns from the human summaries of DUC 2005 (Dang, 2005). We evaluate our model on DUC 2002 to compare with state-of-the-art systems.

Our experimental results show that using coherence patterns for summarization produces more informative (but not redundant) and coherent summaries as compared to several baseline methods and state-of-the-art methods based on ROUGE scores and human judgements.

2 Method

We solve the task of creating coherent summaries by employing coherence patterns. We tightly integrate determining importance, non-redundancy and coherence by applying global optimization, i.e., MIP.

2.1 Document Representation

We use the entity graph (Guinaudeau and Strube, 2013) to represent scientific articles. The entity graph is a bipartite graph which consists of entities and sentences as two disjoint sets of nodes (Figure 2, ii). Entity nodes are connected only with sentence nodes and not among each other. An entity node is connected with a sentence node if and only if the entity is present in the sentence. Entities are the head nouns of noun phrases.

We perform a one-mode projection on sentence nodes to create a directed one-mode projection graph (Figure 2, iii). Two sentence nodes in the one-mode projection graph are connected if they share at least one entity in the entity graph. Edge directions encode the sentence order in the input document.

2.2 Mining Coherence Patterns

We use one-mode projection graphs of abstracts in the *PubMed* corpus (see Section 3.1) to mine coherence patterns. The weight of a coherence pattern, $weight(pat_u)$, is its frequency in the *PubMed* corpus normalized by the maximum number of its occurrence in abstracts in the *PubMed* corpus (Equation 1).

$$weight(pat_u) = \frac{\sum_{k=1}^{q} freq(pat_u, g_k)}{max_{k=1}^{q} freq(pat_u, g_k)}, \quad (1)$$

where q is the number of graphs associated with abstracts in the corpus, and g_k represents the graph of the k^{th} abstract in the *PubMed* corpus.

S_1 The overall $[rates]_{e_1}$ of cesarean $[delivery]_{e_2}$ are increasing significantly in the $[world]_{e_3}$.

S_2 In $[parts]_{e_4}$ of $[England]_{e_5}$ in 2010, the $[proportion]_{e_6}$ of total $[births]_{e_7}$ by cesarean $[section]_{e_8}$ was almost 25%, compared with just 2% in the 1950s.

S_3 In the United States and Australia rates of greater than 33% have been reported and in $[China]_{e_9}$ and $[parts]_{e_4}$ of South $[America]_{e_{10}}$, including Brazil and $[Paraguay]_{e_{11}}$, cesarean $[rates]_{e_1}$ of between 40% and 50% are common.

S_4 $[Concerns]_{e_{12}}$ have been expressed regarding the $[impact]_{e_{13}}$ of a cesarean $[section]_{e_8}$ on subsequent $[pregnancy]_{e_{14}}$ $[outcome]_{e_{15}}$ particularly the $[rate]_{e_{16}}$ of subsequent $[stillbirth]_{e_{17}}$, $[miscarriage]_{e_{18}}$, and ectopic pregnancy.

S_5 Hypothesized biological $[mechanisms]_{e_{19}}$ include placental $[abnormalities]_{e_{20}}$, prior $[infection]_{e_{21}}$, and adhesion $[formation]_{e_{22}}$ due to cesarean $[section]_{e_8}$.

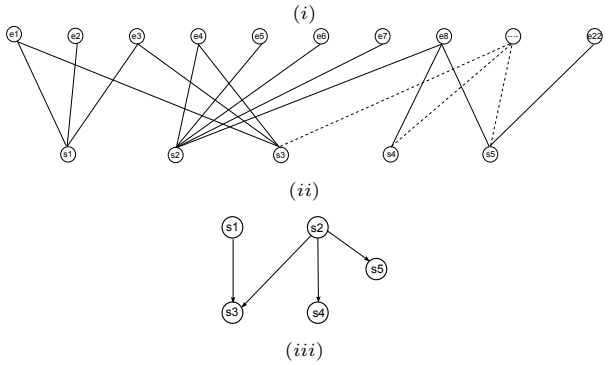

Figure 2: (i) A sample text from *PLOS Medicine*; (ii) entity graph; (iii) projection graph of the text.

The weights of the coherence patterns are not on the same scale. We normalize the weights using the standard score $\left(\frac{x-\mu}{\sigma}\right)$, where μ is the mean and σ is the standard deviation. A sigmoid function scales weights to the interval $[0, 1]$.

2.3 Summary Generation

We maximize importance, non-redundancy and pattern-based coherence with their respective weights λ to generate coherent summaries. The objective function is:

$$max(\lambda_I f_I(S) + \lambda_R f_R(E) + \lambda_C f_C(P)), \quad (2)$$

where S is a set of binary variables for sentences in an article, E is a set of binary variables for entities and P is a set of binary variables for coherence patterns.

Importance ($\mathbf{f_I(S)}$): The importance function quantifies the overall importance of information in the summary, which is calculated by considering the ranks of selected sentences for the summary:

$$f_I(S) = \sum_{i=1}^{n} Rank(sent_i) \cdot s_i. \quad (3)$$

In Equation 3, $Rank\,(sent_i)$ represents the rank of sentence $sent_i$ and s_i is the binary variable of sentence $sent_i$. n is the number of sentences.

Kleinberg (1999) develops the Hubs and Authorities algorithm (HITS) to rank web pages. He divides web pages into two sets: Hubs, pages which contain links to informative web pages, and Authorities, informative web pages. Here, Hubs are entities and Authorities are sentences. We calculate the rank of sentences using the HITS algorithm (Parveen and Strube, 2015). Initial ranks for sentences and entities are computed by Equations 4 and 5 in an entity graph:

$$Rank_{init}(sent_i) = 1 + sim(sent_i, title), \quad (4)$$

$$Rank_{init}(ent_j) = 1. \quad (5)$$

In Equation 4, $sim(sent_i, title)$ is the cosine similarity between the scientific article's title and sentence $sent_i$. In Equation 5, ent_j refers to the j^{th} entity in the entity graph. After applying the HITS algorithm on the entity graph using the above initialization, the final rank of a sentence is its importance.

Non-redundancy ($\mathbf{f_R}$ (E)): In the objective function, $f_R(E)$ represents the non-redundancy of information in the summary. Intuitively, if the summary has unique information in every sentence then the summary is non-redundant. We measure non-redundancy as follows:

$$f_R(E) = \sum_{j=1}^{m} e_j, \quad (6)$$

where m is the number of entities and e_j is a binary variable for each entity. The summary becomes non-redundant if we include only unique entities.

On the basis of $f_I(S)$ and $f_R(E)$ we define the following optimization constraints:

$$\sum_{i=1}^{n} |Sent_i| \cdot s_i \leq l_{max}, \quad (7)$$

$$\sum_{j \in E_i} e_j \geq |E_i| \cdot s_i \quad \text{for } i = 1, \ldots, n, \quad (8)$$

$$\sum_{s_i \in S_j} s_i \geq e_j \quad \text{for } j = 1, \ldots, m. \tag{9}$$

The constraint in Equation 7 limits the length of the summary. l_{max} is the maximal length of the summary and $|Sent_i|$ is the length of sentence $sent_i$.

In Equation 8, the constraint ensures that if sentence $sent_i$ is selected ($s_i = 1$), then all entities E_i present in sentence $sent_i$ must also be selected. In Equation 9, S_j represents the set of binary variables of sentences which contain entity ent_j. This constraint prescribes that if entity ent_j is selected ($e_j = 1$), then at least one of the sentences in S_j must be selected, too.

Coherence ($\mathbf{f_C(P)}$): We use the mined patterns to extract sentences from the input document of *PLOS Medicine* to create a coherent summary. We extract sentences, if the connectivity among nodes in their projection graph matches the connectivity among nodes in a coherence pattern. In Figure 3 we overlay the projection graph from Figure 2, ii with the coherence pattern from Figure 1, i. This results in three instances of this coherence pattern. However, we select only one since we simultaneously optimize for importance and non-redundancy.

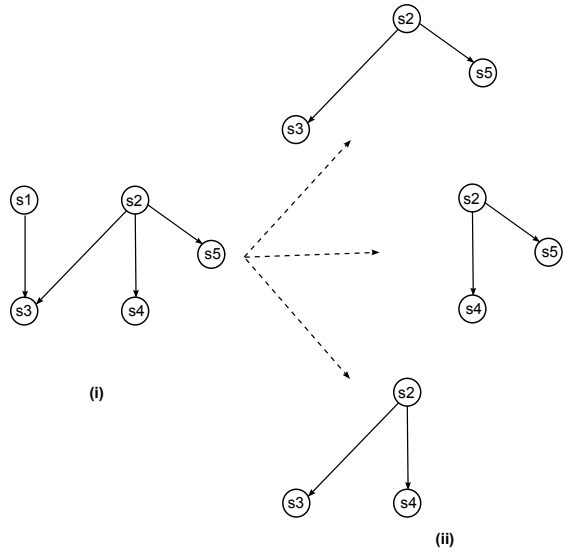

Figure 3: (i) A projection graph; (ii) several instances of a coherence pattern in Figure 1, ii.

In the objective function, $f_C(P)$ measures the coherence of the summary based on the weights of the coherence patterns occurring in it (Section 2.2):

$$f_C(P) = \sum_{u=1}^{U} weight(pat_u) \cdot p_u, \tag{10}$$

where p_u is a boolean variable associated with coherence pattern pat_u.

The optimization considers pattern pat_u for summarizing the input article, if pat_u is a subgraph of the projection graph of the article. To find the coherence pattern in a projection graph we apply a graph matching algorithm (Lerouge et al., 2015).

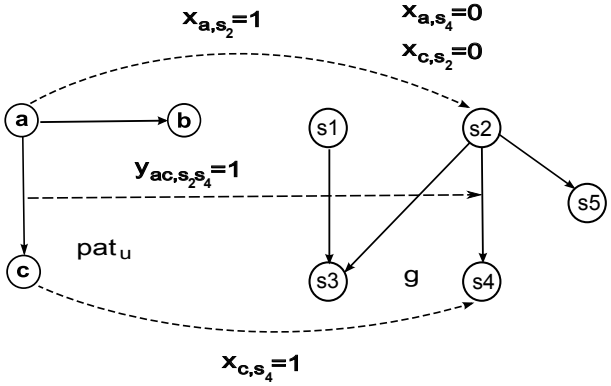

Figure 4: An illustration of mapping variables to overlay graph g with coherence pattern pat_u.

To model the graph matching problem between projection graph $g = (V_g, E_g)$ and patterns $pat_u = (V_{pat_u}, E_{pat_u})$, two kinds of mapping binary variables are used: $x_{i,k}$ for the node map, and $y_{ij,kl}$ for the edge map. $x_{i,k,} = 1$, if vertices $i \in V_{pat_u}$ and $k \in V_g$ match. $y_{ij,kl} = 1$, if for each pair of edges $ij \in E_{pat_u}$ and $kl \in E_g$ match (Figure 4). Constraints for graph matching are as follows:

- Every node of the pattern matches at most one unique node of the graph:

$$\sum_{k \in V_g} x_{i,k} \leq 1 \quad \forall i \in V_{pat_u}. \tag{11}$$

- Every edge of the pattern matches at most one unique edge of the graph:

$$\sum_{kl \in E_g} y_{ij,kl} \leq 1 \quad \forall ij \in E_{pat_u}. \tag{12}$$

- Every node of the graph matches at most one node of the pattern:

$$\sum_{i \in V_{pat_u}} x_{i,k} \leq 1 \quad \forall k \in V_g. \tag{13}$$

- A node of pattern pat_u matches a node of graph g if an edge originating from the node of pat_u matches an edge originating from the node of g:

$$\sum_{kl \in E_g} y_{ij,kl} = x_{i,k} \ \forall k \in V_g, \forall ij \in E_{pat_u}. \tag{14}$$

- A node of pattern pat_u matches a node of graph g if an edge targeting the node of pat_u matches an edge targeting the node of g:

$$\sum_{kl \in E_g} y_{ij,kl} = x_{j,l} \ \forall l \in V_g, \forall ij \in E_{pat_u}. \tag{15}$$

- We need a constraint to extract *induced* patterns[1]:

$$\sum_{i \in V_{pat_u}} x_{i,k} + \sum_{j \in V_{pat_u}} x_{j,l} - \sum_{ij \in E_{pat_u}} y_{ij,kl} \leq 1 \quad \forall kl \in E_g. \tag{16}$$

The constraints in Equations $11-16$ are defined to find pattern pat_u in projection graph g of the input article. However these constraints do not ensure that the pattern is in the summary. For this, we define constraints in Equations $17-19$ to assure that an existing pattern in an article is selected if there are some sentences in the summary which constitute the pattern.

- The constraint in Equation 17 ensures that if sentences s_k and s_l are selected for the summary then the edge between them is selected ($z_{kl} = 1$), too:

$$s_k \cdot s_l = z_{kl} \quad \forall k, l \in V_g. \tag{17}$$

- Pattern pat_u is present in the summary ($p_u = 1$) if and only if one of its instances in the projection graph is included in the summary, i.e., some of the selected sentence nodes must be present in an instance of pattern pat_u. $|V_{pat_u}|$ is the number of nodes in pattern pat_u, and $|E_{pat_u}|$ is the number of edges in pattern pat_u. This constraint is shown below:

$$\sum_{i \in v_{pat_u}} \sum_{k \in v_g} s_k \cdot x_{i,k} + \sum_{ij \in e_{pat_u}} \sum_{kl \in e_g} z_{kl} \cdot y_{ij,kl} = p_u(|V_{pat_u}| + |E_{pat_u}|). \tag{18}$$

- If a sentence is selected then it has to match a node of at least one of the patterns:

$$\sum_{pat_u \in P} \sum_{i \in V_{pat_u}} x_{i,k} \geq s_k \quad \forall k \in V_g. \tag{19}$$

3 Experiments

In this section we discuss the datasets and the experimental setup. We evaluate our model using ROUGE scores and human judgements.

3.1 Datasets

PLOS Medicine: This dataset contains 50 scientific articles. In this dataset every scientific article is accompanied by a summary written by an editor of the month. This editor's summary has a broader perspective than the authors' abstract. We use the editor's summary as a gold summary for calculating the ROUGE scores. We use 700 different *PLOS Medicine* articles from the PubMed[2] corpus to mine coherence patterns from their abstracts and to calculate patterns' weights.

DUC: The DUC 2002 dataset has been annotated for the Document Understanding Conference 2002. It contains 567 news articles for summarization. Every article is accompanied by at least two gold summaries. DUC 2002 articles are shorter than *PLOS Medicine* articles (25 vs. 154 sentences average length). We use all (300) DUC 2005 human summaries to mine coherence patterns and to calculate their weights.

3.2 Experimental Setup

First, we extract the text of an article. We remove figures, tables, references and non-alphabetical characters. Then we use the Stanford parser (Klein and

[1] Pattern pat_u is an induced subgraph of graph g if pat_u contains all possible edges which appear in g.

[2] http://www.ncbi.nlm.nih.gov/pmc/tools/ftp/

Manning, 2003) to determine sentence boundaries. We apply the Brown coherence toolkit (Elsner and Charniak, 2011) to convert the articles into entity grids (Barzilay and Lapata, 2008) which then are transformed into entity graphs. We use gSpan (Yan and Han, 2002) to extract all subgraphs from the projection graphs of the abstracts of the *PubMed* corpus.

It is possible that patterns with a large number of nodes are not at all present in the projection graph. Hence, we use coherence patterns with 3 and 4 nodes, referred to as CP_3 and CP_4, respectively. We use Gurobi (Gurobi Optimization, Inc., 2014) to solve the MIP problem. We use a pronoun resolution system (Martschat, 2013) to replace all pronouns in the summary with their antecedents.

We determine the best values for λ_I, λ_R, and λ_c on the development sets. $\lambda_I = 0.4$, $\lambda_R = 0.3$, and $\lambda_c = 0.3$ are the best weights for the *PLOS Medicine* development set. Weights for the DUC 2002 development set are $\lambda_I = 0.5$, $\lambda_R = 0.2$ and $\lambda_c = 0.3$.

3.3 Results

We evaluate our model in two ways. First, we use ROUGE scores to compare our model with other models. Second, we explicitly evaluate the coherence of the summaries by human judgements.

3.3.1 ROUGE Assessment

The ROUGE score (Lin, 2004) is a standard evaluation score in automatic text summarization. It calculates the overlap between gold summary and system summary. In automatic text summarization ROUGE 1, ROUGE 2 and ROUGE SU4 are usually reported (see Graham (2015) for an assessment of evaluation metrics for summarization).

We compare our system (CP_3 and CP_4) with four baselines: *Lead, Random, Maximal Marginal Relevance (MMR)* and *TextRank*. *Lead* selects adjacent sentences from the beginning of an input article. *Random* selects sentences randomly. *MMR* (Carbonell and Goldstein, 1998) uses a trade-off between relevance and redundancy. *TextRank* is a graph-based system using sentences as nodes and edges weighted by cosine similarity between sentences (Mihalcea and Tarau, 2004).

We compare our system with three state-of-the-art systems: E_{Coh} (Parveen and Strube, 2015), T_{Coh} (Parveen et al., 2015), and *Mead* (Radev et al., 2004). E_{Coh} uses entity graphs which consists of entities and sentences, and T_{Coh} uses topical graphs where entities are replaced by the topics. They both use the outdegree of sentence nodes in the unweighted and the weighted projection graph, respectively, as the coherence measure of each sentence. *Mead* employs a linear combination of three features: centroid score, position score and overlap score. The linear combination is used to add sentences to the summary up to the required length. The centroid score gives the highest score to the most central sentence in the cluster of sentences, the position score gives a higher score to the sentences which are in the beginning of the document, and the overlap score computes the similarity between the sentences of a document. All three features do not take care of the coherence of a summary as they do not have any notion of the order and the structure of a summary.

Table 1: *PLOS Medicine*, editor's summaries with **5 sentences**.

To compare with the state-of-the-art systems on PLOS Medicine, E_{Coh} (Parveen and Strube, 2015) and T_{Coh} (Parveen et al., 2015), we limit the length of summaries to 5 sentences. Table 1 reports ROUGE scores of different systems. Our system outperforms baselines and state-of-the-art systems.

Since the word length limit of a summary is more meaningful than the sentence length limit of a summary, we limit the length of a summary to the average length of editor's summaries in the dataset (750 words). Table 2 shows the performance of different systems with 750 words limit for a summary. In Table 2, we use different versions of ROUGE-SU4 and ROUGE-2 where *W/WO* stands

Table 2: ROUGE scores on *PLOS Medicine* with **750 words**.

for *With/Without*. Here, WO_{Stop} means without considering stopwords while calculating ROUGE scores, and WO_{Stem} means without applying the Porter Stemmer on summaries while calculating ROUGE scores. Our models outperform baseline and state-of-the-art systems (Table 2). We compute statistical significance between E_{Coh} and CP_3 on both scores, ROUGE SU4 is significantly different by 95%. ROUGE 2 is significantly different by 99%.

Upper Bound in Table 2 represents maximum ROUGE scores that can be achieved in extractive summarization on the *PLOS Medicine* dataset. It is calculated by considering the whole scientific article as a summary and the corresponding editor's summary as the gold standard. The *Upper Bound* scores are not very high showing that a significant improvement in ROUGE scores on the *PLOS Medicine* dataset is difficult. Thus, the performance achieved by our systems, CP_3 and CP_4, is a considerable improvement on the *PLOS Medicine* dataset.

Furthermore, we apply CP_3 on the dataset introduced by Liakata et al. (2013). The dataset consists of 28 scientific articles from the chemistry domain. The state-of-the-art system on this dataset is *CoreSC*, which is developed by Liakata et al. (2013). *CoreSC* considers discourse information while summarizing a scientific article. The ROUGE-1 score of CP_3 (0.96) is significantly better than *CoreSC* (0.75) and *Microsoft Office Word 2007 AutoSummarize* (0.73) (García-Hernández et al., 2009), in respect of abstracts. This shows that our system performs well in other domains.

We further calculate the average number of sentences per summary obtained by *Mead* and CP_3. On average *Mead* produces 17.5 sentences per summary whereas CP_3 produces 27.2 sentences per summary. The possibility of longer sentences containing more topic irrelevant entities is higher than shorter sentences (Jin et al., 2010).

We calculate the average percentage of sentences selected from the sections Introduction, Method, Results and Discussion by different systems. CP_3 extracts sentences mainly from Introduction (32.5%) and Method (38.5%), but also a considerable number of sentences from Results (17.67%) and Discussion (11.33%). The distribution is quite similar to *TextRank* and *MMR*. *Lead*, obviously, extracts only from Introduction (80.59%) and Method (19.41%). *Mead* extracts maximum sentences from the beginning of the document using its positional feature. The sentences in a summary extracted by CP_3 are evenly distributed indicating that they are not biased to any sections. This clearly represents that coherence patterns not only seeks for nearby sentences but also for any distant sentences of a scientific article.

Table 3 shows the results on DUC 2002 to compare the results with state-of-the-art systems. There is no significant difference between the ROUGE scores of using CP_3 and CP_4 on DUC 2002. Thus, we only report the results of using CP_3 on DUC 2002.

In Table 3, *LREG* is a baseline system us-

ing logistic regression and hand-made features (Cheng and Lapata, 2016). We compare our model to previously published state-of-the-art systems. These systems show reasonable performance on the DUC 2002 summarization task. ILP_{phrase} is a phrase-based extraction model, which selects important phrases and combines them via integer linear programming (Woodsend and Lapata, 2010). *URANK* utilizes a unified ranking process for single-document and multi-document summarization tasks (Wan, 2010). *UniformLink (k=10)*, considers similar documents for document expansion in the single-document summarization task (Wan and Xiao, 2010). The more recent system, *NN-SE*, utilizes a neural network hierarchical document encoder and an attention-based extractor to extract sentences from a document for a summary (Cheng and Lapata, 2016). ROUGE scores of our approach on this dataset are better than baselines and state-of-the-art systems. This shows that our system performs well even in a different genre (robust) and with considerably shorter input documents (scalable).

3.3.2 Coherence Assessment

ROUGE scores do not evaluate summary coherence, since ROUGE only calculates overlapping recall scores and does not consider the structure of the summary. Haghighi and Vanderwende (2009), Celikyilmaz and Hakkani-Tür (2010) and Christensen et al. (2013) evaluate the overall summary quality by asking human subjects to rank system generated summaries. Parveen and Strube (2015) and Parveen et al. (2015) assess the coherence by asking human assessors to rank system generated summaries and compare their system with baseline systems.

We perform summary coherence assessment by asking one Postdoc, two PhD students and one Masters student from the field of natural language processing. We provide them with the output summaries of four different systems for ten articles. We ask them to rank the summaries, i.e., the best summary gets rank 1, the second best gets rank 2, the third best gets rank 3, and the worst gets rank 4.

The four systems assessed are CP_3, E_{Coh}, *TextRank*, and *Lead*. We apply the Kendall concordance coefficient (W) (Siegel and Castellan, 1988) to measure whether the human assessors agree in ranking the four systems. With W $= 0.6725$ the correlation between the human assessors is high. Applying the χ^2 test shows that W is significant at least at the 99% level indicating that the ranks provided by the human assessors are reliable and informative. Table 4 shows the overall average rank of a system given by the four human assessors. The lower the value of average human scores the more coherent the summary. Unsurprisingly *Lead* gets the best overall average rank. *Lead* extracts adjacent sentences from the beginning of the document. Hence, these summaries are as coherent as the author intends them to be, but they are not informative. However, CP_3 is very close in coherence to *Lead* indicating that our strategy is successful. It also performs substantially better than *TextRank* and E_{Coh}. This confirms that using coherence patterns for sentence extraction yields more coherent summaries.

PLOS Medicine System	Average Human Score

4 Related Work

Summarizing scientific articles is as difficult as multi-document summarization because scientific articles are tend to be long and the important infor-

mation is spread all over the article unlike information in news articles (Teufel and Moens, 2002).

There are various approaches for summarizing scientific articles. Citations have been used by many researchers for summarization in this domain (Elkiss et al., 2008; Mohammad et al., 2009; Qazvinian and Radev, 2008; Abu-Jbara and Radev, 2011). Nanba and Okumura (2000) develop rules for categorizing citations by analyzing citation sentences. Newman (2001) analyzes the structure using a citation network. Similarly, Siddharthan and Teufel (2007) discover scientific attributions using citations. Discourse structure (but not necessarily coherence) has been used by Teufel and Moens (2002), Liakata et al. (2013) and others for summarizing scientific articles.

Several state-of-the-art extractive summarization systems implement summarization as maximizing an objective function using constraints. McDonald (2007) interprets text summarization as a global inference problem, where he is maximizing the importance score of a summary by considering the length constraint. Similarly, various approaches for summarization are based on optimization using ILP (Gillick et al., 2009; Nishikawa et al., 2010; Galanis et al., 2012; Parveen and Strube, 2015).

Until now, only few works have considered coherence while summarizing scientific articles. Abu-Jbara and Radev (2011) work on citation based summarization. They preprocess the citation sentences to filter out irrelevant sentences or sentence fragments, then extract sentences for the summary. Eventually, they refine the summary sentences to improve readability. Jha et al. (2015) consider Minimum Independent Discourse Contexts (MIDC) to solve the problem of non-coherence in extractive summarization. However, none of them deals with the problem of coherence within the task of sentence selection. Sentence selection and ensuring the coherence of summaries are not tightly integrated in their techniques. They model coherence in summarization by only considering adjacent sentences.

There are few methods (Hirao et al., 2013; Parveen and Strube, 2015; Gorinski and Lapata, 2015) which integrate coherence in optimization. These methods do not take into account the overall structure of the summary. Unlike earlier methods, we incorporate coherence patterns in optimization.

5 Conclusion

We introduce a novel graph-based approach to generate coherent summaries of scientific articles. Our approach takes care of coherence distinctively by coherence patterns. We have experimented with *PLOS Medicine* and DUC 2002. The results show that the approach is robust, works on both scientific and news documents and with input documents of different length. It considerably outperforms state-of-the-art systems on both datasets. We collected human assessments to evaluate the coherence of summaries. Our system substantially outperforms baselines and state-of-the-art systems, i.e., incorporating coherence patterns produces more coherent summaries. The results show that our approach performs well in human summary coherence assessment and relevance evaluation (ROUGE scores).

Abstract

This paper studies summarizing key information from news streams. We propose simple yet effective models to solve the problem based on a novel and promising representation of text streams – *Burst Information Networks (BINets)*. A BINet can be aware of redundant information, allows global analysis of a text stream, and can be efficiently built and dynamically updated, which perfectly fits the demands of text stream summarization. Extensive experiments show that the BINet-based approaches are not only efficient and can be used in a real-time online summarization setting, but also can generate high-quality summaries, outperforming the state-of-the-art approach.

1 Introduction

Text stream summarization aims to summarize key information from a text stream containing huge numbers of documents, which is an important and useful task that can be used for many real-world applications. For example, a news portal website editor needs to summarize news streams in the past day for generating a list of headline news; an editor of Sports Weekly may want a summary of the past week news stream for editing the magazine; and geologists and meteorologists will benefit from a summary of disaster events from the past year news stream (as shown in Table 1) for their study.

In contrast to traditional text summarization tasks (e.g., single and multi-document summarization) that have been extensively studied for decades, the task of stream summarization is a younger research problem which attempts to solve a summarization problem in the big-data setting. For a text stream with millions of documents involving various topics and events, traditional single- and multi-document summarization approaches cannot address the information overload challenge. For example, a single-document summarization model will generate 1 million document summaries for a text stream with 1 million documents, which are still overwhelming for a person to learn the key information in the stream. In such cases, one needs to a summary of the whole stream instead of summaries of each document.

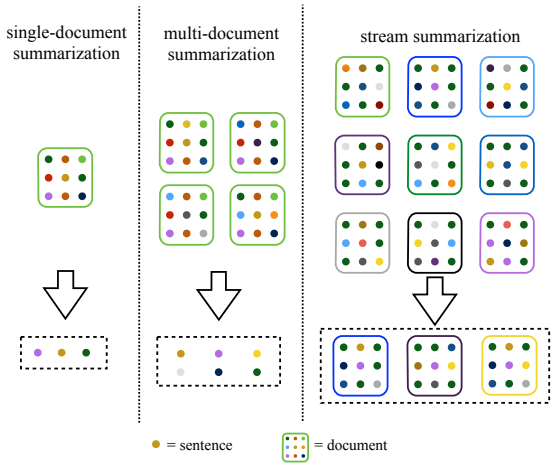

Figure 1: Stream summarization paradigm.

Figure 1 shows the paradigm of stream summarization. Compared with single- and multi-document summarization, stream summarization has three differences: (1) it summarizes a text stream containing millions of documents involving a variety of topics and events while single- and

2009 disaster summary	2010 disaster summary
• ... • Sep 2, 2009: About 60 people die when a 7.1-magnitude earthquake hit the island of Java. • Sep 9, 2009: More than 30 people are killed when fast moving floods caused by heavy rain sweep through Istanbul. • Sep 30, 2009: A 7.6-magnitude earthquake hit the island of Sumatra, leaving more than 1,000 people dead and thousands injured. • ...	• ... • Jan 12, 2010: A 7.0-magnitude earthquake hit Haiti, killing about 200,000 people. • Feb 27, 2010: An 8.8-magnitude earthquake rocked Chile, killing at least 700 people dead and affecting more than 1.5 million people. • Apr 5, 2010: An explosion in a West Virginia coal mine kills at least 25 people and leaves 4 unaccounted for. • ...

Table 1: Stream summary about disasters in 2009 and 2010. The disaster summary of 2009 can be used a reference summary to supervise generating a disaster summary for the 2010 news stream.

multi-document summarization summarizes one or a handful of documents about the same news event; (2) instead of selecting sentences to generate a summary, stream summarization selects representative documents to summarize a text stream; (3) summaries for a text stream may vary significantly for users who have different interests and preferences (e.g., summaries for an environmental expert and a sports fan should not be the same). Therefore, in order to generate targeted summaries for specific users, a stream summary needs to be generated based on a reference summary. For instance, one can use the 2009 disaster summary (the left part in Table 1) as a reference to learn how to write the 2010 disaster summary (the right part in Table 1).

In general, there are three challenges for summarizing a text stream. First, a stream summarization model should be able to be aware of redundant information in the stream for avoiding generating redundant content in the summary; second, a stream summarization algorithm should be capable of analyzing text content on the stream level for identifying the most important information in the stream; third, a stream summarization model should be efficient, scalable and able to run in an online fashion because data size of a text stream is usually huge, and it is dynamic and updated every second.

The previous approaches (e.g., (Ge et al., 2015b)) tend to cluster similar documents as event detection to avoid redundancy, rank the clusters based on their sizes and topical relevance to the reference summaries, and select one document from each cluster as representative documents. Due to the high time complexity of clustering models, their approaches usually run slowly and are not scalable.

To overcome the limitations, we propose Burst Information Networks (BINet) as a novel representation of a text stream. In a BINet (Figure 2), a node is a burst word (including entities) with the time span of one of its burst periods, and an edge between two nodes indicates how strongly they are related. Based on the BINet representation, we propose two models – NodeRank and AreaRank – for summarizing a news stream. We conduct extensive experiments to evaluate our approaches by comparing several baselines and the state-of-the-art approaches in various settings and show that the BINet-based approaches are efficient, scalable and can work in an online fashion and that they can generate high-quality summaries for a news stream, outperforming the state-of-the-art.

The major contributions of this paper are:

- We propose BINets as a novel representation of text streams. BINets can perfectly address the challenges of text stream summarization, which can be aware of information redundancy (Section 3), enables global analysis of the text stream (Section 4.1 and 4.2), and be efficiently built and updated incrementally (Section 4.3).
- We propose two ranking-based models based on the BINet representation, which can effectively learn to summarize a text stream from a reference summary, and outperform the state-of-the-art model.
- We create and release a new benchmark dataset for evaluating real-time stream summarization.

2 Stream Summarization

The task of text stream summarization is to generate a summary including key information from a

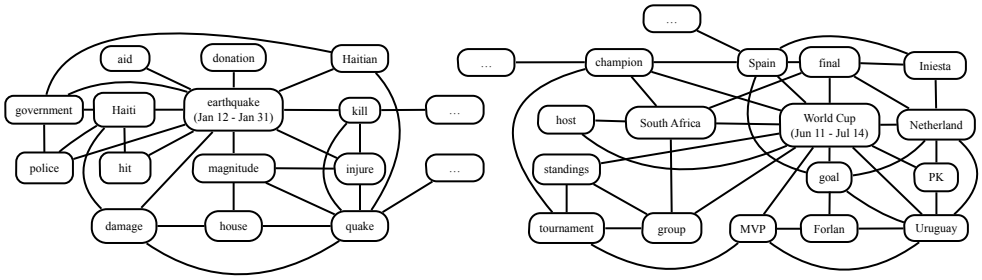

Figure 2: Illustration of a BINet. Due to space limitation, we only show the burst period of some nodes.

given text stream (e.g., 1-year news stream). In contrast to traditional summarization tasks which summarize a single or a handful of documents related to the same event by extracting sentences, the task of stream summarization aims to summarize a text stream which contains huge numbers of documents involving a variety of topics and events by selecting representative documents, as Figure 1 shows. In a stream summary, each selected document is considered as an entry which can be shown using the title or the first paragraph of the document. Since documents in a news stream are always about news events, we also call an entry as *an event entry* and call a stream summary as an *event chronicle* which is a list of event entries, as shown in Table 1. In a stream summary, entries should not be redundant. Formally, we define a stream summary (i.e., event chronicle) $\mathcal{E} = \{\boldsymbol{e_1}, \boldsymbol{e_2}, \cdots, \boldsymbol{e_K}\}$ where $\boldsymbol{e_k} = (t_{\boldsymbol{e_k}}, \boldsymbol{w_{e_k}})$ is an event entry including the event's time information $t_{\boldsymbol{e_k}}$ and text description $\boldsymbol{w_{e_k}}$ which is set of words in text.

Due to the diversity of ways to summarize a text stream as Section 1 discusses, we use a reference summary of a text stream during an early period to supervise summary generation for new text streams. It is a practical setting since many historical manually edited summaries of early streams are available and can be used as an example to demonstrate what kind of information is preferred in a stream summary.

3 Representing a text stream using Burst Information Network

3.1 Burst

A word's burst refers to a remarkable increase in the number of occurrences of the word during a period and might indicate important events or trending topics. For example, as shown in Figure 3, the word *earthquake* has bursts from the Jan 12 to Jan 31, 2010 and from Feb 27 to Mar 8, 2010 because of the strong earthquakes occurring in Haiti and Chile respectively.

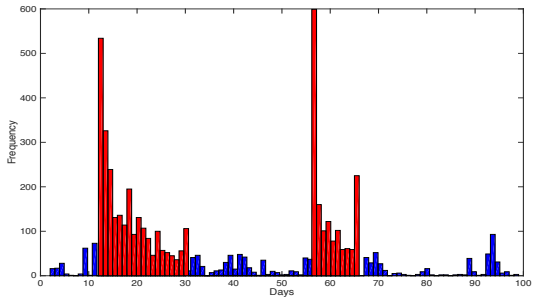

Figure 3: Frequency of *earthquake* during the first 90 days in the 2010 news stream.

Specifically, if a word w is in a burst state at every time t during a period, we call this period as a burst period of w, and w has a burst during this period. In Figure 3, *earthquake* has 2 burst periods (i.e., (Jan 12 - Jan 31) and (Feb 27 - Mar 8))

Formally, we define $\mathcal{P}$ as one burst period of the word w. $\mathcal{P}$ is a consecutive time sequence during which w bursts at every time epoch t:

$$\mathcal{P} = (t_i, t_{i+1}, t_{i+2}, ..., t_{i+n})$$
$$\forall t \in \mathcal{P} \;\; s_t = 1$$

where s_t is a binary indicator of the burst state of w at time t.

3.2 Burst Information Network

To build an information network which can represent associations between key facts in a text stream, we propose a new representation called "*Burst Information Network (BINet)*" by using burst elements as nodes:

A Burst Element is a burst of a word. It can be represented by a tuple: $\langle w, \mathcal{P} \rangle$ where w denotes the

word and $\mathcal{P}$ denotes one burst period of w.

According to the above definition, a burst element is a joint representation of a word type and one of its burst periods. A word may have multiple burst periods while a burst element only has one burst period. A word during its different burst periods will be regarded as different burst elements.

Formally, we define the BINet $G = \langle V, E \rangle$ as follows. Each node $v \in V$ is a burst element and each edge $e \in E$ denotes the association between burst elements. Intuitively, if two burst elements frequently co-occur, the edge between them should be highly weighted. We define $\omega_{i,j}$ as the weight of an edge between v_i and v_j, which is equal to the number of documents where v_i and v_j co-occur.

Besides $w(v)$ and $\mathcal{P}(v)$ that denote a node v's word and burst period respectively, we also record a node's context words[1] and its source documents which the node is from during constructing a BINet. Formally, we use $\mathcal{C}(v)$ and $\mathcal{D}(v)$ to denote the context word set and source document set of v. Also, for a document d in the stream, we use $\mathcal{A}(d)$ to denote the set of nodes whose source documents include d. Since nodes in $\mathcal{A}(d)$ are usually adjacent, we also call $\mathcal{A}(d)$ document d's area on the BINet. The construction of a BINet is efficient: the time complexity of building a BINet is $O(n)$ where n is the number of documents in a stream.

BINets can be properly aware of redundant information: since nodes in a community in a BINet are topically and temporally coherent, information about the same news event tends to be adjacent and redundant information of the same event is naturally removed. For example, assuming that there are hundreds of documents about *Haiti earthquake* in a text stream, by using the BINet representation, the information is concentrated in a few adjacent nodes without redundancy (left part in Figure 2). Moreover, information about different events is not considered as redundant. For example, the information regarding *Haiti earthquake* and *Chile earthquake* is not treated as redundant, which is allocated to different areas in the BINet, as Figure 2 shows. Therefore, as long as we do not select overlapping areas on the BINet, we can avoid selecting redundant content as entries.

[1]Here, the context window size is set to 10. Note that in our experiments, only words frequently (more than 5 times) co-occur in the context will be reserved.

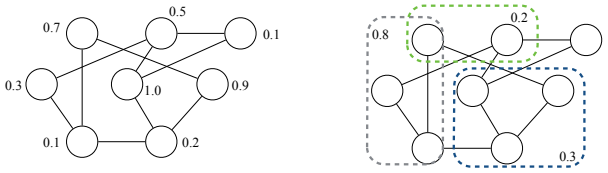

Figure 4: NodeRank (left) and AreaRank (right).

In addition to the awareness of information redundancy, BINets also allow global importance analysis on the stream level and online stream summarization, which will be discussed in Section 4.

4 Summarizing a text stream on the BINet

Based on the BINet representation, we propose two models – NodeRank and AreaRank – to summarize a text stream by generating entries of the summary. As Figure 4 shows, the NodeRank model scores every node on the BINet independently for identifying the most valuable information to be included in the stream summary, while the AreaRank model attempts to score an area that covers a handful of nodes for locating the most informative information blocks.

To train NodeRank and AreaRank models, we use reference summaries and the (reference) BINets built from the text stream during the reference summary's period as supervision.

4.1 NodeRank

Intuitively, if we can find the most valuable information on the BINet that should be included in the summary, then we can generate a high-quality summary of a text stream. For this goal, we label the corresponding nodes of words appearing in the reference summary on the reference BINet as score 1 (positive). Formally, for a reference summary $\mathcal{E}$, we label the following set of nodes in the reference BINet $G_r = \langle V_r, E_r \rangle$ as score 1:

$$V_{pos} = \bigcup_{\boldsymbol{e_k} \in \mathcal{E}} \{v | v \in V_r \wedge w(v) \in \boldsymbol{w}_{\boldsymbol{e_k}} \wedge t_{\boldsymbol{e_k}} \in \mathcal{P}(v)\} \quad (1)$$

where $w(v)$ and $\mathcal{P}(v)$ are word and burst period of node v respectively, $\boldsymbol{e_k}$ is an event entry in the reference summary $\mathcal{E}$, $\boldsymbol{w}_{\boldsymbol{e_k}}$ is the set of words in $\boldsymbol{e_k}$'s text, and $t_{\boldsymbol{e_k}}$ is $\boldsymbol{e_k}$'s time. The nodes that are not in V_{pos} in the reference BINet will be labeled as 0 (negative).

After labeling the reference BINet, we train a learning to rank (L2R) model[2] using the following features for scoring nodes in the target BINet $G_\tau = \{V_\tau, E_\tau\}$ (shown in Figure 4):

- $w(v)$: the word of node v, indicating its semantic information.
- $pr(v)$: node v's PageRank value can reflect the global importance of the node on the stream level, which can be easily obtained by running the PageRank algorithm on the BINet.
- $\mathcal{C}(v)$: the context words of node v defined in Section 3.2, indicating the topic information.

After scoring nodes in the target BINet, we greedily choose a document area $\mathcal{A}(d)$ that covers a set of nodes whose score is the largest:

$$d^* = arg \max_{d \in D_\tau} \sum_{v \in \mathcal{A}(d)} score_{NR}(v) \quad (2)$$

where D_τ is the document sets in the target stream and $score_{NR}(v)$ is the score of node v outputted by NodeRank model. Document d^*'s first paragraph and its document creation time (DCT) will be used to generate an event entry for the summary of the target stream. Note that though we do not normalize the length of a document in Eq (2), we constrain the maximum length of a document's first paragraph is 50 words and will not select the document whose first paragraph is longer than 50 words.

By repeating this step for k times, we can generate a stream summary with k event entries. Note that in order to avoid generating redundant entries in the summary, we will not choose d^* if its document area $\mathcal{A}(d^*)$ overlaps with the areas of the documents that have been already chosen as entries.

4.2 AreaRank

Instead of scoring nodes independently like NodeRank, we propose AreaRank model for scoring an area on the BINet for finding areas that corresponds to the most important news events in the stream.

Different from NodeRank where each instance is one node in the BINet, instances are areas on the BINet in the AreaRank model, as shown in Figure 4. In this paper, we mainly consider document area $\mathcal{A}(d)$ since we select representative documents as entries in the summary.

As NodeRank, we first label reference BINet using the reference summary. In the AreaRank model, we find the areas on the reference BINet corresponding to each event entry in the reference summary and label such areas as score 1 (positive). Formally, for a reference summary $\mathcal{E}$, the positive areas are in the following set:

$$\mathbb{A}_{pos} = \bigcup_{\boldsymbol{e_k} \in \mathcal{E}} \{\mathcal{A} | \mathcal{A} = V_{\boldsymbol{e_k}}\} \quad (3)$$

where $V_{\boldsymbol{e_k}} = \{v | v \in V_r \wedge w(v) \in \boldsymbol{w}_{\boldsymbol{e_k}} \wedge t_{\boldsymbol{e_k}} \in \mathcal{P}(v)\}$ is the set of nodes to which words in $\boldsymbol{e_k}$ correspond in the reference BINet.

We label other document areas that do not overlap any positive area on the reference BINet as score 0. Then, we use the training data to train AreaRank using the following features:

- $\boldsymbol{w}(\mathcal{A})$: words of nodes in area $\mathcal{A}$, indicating the area's semantic and topic information.
- $\boldsymbol{pr}(\mathcal{A})$: this feature includes maximum, sum and average of PageRank value of nodes in the area and sum of top 3 PageRank value of nodes in the area, indicating the area's general importance, which can reflects the impact of the events corresponding to the area in the stream.
- $\mathcal{C}(\mathcal{A})$: context of nodes in area $\mathcal{A}$. This feature is useful for indicating topical information.

In the test phase, we use AreaRank model to score all possible document areas on the target BINet. Then, we greedily choose the document area with the top score to generate an event entry for the summary:

$$d^* = arg \max_{d \in D_\tau} score_{AR}(\mathcal{A}(d)) \quad (4)$$

As NodeRank, d^*'s first paragraph and DCT will be used to generate an event entry for the stream summary if d^*'s area $\mathcal{A}(d)$ does not overlap the areas of the documents that have been already selected for generating event entries. The maximum length of the first paragraph of a document is 50 words. This step will be repeated for multiple times for generating event entries of the summary.

[2]We use SVMRank (Joachims, 2006). During training, we randomly sample 50% of negative examples which are used to generate the training set with positive examples.

4.3 Online stream summarization

An advantage of the BINet is that it can be incrementally updated when new streams arrive, which is useful for online stream summarization. Assuming we have a news stream from time t_0 to t_k at hand, we can detect word bursts and construct a BINet G based on the stream. When the news stream at t_{k+1} comes, we first detect burst words in the newly arriving data, update the BINet and calculate the PageRank value for $G(t_{k+1})$ which denotes the slice of BINet G at time t_{k+1}, which is defined as follows:

$$G(t) = \langle V(t), E(t) \rangle$$

where $V(t) = \{v|t \in \mathcal{P}(v)\}$ and $E(t) = \{e_{i,j}|e_{i,j} \in E \wedge i \in V(t) \wedge j \in V(t)\}$. Then, we can apply NodeRank and AreaRank on $G(t_{k+1})$ to generate a stream summary at t_{k+1}.

5 Experiments and Evaluations

5.1 Experiments on Gigaword corpus

For comparison to the previous work, we use the same data with Ge et al. (2015b) (i.e., 2009 and 2010 APW and XIN news stories in English Gigaword (Graff et al., 2003)) as a news stream. We detect burst words using Kleinberg algorithm (Kleinberg, 2003), which models word burst detection as a burst state decoding problem. In total, there are 140,557 documents in the dataset.

Topic	#Entry	#Entry in corpus
Disaster	35	28
Sports	19	12
Politics	8	5
Military	14	13
Comprehensive	85	64

Table 2: The number of event entries in the reference summaries. The third column is the number of event entries excluding those events that do not appear in the corpus.

We removed stopwords and used Stanford CoreNLP (Manning et al., 2014) to do lemmatization and named tagging, and built BINets on the news stream during 2009 and 2010 separately. On the 2009 news stream, there are 31,888 nodes and 833,313 edges while there are 32,997 nodes and 825,976 edges on the 2010 stream.

Ge et al. (2015b) used manually edited event chronicles of various topics on the web[3] during 2009 as reference summaries for summarizing the news stream during 2010. The information of the reference summaries is summarized in Table 2. In evaluation, they pooled entries in stream sumamries generated by various approaches, annotated each entry based on the reference summary and the manually edited event chronicles on the web, and used *precision@K* to evaluate the quality of top K event entries in a stream summary instead of using *ROUGE* (Lin, 2004) because news stream summaries are event-centric.

In this paper, we adopt the same evaluation setting and use the same reference summaries and the annotations with our previous work (Ge et al., 2015b) to evaluate our summaries' quality. For the event entries that are not in Ge et al. (2015b)'s annotations, we have 3 human judges annotate them according to the previous annotation guideline and consider an entry correct if it is annotated as correct by at least 2 judges.

We evaluate our approaches by comparing to Ge et al. (2015b)'s approach and the baselines in their work:

- RANDOM: this baseline randomly selects documents in the dataset as event entries.
- NB: this baseline uses Naive Bayes to cluster documents for event detection and ranks the clusters based on the combination score of topical relevance and the event impact (i.e., event cluster size). The earliest documents in the top-ranked clusters are selected as entries.
- B-HAC: similar to NB except that BurstVSM representation (Zhao et al., 2012) is used for event detection using Hierarchical Agglomerative Clustering algorithm.
- TAHBM: similar to NB except that the state-of-the-art event detection model (TaHBM) proposed by Ge et al. (2015b) is used for event detection.
- Ge et al. (2015b): the state-of-the-art stream summarization approach which used TaHBM to detect events and L2R model to rank events.

Note that we did not compare with previous multi-document summarization models because the goal and setting of stream summarization are different from multi-document summarization, as Section 1

Table 3: Performance of various approaches on stream summarization on five topics.

discussed. Moreover, these two tasks differ greatly in the data size and redundancy identification mechanism. Therefore, it is not feasible to directly compare multi-document summarization models to our approaches unless they are adapted for our setting.

The results are shown in Table 3. It can be clearly observed that BINet-based approaches outperform baselines and perform comparably to the state-of-the-art model on generating the summaries on most topics: AreaRank achieves the significant improvement over the state-of-the-art model on sports and disasters, and performs comparably on politics and military and NodeRank's performance achieves the comparable performance to previous state-of-the-art model though it is inferior to AreaRank on most topics. Among these five topics, almost all models perform well on disaster and military topics because disaster and military reference summaries have more entries than the topics such as politics and sports and topics of event entries in the summaries are focused. The high-quality training data benefits models' performance especially for AreaRank which is purely data-driven. In contrast, on sports and politics, the number of entries in the reference summaries is small, which results in weaker supervision and affect the performance of models. It is notable that AreaRank does not perform well on generating the comprehensive summary in which topics of event entries are miscellaneous. The reason for the undesirable performance is that the topics of event entries in the comprehensive reference summary are not focused, which results in very few reference (positive) examples for each topic. As a result, the miscellaneousness of topics of positive examples makes them tend to be overwhelmed by large numbers of negative examples during training the model, leading to very week supervision and making it difficult for AreaRank to learn the patterns of positive examples. Compared to AreaRank, the strategy of selecting documents for generating event entries in other baselines and NodeRank use more or less heuristic knowledge, which makes these models perform stably even if the training examples are not sufficient.

Model	**Features**	**Precision@100**
NodeRank	$w(v)$	0.18
	$w(v)$+$pr(v)$	0.22
	$w(v)$+$\mathcal{C}(v)$	0.46
	$w(v)$+$pr(v)$+$\mathcal{C}(v)$	**0.51**
AreaRank	$\boldsymbol{w}(\mathcal{A})$	0.25
	$\boldsymbol{w}(\mathcal{A})$ + $\boldsymbol{pr}(\mathcal{A})$	0.34
	$\boldsymbol{w}(\mathcal{A})$+$\mathcal{C}(\mathcal{A})$	0.58
	$\boldsymbol{w}(\mathcal{A})$+$\boldsymbol{pr}(\mathcal{A})$+$\mathcal{C}(\mathcal{A})$	**0.62**

Table 4: Ablation test on feature combination for generating disaster summaries.

Model	Topic	Irrelevant	Minor	Redundant
NodeRank	disaster	35.3%	64.7%	0
	sports	21.3%	77.5%	1.3%
	comprehensive	-	100%	0
AreaRank	disaster	34.2%	63.1%	2.6%
	sports	7.5%	91.1%	1.5%
	comprehensive	-	100%	0

Table 5: Error analysis of BINet-based approaches.

We conducted an ablation test to study the effects of features on generating summaries in our model. Table 4 shows the performance of models using various feature combination on generating disaster summaries. In both NodeRank and AreaRank models, PageRank features enhance the models that only use word features of nodes, demonstrating the effects of global importance analysis on the stream level. Context features are also useful for improving the results because words (both burst and non-burst words) in context can help the model learn the preference of topics and styles from the reference summary.

We conducted error analysis for NodeRank and AreaRank, shown in Table 5. Among topically irrelevant, minor and redundant event entries, minor (i.e.,

Model	Module	Run time	Can be run in parallel
BINet	burst detection	14ms per word	Yes
	BINet construction	213.88s on 1-year news	Partially
	PageRank	1.36s per iteration	No
	Ranking	negligible	No
Ge et al. (2015b)	Event detection	1,018s per iteration	No
	Ranking	negligible	No

Table 6: Run time of BINet-based approaches and Ge et al. (2015b)'s approach

trivial) event entries that are not important enough to be included in the stream summary account for the majority of errors for both models. This is because it is difficult to distinguish these trivial events since the corpus we used as a text stream is not as ideal as the assumption that the more important events, the more times they are reported. As shown in Table 2, many entries in the reference summaries even do not appear or burst in our corpus because the Gigaword corpus used is just a small sample of news stream during the period. As a result, the importance features (e.g., PageRank value) in our ranking model do not work very well for distinguishing trivial events.

At last, we tested the run time of our BINet approach and compare to the state-of-the-art model proposed by Ge et al. (2015b) in terms of efficiency. The results are shown in Table 6. The run time is tested on a workstation with Intel Xeon 3.5 GHz CPU and 64GB RAM. The efficiency of our model is much better than Ge et al. (2015b)'s approach whose event detection model takes much time to iterate thousands of times for Gibbs sampling. For memory cost, the peak memory cost of our BINet-based approaches is 5GB while Ge et al. (2015b)'s approach needs more than 10GB memory to run the event detection model and thus cannot work on a large dataset.

5.2 Experiments on a real-time news stream

To evaluate our approaches in a real setting, we create a benchmark dataset[4] containing 7.9 million English news stories (without exact duplication) during Feb 5 to Mar 31, 2015, collecting from Bing news portal[5]. On average, there are approximately 150,000 news documents per day.

We applied our BINet-based approaches (i.e., NodeRank and AreaRank) on the real-time stream. Specifically, we used news stream during Feb 5 to Mar 23 for training to generate news summaries for every day during Mar 24 to Mar 30 in an online fashion. This is a practical setting and can be useful for automatically generating headline news every day.

Models	Disaster	Attack
Random	0.012	0.019
Online-B-HAC	0.096	0.138
NodeRank	0.111	0.153
AreaRank	**0.182**	**0.157**

Table 7: MRR of BINet-based approaches on generating summaries for the real-time news stream.

Daily news summaries in *Current Event Portal*[6] at Wikipedia are used as reference summaries for training and gold standard for evaluating our approaches. In this paper, we tested on generating summaries on *Disaster and accident* (Disaster) and *Armed conflicts and attacks* (Attack) topics. Instead of evaluating *Precision@K* as we did on the Gigaword corpus which is a small dataset, we used *Mean Reciprocal Rank (MRR)* which is defined as follows to see the ranking position of event entries of the gold standard in the summaries generated by our approaches:

$$MRR = \frac{\sum_{t \in T_{test}} (\sum_{\boldsymbol{e_k} \in \mathcal{E}^{(t)}_{gold}} \frac{1}{rank^{(t)}_{\boldsymbol{e_k}}})}{\sum_{t \in T_{test}} |\mathcal{E}^{(t)}_{gold}|} \quad (5)$$

where $\mathcal{E}^{(t)}_{gold}$ is the gold standard summaries at time t, T_{test} is the period of test set (i.e., Mar 24 to Mar 30) and $rank^{(t)}_{\boldsymbol{e_k}}$ is the highest rank of an event entry $\boldsymbol{e_k}$ of the gold standard summary in our summary at t. A high MRR means the event entries of gold standard tend to be ranked at top positions in our generated summaries. The evaluation is conducted manually.

Table 7 shows the performance of BINet-based

[4]The dataset and the gold standard are available at http://getao.github.io

[5]https://www.bing.com/news

[6]https://en.wikipedia.org/wiki/Portal:Current_events/

approaches on the real-time news stream. The BINet-based approaches achieve better results than the online version of B-HAC model on both topics, demonstrating the advantages of the BINet representation. It is also notable that AreaRank performs better than NodeRank because it scores a document area as a whole by taking into account various information of the area. For AreaRank, MRR on the disaster topic is about 0.2, meaning that the average ranking position of gold standard event entries is 5, which is a promising result and shows our approach can be effective to find key information. More importantly, it only takes 500 seconds to build a BINet and 388 seconds to run PageRank for 1,000 iterations for global importance analysis on the 7.9 million documents while other methods in Table 3 even cannot be applied on the stream because they cannot handle so large scale of data or work in an online fashion, which is why we did not compare to them in this setting.

6 Related Work

Stream summarization is not a hot topic in NLP community. Despite the related work that studies corpus summarization of research papers (Sipos et al., 2012), Ge et al. (2015b) is the only work exactly dealing with the news stream summarization challenge. However, they studied the problem on a static timestamped corpus instead of on a dynamic text stream and their proposed pipeline-style approach cannot be applied on a real-time text stream due to high complexity in time and space. Other previous work dealing with stream data is mainly focused on topic and event detection (Yang et al., 1998; Swan and Allan, 2000; Allan, 2002; He et al., 2007; Sayyadi et al., 2009; Sakaki et al., 2010; Zhao et al., 2012; Ge et al., 2015a), dynamic language and topic modelling (Blei and Lafferty, 2006; Iwata et al., 2010; Wang et al., 2012; Yogatama et al., 2014), incremental (temporal) summarization and timeline generation for one major news event (Allan et al., 2001; Hu et al., 2011; Yan et al., 2011; Lin et al., 2012; Li and Li, 2013; Kedzie et al., 2015; Tran et al., 2015; Yao et al., 2016), a sports match (Takamura et al., 2011) or users on the social network (Li and Cardie, 2014).

Different from traditional single and multi-document summarization (Carbonell and Goldstein, 1998; Lin, 2004; Erkan and Radev, 2004; Conroy et al., 2004; Li et al., 2007; Wan and Yang, 2008; Chen and Chen, 2012; Wan and Zhang, 2014) whose focus is to select important sentences, the focus of stream summarization is to select representative documents referring to important news events. The novel paradigm focuses on the summarization problem in the big data age and is useful for many applications.

7 Conclusions and Future work

In this paper, we study the news stream summarization problem by proposing a novel text stream representation – Burst Information Networks and presenting two summarization models based on it. The proposed approaches can efficiently generate high-quality summaries, achieving the state-of-the-art performance. Moreover, the experiments on our created benchmark dataset showed our approach can be effectively applied on the real-time news stream for finding key information, demonstrating its potential values for many real-world applications (e.g., personalized headline news recommendation).

In the future, we plan to generalize the stream summarization problem to various streams such as social (e.g., Twitter), image (e.g., Imgur) and even video streams (e.g., Youtube), which would yield many interesting and practical applications (Lu et al., 2016) to deal with the information overload challenge in the big data era.

Abstract

We present a new Convolutional Neural Network (CNN) model for text classification that jointly exploits labels on documents and their constituent sentences. Specifically, we consider scenarios in which annotators explicitly mark sentences (or snippets) that support their overall document categorization, i.e., they provide *rationales*. Our model exploits such supervision via a hierarchical approach in which each document is represented by a linear combination of the vector representations of its component sentences. We propose a sentence-level convolutional model that estimates the probability that a given sentence is a rationale, and we then scale the contribution of each sentence to the aggregate document representation in proportion to these estimates. Experiments on five classification datasets that have document labels and associated rationales demonstrate that our approach consistently outperforms strong baselines. Moreover, our model naturally provides explanations for its predictions.

1 Introduction

Neural models that exploit word embeddings have recently achieved impressive results on text classification tasks (Goldberg, 2015). Feed-forward Convolutional Neural Networks (CNNs), in particular, have emerged as a relatively simple yet powerful class of models for text classification (Kim, 2014).

These neural text classification models have tended to assume a standard supervised learning setting in which instance labels are provided. Here we consider an alternative scenario in which we assume that we are provided a set of *rationales* (Zaidan et al., 2007; Zaidan and Eisner, 2008; McDonnell et al., 2016) in addition to instance labels, i.e., sentences or snippets that support the corresponding document categorizations. Providing such rationales during manual classification is a natural interaction for annotators, and requires little additional effort (Settles, 2011; McDonnell et al., 2016). Therefore, when training new classification systems, it is natural to acquire supervision at both the document and sentence level, with the aim of inducing a better predictive model, potentially with less effort.

Learning algorithms must be designed to capitalize on these two types of supervision. Past work (Section 2) has introduced such methods, but these have relied on linear models such as Support Vector Machines (SVMs) (Joachims, 1998), operating over sparse representations of text. We propose a novel CNN model for text classification that exploits both document labels and associated rationales.

Specific contributions of this work as follows. (1) This is the first work to incorporate rationales into neural models for text classification. (2) Empirically, we show that the proposed model uniformly outperforms relevant baseline approaches across five datasets, including previously proposed models that capitalize on rationales (Zaidan et al., 2007; Marshall et al., 2016) and multiple baseline CNN variants, including a CNN equipped with an attention mechanism. We also report state-of-the-art results on the important task of automatically assessing the risks of bias in the studies described in full-text biomedical articles (Marshall et al., 2016). (3) Our model naturally provides *explanations* for its predic-

tions, providing interpretability.

We have made available online both a Theano[1] and a Keras implementation[2] of our model.

2 Related Work

2.1 Neural models for text classification

Kim (2014) proposed the basic CNN model we describe below and then build upon in this work. Properties of this model were explored empirically in (Zhang and Wallace, 2015). We also note that Zhang et al. (2016) extended this model to jointly accommodate multiple sets of pre-trained word embeddings. Roughly concurrently to Kim, Johnson and Zhang (2014) proposed a similar CNN architecture, although they swapped in one-hot vectors in place of (pre-trained) word embeddings. They later developed a semi-supervised variant of this approach (Johnson and Zhang, 2015).

In related recent work on Recurrent Neural Network (RNN) models for text, Tang et al. (2015) proposed using a Long Short Term Memory (LSTM) layer to represent each sentence and then passing another RNN variant over these. And Yang et al. (2016) proposed a hierarchical network with two levels of attention mechanisms for document classification. We discuss this model specifically as well as attention more generally and its relationship to our proposed approach in Section 4.3.

2.2 Exploiting *rationales*

In long documents the importance of sentences varies; some are more central than others. Prior work has investigated methods to measure the relative importance sentences (Ko et al., 2002; Murata et al., 2000). In this work we adopt a particular view of sentence importance in the context of document classification. In particular, we assume that documents comprise sentences that directly support their categorization. We call such sentences *rationales*.

The notion of rationales was first introduced by Zaidan et al. (2007). To harness these for classification, they proposed modifying the Support Vector Machine (SVM) objective function to encode a preference for parameter values that result in instances containing manually annotated rationales being more confidently classified than 'pseudo'-instances from which these rationales had been stripped. This approach dramatically outperformed baseline SVM variants that do not exploit such rationales. Yessenalina et al. (2010) later developed an approach to *generate* rationales.

Another line of related work concerns models that capitalize on *dual supervision*, i.e., labels on individual *features*. This work has largely involved inserting constraints into the learning process that favor parameter values that align with *a priori* feature-label affinities or rankings (Druck et al., 2008; Mann and McCallum, 2010; Small et al., 2011; Settles, 2011). We do not discuss this line of work further here, as our focus is on exploiting provided rationales, rather than individual labeled features.

3 Preliminaries: CNNs for text classification

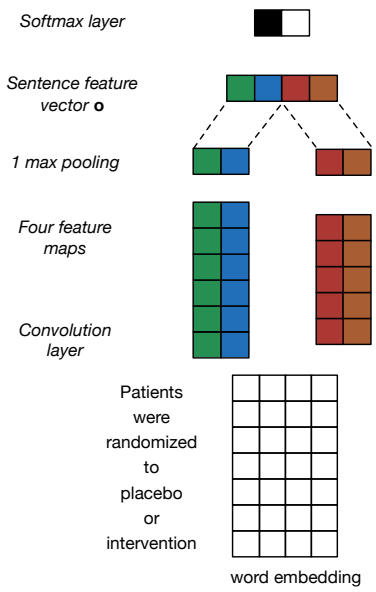

Figure 1: A toy example of a CNN for sentence classification. Here there are four filters, two with heights 2 and two with heights 3, resulting in feature maps with lengths 6 and 5 respectively.

We first review the simple one-layer CNN for sentence modeling proposed by Kim (2014). Given a sentence or document comprising n words $w_1, w_2, ..., w_n$, we replace each word with its d-dimensional pretrained embedding, and stack them row-wise, generating an instance matrix $A \in \mathbb{R}^{n \times d}$.

[1] https://github.com/yezhang-xiaofan/Rationale-CNN
[2] https://github.com/bwallace/rationale-CNN

We then apply convolution operations on this matrix using multiple linear filters, these will have the same width d but may vary in *height*. Each filter thus effectively considers distinct n-gram features, where n corresponds to the filter height. In practice, we introduce multiple, redundant features of each height; thus each filter height might have hundreds of corresponding instantiated filters. Applying filter i parameterized by $W_i \in \mathbb{R}^{h_i \cdot d}$ to the instance matrix induces a *feature map* $f_i \in \mathbb{R}^{n-h_i+1}$. This process is performed by sliding the filter from the top of the matrix (the start of the document or sentence) to the bottom. At each location, we apply element-wise multiplication between filter i and sub-matrix $A[j : j + h_i - 1]$, and then sum up the resultant matrix elements. In this way, we induce a vector (feature map) for each filter.

We next run the feature map through an element-wise non-linear transformation. Specifically, we use the *Rectified Linear Unit*, or ReLU (Krizhevsky et al., 2012). We extract the maximum value o_i from each feature map i (*1-max pooling*).

Finally, we concatenate all of the features o_i to form a vector representation $\mathbf{o} \in \mathbb{R}^{|F|}$ for this instance, where $|F|$ denotes the total number of filters. Classification is then performed on top of $\mathbf{o}$, via a softmax function. Dropout (Srivastava et al., 2014) is often applied at this layer as a means of regularization. We provide an illustrative schematic of the basic CNN architecture just described in Figure 1. For more details, see (Zhang and Wallace, 2015).

This model was originally proposed for sentence classification (Kim, 2014), but we can adapt it for document classification by simply treating the document as one long sentence. We will refer to this basic CNN variant as ***CNN*** in the rest of the paper. Below we consider extensions that account for document structure.

4 Rationale-Augmented CNN for Document Classification

We now move to the main contribution of this work: a rationale-augmented CNN for text classification. We first introduce a simple variant of the above CNN that models document structure (Section 4.1) and then introduce a means of incorporating rationale-level supervision into this model (Section 4.2). In Section 4.3 we discuss connections to attention mechanisms and describe a baseline equipped with one, inspired by Yang et al. (2016).

4.1 Modeling Document Structure

Recall that rationales are snippets of text marked as having supported document-level categorizations. We aim to develop a model that can exploit these annotations during training to improve classification. Here we achieve this by developing a hierarchical model that estimates the probabilities of individual sentences being rationales and uses these estimates to inform the document level classification.

As a first step, we extend the CNN model above to explicitly account for document structure. Specifically, we apply a CNN to each individual sentence in a document to obtain sentence vectors independently. We then sum the respective sentence vectors to create a document vector.[3] As before, we add a softmax layer on top of the document-level vector to perform classification. We perform regularization by applying dropout both on the individual sentence vectors and the final document vector. We will refer to this model as ***Doc-CNN***. Doc-CNN forms the basis for our novel approach, described below.

4.2 RA-CNN

In this section we present the Rationale-Augmented CNN (***RA-CNN***). Briefly, RA-CNN induces a document-level vector representation by taking a *weighted* sum of its constituent sentence vectors. Each sentence weight is set to reflect the estimated probability that it is a rationale in support of the most likely class. We provide a schematic of this model in Figure 2.

RA-CNN capitalizes on both sentence- and document-level supervision. There are thus two steps in the training phase: *sentence level* training and *document level* training. For the former, we apply a CNN to each sentence j in document i to obtain sentence vectors $\mathbf{x}_{\text{sen}}^{ij}$. We then add a softmax layer parametrized by $\mathbf{W}_{\text{sen}}$; this takes as input sentence vectors. We fit this model to maximize the probabilities of the observed rationales:

[3] We also experimented with taking the average of sentence vectors, but summing performed better in informal testing.

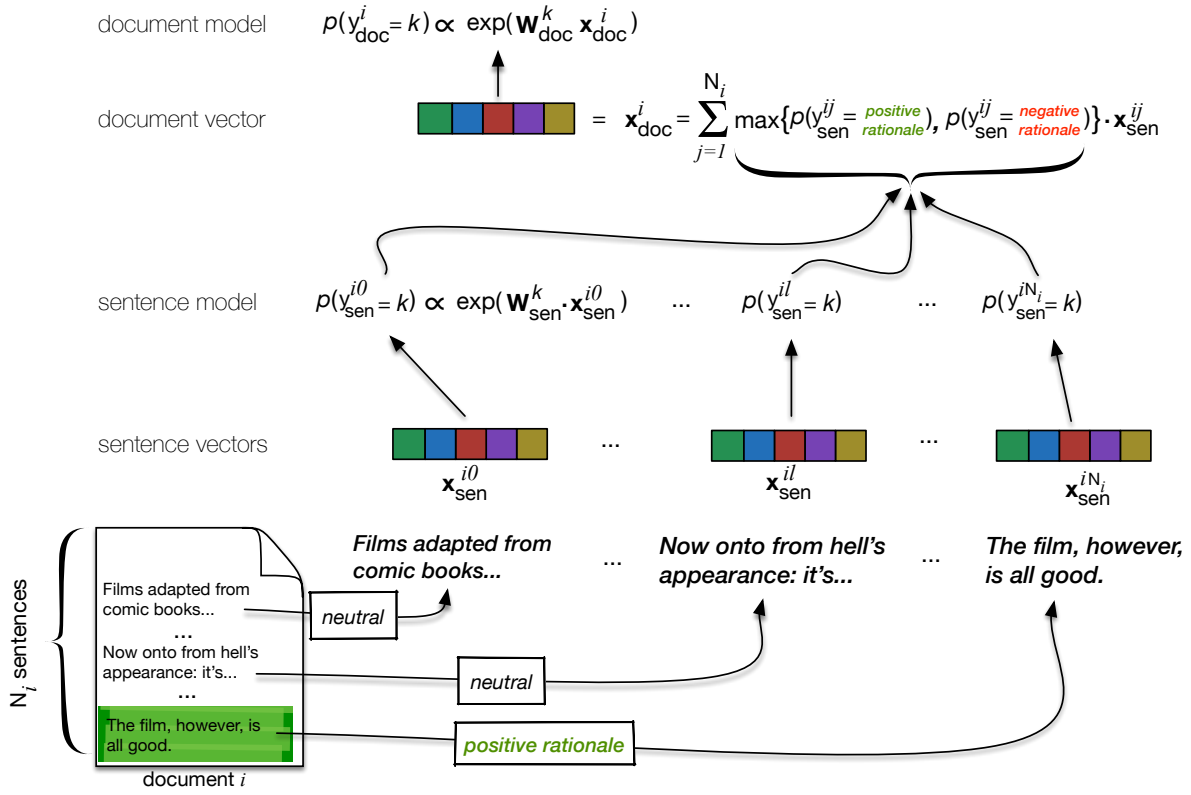

Figure 2: A schematic of our proposed Rationale-Augmented Convolution Neural Network (RA-CNN). The sentences comprising a text are passed through a sentence model that outputs probabilities encoding the likelihood that sentences are neutral or a (positive or negative) rationale. Sentences likely to be rationales are given higher weights in the global document vector, which is the input to the document model.

$$p(y^{ij}_{\text{sen}} = k; \mathbf{E}, \mathbf{C}, \mathbf{W}_{\text{sen}}) = \frac{\exp(\mathbf{W}^{(k)T}_{\text{sen}} \mathbf{x}^{ij}_{\text{sen}})}{\sum_{k=1}^{K_{\text{sen}}} \exp(\mathbf{W}^{(k)T}_{\text{sen}} \mathbf{x}^{ij}_{\text{sen}})} \quad (1)$$

Where y^{ij}_{sen} denotes the rationale label for sentence j in document i, K_{sen} denotes the number of possible classes for sentences, $\mathbf{E}$ denotes the word embedding matrix, $\mathbf{C}$ denotes the convolution layer parameters, and $\mathbf{W}_{\text{sen}}$ is a matrix of weights (comprising one weight vector per sentence class).

In our setting, each sentence has three possible labels ($K_{\text{sen}} = 3$). When a rationale sentence appears in a positive document,[4] it is a *positive rationale*; when a rationale sentence appears in a negative document, it is a *negative rationale*. All other sentences belong to a third, neutral class: these are *non-rationales*. We also experimented with having only two sentence classes: *rationales* and *non-rationales*, but this did not perform as well as explicitly maintaining separate classes for rationales of different polarities.

We train an estimator using the provided rationale annotations, optimizing over $\{\mathbf{E}, \mathbf{C}, \mathbf{W}_{\text{sen}}\}$ to minimize the categorical cross-entropy of sentence labels. Once trained, this sub-model can provide conditional probability estimates regarding whether a given sentence is a positive or a negative rationale, which we will denote by p_{pos} and p_{neg}, respectively.

We next train the document-level classification model. The inputs to this are vector representations of documents, induced by summing over constituent sentence vectors, as in Doc-CNN. However, in the RA-CNN model this is a weighted sum. Specifically, weights are set to the estimated probabilities

[4] All of the document classification tasks we consider here are binary, although extension of our model to multi-class scenarios is straight-forward.

that corresponding sentences are rationales in the most likely direction. More precisely:

$$\mathbf{x}^i_{\text{doc}} = \sum_{j=1}^{N_i} \mathbf{x}^{ij}_{\text{sen}} \cdot \max\{p^{ij}_{\text{pos}}, p^{ij}_{\text{neg}}\} \quad (2)$$

Where N_i is the number of sentences in the ith document. The intuition is that sentences likely to be rationales will have greater influence on the resultant document vector representation, while the contribution of neutral sentences (which are less relevant to the classification task) will be minimized.

The final classification is performed by a softmax layer parameterized by $\mathbf{W}_{\text{doc}}$; the inputs to this layer are the document vectors. The $\mathbf{W}_{\text{doc}}$ parameters are trained using the document-level labels, y^i_{doc}:

$$p(y^i_{\text{doc}} = k; \mathbf{E}, \mathbf{C}, \mathbf{W}_{\text{doc}}) = \frac{\exp(\mathbf{W}^{(k)T}_{\text{doc}} \mathbf{x}^i_{\text{doc}})}{\sum_{k=1}^{K_{\text{doc}}} \exp(\mathbf{W}^{(k)T}_{\text{doc}} \mathbf{x}^i_{\text{doc}})} \quad (3)$$

where K_{doc} is the cardinality of the document label set. We optimize over parameters to minimize cross-entropy loss (w.r.t. the document labels).

We note that the sentence- and document-level models share word embeddings $\mathbf{E}$ and convolution layer parameters $\mathbf{C}$, but the document-level model has its own softmax parameters $\mathbf{W}_{\text{doc}}$. When training the document-level model, $\mathbf{E}$, $\mathbf{C}$ and $\mathbf{W}_{\text{doc}}$ are fit, but we hold $\mathbf{W}_{\text{sen}}$ fixed.

The above two-step strategy can be equivalently described as follows. We first estimate $\mathbf{E}$, $\mathbf{C}$ and $\mathbf{W}_{\text{sen}}$, which parameterize our model for identifying rationales in documents. We then move to fitting our document classification model. For this we initialize the word embedding and convolution parameters to the $\mathbf{E}$ and $\mathbf{C}$ estimates from the preceding step. We then directly minimize the document level classification objective, tuning $\mathbf{E}$ and $\mathbf{C}$ and simultaneously fitting $\mathbf{W}_{\text{doc}}$.

Note that this sequential training strategy differs from the *alternating* training approach commonly used in multi-task learning (Collobert and Weston, 2008). We found that the latter approach does not work well here, leading us to instead adopt the cascade-like feature learning approach (Collobert and Weston, 2008) just described.

One nice property of our model is that it naturally provides explanations for its predictions: the model identifies rationales and then categorizes documents informed by these. Thus if the model classifies a test instance as *positive*, then by construction the sentences associated with the highest p^{ij}_{pos} estimates are those that the model relied on most in coming to this disposition. These sentences can of course be output in conjunction with the prediction. We provide concrete examples of this in Section 7.2.

4.3 Rationales as 'Supervised Attention'

One may view RA-CNN as a supervised variant of a model equipped with an *attention mechanism* (Bahdanau et al., 2014). On this view, it is apparent that rather than capitalizing on rationales directly, we could attempt to let the model learn which sentences are important, using *only* the document labels. We therefore construct an additional baseline that does just this, thereby allowing us to assess the impact of learning directly from rationale-level supervision.

Following the recent work of Yang et al. (2016), we first posit for each sentence vector a hidden representation $\mathbf{u}^{ij}_{\text{sen}}$. We then define a sentence-level *context vector* $\mathbf{u}_s$, which we multiply with each $\mathbf{u}^{ij}_{\text{sen}}$ to induce a weight α_{ij}. Finally, the document vector is taken as a weighted sum over sentence vectors, where weights reflect α's. We have:

$$\mathbf{u}^{ij}_{\text{sen}} = \tanh(\mathbf{W}_s \mathbf{x}^{ij}_{\text{sen}} + b_s) \quad (4)$$

$$\alpha_{ij} = \frac{\exp(\mathbf{u}_s^T \mathbf{u}^{ij}_{\text{sen}})}{\sum_j^{N_i} \exp(\mathbf{u}_s^T \mathbf{u}^{ij}_{\text{sen}})} \quad (5)$$

$$\mathbf{x}^i_{\text{doc}} = \sum_j^{N_i} \alpha_{ij} \mathbf{x}^{ij}_{\text{sen}} \quad (6)$$

where $\mathbf{x}^i_{\text{doc}}$ again denotes the document vector fed into a softmax layer, and $\mathbf{W}_s$, $\mathbf{u}_s$ and b_s are learned during training. We will refer to this attention-based method as *AT-CNN*.

5 Datasets

We used five text classification datasets to evaluate our approach in total. Four of these are biomedical text classification datasets (5.1) and the last is a collection of movie reviews (5.2). These datasets share the property of having recorded rationales associated

with each document categorization. We summarize attributes of all datasets used in this work in Table 1.

5.1 Risk of Bias (RoB) Datasets

We used a collection *Risk of Bias* (RoB) text classification datasets, described at length elsewhere (Marshall et al., 2016). Briefly, the task concerns assessing the reliability of the evidence presented in full-text biomedical journal articles that describe the conduct and results of randomized controlled trials (RCTs). This involves, e.g., assessing whether or not patients were properly blinded as to whether they were receiving an active treatment or a comparator (such as a placebo). If such blinding is not done correctly, it compromises the study by introducing statistical bias into the treatment efficacy estimate(s) derived from the trial.

A formal system for making bias assessments is codified by the Cochrane Risk of Bias Tool (Higgins et al., 2011). This tool defines multiple *domains*; the risk of bias may be assessed in each of these. We consider four domains here. (1) Random sequence generation (RSG): were patients were assigned to treatments in a truly random fashion? (2) Allocation concealment (AC): were group assignments revealed to the person assigning patients to groups (so that she may have knowingly or unknowingly) influenced these assignments? (3) Blinding of Participants and Personnel (BPP): were all trial participants and individuals involved in running the trial blinded as to who was receiving which treatment? (4) Blinding of outcome assessment (BOA): were the parties who measured the outcome(s) of interest blinded to the intervention group assignments? These assessments are somewhat subjective. To increase transparency, researchers performing RoB assessment therefore record rationales (sentences from articles) supporting their assessments.

5.2 Movie Review Dataset

We also ran experiments on a movie review (MR) dataset with accompanying rationales. Pang and Lee (2004) developed and published the original version of this dataset, which comprises 1000 positive and 1000 negative movie reviews from the Internet Movie Database (IMDB).[5] Zaidan et al. (2007) then augmented this dataset by adding rationales corresponding to the binary classifications for 1800 documents, leaving the remaining 200 for testing. Because 200 documents is a modest test sample size, we ran 9-fold cross validation on the 1800 annotated documents (each fold comprising 200 documents). The rationales, as originally marked in this dataset, were sub-sentential snippets; for the purposes of our model, we considered the entire sentences containing the marked snippets as rationales.

6 Experimental Setup

6.1 Baselines

We compare against several baselines to assess the advantages of directly incorporating rationale-level supervision into the proposed CNN architecture. We describe these below.

SVMs. We evaluated a few variants of linear Support Vector Machines (SVMs). These rely on sparse representations of text. We consider variants that exploit uni- and bi-grams; we refer to these as *uni-SVM* and *bi-SVM*, respectively. We also re-implemented the rationale augmented SVM (*RA-SVM*) proposed by Zaidan et al. (2007), described in Section 2.

For the RoB dataset, we also compare to a recently proposed multi-task SVM (MT-SVM) model developed specifically for these RoB datasets (Marshall et al., 2015; Marshall et al., 2016). This model exploits the intuition that the risks of bias across the domains codified in the aforementioned Cochrane RoB tool will likely be correlated. That is, if we know that a study exhibits a high risk of bias for one domain, then it seems reasonable to assume it is at an elevated risk for the remaining domains. Furthermore, Marshall et al. (2016) include rationale-level supervision by first training a (multi-task) *sentence-level* model to identify sentences likely to support

RoB assessments in the respective domains. Special features extracted from these predicted rationales are then activated in the *document-level* model, informing the final classification. This model is the state-of-the-art on this task.

CNNs. We compare against several baseline CNN variants to demonstrate the advantages of our approach. We emphasize that our focus in this work is **not** to explore how to induce generally 'better' document vector representations – this question has been addressed at length elsewhere, e.g., (Le and Mikolov, 2014; Jozefowicz et al., 2015; Tang et al., 2015; Yang et al., 2016).

Rather, the main contribution here is an augmentation of CNNs for text classification to capitalize on rationale-level supervision, thus improving performance and enhancing interpretability. This informed our choice of baseline CNN variants: standard CNN (Kim, 2014), Doc-CNN (described above) and AT-CNN (also described above) that capitalizes on an (unsupervised) attention mechanism at the sentence level, described in Section 4.3.[6]

6.2 Implementation/Hyper-Parameter Details

Sentence splitting. To split the documents from all datasets into sentences for consumption by our Doc-CNN and RA-CNN models, we used the Natural Language Toolkit (NLTK)[7] sentence splitter.

SVM-based models. We kept the 50,000 most frequently occurring features in each dataset. For estimation we used SGD. We tuned the C hyper-parameter using nested development sets. For the RA-SVM, we additionally tuned the μ and $C_{contrast}$ parameters, as per Zaidan et al. (2007).

CNN-based models. For all models and datasets we initialized word embeddings to pre-trained vectors fit via Word2Vec. For the movie reviews dataset these were 300-dimensional and trained on Google News.[8] For the RoB datasets, these were 200-dimensional and trained on biomedical texts in PubMed/PubMed Central (Pyysalo et al., 2013).[9]

[6]We also experimented briefly with LSTM and GRU (Gated Recurrent Unit) models, but found that simple CNN performed better than these. Moreover, CNNs are relatively robust and less sensitive to hyper-parameter selection.

[7]http://www.nltk.org/api/nltk.tokenize.html

[8]https://code.google.com/archive/p/word2vec/

[9]http://bio.nlplab.org/

Training proceeded as follows. We first extracted all sentences from all documents in the training data. The distribution of sentence types is highly imbalanced (nearly all are neutral). Therefore, we downsampled sentences before each epoch, so that sentence classes were equally represented. After training on sentence-level supervision, we moved to document-level model fitting. For this we initialized embedding and convolution layer parameters to the estimates from the preceding sentence-level training step (though these were further tuned to optimize the document-level objective).

For RA-CNN, we tuned the dropout rate (range: 0-.9) applied at the sentence vector level on each training fold (using a subset of the training data as a validation set) during the document level training phase. Anecdotally, we found this has a greater effect than the other model hyperparameters, which we thus set after a small informal process of experimentation on a subset of the data. Specifically, we fixed the dropout rate at the document level to 0.5, and we used 3 different filter heights: 3, 4 and 5, following (Zhang and Wallace, 2015). For each filter height, we used 100 feature maps for the baseline CNN, and 20 for all the other CNN variants.

For parameter estimation we used ADADELTA (Zeiler, 2012), mini-batches of size 50, and an early stopping strategy (using a validation set).

7 Results and Discussion

7.1 Quantitative Results

For all CNN models, we replicated experiments 5 times, where each replication constituted 5-fold and 9-fold CV respectively the RoB and the movies datasets, respectively. We report the mean and observed ranges in accuracy across these 5 replications for these models, because attributes of the model (notably, dropout) and the estimation procedure render model fitting stochastic (Zhang and Wallace, 2015). We do not report ranges for SVM-based models because the variance inherent in the estimation procedure is much lower for these simpler, linear models.

Results on the RoB datasets and the movies dataset are shown in Tables 2 and Table 3, respectively. RA-CNN consistently outperforms all of the baseline models, across all five datasets. We also

Table 2: Accuracies on the four RoB datasets. Uni-SVM: unigram SVM, Bi-SVM: Bigram SVM, RA-SVM: Rationale-augmented SVM (Zaidan et al., 2007), MT-SVM: a multi-task SVM model specifically designed for the RoB task, which also exploits the available sentence supervision (Marshall et al., 2016). We also report an estimate of human-level performance, as calculated using subsets of the data for each domain that were assessed by two experts (one was arbitrarily assumed to be correct). We report these numbers for reference; they are not directly comparable to the cross-fold estimates reported for the models.

observe that CNN/Doc-CNN do not necessarily improve over the results achieved by SVM-based models, which prove to be strong baselines for longer document classification. This differs from previous comparisons in the context of classifying shorter texts. In particular, in previous work (Zhang and Wallace, 2015) we observed that CNN outperforms SVM uniformly on sentence classification tasks (the average sentence-length in these datasets was about 10). In contrast, in the datasets we consider in the present paper, documents often comprise hundreds of sentences, each in turn containing multiple words. We believe that it is in these cases that explicitly modeling which sentences are most important will result in the greatest performance gains, and this aligns with our empirical results.

Another observation is that AT-CNN does often improve performance over vanilla variants of CNN (i.e., without attention), especially on the RoB datasets, probably because these comprise longer documents. However, as one might expect, RA-CNN clearly outperforms AT-CNN by exploiting rationale-level supervision directly. And by exploiting rationale information directly, RA-CNN is able to consistently perform better than baseline CNN and SVM model variants. Indeed, we find that RA-CNN outperformed MT-SVM on all of the RoB datasets, and this was accomplished without exploiting cross-domain correlations (i.e., without multi-task learning).

Method	Accuracy
Uni-SVM	86.44
Bi-SVM	86.94

AT-CNN	86.69 (86.28, 87.17)
RA-CNN	**90.43 (90.11, 91.00)**

Table 3: Accuracies on the movie review dataset.

7.2 Qualitative Results: Illustrative Rationales

In addition to realizing superior classification performance, RA-CNN also provides *explainable* categorizations. The model can provide the highest scoring rationales (ranked by $\max\{p_{\text{pos}}, p_{\text{neg}}\}$) for any given target instance, which in turn – by construction – are those that most influenced the final document classification.

For example, a sample positive rationale supporting a correct designation of a study as being at low risk of bias with respect to blinding of outcomes assessment reads simply *The study was performed double blind*. An example rationale extracted for a study (correctly) deemed at high risk of bias, meanwhile, reads *as the present study is retrospective, there is a risk that the woman did not properly recall how and what they experienced ....*

Turning to the movie reviews dataset, an example rationale extracted from a glowing review of 'Goodfellas' (correctly classified as positive) reads *this cinematic gem deserves its rightful place among the best films of 1990s*. While a rationale extracted

from an unfavorable review of 'The English Patient' asserts that *the only redeeming qualities about this film are the fine acting of Fiennes and Dafoe and the beautiful desert cinematography*.

In each of these cases, the extracted rationales directly support the respective classifications. This provides direct, meaningful insight into the automated classifications, an important benefit for neural models, which are often seen as opaque.

8 Conclusions

We developed a new model (RA-CNN) for text classification that extends the CNN architecture to directly exploit *rationales* when available. We showed that this model outperforms several strong, relevant baselines across five datasets, including vanilla and hierarchical CNN variants, and a CNN model equipped with an attention mechanism. Moreover, RA-CNN automatically provides explanations for classifications made at test time, thus providing interpretability.

Moving forward, we plan to explore additional mechanisms for exploiting supervision at lower levels in neural architectures. Furthermore, we believe an alternative approach may be a hybrid of the AT-CNN and RA-CNN models, wherein an auxiliary loss might be incurred when the attention mechanism output disagrees with the available direct supervision on sentences.

Transferring User Interests Across Websites with Unstructured Text for Cold-Start Recommendation

Abstract

In this work, we investigate the possibility of cross-website transfer learning for tackling the cold-start problem. To address the cold-start issues commonly present in a collaborative filtering (CF) system, most existing cross-domain CF models require auxiliary rating data from another domain; nevertheless, under the cross-website scenario, such data is often unobtainable. Therefore, we propose the nearest-neighbor transfer matrix factorization (NT-MF) model, where a topic model is applied to the unstructured user-generated content in the source domain, and the similarity between users in the latent topic space is utilized to guide the target-domain CF model. Specifically, the latent factors of the nearest-neighbors are regarded as a set of pseudo observations, which can be used to estimate the unknown parameters in the model. Improvement over previous methods, especially for the cold-start users, is demonstrated with experiments on a real-world cross-website dataset.

1 Introduction

While collaborative filtering (CF) approaches are one of the most successful methods for building recommender systems, their performance deteriorates dramatically under *cold-start* situations. That is, low prediction accuracy is observed for users/items with very few ratings. Content-based recommender systems may also suffer from the cold-start problem. For instance, content-based nearest-neighbor models (Pazzani and Billsus, 2007) might not be as effective if some users contain too few information to generate a meaningful set of neighbors.

Two types of solutions have been proposed to address the cold-start problem. The first is to create hybrid recommendation models that impose a content-based model on a CF model to enrich the information for users/items with sparse rating profiles (Burke, 2002; Burke, 2007). The second is to transfer the information from auxiliary domains as a remedy to the cold-start individuals (Deng et al., 2015). This paper aims at bringing a marriage between these two types of strategies.

Although transfer learning gradually gains popularity in handling the cold-start issue (Roy et al., 2012), most of them assume a homogeneous model where observations in both domains are of the same type. That is, to transfer knowledge to a rating-based/text-based recommender system, the source system must also be rating-based/text-based. Some earlier works even require the ratings from both domains to be in the same format (Li et al., 2009), or assume specific structured text, such as user-provided tags (Shi et al., 2011; Deng et al., 2015). In this work, by contrast, no source-domain ratings are available and unstructured user-generated content is treated as the auxiliary data. We propose a *heterogeneous transfer learning* framework to utilize unstructured auxiliary text for a better target-domain CF model.

As there is no single service satisfying all social needs, users nowadays hold multiple accounts across many websites. Furthermore, the account linking mechanism is often available on these websites. This allows a precise mapping between the accounts of the same user to be built. One major application of our approach is to improve the recom-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 805–814,
Austin, Texas, November 1-5, 2016.

mendation quality in the target service using auxiliary data obtained from another seemingly irrelevant service.

For instance, consider a new user on YouTube. The initial recommended videos for this user is likely to be irrelevant as there is very few information available. However, with the account linking mechanism, YouTube accounts can be linked to Twitter accounts with a simple click. Our goal is to utilize the content generated by this user on Twitter, despite the possibility that the content is irrelevant to their preference on video browsing, to produce a better video recommendation list on YouTube.

Seemingly intuitive, there exist some difficulties in such *cross-website transfer learning* approach. The biggest challenge lies in the fact that most users do not use multiple services (e.g. social media sites) for the same purpose. Usually a user registers for multiple services because each of them serves its own purpose. As a result, we cannot assume the existence of direct mentions about target-domain items in the source-domain text data. For example, a regular YouTube viewer does not necessarily tweet about the videos he/she has viewed. Thus simple methods such as keyword matching are likely to fail. The same reasoning also implies that, when transferring knowledge across websites or services, the assumption of a shared rating format or structured text is overly optimistic. Even websites aiming for the same purpose often violate this assumption, let alone websites of different types. Therefore, we expect that the source and target services contain heterogeneous information (e.g. content vs. rating). In our model, we make a less strong assumption: regardless of the type of information available in each domain, the users that are similar in one domain should have similar taste in the other domain. Thus, instead of directly transfer the content material from source to target domain, we transfer the *similarity* between users, and use it as a guide to improve the CF model in the target domain.

2 LDA-MF Model

We first introduce an intuitive model to realize the above-mentioned idea, and point out several intrinsic weaknesses making it unsuitable for cross-website transfer learning.

Here we rely on the probabilistic matrix factorization (PMF) model as our target-domain CF model. In the PMF model, each user latent factor is modeled (a priori) by a zero-mean Gaussian. To incorporate source-domain information into the target-domain PMF model, for each user i, a topic vector θ_i is extracted from source-domain text content and assigned as the prior mean of this user's PMF latent factor, that is,

$$u_i \sim \mathcal{N}(\theta_i, \lambda_U^{-1} I), \tag{1}$$

where λ_U is the precision parameter and I is the identity matrix. Different from the original PMF model, prior distributions of different user latent factors are no longer identical. For users having similar source-domain topic vectors, their latent factors are expected to be close in the target-domain latent space. Such property allows the similarity between users to be transferred from source domain to the target domain.

With the latent Dirichlet allocation (LDA) (Blei et al., 2003) topic model being used, the graphical model is depicted in Figure 1. This model is similar in structure to the recently proposed collaborative topic regression (CTR) (Wang and Blei, 2011) model. The main difference is that, instead of modeling description about items, now user-generated content *from the source domain* is modeled in our problem. We call this model the LDA-MF model.

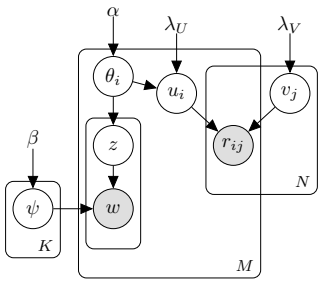

Figure 1: The LDA-MF model.

Although LDA-MF indeed incorporates knowledge from the source domain, it has certain weaknesses which need to be addressed. The most significant drawback is that the dimensionalities of the LDA topic vector θ_i and the PMF user latent factor u_i are required to be equal. These two variables are of very different nature. One is extracted from text data in the source domain to model the topics

of the user-generated content, and the other is generated from the rating data in the target domain to model the latent interests of users. It is an overly strong assumption to assume the optimal dimensionalities for LDA and PMF are equal. In practice, if we choose the dimensionality to optimize the predictive power of PMF (e.g. by cross-validation on the rating data), the LDA model is likely to yield sub-optimal results and vice versa. The experiments that will be shown later confirm this concern. Furthermore, since the two variables are modeling different types of observations coming from different websites, the underlying meanings of the latent dimensions are unlikely to be identical. By treating the LDA topic vector as the prior mean of the PMF user latent factor, the latent dimensions are forced to be one-to-one aligned, which is again a strong assumption. Finally, the topic vectors are drawn from the Dirichlet distribution which has a bounded (and positive) support S, while the latent factors in PMF are unbounded Gaussian random vectors. If the optimal solution of u_i is far from S, the performance of the model could be affected, particularly in the cold-start situation where data is sparse and the prior plays an important role.

3 Nearest-Neighbor Transfer MF Model

To alleviate the drawbacks of the LDA-MF model, here we propose *nearest-neighbor transfer matrix factorization* (NT-MF) model to transfer user interests across websites. The entire framework is depicted in Figure 2.

We begin by describing the scenario in which our model operates. First, there is a rating-based recommender system (i.e. PMF) in the target domain, which suffers from the cold-start problem. The target domain might or might not contain content information. For example, in the video recommendation task, we can use the titles of all rated videos of a user to generate content information in the target domain. Such information is not available for the cold-start users since they have not rated any videos. However, in the source domain there are some content information available for these users. This can be, say, the content of a user's tweets. As previously mentioned, this type of auxiliary text data is immediately available when a user connects the accounts

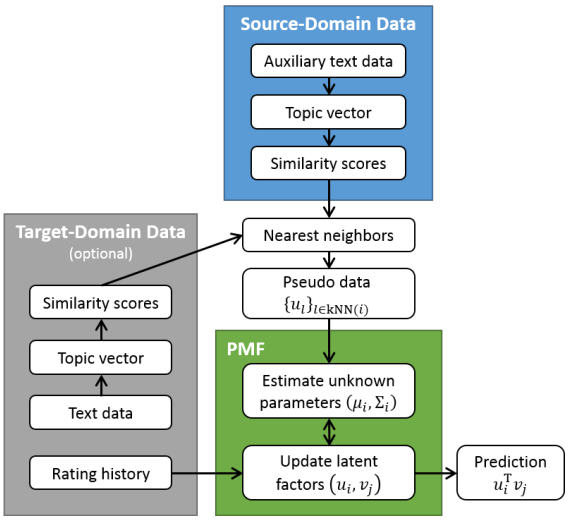

Figure 2: The entire system.

from two domains. Therefore, we assume this auxiliary text data is available for all users.

3.1 Model Outline

Next, we describe the high level concept of our model. As described previously, we have observed that the hypotheses encoded by the LDA-MF model is too strong as the PMF latent factor is enforced to inherit certain mathematical properties from the LDA topic vector. Here we loosen the constraint to only enforce that users should have similar distributions over the target-domain PMF latent factors if there is a high similarity between their source-domain topic vectors.

It is a reasonable hypothesis since our objective is to make the target-domain rating matrix factorize in a way that is consistent with the knowledge extracted from source-domain text. After all, the factorization of incomplete matrix is not unique, and there is no reason that the latent factor should match the topic factor of the user. In fact, our hypothesis implies a different distribution over the PMF latent factor for each user, i.e. $u_i \sim \mathcal{N}(\mu_i, \Sigma_i)$, where (μ_i, Σ_i) are unknown parameters, and are (possibly) different for each user.

To estimate the unknown parameters in a distribution, normally we need a set of observations, $(u_i^{(1)}, u_i^{(2)}, \dots)$. However, the parameters now belong to a distribution over a latent variable, which is non-trivial to estimate since we have no observations about the user latent factor. An exhaustive search

over the parameter space is obviously intractable. Even if we treat the entire model as a hierarchical model and learn the parameters indirectly from rating data, the cold-start problem immediately comes in and forbids us from learning a representative distribution for users.

We propose the idea of using the latent factors of the nearest-neighbors to estimate the unknown parameters in the distribution for a user. That is, the latent factors of the nearest-neighbors, $\{u_l\}_{l \in k\text{NN}(i)}$, are regarded as a set of *pseudo observations* to replace the unavailable data, $(u_i^{(1)}, u_i^{(2)}, \dots)$. However, the definition of "closeness" is not based on target-domain rating data, but computed by the topic vectors obtained from the content in the source domain (and the target domain, if available). Our model is thus not hampered by the cold-start problem.

Note that, in addition to the set of k-nearest-neighbors $k\text{NN}(i)$, we also have the corresponding similarity scores $sim(i, l)$ between each neighbor l and user i. The similarity scores along with the list of nearest-neighbors are transferred to the target domain to form a set of weighted samples, $\mathcal{D}$, which can be used to estimate the unknown parameters (μ_i, Σ_i), i.e.,

$$\mathcal{D} \equiv \begin{cases} \{u_l\}_{l \in k\text{NN}(i)} \\ w_l = sim(i, l). \end{cases} \tag{2}$$

The main purpose of assigning a sample weight w_l to each of the pseudo observations u_l is that by doing so, users with a higher source-domain similarity to user i will have a larger impact on the estimation of the target-domain parameters (μ_i, Σ_i). In other words, with this model specification, the *similarity between users* is transferred across domains.

3.2 Inference in NT-MF Model

To perform inference in our model, we adopt the maximum a posteriori (MAP) strategy and alternately update the user and item latent factors (i.e. by block coordinate ascent), similar to some previous solutions (Salakhutdinov and Mnih, 2007; Wang and Blei, 2011).

To solve for the optimal user latent factor u_i, we need to first estimate the unknown parameters (μ_i, Σ_i). Therefore, in our coordinate ascent algorithm, different from the original PMF model, we update the user latent factors one by one. That is, all user latent factors are regarded as fixed constants except for the one, u_i, to be updated. By doing so, for each user i, a set of *pseudo observations* about u_i (Eq. 2) is available. Using these pseudo observations, the unknown parameters (μ_i, Σ_i) can then be estimated with standard techniques such as maximum likelihood estimation (MLE). After an estimator of (μ_i, Σ_i) is obtained, we can analytically solve for the MAP solution of the user latent factor u_i. Then, we move on to the next user, and the coordinate ascent procedure continues. These two steps, namely the estimation of unknown parameters and the updating of the latent factors, are repeated until convergence.

One advantage of this procedure is that the list of nearest-neighbors and the similarities in Eq. 2 need not be recomputed during inference, avoiding expensive recomputation of pairwise similarities. It is also noticeable that, different from other transfer-based approaches, rating information and structured text from the source domain are not required in this procedure of model optimization. This further adds a level of flexibility to our framework for transferring user interests across websites.

3.3 Case Study: Inferring Unknown Mean

To clarify the previous discussions, we present a simple but detailed case-study on how an NT-MF model and its optimization procedure can be derived. The latent factor u_i for each user is assumed to be generated from a multivariate normal distribution with unknown mean μ_i and a known precision parameter λ_U, which is shared among the users.

The generative process proceeds as follows:

1. For each user i, draw user latent factor $u_i \sim \mathcal{N}(\mu_i, \lambda_U^{-1} I)$.
2. For each item j, draw item latent factor $v_j \sim \mathcal{N}(0, \lambda_V^{-1} I)$.
3. For each observed user-to-item pair (i, j), draw the rating $r_{ij} \sim \mathcal{N}(u_i^T v_j, \lambda_0^{-1})$,

where λ_0 is the precision parameter of the ratings, and λ_U, λ_V are the precision parameter of the

users and items, respectively. We use the notation $\mathcal{N}(x|\mu, \Sigma)$ to denote the Gaussian pdf with mean μ and covariance Σ.

The model is optimized by maximizing the posterior likelihood of the latent variables (an additive term is omitted),

$$\mathcal{L} = -\frac{\lambda_0}{2}\sum_{i=1}^{M}\sum_{j=1}^{N}\gamma_{ij}\left(r_{ij} - u_i^T v_j\right)^2 - \frac{\lambda_U}{2}\sum_{i=1}^{M}\left(u_i - \mu_i\right)^T\left(u_i - \mu_i\right) - \frac{\lambda_V}{2}\sum_{j=1}^{N} v_j^T v_j, \tag{3}$$

where γ_{ij} is an indicator variable which is equal to 1 if item j is rated by user i, and 0 otherwise.

To solve the MAP problem, we need to first estimate the unknown parameters in the distribution, which in this case is the mean vector μ_i. The likelihood function over the pseudo observations, $\{u_l\}_{l\in k\text{NN}(i)}$, is defined as,

$$p(\mathcal{D}|\mu_i, \lambda_U) = \prod_{l\in k\text{NN}(i)} \mathcal{N}(u_l|\mu_i, \lambda_U^{-1} I). \tag{4}$$

By taking derivative of Eq. 4 with respect to μ_i and set it to zero, we obtain,

$$\sum_{l\in k\text{NN}(i)} (u_l - \mu_i) = 0, \tag{5}$$

which implies that the MLE of μ_i is the sample mean. However, since we are dealing with a set of *weighted samples*, the sample mean is replaced by the weighted average (the weights w_l are assumed to add up to one):

$$\mu_i = \sum_{l\in k\text{NN}(i)} w_l u_l. \tag{6}$$

Our model yields an intuitive result: to estimate the mean vector μ_i of u_i, we can simply take the weighted average of the latent factors u_l from the nearest-neighbors as an estimator, where the weights are the similarity scores between the textual profiles of user i and its neighbors.

Given μ_i, we can now maximize Eq. 3 with respect to u_i and v_j. By taking derivative of Eq. 3 with respect to u_i and v_j and set it to zero, we obtain the update equations,

$$\left(\sum_{j=1}^{N}\gamma_{ij} v_j v_j^T + \frac{\lambda_U}{\lambda_0} I\right) u_i = \sum_{j=1}^{N}\gamma_{ij} r_{ij} v_j + \frac{\lambda_U}{\lambda_0}\mu_i \tag{7}$$

$$\left(\sum_{i=1}^{M}\gamma_{ij} u_i u_i^T + \frac{\lambda_V}{\lambda_0} I\right) v_j = \sum_{i=1}^{M}\gamma_{ij} r_{ij} u_i. \tag{8}$$

Now with Eq. 6 to Eq. 8 at hand, we can iteratively solve for μ_i, u_i and v_j for all users and items until the model converges.

It can be seen from this case-study that NT-MF eliminates the three major drawbacks of the previously mentioned LDA-MF model. First, the topic vectors and the user latent factors are not required to have equal dimensionalities, which allows for the optimal dimensionality to be chosen in both models. Second, the mean vector, that is, the kNN weighted average in Eq. 6, is a linear combination of a set of user latent factors; as a result, the latent dimensions of u_i and μ_i are naturally aligned. Third, the mean vector μ_i has the same support as the user latent factor u_i, avoiding the risk of prior misspecification in cold-start situations.

4 Experiment

We use YouTube video recommendation to test the usefulness of NT-MF under the cold-start scenario. The NT-MF model used in this section follows the optimization procedure derived in Section 3.3.

4.1 Dataset and Statistics

To construct a dataset containing both the users' rating history and textual information, we begin with the user profile pages on Google+. A large proportion of Google+ users provide links to their profile pages from other social network services (e.g. Twitter). More importantly, if a user owns a YouTube account, a link to the user's YouTube channel will be automatically added to his Google+ profile. This makes a fully aligned dataset available. Users' Twitter accounts are obtained via their Google+ profile page, and the concatenation of tweets is regarded as the auxiliary text data. It has been shown that by concatenating the tweets, more representative user

topic vectors can be obtained (Hong and Davison, 2010). We refer to this text data as the *Twitter corpus*.

Videos in a user's "liked" or "favorite" playlists are considered to have a rating $r_{ij} = 1$. Other videos are assigned $r_{ij} = 0$. In other words, we are dealing with a one-class collaborative filtering (OCCF) problem (Pan et al., 2008). We adopt the same strategy as in (Wang and Blei, 2011) to deal with OCCF. First, all ratings are assumed to be observed, i.e. $\gamma_{ij} = 1$ for all user-item pairs. Next, a confidence parameter c_{ij} is introduced to reduce the influence of the huge number of zeroes during model optimization. The confidence parameter takes place of the original rating precision parameter λ_0 and is defined in (Wang and Blei, 2011) as $c_{ij} = a$ if $r_{ij} = 1$ and $c_{ij} = b$ otherwise $(a > b > 0)$. All the derivations in the previous sections follow intuitively.

The titles of the liked videos are concatenated and treated as the text data in the target domain (which we refer to as the *YouTube corpus*). As for the vocabulary, stopwords are first removed, and then 5000 words are selected from the YouTube corpus based on their TF-IDF scores (Blei and Lafferty, 2009). On average, each user's Twitter text data contains 5149 words and 1193 distinct terms, and each user's YouTube text data contains 158 words and 116 distinct terms. These statistics are in accordance with our assumption that text data in the source domain is abundant comparing to that in the target domain.

To validate the prediction result, each user has at least 10 liked videos. Videos with less than 5 likes are removed from the dataset. After data cleansing, there are 7328 users and 18691 videos in the dataset. The maximum number of likes received by a video is 98, and the average is 19.1. Among all videos, 92% of them are liked by less than 40 users. The maximum number of likes given by a user is 908, and the average is 48.8. Among all users, 89% of them have liked less than 100 videos. The sparsity (ratio of zeroes to the total number of entries) of the rating matrix is 99.74%, which illustrates the difficulty of this recommendation task.

4.2 Evaluation and Scenario

We choose the area under ROC curve (AUC) as the evaluation metric. AUC is often used to compare models when there is severe class imbalance, which is the case in our OCCF problem since we regard all zeroes as observed. All reported results are the average of 5 random data splits.

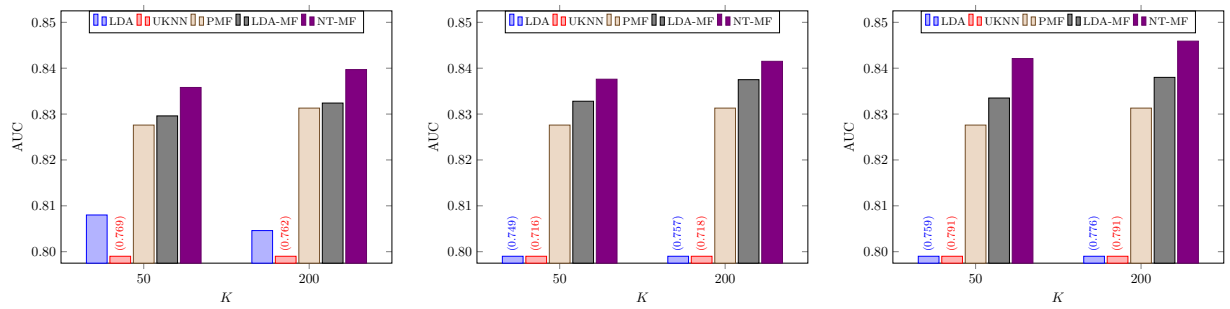
Similar to the experiments performed in (Wang and Blei, 2011), we test the performance of each model under two different scenarios. The first one is the task of *in-matrix* prediction. In this task, the likes received by each video are partitioned into three sets, namely the training, validation and testing sets. The ratio of data partition is 3:1:1. There are no cold-start users for the in-matrix prediction.

The second task is the *out-of-matrix* prediction, where the *users* are partitioned into three sets with the same 3:1:1 ratio. To make the two tasks comparable, we randomly split the data until the number of observations in each of the three sets is closed to that of the in-matrix task. Users in the testing set are all cold-start users. The only data we have when making prediction on the cold-start users is the auxiliary text data.

4.3 Baseline Methods

- **LDA:** We run linear regression on the LDA features to predict the ratings. This model serves as a content-based baseline.
- **UKNN:** The user-kNN algorithm (Herlocker et al., 1999) based on LDA features is implemented. This model serves as a neighborhood-based baseline.
- **PMF:** PMF (Salakhutdinov and Mnih, 2007) is a classic and widely-used CF model. It uses only the rating information, and thus is not capable of performing the out-of-matrix task.
- **LDA-MF:** This model is implemented as has been described in Section 2. It is similar to CTR (Wang and Blei, 2011) in structure. Since the optimization of the full model converges badly, we pre-train the LDA part of the model, and fix the topic vector when optimizing the PMF part.

All hyperparameters are tuned on the validation set. Due to efficiency and storage considerations, for UKNN and NT-MF, the k-nearest-neighbors are computed approximately with the FLANN library



(a) YouTube corpus (b) Twitter corpus (c) YouTube + Twitter corpus

Figure 3: In-matrix AUC using different corpus. For methods significantly worse than others, we cut off the plot and put the AUC values on top of the bars. NT-MF is significantly better than the baselines in all plots, according to a paired t-test ($p < 0.05$).

(Muja and Lowe, 2014). The symmetric Kullback-Leibler divergence is chosen to be the distance metric between topic vectors. For all baseline methods, we use K to denote the dimensionality of the latent variables. However, when discussing about NT-MF, since the number of topics can be different from the number of user latent factors, we use T to denote the former and K to denote the latter to avoid confusion.

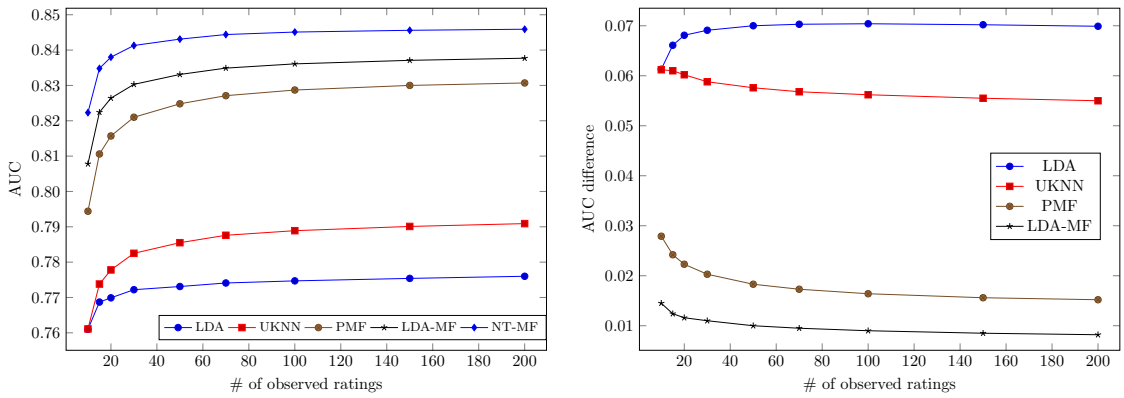
4.4 In-Matrix Prediction

In this section, the in-matrix prediction is discussed. First, we test the model's general performance on different corpora. Normally, the optimal number of topics will not be the same for different corpora. Since the LDA model performs the best with $K = 50$ on the YouTube corpus and $K = 200$ on the Twitter corpus, we report the results when K is set to these two numbers.

Figure 3(a) shows the results when no source-domain information is available and thus no transfer learning is performed. That is, all models are provided only with the YouTube ratings and the YouTube corpus. Because the YouTube corpus is scarce, the LDA model results in lower AUC when more topics are used, signifying overfitting. The same reason also leads to limited improvement of LDA-MF over PMF. Using neighborhood information alone, UKNN performs poorly. On the other hand, as a model bringing neighborhood information into PMF, NT-MF outperforms all baselines significantly. The above analysis shows that, although using either content (LDA) or neighborhood (UKNN) information alone is insufficient to generate good predictions, they can effectively improve the factorization of the rating matrix if used correctly.

To demonstrate the advantage of transfer learning, we study the scenario where only source-domain text and target-domain ratings are available. That is, the YouTube corpus in the previous analysis is replaced with the Twitter corpus. The result is shown in Figure 3(b). Comparing to Figure 3(a), we can see that although the Twitter corpus is larger than the YouTube corpus, it leads to a worse performance for LDA and UKNN. Content information from the noisy Twitter corpus alone is not sufficient to capture the rating behavior of users. However, by integrating the content information and rating history, both LDA-MF and NT-MF benefit from a larger corpus.

In the following analyses, we use data from both websites. For LDA, PMF and LDA-MF, we merge the two corpora by summing up the word counts. For UKNN and NT-MF, however, there is a more elegant way to combine the knowledge from different websites. First, we compute user similarity separately from the two corpora. Then, the two sets of similarity scores are weighted and averaged. Finally, the nearest-neighbors are computed based on this set of newly generated similarity scores. By applying this strategy to NT-MF, not only can θ_i and u_i differ in dimensionality, but also the optimal number of topics can be used for different corpora. Regardless of K, we use $T = 50$ for YouTube and $T = 200$ for Twitter in our NT-MF model. The result is shown in Figure 3(c). By comparing it with Figure 3(b), we can see that the AUC of NT-MF increases while that of LDA-MF remains unchanged. UKNN also benefits from this strategy. These facts show that, instead of merging the two corpora directly, our strategy of averaging the similarities is more advantageous.



(a) (b)

Figure 4: (a) Cumulative in-matrix AUC. Each point (x, y) in the figure means that the model gives an averaged AUC of y among all users who have less than or equal to x observed ratings. (b) Difference in cumulative in-matrix AUC between NT-MF and baseline methods.

Next, as a preliminary investigation of the performance on cold-start users, in Figure 4(a), we plot the *cumulative* AUC with respect to the total number of observed ratings. NT-MF outperforms other methods in terms of cumulative AUC regardless of the number of observed ratings. The advantage of NT-MF over the baseline methods is even greater as the number of observed ratings decreases (except for LDA). To make it clear, we plot the difference in AUC between NT-MF and the baseline methods in Figure 4(b). This phenomenon sheds light on the advantage of NT-MF under cold-start scenario.

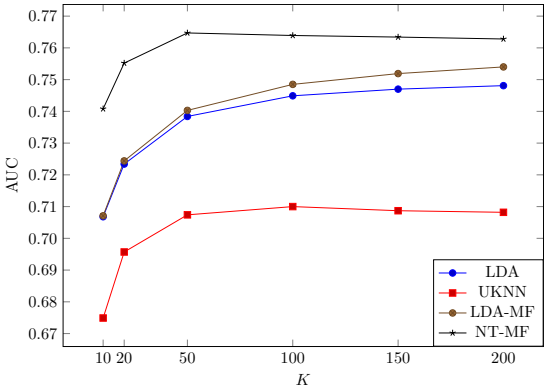


Figure 5: Out-of-matrix AUC. NT-MF is significantly better than the baselines, according to a paired t-test ($p < 0.05$).

4.5 Out-of-Matrix Prediction

In this section, we discuss the *out-of-matrix* prediction. Users in the testing set are all completely cold-start users. That is, we are only provided the Twitter corpus when making prediction for these users. Therefore, our previous strategy of averaging the similarities only applies to users in the training set. For this study we adopt the strategy of merging the two corpus instead of averaging the similarities. The number of topics $T = 150$ is chosen for NT-MF with respect to the validation AUC.

The result is presented in Figure 5. We plot the AUC against the dimensionality of the latent variables K. It can be observed that NT-MF beats all baseline methods regardless of K. Comparing to Figure 3, the out-of-matrix AUC is much lower, signifying the difficulty of cold-start recommendation.

Under the cold-start scenario, the latent factor used in the prediction phase is taken to be the prior mean for the MF-based models. For LDA-MF the prior mean is the topic vector θ_i, while for NT-MF it is the weighted average μ_i given by Eq. 6.

Since θ_i is used in place of u_i in the LDA-MF model when generating predictions, the curves of LDA and LDA-MF look very similar. A paired t-test ($p < 0.05$) shows no statistically significant difference between these two methods when $K = 10$ ($p = 0.48$) and $K = 20$ ($p = 0.09$). Despite the fact that $u_i = \theta_i$ is fixed for the cold-start users in the LDA-MF model, as K becomes larger, the item latent factors can carry more information in the rating data, which results in a higher AUC than LDA. However, since the dimensionalities of the LDA part and PMF part must match, the inference procedure of LDA-MF becomes very slow when K is large. To

make a better use of the available data, the computational efficiency must be sacrificed.

On the other hand, note that NT-MF achieves the highest AUC when $K = 50$. In fact, not only does NT-MF beat all baseline methods under different K values, it also outperforms the best LDA-MF model ($K = 200$) with fewer latent factors ($K = 20$). Unlike LDA-MF, the latent factors of the cold-start users are not fixed in NT-MF. Therefore, NT-MF can represent the information in a more concise way. In this case, NT-MF is better than LDA-MF in terms of both execution speed and predictive power.

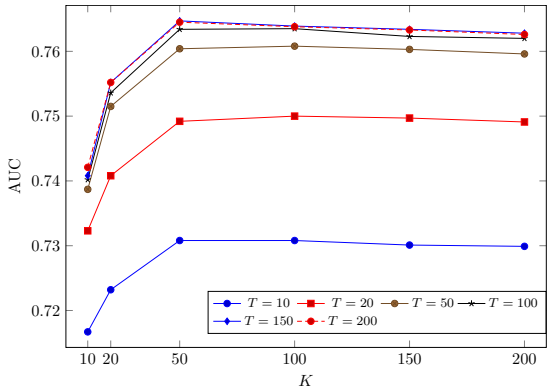

Figure 6: Performance of NT-MF based on out-of-matrix AUC for different values of K and T.

In Figure 6 we investigate the effect of different values of K and T. For each curve, we can see that the performance is about the same for $K \geq 50$. This is in accordance with the observation that NT-MF does not need as many latent factors as LDA-MF to achieve the same level of performance. Also, while increasing the number of topics T improves the performance in general, increasing T from 150 to 200 gives no significant improvement. The most important observation is that the highest AUC is achieved when $K = 50$ and $T = 150$. In other words, the optimal number of topics is different from that of user latent factors. This further justifies the advantage of NT-MF against previous methods.

5 Related Work

Although not directly aiming to solve the problem we have proposed, there exists some models of similar structure or adopt similar ideas.

As previously mentioned, LDA-MF is similar in structure to CTR. Collaborative topic Poisson factorization (CTPF) (Gopalan et al., 2014) combines the ideas of CTR and Poisson factorization (Gopalan et al., 2013) for a better performance. We have also tried CTPF on our dataset; nevertheless, there is no significant improvement over LDA-MF.

Recently, the neighborhood-aware probabilistic matrix factorization (NHPMF) model is proposed (Wu et al., 2012) as a method to combine kNN and PMF. It is originally proposed to leverage tagging data for improving PMF. This model can also be applied to our problem if we use the Twitter corpus in place of the unavailable tagging data. However, in the NHPMF model, the mean parameters are not treated as constants when the user latent factors are updated. As a result, an extra term appears in the gradient formula, which leads to an $O(k^2)$ time complexity, with k being the number of nearest-neighbors considered. On the other hand, the computation of the weighted average (i.e. Eq. 6) takes $O(k)$ time complexity. We have implemented NHPMF for comparison. As we increase k, NHPMF becomes significantly slower than NT-MF, while its performance is no better than NT-MF on our dataset.

6 Conclusion

In this work, we propose NT-MF, a cross-website transfer learning model which integrates content, neighborhood and rating information to alleviate the cold-start problem. A significant improvement over previous methods is demonstrated on a real-world cross-website dataset. The improvement is even more significant under the cold-start scenario.

So far we use the LDA topic vector to represent a user. As future work, different aspects of text can be taken into account to generate a more comprehensive user model. For example, writing styles or opinion mining may provide different insights on user behavior. Another possible extension is to apply our idea to more realistic settings such as large-scale and online recommender systems.

Abstract

Speculation and negation are important information to identify text factuality. In this paper, we propose a Convolutional Neural Network (CNN)-based model with probabilistic weighted average pooling to address speculation and negation scope detection. In particular, our CNN-based model extracts those meaningful features from various syntactic paths between the cues and the candidate tokens in both constituency and dependency parse trees. Evaluation on BioScope shows that our CNN-based model significantly outperforms the state-of-the-art systems on Abstracts, a sub-corpus in BioScope, and achieves comparable performances on Clinical Records, another sub-corpus in BioScope.

1 Introduction

Factual information is critical to understand a sentence or a document in most typical NLP applications. Speculation and negation extraction has been drawing more and more attentions in recent years due to its importance in distinguishing counterfactual or uncertain information from the facts. Generally speaking, speculation is a type of uncertain expression between certainty and negation, while negation is a grammatical category which reverses the truth value of a proposition.

Commonly, speculation and negation extraction involves two typical subtasks: cue identification and scope detection. Here, a cue is a word or phrase that has speculative or negative meaning (e.g., suspect, guess, deny, not), while a scope is a text fragment governed by the corresponding cue in a sentence. Consider the following two sentences for examples:

(S1) *The doctors warn that smoking [**may** harm our lungs]*.

(S2) *He does [**not** like playing football] but likes swimming*.[1]

In sentence S1, the speculative cue "***may***" governs the scope "***may** harm our lungs*", while the negative cue "***not***" governs the scope "***not** like playing football*" in sentence S2.

Previous work have achieved quite success on cue identification (e.g., with F1-score of 86.79 for speculative cue detection in Tang et al. (2010)). In comparison, speculation and negation scope detection is still a challenge due to its inherent difficulties and those upstream errors. In this paper, we focus on scope detection. Previous work on scope detection can be classified into heuristic rules based methods (e.g., Özgür et al., 2009; Øvrelid et al., 2010), machine learning based methods (e.g., Tang et al., 2010; Zou et al., 2013), and hybrid approaches which integrate empirical models with manual rules (Velldal et al., 2012).

Different from those previous studies, this paper presents a Convolutional Neural Network (CNN)-based approach for scope detection. CNN models, firstly invented to capture more abstract features for computer vision (LeCun et al., 1989), have achieved certain success on various NLP tasks in

[1] In this paper, cues are in ***bold face***, and scopes are in *[brackets]* in the example sentences.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 815–825,
Austin, Texas, November 1-5, 2016.

recent years, such as semantic role labeling (Collobert et al., 2011), machine translation (Meng et al., 2015; Hu et al., 2015), event extraction (Chen et al., 2015; Nguyen et al., 2015), etc. These studies have proved the ability of CNN models in learning meaningful features.

In particular, our CNN-based model extracts various kinds of meaningful features from the syntactic paths between the cue and the candidate token in both constituency and dependency parse trees. The importance of syntactic information in scope detection has been justified in previous work (Velldal et al., 2012; Lapponi et al., 2012; Zou et al., 2013, etc). Our model can also benefit from the ability of neural networks in extracting useful information from syntactic paths (Xu et al., 2015a; Xu et al., 2015b) or more complex syntactic trees (Ma et al., 2015; Tai et al., 2015). Moreover, instead of traditional average pooling, our CNN-based model utilizes probabilistic weighted average pooling to alleviate the overfitting problem (Zeiler et al., 2013). Experimental results on BioScope prove the effectiveness of our CNN-based model.

The reminder of this paper is organized as follows: Section 2 gives an overview of the related work. Section 3 describes our CNN-based model with probabilistic weighted average pooling for scope detection. Section 4 illustrates the experimental settings, and reports the experimental results and analysis. Finally, Section 5 draws the conclusion.

2 Related Work

In this section, we give an overview of previous work on both scope detection and utilization of CNNs in NLP applications.

2.1 Scope Detection

Earlier studies on speculation and negation scope detection focused on developing various heuristic rules manually to detect scopes.

Chapman et al. (2001) developed various regular expressions for negation scope detection. Subsequently, various kinds of heuristic rules began to emerge. Özgür et al. (2009) resorted to the part-of-speech of the speculative cues and the syntactic structures of the current sentences for identifying scopes, and developed heuristic rules according to the syntactic trees. Øvrelid et al. (2010) constructed a set of heuristic rules on dependency structures and obtained the accuracy of 66.73% on the CoNLL evaluation data. The approaches based on heuristic rules were effective because the sentence structures in BioScope satisfy some grammatical rules to a certain extent.

With the release of the BioScope corpus (Szarvas et al., 2008), machine learning based methods began to dominate the research of speculation and negation scope detection.

Morante et al. (2008) regarded negation scope detection as a chunk classification task utilizing lexical and syntactic features. Morante et al. (2009a) further implemented a scope detection system combining three classifiers, i.e., TiMBL, SVM and CRF, based on shallow syntactic features, and achieved the performance of 77.13% and 73.36% in Percentage of Correct Scopes (PCS) on speculation and negation scope detection on Abstracts, a sub-corpus of BioScope. Velldal et al. (2012) explored a hybrid method, adopting manually crafted rules over dependency parse trees and a discriminative ranking function over nodes in constituent parse trees. Zou et al. (2013) proposed a tree kernel based approach on the syntactic parse trees to detect speculation and negation scopes.

Alternative studies treated scope detection as a sequential labeling task. Tang et al. (2010) proposed a CRF model with POS, chunks, NERs, dependency relations as features. Similarly, Lapponi et al. (2012) employed a CRF model with lexical and dependency features for negation scope and event resolution on the Conan Doyle corpus. These machine learning methods manifest the effectiveness of syntactic features.

2.2 CNN based NLP Applications

Currently, CNNs have obtained certain success on various NLP tasks, e.g., part-of-speech tagging, chunking, named entity recognition (Collobert et al., 2011). Specifically, CNNs have been proven effective in extracting sentence-level features. For instance, Zeng et al. (2014) utilized a CNN-based model to extract sentence-level features for relation classification. Zhang et al. (2015) proposed a shallow CNN-based model for implicit discourse relation recognition. Chen et al. (2015) presented a CNN-based model with dynamic multi-pooling on event extraction.

More recently, researchers tend to learn features from complex syntactic trees. Ma et al. (2015) use

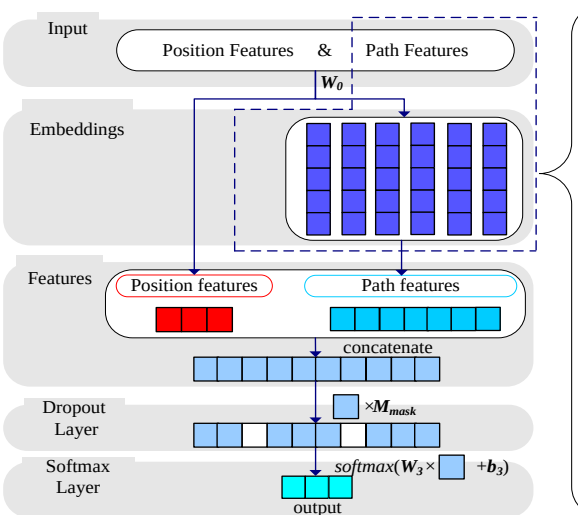

Figure 1: The framework of CNN for scope detection.

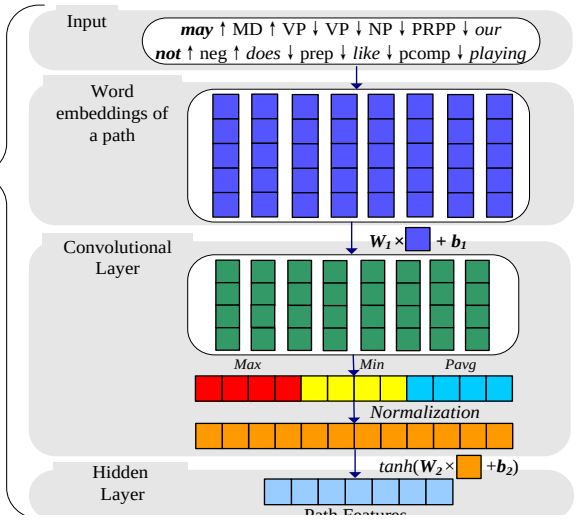

Figure 2: The architecture of CNN-based model to extract path features.

a CNN-based model for sentence embedding, utilizing dependency tree-based n-grams. Xu et al. (2015a) exploited a CNN-based model to learn features from the shortest dependency path between the subject and the object for semantic relation classification.

3 CNN-based Modeling with Probabilistic Weighted Average Pooling

This section describes our CNN-based model for speculation and negation scope detection, which is recast as a classification task to determine whether each token in a sentence belongs to the scope of the corresponding cue or not. Principally, our CNN-based model first extracts path features from syntactic trees with a convolutional layer and concatenates them with their relative positions into one feature vector, which is then fed into a softmax layer to compute the confidence scores of its location labels, described in subsection 3.1.

3.1 Token Labeling

We employ following labeling scheme for each candidate token:

- A token is labeled as ***O*** if it is NOT an element of a speculation or negation scope;
- A token is labeled as ***B*** if it is inside a scope and occurs before the cue, i.e., $P_{token} < P_{cue}$, where P_{token} and P_{cue} are the positions of the token and the cue in a sentence, respectively;
- A token is labeled as ***A*** if it is inside a scope and occurs after the cue (inclusive), i.e., $P_{token} \geqslant P_{cue}$.

Under this scheme, each token in a sentence is classified into ***B***, ***A*** or ***O***. For example, the labels of all the tokens in sentence S3 are shown in sentence S4.

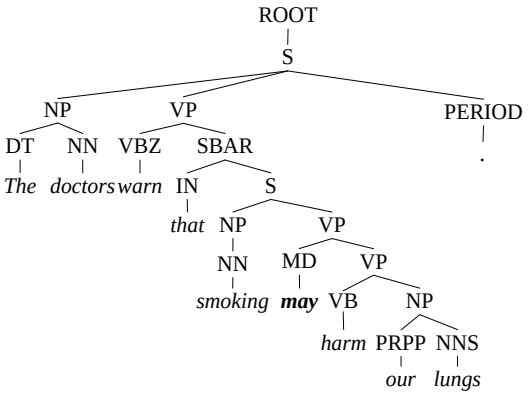
(S3) *They think that [those bacteria **may** be killed by white blood cells] , but other researchers do not think so.*

(S4) *They/O think/O that/O [those/B bacteria/B **may/A** be/A killed/A by/A white/A blood/A cells/A] ,/O but/O other/O researchers/O do/O not/O think/O so/O ./O*

The advantage of our scheme is that it can describe the location relationship among the tokens, cues and scopes more precisely than some previous studies, which regarded scope detection as a binary classification task (Øvrelid et al., 2010; Zou et al., 2013). Compared to other schemes with more than two labels (Morante et al., 2009a; Tang et al., 2010; Lapponi et al., 2012), our scheme can much alleviate the imbalance of labels, because the tokens occurring at the first or last positions of the scopes are much fewer than other tokens.

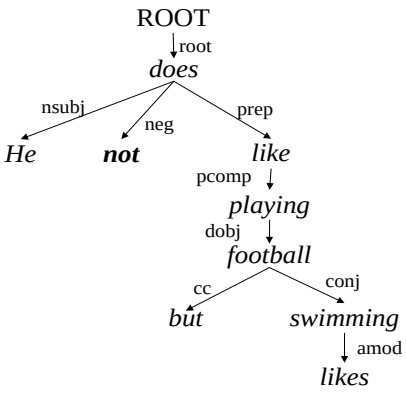
3.2 Input Representation

Figure 1 shows the framework of our model based on neural network. We concentrate on **Path Feature** and **Position Feature**. They are concatenated into one feature vector, which is finally fed into the softmax layer to obtain the output vector.



Cue: ***may***
Current candidate token: *our*
Constituency path:
may ↑ MD ↑ VP ↓ VP ↓ NP ↓ PRPP ↓ *our*

Figure 3: An example for the constituency parse tree of sentence S1 and the path from the cue to the candidate token.



Cue: ***not***
Current candidate token: *playing*
Dependency path:
not ↑ neg ↑ *does* ↓ prep ↓ *like* ↓ pcomp ↓ *playing*

Figure 4: An example for the dependency parse tree of sentence S2 and the path from the cue to the candidate token.

Relative Position has been proven useful in previous studies (Zeng et al., 2014; Chen et al., 2015). In this paper, relative position is defined as the relative distance of the cue to the candidate token. For instance, in sentence S1, the relative distances of the cue "***may"*** to the candidate tokens "*warn"* and "*our"* are 3 and -2, respectively. The values of position features are mapped into a vector $\boldsymbol{P}$ of dimension d_p, with $\boldsymbol{P}$ initialized randomly.

Instead of the word sequence (e.g., Zeng et al., 2014; Zhang et al. 2015; Chen et al., 2015), we argue that the **Shortest Syntactic Path** from the cue to the candidate token can offer effective features to determine whether a token belongs to the scope. It is remarkable that the lowest common ancestor node of the cue and the token is the highest tree node in the path.

Figure 2 illustrates the architecture of our CNN-based model to extract path features. Here, convolutional features are first extracted from the matrix of embeddings of the path, and then fed into the hidden layer to produce more complicated features.

In this paper, the syntactic paths between the cues and the candidate tokens in constituency and dependency parse trees are both considered. Figure 3 presents the constituency parse tree of sentence S1 and the constituency path from the cue "***may***" to the candidate token "*our*". It shows that the tokens are at both the beginning and the end of the path with the arrows indicating the directions. Meanwhile, Figure 4 displays the dependency parse tree of sentence S2 and the dependency path from the cue "***not***" to the token "*playing*".

As the input of our CNN-based model, both the constituency path and the dependency path between the cue and the token can be regarded as the special "sentences" $S=(t_1, t_2, \ldots, t_n)$, whose "words" can be tokens of sentences, syntactic categories, dependency relations, and arrows.

Similar to other CNN-based models, we also consider a fixed size window of tokens around the current token to capture its local features in the path. Here, the window size is set as an odd number w, indicating that there are (w-1)/2 tokens before and after the candidate token, respectively. In this case, path S is transferred into matrix $\boldsymbol{X}_0 \in \mathbf{R}^{w d_0 \times n}$ according to embedding table $\boldsymbol{W}_0 \in \mathbf{R}^{d_0 \times |T_0|}$, where d_0 is the dimension of the embeddings and $|T_0|$ is the size of the table.

3.3 Convolutional Neural Networking

After fed into the convolutional layer, the matrix of the syntactic path $\boldsymbol{X_0}$ is processed with a linear operation:

$$\boldsymbol{Y}_1 = \boldsymbol{W}_1 \boldsymbol{X}_0 + \boldsymbol{b}_1 \quad (1)$$

where $\boldsymbol{W}_1 \in \mathbf{R}^{n_1 \times w d_0}$ is the parameter matrix, and $\boldsymbol{b}_1 \in \mathbf{R}^{n_1}$ is the bias term. To extract the most active convolutional features from $\boldsymbol{Y}_1 \in \mathbf{R}^{n_1 \times n}$, we consider two features ***Cmax*** and ***Cmin*** whose elements are maximum, minimum values of rows in $\boldsymbol{Y_1}$, respectively:

$$\boldsymbol{Cmax}(r) = max[\boldsymbol{Y_1}(r,0), \boldsymbol{Y_1}(r,1), ..., \boldsymbol{Y_1}(r,n-1)] \quad (2)$$

$$\boldsymbol{Cmin}(r) = min[\boldsymbol{Y_1}(r,0), \boldsymbol{Y_1}(r,1), ..., \boldsymbol{Y_1}(r,n-1)] \quad (3)$$

where $0 \le r \le n_1 - 1$. Moreover, we extract a convolutional feature ***Cpavg***, whose elements are probabilistic weighted average values of rows in $\boldsymbol{Y_1}$. Formally, ***Cpavg*** can be written as:

$$\boldsymbol{Cpavg}(r) = \sum_{i=0}^{n-1} p_i \cdot \boldsymbol{Y_1}(r,i) \quad (4)$$

In Equation (4), p_i is the probability of the element $\boldsymbol{Y_1}(r,i)$ in the vector $\boldsymbol{Y_1}(r,\cdot)$:

$$p_i = \frac{\left|\boldsymbol{Y_1}(r,i)\right|}{\sum_{j=0}^{n-1} \left|\boldsymbol{Y_1}(r,j)\right|} \quad (5)$$

Cpavg is a variant probabilistic weighted average pooling used by Zeiler et al. (2013). Compared to the standard average pooling, each element in ***Cpavg*** has a weight depending on its value. That is, during computing ***Cpavg***, the most active elements with the largest absolute values (i.e., the maximum and minimum values) play the leading roles, while those less active elements with smaller absolute values have less effect. In this way, we can reduce the influence of less active elements, and can capture more active information in $\boldsymbol{Y_1}(r,\cdot)$. From this respect, ***Cpavg*** can be regarded as a meaningful convolutional feature.

The extracted convolutional features above are first concatenated into $\boldsymbol{C} \in \mathbf{R}^{3n_1}$, as the output of the convolutional layer:

$$\boldsymbol{C} = [\boldsymbol{Cmax}, \boldsymbol{Cmin}, \boldsymbol{Cpavg}] \quad (6)$$

Then, ***C*** is fed into the hidden layer to learn more complex and meaningful features. Here, we process ***C*** with a linear operation just like in the convolutional layer, and choose hyperbolic *tanh* as the activation function to get $\boldsymbol{Y_2} \in \mathbf{R}^{n_2}$:

$$\boldsymbol{Y_2} = tanh(\boldsymbol{W_2 C} + \boldsymbol{b_2}) \quad (7)$$

where $\boldsymbol{W_2} \in \mathbf{R}^{n_2 \times 3n_1}$ is the parameter matrix, and $\boldsymbol{b_2} \in \mathbf{R}^{n_2}$ is the bias term. To produce the output of the hidden layer, a normalization operation is applied to eliminate the manifold differences among various features:

$$\boldsymbol{H} = \boldsymbol{Y_2} / \left\|\boldsymbol{Y_2}\right\| \quad (8)$$

In this way we obtain the path feature $\boldsymbol{H} \in \mathbf{R}^{n_2}$ for each candidate token and then concatenate it with the position feature ***P*** into one vector $\boldsymbol{F_0}$:

$$\boldsymbol{F_0} = [\boldsymbol{P}^T, \boldsymbol{H}^T]^T \quad (9)$$

where $\boldsymbol{F_0} \in \mathbf{R}^{n_f}$ is the feature vector of a candidate token with the dimension equaling the sum of n_2 and the dimension of ***P***. Besides, we also consider the dropout operation for regularization to prevent the co-adaptation of hidden units on the penultimate layer:

$$\boldsymbol{F_1} = \boldsymbol{F_0} \circ \boldsymbol{M} \quad (10)$$

where $\circ$ is an element-wise multiplication and ***M*** is a mask vector whose elements follow the Bernoulli distribution with the probability p of being 1. We determine whether the candidate token is in the scope of the current cue according to its $\boldsymbol{F_1}$.

3.4 Output

Finally, $\boldsymbol{F_1}$ is fed into the softmax layer:

$$\boldsymbol{O} = softmax(\boldsymbol{W_3 F_1} + \boldsymbol{b_3}) \quad (11)$$

where $\boldsymbol{W_3} \in \mathbf{R}^{n_3 \times n_f}$ is the parameter matrix, and $\boldsymbol{b_3} \in \mathbf{R}^{n_3}$ is the bias term. The dimension of ***O*** is n_3=3, which is equal to the number of labels representing whether the token is an element of the scope, just as described in subsection 3.1, and the elements of ***O*** can be interpreted as the confidence scores of the three labels, i.e., ***B***, ***A*** and ***O***.

To learn the parameters of the network, we supervise the predicted labels of ***O*** with the gold labels in the training set, and utilize the following training objection function:

$$J(\theta) = -\frac{1}{m}\sum_{i=1}^{m} \log\, p(y_i \mid x_i, \theta) + \frac{\lambda}{2}\left\|\theta\right\|^2 \quad (12)$$

where $p(y_i \mid x_i, \theta)$ is the confidence score of the golden label y_i (***B***, ***A***, ***O***) of the training instance x_i, m is the number of the training instances, λ is the regularization coefficient and θ={$\boldsymbol{W_0}$, $\boldsymbol{W_1}$, $\boldsymbol{b_1}$, $\boldsymbol{W_2}$, $\boldsymbol{b_2}$, $\boldsymbol{W_3}$, $\boldsymbol{b_3}$} is the set of parameters. To train the CNN-based model, the Stochastic Gradient Descent algorithm is applied to fine-tune θ.

4 Experimentation

In this section, we first introduce the evaluation data, and then describe the experimental settings. Finally, we report the experimental results and analysis.

4.1 Corpus

We evaluate our CNN-based model on BioScope (Szarvas et al., 2008; Vincze et al., 2008), a widely used and freely available resource consisting of sentences annotated with speculative and negative cues and their scopes in biomedical domain.

		Abs	Papers	Cli

	Ave. Len Sentences	29.28	30.55	8.53
	Ave. Len Scopes	7.60	7.35	3.87

(Notes: "Ave. Len" denotes average length; "Abs", "Papers" and "Cli" denote Abstracts, Full Papers and Clinical Records, respectively; "Spe" and "Neg" denote speculation and negation, respectively.)

Table 1: Statistics on the BioScope corpus.

BioScope includes 3 different sub-corpora: Abstracts of biological papers from the GENIA corpus (Collier et al., 1999), Full scientific Papers from Flybase and BMC Bioinformatics website, and Clinical radiology Records corpus. These texts in three sub-corpora ensure that BioScope can capture the heterogeneity of language use in biomedical domain. While Abstracts and Full Papers share the same genre, Clinical Records consists of shorter sentences. Previous studies regarded Abstracts as the main resource for text mining applications due to its public accessibility (e.g. through PubMed).

Table 1 shows the statistics of the BioScope corpus. While in both Abstracts and Full Papers, the average lengths of speculation and negation sentences are comparable (Abstracts: 29.77 vs 29.28; Full Papers: 30.76 vs 30.55). However, their average lengths of the negation scopes are shorter than those of speculation ones (Abstracts: 7.60 vs 15.10; Full Papers: 7.35 vs 13.38). Moreover, both the average lengths of sentences and scopes in Clinical Records are shorter than those of other two sub-corpora (Average length: 11.96 (speculation sentence), 8.53 (negation sentence), 4.92 (speculation scope) and 3.87 (negation scope)).

4.2 Experimental Settings

Following the previous work (e.g., Özgür et al., 2009; Morante et al., 2009a, 2009b; Zou et al., 2013), we divide the Abstracts sub-corpus into 10 folds to perform 10-fold cross-validation. Moreover, to examine the robustness of our CNN-based model towards different text types within biomedical domain, all the models are trained on the same Abstracts sub-corpus. Therefore, the results on Abstracts can be regarded as in-domain evaluation while the results on Clinical Records and Full Papers can be regarded as cross-domain evaluation.

For the measurement, traditional Precision, Recall, and F1-score are used to report the token-based performance in scope detection, while the Percentage of Correct Scopes (PCS) is adopted to report the scope-based performance, which considers a scope correct if all the tokens in the sentence have been assigned the correct scope classes for a specific cue. Obviously, PCS can better describe the overall performance in scope detection. Besides, Percentage of Correct Left Boundaries (PCLB) and Percentage of Correct Right Boundaries (PCRB) are reported as partial measurements.

In all our experiments, both the constituency and dependency parse trees are produced by Stanford Parser[2]. Specially, we train the parser on the GENIA Treebank 1.0[3] (Tateisi et al., 2005), which contains Penn Treebank-style syntactic (phrase structure) annotation for the GENIA corpus. The parser achieves the performance of 87.12% in F1-score in terms of 10-fold cross-validation on GENIA TreeBank 1.0.

For the hyper-parameters in our CNN-based model, we set d_0=100, d_p=10, w=3, n_1=200, n_2=500, λ=10^{-4}, p=0.8. The embeddings of the tokens in ordinary sentences (as word sequences) are initialized by Word2Vec[4] (Mikolov et al., 2013).

For the baseline, we utilize the classifier-based baseline developed by Zou et al. (2013). Besides those typical features, constituency and dependen-

Table 2: The performances on the Abstracts sub-corpus.

cy syntactic features are also included. Furthermore, Mallet[5] is selected as the classifier.

In addition, since our CNN-based model may result in discontinuous blocks, we utilize a post-processing algorithm (Morante et al., 2008) to ensure the continuity of scopes. Meanwhile, the cue must be in its scope as defined in Bioscope.

4.3 Experimental Results on Abstracts

Table 2 summarizes the performances of scope detection on Abstracts. In Table 2, CNN_C and CNN_D refer the CNN-based model with constituency paths and dependency paths, respectively (the same below). It shows that our CNN-based models (both CNN_C and CNN_D) can achieve better performances than the baseline in most measurements. This indicates that our CNN-based models can better extract and model effective features. Besides, compared to the baseline, our CNN-based models consider fewer features and need less human intervention. It also manifests that our CNN-based models improve significantly more on negation scope detection than on speculation scope detection. Much of this is due to the better ability of our CNN-based models in identifying the right boundaries of scopes than the left ones on negation scope detection, with the huge gains of 29.44% and 25.25% on PCRB using CNN_C and CNN_D, respectively.

Table 2 illustrates that the performance of speculation scope detection is higher than that of negation (Best PCS: 85.75% vs 77.14%). It is mainly attributed to the shorter scopes of negation cues. Under the circumstances that the average length of negation sentences is almost as long as that of speculation ones (29.28 vs 29.77), shorter negation scopes mean that more tokens do not belong to the scopes, indicating more negative instances. The imbalance between positive and negative instances has negative effects on both the baseline and the CNN-based models for negation scope detection.

Table 2 also shows that our CNN_D outperforms CNN_C in negation scope detection (PCS: 77.14% vs 70.86%), while our CNN_C performs better than CNN_D in speculation scope detection (PCS: 85.75% vs 74.43%). To explore the results of our CNN-based models in details, we present the analysis of top 10 speculative and negative cues below on CNN_C and CNN_D, respectively.

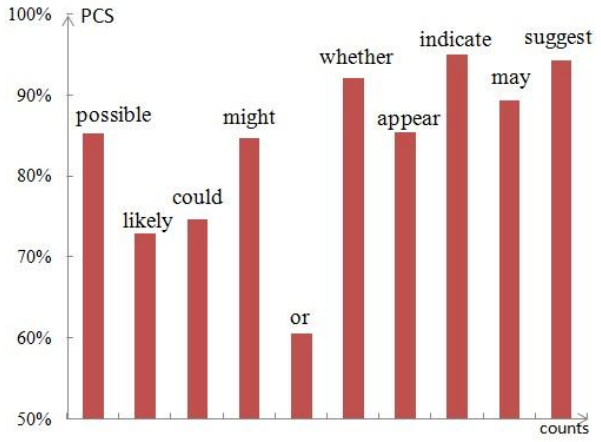

Figure 5: PCSs of top 10 speculative cues for scope detection in Abstracts sub-corpus.

Figure 5 illustrates the PCSs of the most frequent 10 speculative cues using CNN_C. The cues in the horizontal axis are in the order of lowest to highest in frequency. Among those cues, "*suggest"*, *"may"*, *"indicate"*, and "*appear"* are commonly used to express opinions of certain individuals. The scopes of these cues are integrated semantic fragments (probably clauses) governed by corresponding cues in grammatical sense, and the tokens in the scope tend to share the same chunk with the cue in the constituency parse tree. Hence, constituency paths are more useful for speculation scope detection. Figure 5 also shows that the PCSs of all the top 10 speculative cues are higher than 70% except "*or"* (PCS: 60.44%), mainly due to the flexible usage of "*or"*, which

[5] http://mallet.cs.umass.edu/

	Systems		P(%)	R(%)	F1	PCLB(%)	PCRB(%)	PCS(%)
Speculation	Clinical Records	CNN_C	86.85	**93.84**	**90.21**	**84.35**	**86.87**	**73.92**
		CNN_D	**89.02**	85.41	87.18	82.91	76.17	64.39
	Full Papers	CNN_C	**86.78**	**86.59**	**86.69**	**86.01**	**68.60**	**59.82**
		CNN_D	86.13	85.09	85.61	80.95	64.14	52.98

	Full Papers	CNN_C	80.92	82.26	81.58	82.71	**67.29**	**55.32**
		CNN_D	**82.08**	**84.90**	**83.46**	**84.04**	64.89	53.99

Table 3: The performances of our CNN-based models on Clinical Records and Full Papers.

can connect two words, two professional terms, or even two clauses.

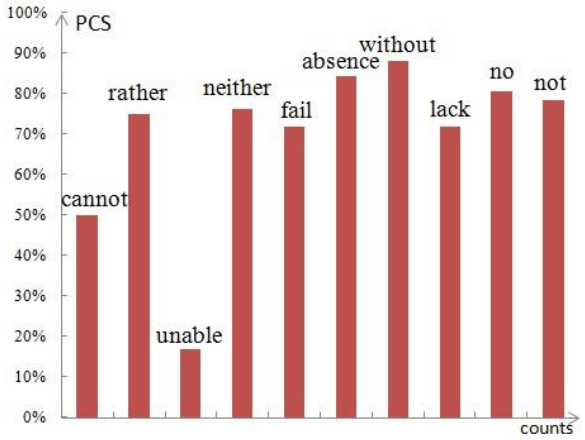

Figure 6: PCSs of top 10 negative cues for scope detection in Abstracts sub-corpus.

Figure 6 illustrates the performances of the most frequent 10 negative cues using CNN_D. In those negative cues, "*not"* is in the absolute majority, and "*not"* and "*no"* cover over 70%. We have noticed that most negative cues (e.g., "*not", "no", "without", "fail"*) are often applied to negate phrases, and the tokens in negation scope tend to have the tight dependency relationship with them. Therefore, our model can achieve better results using dependency paths for negation scope.

In Figure 6, most negative cues have good PCSs (higher than 70%). However, "*unable"* has poor PCS of 16.67%. This is due to the fact that "*unable"* usually occurs in the phrase structure "*be unable to"*, which often follows a subject. It is notable that a cue is always in its scope and most cues in BioScope are much closer to the left boundaries than to the right ones. Hence, the tokens labeled as ***B*** (i.e., inside the scope and before the cue) are much fewer than the ones labeled as ***A*** or ***O***. Such imbalance makes it hard to judge whether the tokens before "*unable"* are in of its scope or not.

4.4 Experimental Results on Clinical Records and Full Papers

The performances of our CNN-based models on the other two sub-corpora, i.e., Clinical Records and Full Papers, are presented in Table 3. Although Abstracts and Clinical Records have different genres, our CNN-based models can obtain satisfactory results on Clinical Records using both constituency paths and dependency paths, proving the portability of our models.

Table 3 also shows that the results of negation scope are better than those of speculation scope on Clinical Records (PCS: 89.66% vs 73.92%). We argue the reason is that both the lengths of negation sentences and scopes (8.53 and 3.87, respectively) in Clinical Records are much shorter, indicating that the structures of negation sentences are simpler than those of speculation ones. After error analysis of speculation scopes, we find that 54.83% of our error scopes contain the annotated scopes, just like sentence S5:

(S5) *This does not [**appear** to represent a stone] and is not mobile.*

The annotated scope of the cue "***appear***" is "***appear*** *to represent a stone*". However, our CNN-based model identifies the whole sentence as the scope. These errors indicate that some words may be wrongly identified as the components of scopes because the scopes in Clinical Records are short and their structures are simple.

Compared with Abstracts and Clinical Records, the results on Full Papers are much lower. This is mainly due to the poor PCRBs, indicating a considerable quantity of right boundaries of scopes cannot be identified correctly. We should note that the average lengths of both speculation and negation sentences (30.76 and 30.55, respectively) in Full Papers are longer than those in Abstracts and

Clinical Records. Normally, longer sentences mean more complicated syntactic structures.

Besides the results trained on Abstracts, we also consider the 10-fold cross-validation on Clinical Records and Full Papers. The PCSs of speculation and negation scope detection are 74.73% (CNN_C) and 91.03% (CNN_C) on Clinical Records, which are both higher than the ones trained on Abstracts. Remember that Abstracts and Clinical Records come from the different genres. However, we get lower PCSs on Full Papers (49.54% for speculation scope detection using CNN_C, and 44.67% for negation scope detection using CNN_C). In addition to the complex structures of long sentences, another reason is that the smaller size of the Full Papers sub-corpus compared to the other two sub-corpora. Fewer sentences and scopes (only 672 speculation scopes in 519 sentences and 376 negation scopes in 339 sentences) mean that we cannot get an excellent model.

4.5 Comparison with the State-of-the-Art

Table 4 compares our CNN-based models with the state-of-the-art systems. It shows that our CNN-based models can achieve higher PCSs (+1.54%) than those of the state-of-the-art systems for speculation scope detection and the second highest PCS for negation scope detection on Abstracts, and can get comparable PCSs on Clinical Records (73.92% vs 78.69% for speculation scopes, 89.66% vs 90.74% for negation scopes). It is worth noting that Abstracts and Clinical Records come from different genres.

It also displays that our CNN-based models perform worse than the state-of-the-art on Full Papers due to the complex syntactic structures of the sentences and the cross-domain nature of our evaluation. Although our evaluation on Clinical Records is cross-domain, the sentences in Clinical Records are much simpler and the results on Clinical Records are satisfactory. Remind that our CNN-based models are all trained on Abstracts. Another reason is that those state-of-the-art systems on Full Papers (e.g., Li et al., 2010; Velldal et al., 2012) are tree-based, instead of token-based. Li et al. (2010) proposed a semantic parsing framework and focused on determining whether a constituent, rather than a word, is in the scope of a negative cue. Velldal et al. (2012) presented a hybrid framework, combining a rule-based approach using dependency structures and a data-driven approach for selecting appropriate subtrees in constituent structures. Normally, tree-based models can better capture long-distance syntactic dependency than token-based ones. Compared to those tree-based models, however, our CNN-based model needs less manual intervention. To improve the performances of scope detection task, we will explore this alternative in our future work.

Table 4: Comparison of our CNN-based model with the state-of-the-art in PCS.

5 Conclusion

This paper proposes a CNN-based model for speculation and negation scope detection. Compared with various lexical and syntactic features adopted in previous studies (e.g., Lapponi et al., 2012; Zou et al., 2013), our CNN-based model only considers the position feature and syntactic path feature.

Experimental results on the BioScope corpus show that our CNN-based model can get the best performances for speculation scopes and the second highest performances for negation scopes on Abstracts in in-domain evaluation. In cross-domain evaluations, we can achieve comparable results on Clinical Records, but our CNN-based model performs worse on Full Papers. This suggests our future direction to extend the model from token level to parse tree level in better capturing long-distance syntactic dependency and to address the cross-domain adaptation issue.

Abstract

Sentence modelling is a fundamental topic in computational linguistics. Recently, deep learning-based sequential models of sentence, such as recurrent neural network, have proved to be effective in dealing with the non-sequential properties of human language. However, little is known about how a recurrent neural network captures linguistic knowledge. Here we propose to correlate the neuron activation pattern of a LSTM language model with rich language features at sequential, lexical and compositional level. Qualitative visualization as well as quantitative analysis under multilingual perspective reveals the effectiveness of gate neurons and indicates that LSTM learns to allow different neurons selectively respond to linguistic knowledge at different levels. Cross-language evidence shows that the model captures different aspects of linguistic properties for different languages due to the variance of syntactic complexity. Additionally, we analyze the influence of modelling strategy on linguistic knowledge encoded implicitly in different sequential models.

1 Introduction

Sentence modelling is a central and fundamental topic in the study of language generation and comprehension. With the application of popular deep learning methods, researchers have found that recurrent neural network can successfully model the non-sequential linguistic properties with sequential data input (Vinyals et al., 2015; Zhou and Xu, 2015; Rocktäschel et al., 2015). However, due to the complexity of the neural networks and the lack of effective analytic methodology, little is known about how a sequential model of sentence, such as recurrent neural network, captures linguistic knowledge. This makes it hard to understand the underlying mechanism as well as the model's strength and weakness. Previous work (Li et al., 2016) has attempted to visualize neural models in NLP, but only focus on analyzing the hidden layer and sentiment representation rather than grammar knowledge.

Currently, there have been a few attempts (Yogatama et al., 2014; Köhn, 2015; Faruqui and Dyer, 2015) at understanding what is embedded in the word vectors or building linguistically interpretable embeddings. Few works focus on investigating the linguistic knowledge encoded in a sequential neural network model of a sentence, not to mention the comparison of model behaviours from a cross-language perspective. Our work, therefore, aims to shedding new insights into the following topics:

a) How well does a sequential neural model (e.g. language model) encodes linguistic knowledge of different levels?
b) How does modelling strategy (e.g. the optimization objective) influence the neuron's ability of capturing linguistic knowledge?
c) Does the sequential model behave similarly towards typologically diverse languages?

To tackle the questions above, we propose to visualize and analyze the neuron activation pattern

so as to understand how a sequential neural model of sentence encodes linguistic properties of different level. By training vanilla LSTM language models with multilingual data and correlating the model neuron's activation with various linguistic features, we not only qualitatively show the activation pattern of a certain model neuron, but also quantify the selectivity of the neuron towards input language data or certain linguistic properties.

2 Methodology

2.1 A 'Brain' Metaphor of Artificial Model

Mitchell et al. (2008) correlates brain activities with linguistic stimuli under a popular brain-mapping paradigm. Since brain is a 'black box', researchers want to decode what is represented in a certain neuronal cluster of the brain at a certain time step. Here we propose that this paradigm can be applied to similar 'black-box' model, such as the neural network. This is what we call a 'brain' metaphor of the artificial model, as is visualized in Figure 1. We treat the neural network as a simplified 'brain'. We correlate the neuron behaviours with the input stimuli and design experiments to map the neuron activation to an explicit linguistic feature.

A sentence is, of course, a linear sequential arrangement of a cluster of words, but more than just a simple addition of words, as there exist complicated non-sequential syntactic relations. Thus, we consider three levels of features in the analysis of model behaviours, a) Sequential feature, a kind of superficial feature shared by any sequence data, b) Lexical feature, which is stable and almost independent of the sentence context, and c) Compositional feature, which is required for building the meaning of a sentence. Table 1 lists the details of the features involved in this paper.

2.2 Model Description

Since the goal is to understand the internal neurons' behaviour and how the behaviour patterns can be interpreted as a way to encode dynamic linguistic knowledge, we choose the most fundamental sequential sentence models as the research objects. We do not consider tree-structured model, as it explicitly involves linguistic structure in model architecture. We focus on word-based language model and compare it to two other counterparts in this paper.

Word-based Language Model Word-based language model (Mikolov et al., 2010) predicts the incoming word given the history context.

Character-based Language Model Instead of predicting the next word, character-based language model (Hermans and Schrauwen, 2013) predicts the incoming character given the history character sequence.

Task-specific Model A common task-specific model takes word sequence as input, but only predicts the category (e.g. sentiment) of the sentence after all the words are processed. In this paper, we consider a sequential model utilized for sentiment analysis task.

All the three sequential models are built on recurrent neural network with LSTM unit (Hochreiter and Schmidhuber, 1997). LSTM unit has a memory cell c and three gates: input gate i, output gate o and forget gate f, in addition to the hidden layer h of a vanilla RNN. The states of LSTM are updated as follows:

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i), \quad (1)$$

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f), \quad (2)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c), \quad (3)$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_{t-1} + b_o), \quad (4)$$

$$h_t = o_t \odot \tanh(c_t), \quad (5)$$

where x_t is the input vector at the current time step, σ denotes the logistic sigmoid function and $\odot$ denotes elementwise multiplication.

The dimension of the embeddings and the LSTM unit is 64. All three models use pretrained word embedding from Polyglot multilingual embeddings (Al-Rfou et al., 2013) trained with C&W (Collobert et al., 2011) model on Wikipedia. We train a lot of word-based and character-based LSTM language models with multilingual data from the Universal Treebank 1.2 (Joakim Nivre and Zhu, 2015), as well as a task-specific sentiment model on Stanford Sentiment Treebank (Socher et al., 2013b). We separate the training and testing data according to 90%/10% principle. We stop training when the loss of the test data does not decrease.

Regarding the analysis of the model behaviours, we collect the internal neuron activation of the hidden layer, three gates, and memory cell for all the data in the treebank/sentiment corpus[1]. For the sake of notation, we refer the hidden layer, input gate, output gate, forget gate and memory cell as h, i, f, o, c for three models, word-based language model (WL), character-based language model (CL) and task-specific model for sentiment analysis (SA). We mark the index of the neuron in the superscript and the meta information about the model in the subscript.

3 Qualitative Analysis

3.1 Sequential Feature

Karpathy et al. (2015) finds that some memory neurons of the character language model are selective towards the length of the input sequence. Similar patterns are also observed among the memory neuron activation pattern of the word-level language model as is shown in Figure 2, where deep purple color indicate strong negative activation and deep green color indicate strong positive activation. Moreover, we compute the correlation between the input sequence length and the activation pattern of every single neuron of h, i, f, o, c. Quantitative results in Figure 3 reveal that none of the hidden layer or gate neurons are strongly correlated with this sequential feature.

[1]The analyses cover languages such as English (en), German (de), Latin (la), Ancient Greek (grc), Bulgarian (bg), Spanish (es), Portuguese (pt), Italian (it), French (fr), Dutch (nl), Norwegian (no), Hindi (hi), Slovenian (sl), Hungarian (hu), Indonesian (id) and Chinese (zh).

(a) $h^{30}_{en,WL}$ + raw sent (b) $h^{30}_{en,WL}$ + shuffled sent

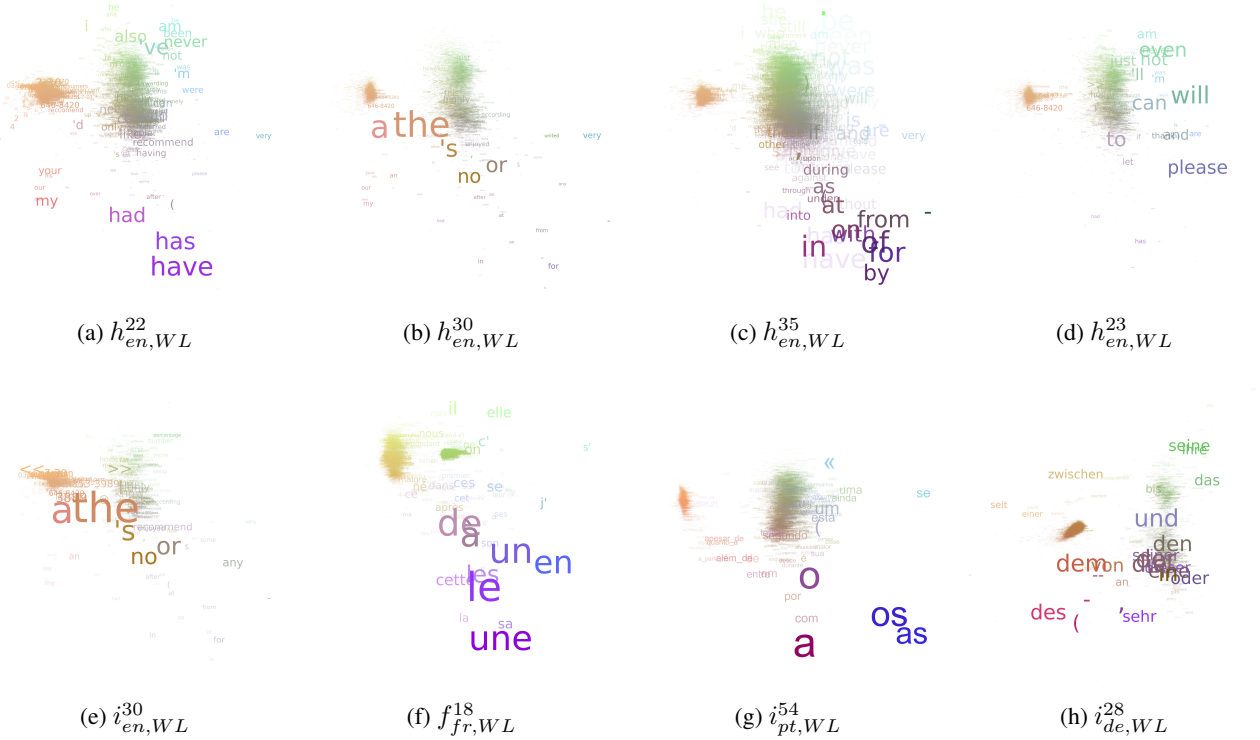
Figure 4: Visualising the activation of a neuron towards raw English sentences and sentences with shuffled word order.

3.2 Lexical Feature

For a inner neuron of the model, we can get the activation of a certain neuron in a certain model component towards a certain input word. A model neuron may be most active towards the words of some category instead of other words.

We notice that some neurons (e.g. Neuron $h^{30}_{en,WL}$) strongly activate towards functional words such as the determiners 'a', as is visualized in Figure 4. This activation can be observed even when we feed the model with a abnormal English sentence with shuffled word order.

Since it is not easy to go through all the neuron activation pattern, we design a visualization method to vividly show how a neuron selectively respond to



(a) $h^{22}_{en,WL}$ (b) $h^{30}_{en,WL}$ (c) $h^{35}_{en,WL}$ (d) $h^{23}_{en,WL}$

(e) $i^{30}_{en,WL}$ (f) $f^{18}_{fr,WL}$ (g) $i^{54}_{pt,WL}$ (h) $i^{28}_{de,WL}$

Figure 5: Visualising the lexical space responded by a certain neuron of the word-level language model trained on different languages.

certain words, inspired by the work in Cukur et al. (2013) and Huth et al. (2016).

Suppose the vocabulary of a language spans a default lexical space. An internal neuron of the artificial model modulates this linguistic space via showing selective activation pattern towards certain words. we carry out PCA on all the word embedding in the language model and extract the most prominent 3 principal components as the bases. Then we project the word vectors onto these three basis to get a new representation of the words in a low dimensional space. We draw all the words on a plane, where the location of each word is determined by the first two components and the text color is determined by three main components as RGB value. To visualize how a target neuron x respond to this lexical space, we modify the appearance of the word by scaling the size of the word text against the product of the log-transformed word frequency and the absolute value of the mean activation, and setting the degree of transparency of the text against the relative positive/negative activation strength among all the existed activation value of a target neuron x. In this way, large font size and low degree of transparency of a word w indicate that the target neuron x frequently activates towards the word w. This means that we can interpret a neuron's selectivity towards the lexical space just by looking for large and explicit words on the visualized two-dimensional space.

Figure 5 visualizes the lexical space responded by four hidden layer neuron of the English language model, as well as four gate neurons of different languages respectively. We can see that words with the similar grammatical functions are located near each other. Besides, it is interesting to see that some hidden layer neurons activate selectively towards determiner words, pronoun, preposition or auxiliary verbs. This phenomena have also been observed on gate neurons. For example, forget gate neuron $f^{18}_{fr,WL}$ activates towards the determiners in French. Input gate neuron $i^{54}_{pt,WL}$ activates towards the determiners in Portuguese. Notice that not all of the inner neurons show interpretable activation pattern towards the lexical space.

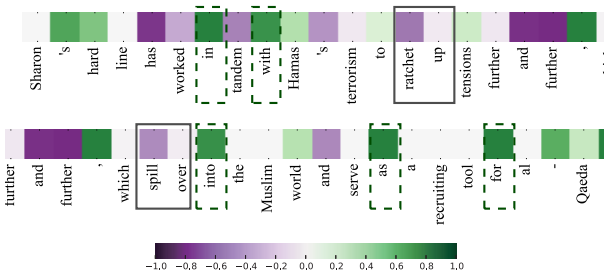


Figure 6: Visualising the Neuron $h^{35}_{en,WL}$ neuron activation towards verb-preposition composition.

3.3 Compositional Feature

To validate whether the internal neuron of the model can discriminate the local composition and long-distance composition, we choose the preposition as the object for observation.

In English, preposition can be combined with the previous verb to form a compound verbal phrase, such as 'check it *in*','give him *up*', 'find *out* what it will take'. This function of the preposition is annotated as the compound particle in the Universal Dependency Treebank. Another function of the preposition is to serve as the case marker, such as the preposition in the phrase 'lives *in* the central area', 'Performances will be performed *on* a project basis'. Given that these two functions of the preposition are not explicitly discriminated in the word form, the language model should tell the difference between the prepositions served as the compound particle and the prepositions served as the case marker if it indeed has the ability to handle word meaning composition.

For the hidden layer, we notice that hidden layer neuron $h^{35}_{en,WL}$ is sensitive to the function of the preposition. It only activates when the possible preposition does not form a composition with the former verb, as is vividly shown in Figure 6. The prepositions marked by dashed box serve as case marker while those in solid box form a phrase with previous verb. The activation pattern are obviously different. Similar pattern is also found in the gate neurons.

4 Quantitative Analysis

4.1 Decoding Lexical/Compositional Feature

Visualization only provides us with an intuitive idea of what a single neuron is encoding when processing language data. In this section, we employ a mapping paradigm to quantitatively reveal the linguistic knowledge distributed in the model components.

Instead of looking at one single neuron, here we use the whole 64 neurons of each model component as a 64-dimensional vector h, i, f, o, c respectively. The basic method is to decode interpretable linguistic features from target neuron clusters, which has been used in (Köhn, 2015; Qian et al., 2016). We hypothesize that there exists a map between a neuron cluster activation vector x and a high-level sparse linguistic feature vector y if the neuron cluster's activation pattern implicitly encode sufficient information about a certain lexical or compositional feature.

Hence we design a series of experiments to map the hidden layer, three gates, and memory cell vector activated by a target input word w in a sentence to the corresponding linguistic features of the word w, which are annotated in the Universal Dependency Treebank. Our experiments cover POS TAG, SYNTACTIC ROLE, GENDER, CASE, DEFINITENESS, VERB FORM and MOOD. These linguistic features are all represented as a one-hot vector. The mapping model is a simple softmax layer, with the activation vector as the input and the sparse vector as the output. For each linguistic feature of each language, a mapping model is trained on the randomly-selected 90% of all the word tokens and evaluated over the remaining 10%. Notice that GENDER, CASE, DEFINITENESS, VERB FORM, and MOOD only apply to certain word categories. We give a default 'N/A' tag to the words without these annotations so that all the word can be used for training. The evaluation result is only computed from the words with the features. This requires the mapping model to not only recognize the differences between the sub-categories of a linguistic feature (e.g. CASE), but also discriminate the words that we are interested in from other unrelated words (e.g. words without CASE annotations). Accuracies for each model component h, i, f, o, c are reported in Figure 7 and 8.

Comparing different model components, we notice that gate neurons except output gate are generally better than hidden layer and memory cell neurons on decoding linguistic knowledge. Input gate and

forget gate are the best, while memory cell is the worst. It shows that the gates of a recurrent language model are more sensitive to the grammar knowledge of the input words.

Comparing decoding results on different languages, we find that it is generally easier to decode POS TAG than SYNTACTIC ROLE for all the languages. One interesting thing is that the mapping model works better with Bulgarian, a slavic language, but worse on Norwegian on decoding CASE while the situation is opposite on decoding GENDER. It might be because that gender is a weakened grammatical feature in Bulgarian. Therefore, knowledge about GENDER may not be so important in building the grammatical structure of the Bulgarian language data.

4.2 The Dynamics of Neuron Behaviour

Since sentence meaning is dynamically constructed by processing the input sequence in a word-by-word way, it is reasonable to hypothesize that the linguistic feature of an input word w won't sharply decay in the process. Naturally, we would like to ask whether it is possible to decode, or at least partially infer, a word's property from the neuron behaviours of its context words. Specifically, if the model process a verbal phrase '*spill over*' or '*in the garden*', will the property of the word '*spill*', '*in*' be combined with the following word and decodable from the model neuron activation behaviours towards the following word, or will the property of the word '*over*', '*the garden*' be primed by the previous word and decodable from the model neuron behaviours towards the previous word?

To quantitatively explore this question, we carry out a mapping experiment similar to the previous one. The difference is that here we map the hidden layer, three gates, and memory cell vector activated by a target input word w in a sentence to the corresponding linguistic features of the previous/following word $w_{-2/-1}/w_{+1/+2}$ in a 5-word window context. Results in Figure 9 shows that the linguistic feature POS TAG is partially primed or

kept in the context words in English. The longer distance, the less probability to decode it from the neuron activations. Still, the nearest context words w_{-1} and w_{+1} prime/keep the most relevant information of the target word w. Similar patterns are also found for other linguistic feature in other languages.

4.3 Correlation with Dependency Tree

Since the sequential model can modelling non-sequential input, we naturally want to know whether any component of the model is dynamically correlated with the statistics of tree structure. Inspired by the case study in Zhou and Xu (2015), we count the syntactic depth of each word in a sentence and compute the correlation between the depth sequence and the dynamics of the average activation of the model neurons in Table 2. We did not find strong correlation between the mean neuron activation dynamics with the syntactic tree depth. One possible explanation is that the language model only use the history information, while the depth of a word is computed in a relative global context.

5 Model Comparison

In this section, we would like to investigate whether different sentence modelling strategy and optimization objective affect the neuron's implicit encoding of linguistic knowledge, especially the grammatical properties.

5.1 Word vs. Character

It is obvious that word-based language model and character-based language model intend to model the language data at different granularity. Although both of them are effective, the latter is often criticized for an unreasonable modelling strategy.

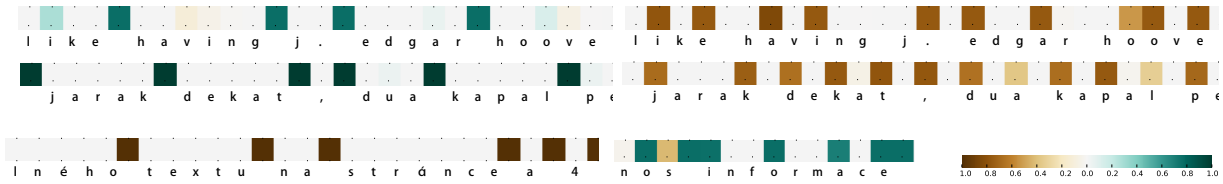
In addition to the findings in Karpathy et al. (2015), we see that some of the hidden layer neurons of the character-based language model seems to be sensitive to specific characters and character clusters, as is indicated from the visualization of the neuron activation pattern in Figure 10. We are surprised to find that some neuron of the hidden layer activates selectively towards white space character. This is interesting as it means that the model learns to detect word boundary, which is exactly an important linguistic feature.

Besides, some neuron activates selectively towards vowel/consonant characters in a phonographic language, such as English. This interesting phenomenon also indicates that the model implicitly captures the phonology system, since it can discriminate the vowel character clusters from the consonant character clusters. We also find these two detectors in other languages, such as Indonesian and Czech in Figure 10.

5.2 Word Prediction vs. Task-specific Model

We compare a word-based LSTM language model and a word-based LSTM sentiment model. Here, for a fair comparison, all the models are trained only on the Stanford Sentiment Treebank Dataset (Socher et al., 2013a). The results show that the neurons in these two models displays similar behaviours towards superficial sequential features, but totally different behaviours towards high-level linguistic features, such as semantic and syntactic knowledge.

Both some of the internal neurons of the memory cell in the language model and the sentiment model emerge to be sensitive to the length of the



(a) $h^{19}_{en,CL}$, $h^{33}_{id,CL}$, $h^{9}_{cs,CL}$ detect white space. (b) $h^{16}_{en,CL}$, $h^{7}_{id,CL}$, $h^{15}_{cs,CL}$ detect phonology.

Figure 10: Visualising the activation of hidden neurons of English, Indonesian and Czech language model.

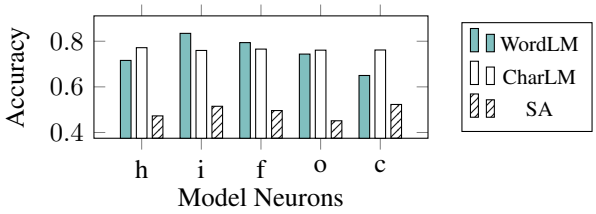


Figure 11: Comparison between the internal neurons of English word-based language model, character-based language model and sentiment model on decoding POS TAG.

input sequence, as we expected, since the sentence length is a non-linguistic features shared by all the sequential input. However, different optimization objectives force the models to represent and capture the linguistic properties of different aspects. The language model focus more on the syntactic aspect, as is visualized and quantified in previous sections. Neurons of the sentiment model tends to be sensitive only towards the sentiment aspect of the words, although the sentiment model use the similar LSTM unit, dimensionality and pretrained embedding. We apply the same visualization method in Section 3.2 to the 64 hidden layer neurons of the sentiment model and manually interpret the visualization results one by one. We did not see any strong activation pattern towards the functional words like those found in language model hidden layer neurons.

To quantify the differences of the linguistic knowledge encoded in different sentential model, we again use the previous feature-decoding experiment method. We compare the performance of the components in three models on decoding POS TAG from English data. Notice that we use Stanford POS Tagger (Kristina Toutanova and Singer, 2003) to automatically tag the sentences in the sentiment data. For the character-based language model, we use the neuron activation towards the end character of each words in the decoding experiment.

Results in Figure 11 shows that even a character-based language model can achieve pretty well on decoding the most important lexical features from the activation pattern of the internal neurons. This is a strong evidence that word-level feature detector can emerge from a pure character-based model. Sentiment model, on the contrary, fails to capture the grammatical knowledge, although we might think that a successful sentiment analysis model should be able to combines the grammar property of the words with the sentiment information. Current results indicate that for pure sequential model with vanilla LSTM units, the objective of the sentence modelling tasks will largely affect how the model acquires and encodes linguistic knowledge.

6 Related Works

Karpathy et al. (2015) explores the memory cell in character-based language model. Their visualization results show some interesting properties of the memory neurons in LSTM unit. However, their exploration on character-based model does not intend to correlate high-level linguistic knowledge, which are intuitively required for sequential modelling of a sentence.

Li et al. (2016) propose a method for visualizing RNN-based sentiment analysis models and word-based LSTM auto-encoder in NLP tasks. Li et al. (2015) investigates the necessity of tree structure for the modelling non-sequential properties of languages. Bowman et al. (2015) studies the LSTM's ability of capturing non-sequential tree structure. Despite the useful findings, these works make no attempts to investigate the internal states of the neurons for a better understanding of the model's power or weakness.

Our work not only provides qualitative visualization of model neurons' behaviours and detailed

quantitative investigation with multilingual evidence (16 for POS decoding experiment), but also reveal the influence of language syntactic complexity and modelling strategy on how well the internal neurons capture linguistic knowledge, which have been overlooked by previous work on interpreting neural network models.

7 Conclusion

In this work, we analyze the linguistic knowledge implicitly encoded in the sequential model of sentence. Through the visualization and quantification of the correlation between the neuron activation behaviour of different model components and linguistic features, we summarize that:

- Model neurons encode linguistic features at different level. Gate neurons encode more linguistic knowledge than memory cell neurons.
- Low-level sequential features are shared across models while high-level linguistic knowledge (lexical/compositional feature) are better captured by language model instead of task-specified model on sentiment analysis.
- Multilingual evidence indicates that the model are sensitive to the syntactic complexity of the language. It would also be a promising direction to incorporate the factor of language typological diversity when designing advanced general sequential model for languages other than English.
- Word-level feature detector can emerge from a pure character-based model, due to the utility of character composition.

Keyphrase Extraction Using Deep Recurrent Neural Networks on Twitter

Qi Zhang, Yang Wang, Yeyun Gong, Xuanjing Huang

{qz, ywang14, yygong12, xjhuang}@fudan.edu.cn

Abstract

Keyphrases can provide highly condensed and valuable information that allows users to quickly acquire the main ideas. The task of automatically extracting them have received considerable attention in recent decades. Different from previous studies, which are usually focused on automatically extracting keyphrases from documents or articles, in this study, we considered the problem of automatically extracting keyphrases from tweets. Because of the length limitations of Twitter-like sites, the performances of existing methods usually drop sharply. We proposed a novel deep recurrent neural network (RNN) model to combine keywords and context information to perform this problem. To evaluate the proposed method, we also constructed a large-scale dataset collected from Twitter. The experimental results showed that the proposed method performs significantly better than previous methods.

1 Introduction

Keyphrases are usually the selected phrases that can capture the main topics described in a given document (Turney, 2000). They can provide users with highly condensed and valuable information, and there are a wide variety of sources for keyphrases, including web pages, research articles, books, and even movies. In contrast to keywords, keyphrases usually contain two or more words. Normally, the meaning representations of these phrases are more precise than those of single words. Moreover, along with the increasing development of the internet, this kind of summarization has received continuous consideration in recent years from both the academic and entiprise communities (Witten et al., 1999; Wan and Xiao, 2008; Jiang et al., 2009; Zhao et al., 2011; Tuarob et al., 2015).

Because of the enormous usefulness of keyphrases, various studies have been conducted on the automatic extraction of keyphrases using different methods, including rich linguistic features (Barker and Cornacchia, 2000; Paukkeri et al., 2008), supervised classification-based methods (Witten et al., 1999; Wu et al., 2005; Wang et al., 2006), ranking-based methods (Jiang et al., 2009), and clustering-based methods (Mori et al., 2007; Danilevsky et al., 2014). These methods usually focus on extracting keyphrases from a single document or multiple documents. Typically, a large number of words exist in even a document of moderate length, where a few hundred words or more is common. Hence, statistical and linguistic features can be considered to determine the importance of phrases.

In addition to the previously mentioned methods, a few researchers have studied the problem of extracting keyphrases from collections of tweets (Zhao et al., 2011; Bellaachia and Al-Dhelaan, 2012). In contrast to traditional web applications, Twitter-like services usually limit the content length to 140 characters. In (Zhao et al., 2011), the context-sensitive topical PageRank method was proposed to extract keyphrases by topic from a collection of tweets. NE-Rank was also proposed to rank keywords for the purpose of extracting topical

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 836–845,
Austin, Texas, November 1-5, 2016.

keyphrases (Bellaachia and Al-Dhelaan, 2012). Because multiple tweets are usually organized by topic, many document-level approaches can also be adopted to achieve the task. In contrast with the previous methods, Marujo et al. (2015) focused on the task of extracting keywords from single tweets. They used several unsupervised methods and word embeddings to construct features. However, the proposed method worked on the word level.

In this study, we investigated the problem of automatically extracting keyphrases from single tweets. Compared to the problem of identifying keyphrases from documents containing hundreds of words, the problem of extracting keyphrases from a single short text is generally more difficult. Many linguistic and statistical features (e.g., the number of word occurrences) cannot be determined and used. Moreover, the standard steps of keyphrase extraction usually include keyword ranking, candidate keyphrase generation, and keyphrase ranking. Previous works usually used separate methods to handle these steps. Hence, the error of each step is propagated, which may highly impact the final performance. Another challenge of keyphrase extraction on Twitter is the lack of training and evaluation data. Manual labelling is a time-consuming procedure. The labelling consistency of different labellers cannot be easily controlled.

To meet these challenges, in this paper, we propose a novel deep recurrent neural network (RNN) model for the joint processing of the keyword ranking, keyphrase generation, and keyphrase ranking steps. The proposed RNN model contains two hidden layers. In the first hidden layer, we capture the keyword information. Then, in the second hidden layer, we extract the keyphrases based on the keyword information using a sequence labelling method. In order to train and evaluate the proposed method, we also proposed a novel method to construct a dataset that contained a large number of tweets with golden standard keyphrases. The proposed dataset construction method was based on the hashtag definitions in Twitter and how these were used in specific tweets.

The main contributions of this work can be summarized as follows:

- We proposed a two-hidden-layer RNN-based method to jointly model the keyword ranking, keyphrase generation, and keyphrase ranking steps.
- To train and evaluate the proposed method, we proposed a novel method for constructing a large dataset, which consisted of more than one million words.
- Experimental results demonstrated that the proposed method could achieve better results than the current state-of-the-art methods for these tasks.

2 Proposed Methods

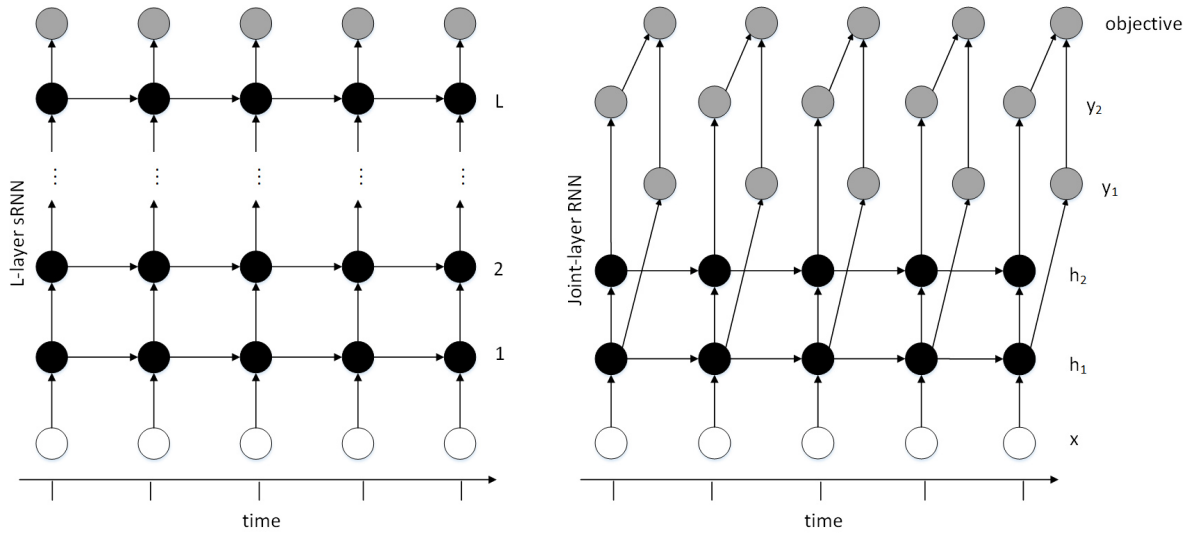
In this paper, we will first describe the deep recurrent neural network (RNN). Then, we will discuss the proposed joint-layer recurrent neural network model, which jointly processes the keyword ranking, keyphrase generation, and keyphrase ranking.

2.1 Deep Recurrent Neural Networks

One way to capture the contextual information of a word sequence is to concatenate neighboring features as input features for a deep neural network. However, the number of parameters rapidly increases according to the input dimension. Hence, the size of the concatenating window is limited. A recurrent neural network (RNN) can be considered to be a deep neural network (DNN) with an indefinite number of layers, which introduces the memory from previous time steps. A potential weakness of a RNN is its lack of hierarchical processing for the input at the current time step. To further provide hierarchical information through multiple time scales, deep recurrent neural networks (DRNNs) are explored (Hermans and Schrauwen, 2013). Fig. 1 (a) shows an L intermediate layer DRNN with full temporal connections (called a stacked RNN (sRNN) in (Pascanu et al., 2013)).

2.2 Joint-layer Recurrent Neural Networks

The proposed joint-layer recurrent neural network (joint-layer RNN) is a variant of an sRNN with two hidden layers. The joint-layer RNN has two output layers, which are combined into a objective layer. Suppose there is an L intermediate layer sRNN that has an output layer for each hidden layer. The l-th



(a) (b)

Figure 1: Deep recurrent neural network (DRNN) architectures: arrows represent connection matrices; white, black, and grey circles represent input frames, hidden states, and output frames, respectively; (a): L intermediate layer DRNN with recurrent connections at all levels (called stacked RNN); (b): joint-layer RNN folded out in time. Each hidden layer can be interpreted to be an RNN that receives the time series of the previous layer as input, where the hidden layer transforms into an output layer. Two output layers are combined via linear superposition into the objective function.

hidden activation is defined as:

$$\begin{aligned} \mathbf{h}_t^l &= f_h(\mathbf{h}_t^{l-1}, \mathbf{h}_{t-1}^l) \\ &= \phi_l(\mathbf{U}^l \mathbf{h}_{t-1}^l + \mathbf{W}^l \mathbf{h}_t^{l-1}), \end{aligned} \quad (1)$$

where $\mathbf{h}_t^l$ is the hidden state of the l-th layer at time t. $\mathbf{U}^l$ and $\mathbf{W}^l$ are the weight matrices for the hidden activation at time $t-1$ and the lower level activation $\mathbf{h}_t^{l-1}$, respectively. When $l = 1$, the hidden activation is computed using $\mathbf{h}_t^0 = \mathbf{x}_t$. ϕ_l is an element-wise non-linear function, such as the sigmoid function. The l-th output activation is defined as:

$$\begin{aligned} \hat{\mathbf{y}}_t^l &= f_o(\mathbf{h}_t^l) \\ &= \varphi_l(\mathbf{V}^l \mathbf{h}_t^l), \end{aligned} \quad (2)$$

where $\mathbf{V}^l$ is the weight matrix for the l-th hidden layer $\mathbf{h}_t^l$. φ_l is also an element-wise non-linear function, such as the softmax function.

A joint-layer recurrent neural network is an extension of a stacked RNN with two hidden layers. At time t, the training input, $\mathbf{x}_t$, of the network is the concatenation of features from a mixture within a window. We use word embedding as a feature in this paper. The output targets, $\mathbf{y}_t^1$ and $\mathbf{y}_t^2$, and output predictions, $\hat{\mathbf{y}}_t^1$ and $\hat{\mathbf{y}}_t^2$, of the network indicate whether the current word is a keyword and part of a keyphrase, respectively. $\hat{\mathbf{y}}_t^1$ just has two values $True$ and $False$ indicating whether the current word is keyword. $\hat{\mathbf{y}}_t^2$ has 5 values $Single$, $Begin$, $Middle$, End and Not indicating the current word is a single keyword, the beginning of a keyphrase, the middle (neither beginning nor ending) of a keyphrase, the ending of a keyphrase or not a part of a keyphrase.

Since our goal is to extract a keyphrase from a word sequence, we adopt a framework to simultaneously model keyword finding and keyphrase extraction. Figure 1 (b) shows the architecture of our model. The hidden layer formulation is defined as:

$$\mathbf{h}_t^1 = f_h(\mathbf{x}_t, \mathbf{h}_{t-1}^1) \quad (3)$$

$$\mathbf{h}_t^2 = f_h(\mathbf{h}_t^1, \mathbf{h}_{t-1}^2). \quad (4)$$

The output layer formulation is defined as:

$$\hat{\mathbf{y}}_t^1 = f_o(\mathbf{h}_t^1) \quad (5)$$

$$\hat{\mathbf{y}}_t^2 = f_o(\mathbf{h}_t^2). \quad (6)$$

2.3 Training

In this work, we joined learning the parameters θ in the deep neural network.

$$\boldsymbol{\theta} = \{\mathbf{X}, \mathbf{W}^1, \mathbf{W}^2, \mathbf{U}^1, \mathbf{U}^2, \mathbf{V}^1, \mathbf{V}^2\},$$

where $\mathbf{X}$ are the words embeddings, the other parameters are defined before. Once give a labeled sentence we can know both the keyword and keyphrase (keyphrase is made of keywords). At the first output layer we use our model to discriminate keyword and at the second output layer we use our model to discriminate keyphrase. Then we combine these two sub-objective which at different discrimination level into the final objective. The final objection is defined as:

$$J(\boldsymbol{\theta}) = \alpha J_1(\boldsymbol{\theta}) + (1-\alpha) J_2(\boldsymbol{\theta}), \tag{7}$$

where α is linear weighted factor. Given N training sequences $D = \left\{ \left(\mathbf{x}_t, \mathbf{y}_t^1, \mathbf{y}_t^2\right)_{t=1}^{T_n} \right\}_{n=1}^{N}$, the sub-objective formulation is defined as:

$$J_1(\boldsymbol{\theta}) = \frac{1}{N} \sum_{n=1}^{N} \sum_{t=1}^{T_n} d(\hat{\mathbf{y}}_t^1, \mathbf{y}_t^1) \tag{8}$$

$$J_2(\boldsymbol{\theta}) = \frac{1}{N} \sum_{n=1}^{N} \sum_{t=1}^{T_n} d(\hat{\mathbf{y}}_t^2, \mathbf{y}_t^2), \tag{9}$$

where $d(\mathbf{a}, \mathbf{b})$ is a predefined divergence measure between **a** and **b**, such as Euclidean distance or cross-entropy.

Eq. (8) and Eq. (9) show that we discover keyword and extract keyphrase at different level simultaneously. The experimental results will show that combination of different granularity discrimination can significantly improve the performance.

To minimize the objective function, we optimize our models by back-propagating the gradients with respect to the training objectives. The stochastic gradient descent (SGD) algorithm is used to train the models. The update rule for the i-th parameter θ_i at epoch e is as follows:

$$\theta_{e,i} = \theta_{e-1,i} - \lambda g_{e,i}, \tag{10}$$

where the λ is a global learning rate shared by all dimensions. g_e is the gradient of the parameters at the e-th iteration. We select the best model according to the validation set.

#tweets	W	T	$\bar{N}_w$	$\bar{N}_t$
41,644,403	147,377	112,515	13.22	1.0

Table 1: Statistical information of dataset. W, T, $\bar{N}_w$, and $\bar{N}_t$ are the vocabulary of words, number of tweets with hashtags, average number of words in each tweet, and average number of hashtags in each tweet, respectively.

3 Experiments

3.1 Data Construction

To analyze the effectiveness of our model for keyphrase extraction on Twitter, we constructed an evaluation dataset. We crawled a large number of tweets. Generally, for each user, we gathered about 3K tweets, with a final total of more than 41 million tweets.

From analyzing these tweets, we found that some of the hashtags can be considered as the keyphrases of the tweet. For example: "The Warriors take Game 1 of the #NBAFinals 104-89 behind a playoff career-high 20 from Shaun Livingston.". "NBA Finals" can be considered as the keyphrase of the twitter. Based on this intuition, to construct the dataset, we firstly filtered out all non-Latin tweets using regular expressions. Then, we removed any URL links from the tweets since we were focusing on the textual content. Tweets that start with the "@username" are generally considered replies and have a conversational nature more than topical nature. Therefore, we also removed any tweets that start with "@username" to focus on topical tweets only. Moreover, we designed some rules about the hashtags in tweets to filter the remaining tweets. First, one tweet could have only one hashtag. Second, the position of the hashtag had to be inside the tweet because we needed the hashtag and tweet to be semantically inseparable. When a hashtag appears inside a tweet, it is most likely to be an inseparable semantical part of the tweet and has important meaning. Therefore, we regarded this hashtag as a keyphrase of the tweet.

Each hashtag was split into keywords if it encompassed more than one word, for example "OldStockCanadians" for "Old Stock Canadians". After an effort to filter the tweets we finally had 110K tweets with the hashtags which could meet our

Algorithm 1 Twitter Dataset Construction

Require: Tweets list $tList$
Ensure: Filtered Tweets and hashtags

```
resultList ← ∅
while t in tList do
    if t not contains latin letters then
        continue
    end if
    if t starts with "@username" then
        continue
    end if
    removed any URL links from t
    if t not exactly contains one hashtag then
        continue
    end if
    get hashtag from t
    split hashtag into keywords
    resultList.append((t, hashtag))
end while
return resultList
```

needs. The pseudocode is defined in Alg. 1. The statistical information of the dataset can be seen in Table 1. To evaluate the quality of the tweets in our dataset, we randomly selected 1000 tweets from our dataset and chose three volunteers. Every tweet was assigned a score of 2 (perfectly suitable), 1 (suitable), or 0 (unsuitable) to indicate whether the hashtag of the tweet was a good keyphrase for it. The results showed that 90.2% were suitable and 66.1% were perfectly suitable. This demonstrated that our constructed dataset was good for keyphrase extraction on Twitter.

3.2 Experiment Configurations

To perform an experiment on extracting keyphrases, we used 70% as a training set, 10% as a development set, and 20% as a testing set. For evaluation metrics, we used the precision (P), recall (R), and F1-score (F1) to evaluate the performance. The precision was calculated based on the percentage of keyphrases truly identified among the keyphrases labeled by the system. Recall was calculated based on the keyphrases truly identified among the golden standard keyphrases.

In the experiments, we use word embeddings as input to the neural network. The word embeddings we used in this work were pre-trained vectors trained on part of a Google News dataset (about 100 billion words). A skip-gram model (Mikolov et al., 2013) was used to generate these 300-dimensional vectors for 3 million words and phrases. We used the word embeddings to initialize our word weight matrix. The matrix was updated in the training process.

The default parameters of our model are as follows: The window size is 3, number of neurons in the hidden layer is 300, and α is 0.5, which were chosen based on the performance using the valid set.

3.3 Methods for Comparison

Several algorithms were implemented and used to evaluate the validity of the proposed approach. Among these algorithms, CRF, RNN, LSTM, and R-CRF treat the keyphrase extraction task as a sequence labelling task. Automatic keyword extraction on Twitter (AKET) uses an unsupervised method to extract keywords on Twitter.

- **CRF**: The keyphrase extraction task can be formalized as a sequence labeling task that involves the algorithmic assignment of a categorical label to each word of a tweet. CRF is a type of discriminative undirected probabilistic graphical model and can process a sequence labeling task. Hence, we applied CRF to extract keyphrases on Twitter.

- **RNN**: A recurrent neural network (RNN) is a type of artificial neural network where the connections between units form a directed cycle. This creates an internal state of the network that allows it to exhibit dynamic temporal behavior. In an RNN model, word embedding is introduced to represent the semantics of words.

- **LSTM**: Long short-term memory (LSTM) is a recurrent neural network (RNN) architecture. Unlike traditional RNNs, an LSTM network is well-suited to learn from experience to classify, process, and predict time series when there are very long time lags of unknown size between important events.

- **R-CRF**: A recurrent conditional random field (R-CRF)(Yao et al., 2014) is a mixture model

	P	R	F1
CRF	72.37%	71.82%	72.09%
RNN	78.65%	70.08%	74.14%
LSTM	77.52%	71.19%	74.22%
R-CRF	79.29%	73.15%	76.10%
AKET	11.00%	46.10%	17.80%
Joint-layer RNN	**80.74**%	**81.19**%	**80.97**%

Table 2: Keyphrase Extraction on Twitter

combining an RNN and a CRF. This model has the advantages of both the CRF and RNN. The previous work showed that the performance of R-CRF can be significantly improved.

- **AKET** (Automatic Keyword Extraction on Twitter) (Marujo et al., 2015): Several unsupervised methods and word embeddings were used to construct features to obtain keyword.

3.4 Experiment Results

Table 2 shows the performances of different methods on the dataset for keyphrase extraction. From the results, we observe that the joint-layer RNN achieved a better performance than the state-of-the-art methods. The relative improvement in the F-score of the joint-layer RNN over the second best result was 6.1%. AKET performed the worst. This was because AKET worked on the word level. Of the other methods, CRF performed the worst, RNN and LSTM were almost the same but better than CRF, and R-CRF was the best of these methods, with the exception of our joint-layer RNN. The results can be explained by the word embedding and long short-term memory cell providing some benefits. The best result was found with our joint-layer RNN. This indicated that the joint processing of the keyword finding and keyphrase extraction worked well and could to some degree demonstrate the effectiveness of our model in keyphrase extraction on Twitter.

To further analyze the keyword extraction results on Twitter, we compared AKET and our method. In Table 3, we can see that except for the recall, AKET is a little better than our method, but our method performed significantly better than AKET in the precision and F-score. This indicates that our model indeed has better performance in keyword finding.

	P	R	F1
AKET	20.68%	**87.56**%	33.46%
Joint-layer RNN	**87.45**%	85.38%	**86.40**%

Table 3: Keyword Extraction on Twitter

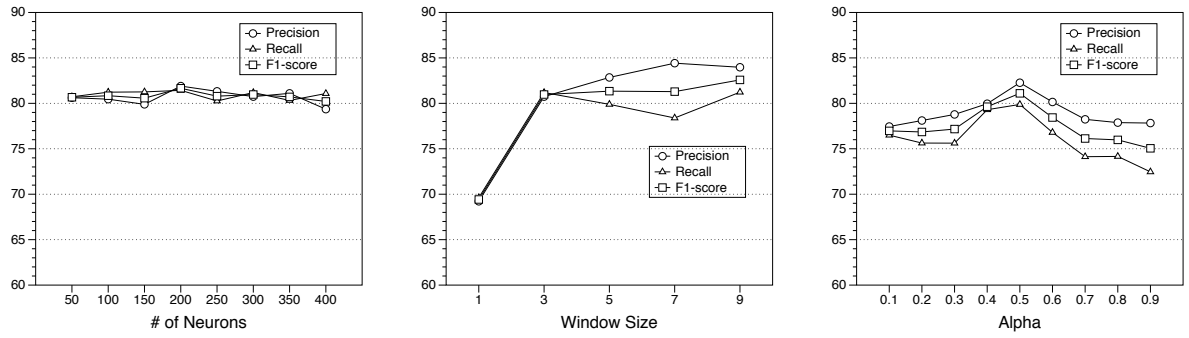
In summary, the experimental results conclusively demonstrated that the proposed joint-layer RNN method is superior to the state-of-the-art methods when measured using commonly accepted performance metrics on Twitter.

To analysis the sensitivity of the hyper-parameters of the joint-layer RNN, we conducted several empirical experiments on the dataset.

Fig.2(a) shows the performances of the joint-layer RNN with different numbers of neurons in the hidden layers. To simplify, we made hidden layer 1 and hidden layer 2 have the same number of neurons. In the figure, the x-axis denotes the number of neurons, and the y-axis denotes the precision, recall, and F-score. The data used for constructing the test set were the same as we used in the previous section. From the figure, we can observe that the number of neurons in the hidden layers do not highly affect the final performance. Three performance indicators of the joint-layer RNN change stably with different numbers of neurons.

Fig.2(b) shows the performances of the joint-layer RNN with different window sizes. In the figure, the x-axis denotes the different window size, and the y-axis denotes the precision, recall, and F-score. From the figure, we observe that when the window size is one, the three performance indicators of joint-layer RNN perform badly. Then, as the window size increases, the three performance indicators change stably. The main reason may possibly be that when the window size is one, the model just uses the current word information. When the window size increases, the model uses the context information of the current word but the most important context information is nearby the current word.

Fig.2(c) shows the performances of the joint-layer RNN with different α values. In the figure, the x-axis denotes the value of α used for training, and the y-axis denotes the precision, recall, and F-score.



(a) (b) (c)

Figure 2: (a): Performance with varying number of neurons in the hidden layer; (b): Performance with varying window size; (c): Performance with varying α.

	P	R	F1
WEU	80.74%	81.19%	80.97%
WENU	74.10%	69.30%	71.62%
REU	79.01%	79.75%	79.38%
RENU	78.16%	64.55%	70.70%

Table 4: Effects of embedding on performance. WEU, WENU, REU and RENU represent word embedding update, word embedding without update, random embedding update and random embedding without update respectively.

We can see that the best performance is obtained when α is around 0.5. This indicates that our model emphasizes the combination of keyword finding and keyphrase extraction.

Table 4 lists the effects of word embedding. We can see that the performance when updating the word embedding is better than when not updating, and the performance of word embedding is a little better than random word embedding. The main reason is that the vocabulary size is 147,377, but the number of words from tweets that exist in the word embedding trained on the Google News dataset is just 35,133. This means that 76.2% of the words are missing. This also confirms that the proposed joint-layer RNN is more suitable for keyphrase extraction on Twitter.

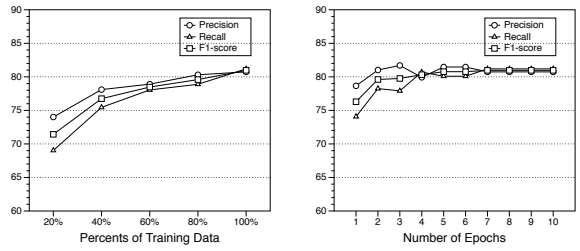
Fig.3(a) shows the performances of the joint-layer RNN with different percentages of training data. In the figure, the x-axis denotes the percentages of data used for training, and the y-axis denotes the precision, recall, and F-score. From the figure, we observe that as the amount of training data increases, the three performance indicators of the joint-layer RNN consequently improve. When the percentage of training data is greater than 60% of the whole dataset, the performance indicators slowly increase. The main reason may possibly be that the number concepts included in these data sets are small. However, on the other hand, we can say that the proposed joint-layer RNN method can achieve acceptable results with a few ground truths. Hence, it can be easily adopted for other data sets.

Since the keyphrase extraction training process is solved using an iterative procedure, we also evaluated its convergence property. Fig.3 (b) shows the precision, recall, and F-score performances of the joint-layer RNN. In the figure, the x-axis denotes the number of epochs for optimizing the model, and the y-axis denotes the precision, recall, and F-score. From the figure, we observe that the joint-layer RNN can coverage with less than six iterations. This means that the joint-layer RNN can achieve a stable and superior performance under a wide range of parameter values.

4 Related Work

In general, keyphrase extraction methods can be roughly divided into two groups: supervised machine learning approaches and unsupervised ranking approaches.

In the supervised line of research, keyphrase extraction is treated as a classification problem, in which a candidate must be classified as either a keyphrase (i.e., keyphrases) or not (i.e., non-



(a) (b)

Figure 3: (a): Effects of train size on performance; (b): Effects of the number of epochs on performance.

keyphrases). A classifier needs to be trained using annotated training data. The trained model is then applied to documents for which keyphrases are to be identified. For example (Frank et al., 1999) developed a system called KEA that used two features: tf-idf and first occurrence of the term and used them as input to Naive Bayes (Hulth, 2003) used linguistic knowledge (i.e., part-of-speech tags) to determine candidate sets: potential pos-patterns were used to identify candidate phrases from the text. Tang et al. (2004) applied Bayesian decision theory for keyword extraction. Medelyan and Witten extended the KEA to KEA++, which uses semantic information on terms and phrases extracted from a domain specific thesaurus, thus enhances automatic keyphrase extraction (Medelyan and Witten, 2006).

In the unsupervised line of research, keyphrase extraction is formulated as a ranking problem. A well-known approach is the Term Frequency Inverse Document Frequency (TF-IDF) (Sparck Jones, 1972; Zhang et al., 2007; Lee and Kim, 2008). Measures like term frequencies (Wu and Giles, 2013; Rennie and Jaakkola, 2005; Kireyev, 2009), inverse document frequencies, topic proportions, etc. and knowledge of specific domain are applied to rank terms in documents which are aggregated to score the phrases. The ranking based on tf-idf has been shown to work well in practice (Hasan and Ng, 2010). Mihalcea et al. proposed the TextRank, which constructs keyphrases using the PageRank values obtained on a graph based ranking model for graphs extracted from texts (Mihalcea and Tarau, 2004). Liu et al. proposed to extract keyphrases by adopting a clustering-based approach, which ensures that the document is semantically covered by these keyphrases (Liu et al., 2009). Ali Mehri et al. put forward a method for ranking the words in texts, which can also be used to classify the correlation range between word-type occurrences in a text, by using non-extensive statistical mechanics (Mehri and Darooneh, 2011).

Recurrent neural networks(RNNs) (Elman, 1990) has been applied to many sequential prediction tasks, which is an important class of naturally deep architecture. In NLP, RNNs deal with a sentence as a sequence of tokens and have been successfully applied to various tasks like spoken language understanding (Mesnil et al., 2013) and language modeling (Mikolov et al., 2011). Classical recurrent neural networks incorporate information from preceding, there are kinds of variants, bidirectional RNNs are also useful for NLP tasks, especially when making a decision on the current token, information provided by the following tokens is generally useful.

5 Conclusion

In this work, we proposed a novel deep recurrent neural network (RNN) model to combine keywords and context information to perform the keyphrase extraction task. The proposed model can jointly process the keyword ranking and keyphrase generation task. It has two hidden layers to discriminate keywords and classify keyphrases, and these two sub-objectives are combined into a final objective function. We evaluated the proposed method on a dataset filtered from ten million crawled tweets. The proposed method can achieve better results than the state-of-the-art methods. The experimental results demonstrated the effectiveness of the proposed method for keyphrase extraction on single tweets.

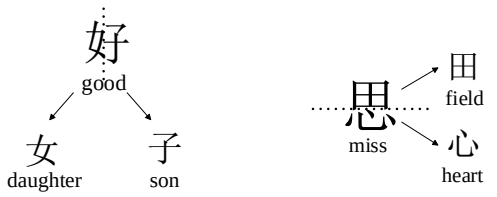
Abstract

Chinese character riddle is a riddle game in which the riddle solution is a single Chinese character. It is closely connected with the shape, pronunciation or meaning of Chinese characters. The riddle description (sentence) is usually composed of phrases with rich linguistic phenomena (such as pun, simile, and metaphor), which are associated to different parts (namely radicals) of the solution character. In this paper, we propose a statistical framework to solve and generate Chinese character riddles. Specifically, we learn the alignments and rules to identify the metaphors between phrases in riddles and radicals in characters. Then, in the solving phase, we utilize a dynamic programming method to combine the identified metaphors to obtain candidate solutions. In the riddle generation phase, we use a template-based method and a replacement-based method to obtain candidate riddle descriptions. We then use Ranking SVM to rerank the candidates both in the solving and generation process. Experimental results in the solving task show that the proposed method outperforms baseline methods. We also get very promising results in the generation task according to human judges.

1 Introduction

The riddle is regarded as one of the most unique and vital elements in traditional Chinese culture, which is usually composed of a riddle description and a corresponding solution. The character riddle is one of the most popular forms of various riddles in which the riddle solution is a single Chinese character. While English words are strings of letters together, Chinese characters are composed of radicals that associate with meaning or metaphor. In other words, Chinese characters are usually positioned into some common structures, such as upper-lower structure, left-right structure, inside-outside structure, which means they can be decomposed into other characters or radicals. For example, "好" (good), a character with left-right structure, can be decomposed into "女" (daughter) and "子" (son). As illustrated in Figure 1(a), the left part of "好" is "女" and the right part is "子". "女" and "子" are called the "radical" of "好". Figure 1(b) is another example of the character "思" (miss) with an upper-lower structure.



(a) Left-Right Structure (b) Upper-Lower Structure

Figure 1: Examples of the structure of Chinese characters

One of the most important characteristics of character riddle lies in the structure of Chinese characters. Unlike the common riddles which imply the object in the riddle descriptions, character riddles pay more attention to structures such as combination of radicals and decomposition of characters. According to these characteristics, metaphors in the

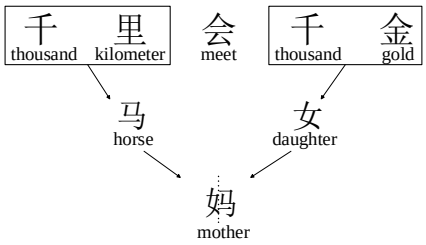

Figure 2: An example of Chinese character riddle: The solution "妈" is composed of the radical "女" derived from "千 金" and "马" derived from "千 里".

riddles always imply the radicals of characters.

We show an example of a Chinese character riddle in Figure 2. The riddle description is "千 里 会 千 金" and the riddle solution is "妈". In this example, "千 里" (thousand kilometer) aligns with "马" (horse) because in Chinese culture it is said that a good horse can run thousands of kilometers per day. Furthermore, "千 金" (thousand gold) aligns with "女" (daughter) because of the analogy that a daughter is very important in the family. The final solution "妈" is composed of these two metaphors because the radical "女" meets the radical "马". Radicals can be derived not only from the meaning of metaphors, but also from the structure of characters. We will describe the alignments and rules in detail in Section 3.

In this paper, we propose a statistical framework to solve and generate Chinese character riddles. We show our pipeline in Figure 3. First, we learn the common alignments and the combination rules from large riddle-solution pairs which are mined from the Web. The alignments and rules are used to identify the metaphors in the riddles. Second, in the solving phase, we utilize a dynamic programming algorithm on the basis of the alignments and rules to figure out the candidate solutions. For the generating phase, we use a template-based method and a replacement-based method based on the decomposition of the character to generate the candidate riddles. Finally, we employ Ranking SVM to rank the candidates in both the solving and generation task. We conduct the evaluation on 2,000 riddles in the riddle solving task and 100 Chinese characters in the riddle generation task. Experimental results show that the proposed method outperforms baseline methods in the solving task. We also get very promising results in the generation task according to human judges.

2 Related Work

To the best of our knowledge, no previous work has studied on Chinese riddles. For other languages, there are a few approaches concentrated on solving English riddles. Pepicello and Green (1984) describe the various strategies incorporated in riddles. (De Palma and Weiner, 1992; Weiner and De Palma, 1993) use the knowledge representation system to solve English riddles that consist of a single sentence question followed by a single sentence answer. They propose to build the relation between the phonemic representation and their associated lexical concepts. Binsted and Ritchie (1994) implement a program JAPE which generates riddles from humour-independent lexical entries and evaluate the behaviour of the program by 120 children (Binsted et al., 1997). Olaosun and Faleye (2015) identify meaning construction strategies in selected English riddles in the web and account for the mental processes involved in their production, which shows that the meaning of a riddle is an imposed meaning that relates to the logical, experiential, linguistic, literary and intuitive judgments of the riddles. Besides, there are some studies in Yoruba(Akínyemí, 2015b; Akínyemí, 2015a; Magaji, 2014). All of these works focus on the semantic meaning, which is different from Chinese character riddles that focus on the structure of characters.

Another popular word game is Crossword Puzzles (CPs) that normally has the form of a square or rectangular grid of white and black shaded squares. The white squares on the border of the grid or adjacent to the black ones are associated with clues. Compared with our riddle task, the clues in the CPs are derived from each question where the radicals in solution are derived from the metaphors in the riddles. Proverb (Littman et al., 2002) is the first system for the automatic resolution of CPs. Ernandes et al. (2005) utilize a web-search module to find sensible candidates to questions expressed in natural language and get the final answer by ranking the candidates. And the rule-based module and the dictionary module are mentioned in his work. The tree kernel is used to rerank the candidates proposed by Barlacchi et al. (2014) for automatic resolution of crossword puzzles.

From another perspective, there are a few projects

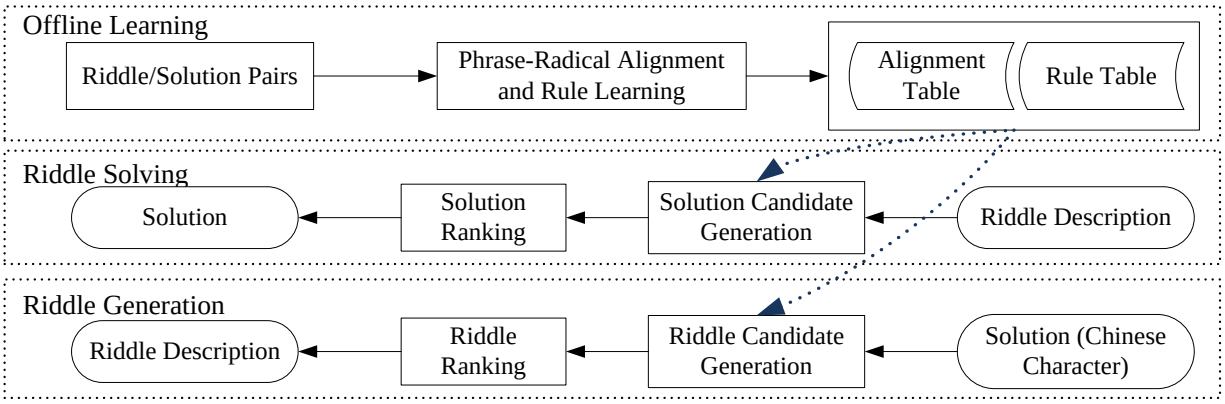

Figure 3: The pipeline of offline learning, riddle solving and riddle generation

on Chinese language cultures, such as the couplet generation and the poem generation. A statistical machine translation (SMT) framework is proposed to generate Chinese couplets and classic Chinese poetry (He et al., 2012; Zhou et al., 2009; Jiang and Zhou, 2008). Jiang and Zhou (2008) use a phrase-based SMT model with linguistic filters to generate Chinese couplets satisfied couplet constraints, using both human judgments and BLEU scores as the evaluation. Zhou et al. (2009) use the SMT model to generate quatrain with a human evaluation. He et al. (2012) generate Chinese poems with the given topic words by combining a statistical machine translation model with an ancient poetic phrase taxonomy. Following the approaches in SMT framework, it is valid to regard the metaphors with its radicals as the alignments. There are several works using neural network to generate Chinese poems(Zhang and Lapata, 2014; Yi et al., 2016). Due to the limited data and strict rules, it is hard to transfer to the riddle generation.

3 Phrase-Radical Alignments and Rules

The metaphor is one of the key components in both solving and generation. On the one hand we need to identify these metaphors since each of them aligns a radical in the final solution. On the other hand, we need to integrate these metaphors into the riddle descriptions to generate riddles. Thus, how to extract the metaphors of riddles becomes a big challenge in our task. Below we introduce our method to extract the metaphors based on the phrase-radical alignments and rules.

We exploit the phrase-radical alignments as to describe the simple metaphors, e.g. "千 里" aligns "马", which aligns the phrase and the radical by the meaning. We employ a statistical framework with a word alignment algorithm to automatically mine phrase-radical metaphors from riddle dataset. Considering the alignment is often represented as the matching between successive words in the riddle and a radical in the solution, we propose two methods specifically to extract alignments. The first method in according with (Och and Ney, 2003) is described as follows. With a riddle description q and corresponding solution s, we tokenize the input riddle q to character as $(w_1, w_2, \ldots, w_n)$ and decompose the solution s into radicals as $(r_1, r_2, \ldots, r_m)$. We count all $([w_i, w_j], r_k)(i, j \in [1, n], k \in [1, m])$ as alignments. The second method takes into account more structural information of characters. Let (w_1, w_2) denote two successive characters in the riddle q. If w_1 is a radical of w_2 and the rest parts of w_2 as r appear in the solution q, we strongly support that $((w_1, w_2), r)$ is a alignment. It is identical if w_2 is a radical of w_1. We count all alignments and filter out the alignments whose occurrence number is lower than 3. Some high-frequency alignments are shown in Table 1. For example, "四方"(square) aligns "口"(mouth) because of the similar shape and "二十载"(two decades) aligns "艹"(grass) because "艹" looks like two small "十"s.

Besides alignments are represented as common collocations, there is another kind of common metaphors concentrating on the structure of characters. We define 6 categories of rules shown in Table 2 to identify this kind of metaphors. A

Bigram Alignments	Radical	Frequency	Trigram Alignments	Radical	Frequency
西 湖 (west lake)	氵 (water)	77	二 十 载 (two decades)	艹 (grass)	21
四 方 (square)	口 (mouth)	40	党 中 央 (center of party)	口 (mouth)	19
千 里 (thousand kilometer)	马 (horse)	36	意 中 人 (sweetheart)	日 (sun)	16

Table 1: The high-frequency alignments

Category	Description	Examples
Half	take half of the matched placeholder as radicals	[半折断边](.) [half,snap,break,side](.)
A-B	remove the B as radical in A to compose a new Chinese character	[减走无缺](.)(.) [subtract,leave,not,lack](.)(.)
UpperRemove	remove the upper-side radical of the matched placeholder	(.)[字]0,1[下南] (.)[character](0,1)[lower,south]
LowerRemove	remove the lower-side radical of the matched placeholder	[首前上北](.) [top,front,up,north](.)
LeftRemove	remove the left-side radical of the matched placeholder	(.)[字]0,1[右东] (.)[character](0,1)[right,east]
RightRemove	remove the right-side radical of the matched placeholder	(.)[字]0,1[左西] (.)[character](0,1)[left,west]

Table 2: The descriptions and examples of rules

rule is often represented as an operation that applies to a character for obtaining parts of it as radicals. For example, the character "上" (up) is usually represented as an operation to get the upper radical of the corresponding character. We extract the rules from the phrase-radical alignments we just obtain. In a phrase-radical alignment, if a radical appears in the one part of a character, we support that this radical is derived from this character, which means the other words in the phrase may describe an operation to this character. We replace this radical to a placeholder and generate a candidate rule with the corresponding direction by the radical position in this character. Thus, for each phrase-radical alignment $([w_1, w_n], r)$, we count $(w_1, \ldots, w_{i-1}, (.), w_{i+1}, \ldots, w_n)$ as a potential rule only if r is a radical of w_i. We count all rules learned from data, and filter out the rules whose occurrence number is lower than 5. Some rules are shown in Table 2. The word or phrase in the rule "A-B" mostly has the analogous meaning of "removing". The word or phrase in the rule "Half" mostly has the analogous meaning of "half". As for the rules "LeftRemove", "RightRemove", "UpperRemove" and "LowerRemove", there are usually a word or phrase that means "removing" as well as the others mean the "position" and "direction".

We mine 14,090 phrase-radical alignments in total. More than 1,000 Chinese characters have at least one alignment, and there are 27 characters with more than 100 alignments. Common radicals are almost all contained in our alignments set. Chinese character is mostly composed of these common radical, so these alignments are enough for our task. We extract 193 rules in total for all categories of rules, all of them are applied to the riddle solving and the riddle generation.

4 Riddle Solving and Generation

4.1 Solving Chinese Character Riddles

The process of solving riddles has two components. First, we identify the metaphors in the riddle as much as possible by matching the phrase-radical alignments and rules, and integrate these metaphors to obtain a candidate set of solutions. Each candidate contains the corresponding parsing clues that imply how and why it is generated as its features. Second, we employ a ranking model to determine the best solution as output. Below we introduce our method to generate solution candidates, and we will

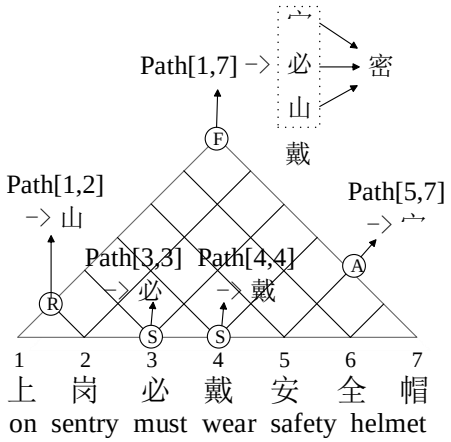

Figure 4: The decoding process of "上 岗 必 戴 安 全 帽". -R: Path[1,2] records the clue that "上 岗" matches "山" by the rule. -S: Path[3,3] records the clue that "必" matches itself and Path[4,4] records "戴". -A: Path[5,7] records the clue that "安 全 帽" matches "宀" by the alignment. -F: We get a final solution candidate in Path[1,7] by above clues. In this example, the character "戴" from Path[4,4] is irrelevant to the solution.

introduce the ranking model in Section 4.3.

It is common that two metaphors do not share a character and the metaphor is composed of successive characters. Therefore, we utilize a dynamic programming algorithm based on the CYK algorithm (Kasami, 1965) to identify the metaphors with the help of the learned alignments and the predefined rules. We describe the algorithm in Algorithm 1.

An example to illustrate our algorithm is "上 岗 必 戴 安 全 帽", where the corresponding solution is "密". As shown in Figure 4, "上 岗"(on sentry) aligns "山" by matching the rule "上(up) (.)" which means to take the upper part of the character "岗". "必" and "戴" aligns itself. And the phrase "安 全 帽"(safety helmet) aligns to the radical "宀" by the alignments because of the analogical shape. Our ranking model will get the final solution "密" by these clues.

4.2 Generating Chinese Character Riddles

Two major components are required in the process of riddle generation. The first step is to generate a list of candidates of riddle descriptions for a Chinese character as the solution. The second step is to rank the candidate riddle descriptions and select the top-N (e.g. 10) candidates as the output. Below we introduce our method to generate candidates of riddle descriptions, and we will introduce the ranking model in Section 4.3.

Algorithm 1: Candidate generation for riddle solving

Input : Riddle q, Alignment, Rule
Output: Path[1,n]

Tokenize the input riddle q to $w_1, w_2, \ldots, w_n$;
for $len \leftarrow 0$ **to** $n-1$ **do**
  for $j - i = len$ **do**
    if *len = 0* **then**
      Character can align itself ;
      $Path[i,j].Add([w_i, w_i] \rightarrow w_i)$;
    end
    else if $[w_i, w_j]$ *in Alignment* **then**
      Obtain the corresponding radical r in Alignment ;
      $Path[i,j].Add([w_i, w_j] \rightarrow r)$;
    end
    else if $[w_i, w_j]$ *matchs Rule* **then**
      Run the predefined operation of the Rule, obtain radical r ;
      $Path[i,j].Add([w_i, w_j] \rightarrow r)$;
    end
    foreach *k in [i,j-1]* **do**
      $Path[i,j].Add(Path[i,k] \oplus Path[k+1,j])$;
    end
  end
end

We propose two strategies to generate the candidate riddle descriptions for a given Chinese character, called the template-based method and the replacement based-method, respectively. First we show our template-based method to generate riddles. The most natural method is to connect the metaphor of each radical. For a character and its possible splitting RD = rd_i, we select a corresponding metaphor by the alignment or rule, and then we connect all metaphor without any other conjunction words to form a riddle. The further method is to add a few conjunction words between each metaphor, which can make the riddle more coherent. We remove the recognized metaphors in riddle sentences,

Feature	Description
Correct_Radical	number of radicals matched
Missing_Radical	number of radicals not matched
Disappearing_Radical	number of radicals that disappear in all characters of riddle descriptions
Single_Matching	number of clues derived from character itself
Alignment_Matching	number of clues derived from alignments
Rule_Matching	number of clues derived from rules
Length_Rate	ratio of the length of clues
Frequency	prior probability of this character as a solution

Table 3: Features for riddle solving

Feature	Description
Riddle_Length	length in characters of the candidate riddle
Riddle_Relative_Length	abs(Riddle_Length-5) because the length of common riddles is between 3 and 7
Number_Radical	number of radicals that the character decompose
Avg_Freq_Character	average number of frequencies of characters in riddle
Max_Freq_Radical	maximized number of frequencies of characters in riddle
Number_Alignment	number of alignments used for generating the candidate
Length_Alignment	length of words from alignments
Number_Rule	number of rules used for generating the candidate
Length_Rule	length of words from rules
LM_Score_R	score of language model trained by Chinese riddles, poems and couplets
LM_Score_G	score of language model trained by web documents

Table 4: Features for riddle generation

and count the unigram and bigram word frequency of the rest words. These words are usually common conjunctions. We sample these words based on the frequency distribution and add them into the riddles to connect the metaphor of each radical.

Second, we use an alternative replacement-based method to generate the candidate riddle descriptions. Instead of generating the riddle descriptions totally from scratch, we try to replacement part of an existing riddle to generate a new riddle description. Let $w = (w_1, w_2, \ldots, w_n)$ denote the word sequence of a riddle description on our dataset, where n denotes the length of the riddle in character. Let $[w_i, w_j]$ (i,j $\in$ [1,n]) denote the word span that can be aligned to a radical rd, and let X=($x_1, \ldots, x_m$) denotes the corresponding phrase descriptions of rd. We then replace $[w_i, w_j] \in X$ with the other alternative phrases descriptions of rd in X. We try all the possible replacements to generate riddle candidates. This method can generate candidate riddles that are more natural and fluent.

4.3 Ranking Model

Above we introduce the algorithm to solve and generate candidates, respectively. Then, we develop a ranking model to determine the final output. Below we show the ranking model.

The ranking score is calculated as

$$Score(c) = \sum_{i=1}^{m} \lambda_i * g_i(c) \quad (1)$$

where c represents a candidate, $g_i(c)$ represents the i-th feature in the ranking model, m represents the number of features in total, and λ_i represents the weight of the feature. The features of riddle solving and riddle generation are in Table 3 and Table 4, respectively. We use Ranking SVM (Joachims, 2006)[1] to do the model training to get the feature weights. The weights of the features are trained with riddle-solution pairs. Specifically, in the riddle solving task, for the set of solution candidates, we hold that the original solution as the positive sample and others are the negative samples. Using the dynamic programming algorithm to obtain a list of solution candidates, the training process try to optimize the feature weights so that the ranking score of the original solution is greater than any of the ones from the

[1] https://www.cs.cornell.edu/people/tj/svm_light/svm_rank.html

candidate list. In the riddle generation task, we select 100 characters on the basis of the frequency distribution of characters as a solution. For each character we use the riddle generation module to generate a list of riddle candidates. And we label these candidates manually where the better riddle descriptions get the higher score. Then the training process optimizes the feature weights.

5 Experimental Study

5.1 Dataset

We crawl 77,308 character riddles including riddle descriptions with its solution from the Web. All of these riddle-solution pairs concentrate on the structure of characters.

A stroke table, that contains 3,755 characters encoded in the first level of GB2312-80, is provided to describe how a Chinese character is decomposed into its corresponding radicals. Characters may have more than one splitting forms and a character is typically composed of no more than 3 radicals.

The data for training language model in riddle style include two parts: One is the corpus of riddles mentioned above, and the other is a corpus of Chinese poem and Chinese couplets because of the similar language style. We follow the method that proposed by (He et al., 2012; Zhou et al., 2009), to download the <Tang Poems>,<Song Poems>, <Ming Poems>, <Qing Poems>, <Tai Poems> from the Internet, and use the method proposed by Fan et al. (2007) to recursively mine those data with the help of some seed poems and couplets. It amounts to more than 3,500,000 sentences and 670,000 couplets. Besides the language model trained in riddle style, we also train a general language model with the web documents.

5.2 Evaluation on Riddle Solving

We randomly select 2,000 riddles from the riddle dataset as the test data, and 500 riddles as the development data, while the rest as training data.

Our system always returns a ranking list of candidate solutions, so we use the Acc@k (k = 1, 5, 10) as the evaluation metric. The Acc@k is the fraction of questions which obtain correct answers in their top-k results.

Giza++ (Och, 2001) is a common tool to extract the alignment between bilingual corpuses. We use it as our baseline system that extracts the alignments automatically. And we use the Jaccard similarity coefficient as the baseline ranking metric. The Jaccard similarity coefficient is defined as:

$$J(A,B) = \frac{A \bigcap B}{A \bigcup B} \quad (2)$$

where A means the radicals set of the solution and B means the radicals set of the candidate.

Feature Set	Acc@1	Acc@5	Acc@10
G	10.3	12.0	13.6
G+A	17.0	19.2	19.9
A	18.7	22.7	24.2
G+A+R	28.4	31.0	31.4
A+R	**28.8**	**31.8**	**32.1**

Table 5: Results of evaluation on test dataset with 2,000 riddles. -G: The alignments from GIZA++. -A: The alignments extracted following our method in Section 3. -R: Using the rules to identify the metaphors between the phrase and the radical following our method in Section 3. Our method (A+R) achieves better performances than the baseline methods from GIZA++.

Ranking Method	Acc@1	Acc@5	Acc@10
Jaccard Similarity	26.2	30.2	31.2
Ranking SVM	**28.8**	**31.8**	**32.1**

Table 6: Results of evaluation between ranking methods using the feature set (A+R). The Ranking SVM achieves better performances than the baseline metric from Jaccard similarity coefficient.

The results are reported in the Table 5 and Table 6. The baseline method can only give about one-tenth correct solution at the Acc@1. Compared with the baseline model, by using the alignments extracted by our method, the system can improve 6.7% at the Acc@1 and 6.3% at Acc@10. A phenomenon is that only using the alignments we extract has the better results than combining it with the alignments from Giza++ because metaphors matching between phrases and characters are particular in our riddle task. Small changes in the phrase can affect the character that it implies and it may be not a metaphor even if a character in phrase is changed. Furthermore, by using rules to identify the metaphors in riddles, we get an improvement of 10.1% at Acc@1, which proves the validity of the

Score	Criterion
5	Elegant metaphors, totally coherent
4	Correct metaphors, mostly coherent
3	Acceptable metaphors, more of less coherent
2	Tolerable metaphors, little coherent
1	Wrong metaphors, incoherent

Table 7: The criterion of riddle evaluation

rule we define. The results prove that it is valid to use the alignments and rules that we extract to identify the metaphors in our character riddle task. The comparison between Jaccard similarity coefficient and our Ranking SVM method shows that the Ranking SVM is better with an improvement of 2.6% at Acc@1, which prove that compared to the Jaccard similarity coefficient, the Ranking SVM determine the solution more correct if we successfully identify all metaphors in riddle descriptions. Moreover, there is less improvement beyond Acc@5, which means the ranking model gets better results even if the system cannot identify all metaphors in riddle descriptions. We think that unlike the Jaccard similarity coefficient which only uses the features between the candidate character and the correct solution, the ranking model uses extra features in the riddles descriptions, e.g. the number of disappearing radicals, which helps to exclude obvious wrong candidates.

5.3 Evaluation on Riddle Generation

Because there is no previous work about Chinese riddle generation, in order to prove its soundness, we conduct human evaluations on this task in accordance with the following two reasons. Firstly, the generated riddles, which is different from the certain and unique solution in the riddle solving task, are varied. So it is hard to measure the quality of generated riddles with a well defined answer set. Secondly, small differences in riddles have a great effect on the corresponding solution. It may imply distinct radicals even if only a character in the metaphors is changed. The existing metrics such as BLEU, are not suitable for our task. Based on above analysis, each riddle that the system generates is evaluated by human annotators according to a 5 division criterion described in Table 7.

We randomly sample 100 characters following the distribution of the character as a solution. The system generates riddle descriptions following the methods in Section 4.2 for each character. Sometimes the riddles we generate exist in our training data. We remove these riddles for the reason that we want to evaluate the ability of generating new riddles. In order to avoid the influence of annotators and compare the riddles generated by the system with the riddles written by human beings, the riddles are randomly disordered so that the annotators do not know the generating method of each riddle. For each character, we select 5 riddles generated by the template-base method, 5 riddles generated by the replacement-based method, and 2 riddles from the riddles dataset written by human beings, which form a set of 12 riddles in total. The annotators score each riddle according to the above criterion.

Method	Avg(Score)
Template-based Method	3.49
Replacement-based Method	4.14
Riddle from dataset	4.38

Table 8: Human evaluation of different methods

The result is shown in Table 8. The riddles written by human beings from the riddle dataset get the highest score than the riddles generated by the system. The riddles generated by the replacement-based method have a greater improvement than the basic template-based method. We consider that the replacement-based method retains some human information, which makes the generated riddles more coherent.

Another result is that the riddle whose solution is a common character or is composed of common radicals gets the higher score, which is explicit that we can get the better results if we have the more alternative metaphors of a radical.

Below we show two examples of the riddle descriptions generated with the solution “思”(miss) which often decompose into “田”(field) and “心”(heart) shown in Figure 1(b).

- 三 星 伴 月 似 画 里 (Three stars with the moon, like in the picture): The radical “田” is the inside part of “画”. The shape of “心” is three points and a curved line, which looks like three stars around a crescent.
- 日 日 相 系 在 心 头 (Every day in my heart):

The radical "田" is composed of two "日"s, and "心" occurs in the riddle description. The character "头"(top) means the radical "田" is on the top position.

6 Conclusion

We introduce a novel approach to solving and generating Chinese character riddles. We extract alignments and rules to capture the metaphors of phrases in riddle descriptions and radicals in the solution characters. In total, we obtain 14,090 alignments that imply the metaphors between phrases and radicals as well as 193 rules in 6 categories formed as regular expressions. To solve riddles, we utilize a dynamic programming algorithm to combine the identified metaphors based on the alignments and rules to obtain the candidate solutions. To generate riddles, we propose a template-based method and a replacement-based method to generate candidate riddle descriptions. We employ the Ranking SVM to rank the candidates on both the riddle solving and generation. Our method outperforms baseline methods in the solving task. We also get promising results in the generation task by human evaluation.

Structured prediction models for RNN based sequence labeling in clinical text

Abhyuday N Jagannatha[1], **Hong Yu**[1,2]
[1] University of Massachusetts, MA, USA
[2] Bedford VAMC and CHOIR, MA, USA
abhyuday@cs.umass.edu , hong.yu@umassmed.edu

Abstract

Sequence labeling is a widely used method for named entity recognition and information extraction from unstructured natural language data. In the clinical domain one major application of sequence labeling involves extraction of relevant entities such as medication, indication, and side-effects from Electronic Health Record Narratives. Sequence labeling in this domain presents its own set of challenges and objectives. In this work we experiment with Conditional Random Field based structured learning models with Recurrent Neural Networks. We extend the previously studied CRF-LSTM model with explicit modeling of pairwise potentials. We also propose an approximate version of skip-chain CRF inference with RNN potentials. We use these methods[1] for structured prediction in order to improve the exact phrase detection of clinical entities.

1 Introduction

Patient data collected by hospitals falls into two categories, structured data and unstructured natural language texts. It has been shown that natural text clinical documents such as discharge summaries, progress notes, etc are rich sources of medically relevant information like adverse drug events, medication prescriptions, diagnosis information etc. Information extracted from these natural text documents can be useful for a multitude of purposes ranging from drug efficacy analysis to adverse effect surveillance.

A widely used method for Information Extraction from natural text documents involves treating the text as a sequence of tokens. This format allows sequence labeling algorithms to label the relevant information that should be extracted. Several sequence labeling algorithms such as Conditional Random Fields (CRFs), Hidden Markov Models (HMMs), Neural Networks have been used for information extraction from unstructured text. CRFs and HMMs are probabilistic graphical models that have a rich history of Natural Language Processing (NLP) related applications. These methods try to jointly infer the most likely label sequence for a given sentence.

Recently, Recurrent (RNN) or Convolutional Neural Network (CNN) models have increasingly been used for various NLP related tasks. These Neural Networks by themselves however, do not treat sequence labeling as a structured prediction problem. Different Neural Network models use different methods to synthesize a context vector for each word. This context vector contains information about the current word and its neighboring content. In the case of CNN, the neighbors comprise of words in the same filter size window, while in Bidirectional-RNNs (Bi-RNN) they contain the entire sentence.

Graphical models and Neural Networks have their own strengths and weaknesses. While graphical models predict the entire label sequence jointly, they usually rely on special hand crafted features to provide good results. Neural Networks (especially Re-

[1] Code is available at https://github.com/abhyudaynj/LSTM-CRF-models

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 856–865,
Austin, Texas, November 1-5, 2016.

current Neural Networks), on the other hand, have been shown to be extremely good at identifying patterns from noisy text data, but they still predict each word label in isolation and not as a part of a sequence. In simpler terms, RNNs benefit from recognizing patterns in the surrounding input features, while structured learning models like CRF benefit from the knowledge about neighboring label predictions. Recent work on Named Entity Recognition by (Huang et al., 2015) and others have combined the benefits of Neural Networks(NN) with CRF by modeling the unary potential functions of a CRF as NN models. They model the pairwise potentials as a paramater matrix $[A]$ where the entry $A_{i,j}$ corresponds to the transition probability from the label i to label j. Incorporating CRF inference in Neural Network models helps in labeling exact boundaries of various named entities by enforcing pairwise constraints.

This work focuses on labeling clinical events (medication, indication, and adverse drug events) and event related attributes (medication dosage, route, etc) in unstructured clinical notes from Electronic Health Records. Later on in the Section 4, we explicitly define the clinical events and attributes that we evaluate on. In the interest of brevity, for the rest of the paper, we use the broad term "Clinical Entities" to refer to all medically relevant information that we are interested in labeling.

Detecting entities in clinical documents such as Electronic Health Record notes composed by hospital staff presents a somewhat different set of challenges than similar sequence labeling applications in the open domain. This difference is partly due to the critical nature of medical domain, and partly due to the nature of clinical texts and entities therein. Firstly, in the medical domain, extraction of exact clinical phrase is extremely important. The names of clinical entities often follow polynomial nomenclature. Disease names such as *Uveal melanoma* or *hairy cell leukemia* need to be identified exactly, since partial names (*hairy cell* or *melanoma*) might have significantly different meanings. Additionally, important clinical entities can be relatively rare events in Electronic Health Records. For example, mentions of Adverse Drug Events occur once every six hundred words in our corpus. CRF inference with NN models cited previously do improve exact phrase labeling. However, better ways of modeling the pairwise potential functions of CRFs might lead to improvements in labeling rare entities and detecting exact phrase boundaries.

Another important challenge in this domain is a need to model long term label dependencies. For example, in the sentence *"the patient exhibited **A** secondary to **B**"*, the label for ***A*** is strongly related to the label prediction of ***B***. ***A*** can either be labeled as an adverse drug reaction or a symptom if ***B*** is a Medication or Diagnosis respectively. Traditional linear chain CRF approaches that only enforce local pairwise constraints might not be able to model these dependencies. It can be argued that RNNs may implicitly model label dependencies through patterns in input features of neighboring words. While this is true, explicitly modeling the long term label dependencies can be expected to perform better.

In this work, we explore various methods of structured learning using RNN based feature extractors. We use LSTM as our RNN model. Specifically, we model the CRF pairwise potentials using Neural Networks. We also model an approximate version of skip chain CRF to capture the aforementioned long term label dependencies. We compare the proposed models with two baselines. The first baseline is a standard Bi-LSTM model with softmax output. The second baseline is a CRF model using handcrafted feature vectors. We show that our frameworks improve the performance when compared to the baselines or previously used CRF-LSTM models. To the best of our knowledge, this is the only work focused on usage and analysis of RNN based structured learning techniques on extraction of clinical entities from EHR notes.

2 Related Work

As mentioned in the previous sections, both Neural Networks and Conditional Random Fields have been widely used for sequence labeling tasks in NLP. Specially, CRFs (Lafferty et al., 2001) have a long history of being used for various sequence labeling tasks in general and named entity recognition in particular. Some early notable works include McCallum et. al. (2003), Sarawagi et al. (2004) and Sha et. al. (2003). Hammerton et. al. (2003) and Chiu et. al. (2015) used Long Short Term Memory (LSTM)

(Hochreiter and Schmidhuber, 1997) for named entity recognition.

Several recent works on both image and text based domains have used structured inference to improve the performance of Neural Network based models. In NLP, Collobert et al (2011) used Convolutional Neural Networks to model the unary potentials. Specifically for Recurrent Neural Networks, Lample et al. (2016) and Huang et. al. (2015) used LSTMs to model the unary potentials of a CRF.

In biomedial named entity recognition, several approaches use a biological corpus annotated with entities such as protein or gene name. Settles (2004) used Conditional Random Fields to extract occurrences of protein, DNA and similar biological entity classes. Li et. al. (2015) recently used LSTM for named entity recognition of protein/gene names from BioCreative corpus. Gurulingappa et. al. (2010) evaluated various existing biomedical dictionaries on extraction of adverse effects and diseases from a corpus of Medline abstracts.

This work uses a real world clinical corpus of Electronic Health Records annotated with various clinical entities. Jagannatha et. al. (2016) recently showed that RNN based models outperform CRF models on the task of Medical event detection on clinical documents. Other works using a real world clinical corpus include Rochefort et al. (2015), who worked on narrative radiology reports. They used a SVM-based classifier with bag of words feature vector to predict deep vein thrombosis and pulmonary embolism. Miotto et. al. (2016) used a denoising autoencoder to build an unsupervised representation of Electronic Health Records which could be used for predictive modeling of patient's health.

3 Methods

We evaluate the performance of three different Bi-LSTM based structured prediction models described in section 3.2, 3.3 and 3.4. We compare this performance with two baseline methods of Bi-LSTM(3.1) and CRF(3.5) model.

3.1 Bi-LSTM (baseline)

This model is a standard bidirectional LSTM neural network with word embedding input and a Softmax Output layer. The raw natural language input sentence is processed with a regular expression tokenizer into sequence of tokens $\mathbf{x} = [x_t]_1^T$. The token sequence is fed into the embedding layer, which produces dense vector representation of words. The word vectors are then fed into a bidirectional RNN layer. This bidirectional RNN along with the embedding layer is the main machinery responsible for learning a good feature representation of the data. The output of the bidirectional RNN produces a feature vector sequence $\boldsymbol{\omega}(\mathbf{x}) = [\omega(\mathbf{x})]_1^T$ with the same length as the input sequence $\mathbf{x}$. In this baseline model, we do not use any structured inference. Therefore this model alone can be used to predict the label sequence, by scaling and normalizing $[\omega(\mathbf{x})]_1^T$. This is done by using a softmax output layer, which scales the output for a label l where $l \in \{1, 2, ..., L\}$ as follows:

$$P(\tilde{y}_t = j|\mathbf{x}) = \frac{\exp(\omega(\mathbf{x})_t W_j)}{\sum_{l=1}^{L} \exp(\omega(\mathbf{x})_t W_l)} \quad (1)$$

The entire model is trained end-to-end using categorical cross-entropy loss.

3.2 Bi-LSTM CRF

This model is adapted from the Bi-LSTM CRF model described in Huang et. al. (2015). It combines the framework of bidirectional RNN layer$[\omega(\mathbf{x})]_1^T$ described above, with linear chain CRF inference. For a general linear chain CRF the probability of a label sequence $\tilde{y}$ for a given sentence $\mathbf{x}$ can be written as :

$$P(\tilde{y}|\mathbf{x}) = \frac{1}{Z} \prod_{t=1}^{N} \exp\{\phi(\tilde{y}_t) + \psi(\tilde{y}_t, \tilde{y}_{t+1})\} \quad (2)$$

Where $\phi(y_t)$ is the unary potential for the label position t and $\psi(y_t, y_{t+1})$ is the pairwise potential between the positions *t,t+1*. Similar to Huang et. al. (2015), the outputs of the bidirectional RNN layer $\boldsymbol{\omega}(\mathbf{x})$ are used to model the unary potentials of a linear chain CRF. In particular, the NN based unary potential $\phi_{nn}(y_t)$ is obtained by passing $\boldsymbol{\omega}(\mathbf{x})_t$ through a standard feed-forward $tanh$ layer. The binary potentials or transition scores are modeled as a matrix $[A]_{L \times L}$. Here L equals the number of possible labels including the *Outside* label. Each element $A_{i,j}$ represents the transition score from label i to j. The

probability for a given sequence $\tilde{y}$ can then be calculated as :

$$P(\tilde{y}|\mathbf{x};\theta) = \frac{1}{Z}\prod_{t=1}^{T}\exp\{\phi_{nn}(\tilde{y}_t) + A_{\tilde{y}_t,\tilde{y}_{t+1}}\} \quad (3)$$

The network is trained end-to-end by minimizing the negative log-likelihood of the ground truth label sequence $\hat{\mathbf{y}}$ for a sentence $\mathbf{x}$ as follows:

$$\mathcal{L}(\mathbf{x},\hat{\mathbf{y}};\theta) = -\sum_{t}\sum_{y_t}\delta(y_t = \hat{y}_t)\log P(y_t|\mathbf{x};\theta)\} \quad (4)$$

The negative log likelihood of given label sequence for an input sequence is calculated by sum-product message passing. Sum-product message passing is an efficient method for exact inference in Markov chains or trees.

3.3 Bi-LSTM CRF with pairwise modeling

In the previous section, the pairwise potential is calculated through a transition probability matrix $[A]$ irrespective of the current context or word. For reasons mentioned in section 1, this might not be an effective strategy. Some clinical entities are relatively rare. Therefore transition from an *Outside* label to a clinical label might not be effectively modeled by a fixed parameter matrix. In this method, the pairwise potentials are modeled through a non-linear Neural Network which is dependent on the current word and context. Specifically, the pairwise potential $\psi(y_t, y_{t+1})$ in equation 2 is computed by using a one dimensional CNN with 1-D filter size 2 and $tanh$ non-linearity. At every label position t, it takes $[\omega(\mathbf{x})_t; \omega(\mathbf{x})_{t+1}]$ as input and produces a $L \times L$ pairwise potential output $\psi_{nn}(y_t, y_{t+1})$. This CNN layer effectively acts as a non-linear feed-forward neuron layer, which is repeatedly applied on consecutive pairs of label positions. It uses the output of the bidirectional LSTM layer at positions t and $t+1$ to prepare the pairwise potential scores.

The unary potential calculation is kept the same as in Bi-LSTM-CRF. Substituting the neural network based pairwise potential $\psi_{nn}(y_t, y_{t+1})$ into equation 2 we can reformulate the probability of the label sequence $\tilde{y}$ given the word sequence $\mathbf{x}$ as :

$$P(\tilde{y}|\mathbf{x};\theta) = \frac{1}{Z}\prod_{t=1}^{N}\exp\{\phi_{nn}(\tilde{y}_t) + \psi_{nn}(\tilde{y}_t, \tilde{y}_{t+1})\} \quad (5)$$

Labels	Num. of Instances	Avg word length $\pm$ std

Table 1: Annotation statistics for the corpus.

The neural network is trained end-to-end with the objective of minimizing the negative log likelihood in equation 4. The negative log-likelihood scores are obtained by sum-product message passing.

3.4 Approximate Skip-chain CRF

Skip chain models are modifications to linear chain CRFs that allow long term label dependencies through the use of *skip edges*. These are basically edges between label positions that are not adjacent to each other. Due to these skip edges, the skip chain CRF model (Sutton and McCallum, 2006) explicitly models dependencies between labels which might be more than one position apart. The joint inference over these dependencies are taken into account while decoding the best label sequence. However, unlike the two models explained in the preceding section, the skip-chain CRF contains loops between label variables. As a result we cannot use the sum-product message passing method to calculate the negative log-likelihood.The loopy structure of the graph in skip chain CRF renders exact message passing inference intractable. Approximate solutions for these models include loopy belief propagation(BP) which requires multiple iterations of message passing.

However, an approach like loopy BP is prohibitively expensive in our model with large Neural Net based potential functions. The reason for this is that each gradient descent iteration for a combined RNN-CRF model requires a fresh calculation of the marginals. In one approach to mitigate this, Lin et. al. (2015) directly model the messages in the message passing inference of a 2-D grid CRF for image segmentation. This bypasses the need for modeling the potential function, as well as calculating the ap-

proximate messages on the graph using loopy BP.

Approximate CRF message passing inference: Lin et. al. (2015) directly estimate the factor to variable message using a Neural Network that uses input image features. Their underlying reasoning is that the factor-to-variable message from factor F to label variable y_t for any iteration of loopy BP can be approximated as a function of all the input variables and previous messages that are a part of that factor. They only model one iteration of loopy BP, and empirically show that it leads to an appreciable increase in performance. This allows them to model the messages as a function of only the input variables, since the messages for the first iteration of message passing are computed using the potential functions alone.

We follow a similar approach for calculation of variable marginals in our skip chain model. However, instead of estimating individual factor-to-variable messages, we exploit the sequence structure in our problem and estimate groups of factor-to-variable messages. For any label node y_t, the first group contains factors that involve nodes which occur before y_t in the sentence (from left). The second group of factor-to-variable messages corresponds to factors involving nodes occurring later in the sentence. We use recurrent computational units like LSTM to estimate the sum of log factor-to-variable messages within a group. Essentially, we use bidirectional recurrent computation to estimate all the incoming factors from left and right separately.

To formulate this, let us assume for now that we are using skip edges to connect the current node t to m preceding and m following nodes. Each edge, skip or otherwise, is denoted by a factor which contains the binary potential of the edge and the unary potential of the connected node. As mentioned earlier, we will divide the factors associated with node t into two sets, $F_L(t)$ and $F_R(t)$. Here $F_L(t)$, contains all factors formed between the variables from the group $\{y_{t-m}, ..., y_{t-1}\}$ and y_t. So we can formulate the combined message from factors in $F_L(t)$ as

$$\beta_L(y_t) = [\sum_{F \in F_L(t)} \beta_{F \to t}(y_t)] \tag{6}$$

The combined messages from factors in $F_R(t)$ which contains variables from y_{t+1} to y_{t+m} can be formulated as :

$$\beta_R(y_t) = [\sum_{F \in F_R(t)} \beta_{F \to t}(y_t)] \tag{7}$$

We also need the unary potential of the label variable t to compose its marginal. The unary potentials of each variable from $\{y_{t-m}, ..., y_{t-1}\}$ and $\{y_{t+1}, ..., y_{t+m}\}$ should already be included in their respective factors. The log of the unnormalized marginal $\bar{P}(y_t|\mathbf{x})$ for the variable y_t, can therefore be calculated by

$$\log \bar{P}(y_t|\mathbf{x}) = \beta_R(y_t) + \beta_L(y_t) + \phi(y_t) \tag{8}$$

Similar to Lin et. al. (2015), in the interest of limited network complexity, we use only one message passing iteration. In our setup, this means that a variable-to-factor message from a neighboring variable y_i to the current variable y_t contains only the unary potentials of y_i and binary potential between y_i , y_t. As a consequence of this, we can see that $\beta_L(y_t)$ can be written as :

$$\beta_L(y_t) = \sum_{i=t-1}^{t-m} \log \sum_{y_i} [\exp \psi(y_t, y_i) + \phi(y_i)] \tag{9}$$

Similarly, we can formulate a function for $\beta_R(y_t)$ in a similar way :

$$\beta_R(y_t) = \sum_{i=t+1}^{t+m} \log \sum_{y_i} [\exp \psi(y_t, y_i) + \phi(y_i)] \tag{10}$$

Modeling the messages using RNN: As mentioned previously in equation 8, we only need to estimate $\beta_L(y_t)$, $\beta_R(y_t)$ and $\phi(\mathbf{y}_t)$ to calculate the marginal of variable y_t. We can use $\phi_{nn}(\mathbf{y}_t)$ framework introduced in section 3.2 to estimate the unary potential for y_t. We use different directions of a bidirectional LSTM to estimate $\beta_R(y_t)$ and $\beta_L(y_t)$. This eliminates the need to explicitly model and learn pairwise potentials for variables that are not immediate neighbors.

The input to this layer at position t is $[\phi_{nn}(y_t); \psi_{nn}(y_t, y_{t+1})]$ (composed of potential functions described in section 3.3). This can be viewed as an LSTM layer aggregating beliefs about y_t from the unary and binary potentials of $[y]_1^{t-1}$

	Strict Evaluation (Exact Match)			Relaxed Evaluation (Word based)		
Models	**Recall**	**Precision**	**F-score**	**Recall**	**Precision**	**F-score**

Approximate Skip-Chain CRF	**0.8364**	0.8062	**0.8210**	**0.8614**	0.8651	**0.8632**

Table 2: Cross validated micro-average of Precision, Recall and F-score for all clinical tags

to approximate the sum of messages from left side $\beta_L(y_t)$. Similarly, $\beta_R(y_t)$ can be approximated from the LSTM aggregating information from the opposite direction. Formally, $\beta_L(y_t)$ is approximated as a function of neural network based unary and binary potentials as follows:

$$\beta_L(y_t) \approx f([\phi_{nn}(y_i); \psi_{nn}(y_i, y_{i+1})]_1^{t-1}) \quad (11)$$

Using LSTM as a choice for recurrent computation here is advantageous, because LSTMs are able to learn long term dependencies. In our framework, this allows them to learn to prioritize more relevant potential functions from the sequence $[[\phi_{nn}(y_i); \psi_{nn}(y_i, y_{i+1})]_1^{t-1}$. Another advantage of this method is that we can approximate skip edges between all preceding and following nodes, instead of modeling just *m* surrounding ones. This is because LSTM states are maintained throughout the sentence.

The partition function for y_t can be easily obtained by using logsumexp over all label entries of the unnormalized log marginal shown in equation 8 as follows:

$$Z_t = \sum_{y_t} \exp[\beta_R(y_t) + \beta_L(y_t) + \phi(y_t)] \quad (12)$$

Here the partition function Z is a different for different positions of t. Due to our approximations, it is not guaranteed that the partition function calculated from different marginals of the same sentence are equal. The normalized marginal can be now calculated by normalizing $\log \bar{P}(y_t|\mathbf{x})$ in equation 8 using Z_t.

$$\mathcal{L}(\mathbf{x}, \hat{\mathbf{y}}; \theta) = -\sum_t \sum_{y_t} \delta(y_t = \hat{y}_t)(\beta_R(y_t; \theta) + \beta_L(y_t; \theta) + \phi(y_t; \theta) - \log Z_t(\theta)) \quad (13)$$

The model is optimized using cross entropy loss between the true marginal and the predicted marginal. The loss for a sentence $\mathbf{x}$ with a ground truth label sequence $\hat{\mathbf{y}}$ is provided in equation 13.

3.5 CRF (baseline)

We use the linear chain CRF, which is a widely used model in extraction of clinical named entities. As mentioned previously, Conditional Random Fields explicitly model dependencies between output variables conditioned on a given input sequence.

The main inputs to CRF in this model are not RNN outputs, but word inputs and their corresponding word vector representations. We add additional sentence features consisting of four vectors. Two of them are bag of words representation of the sentence sections before and after the word respectively. The remaining two vectors are dense vector representations of the same sentence sections. The dense vectors are calculated by taking the mean of all individual word vectors in the sentence section. We add these features to explicitly mimic information provided by the bidirectional chains of the LSTM models.

4 Dataset

We use an annotated corpus of 1154 English Electronic Health Records from cancer patients. Each note was annotated[2] by two annotators who label clinical entities into several categories. These categories can be broadly divided into two groups, Clinical Events and Attributes. Clinical events include any specific event that causes or might contribute to a change in a patient's medical status. Attributes are phrases that describe certain important properties about the events.

[2]The annotation guidelines can be found at https://github.com/abhyudaynj/LSTM-CRF-models/blob/master/annotation.md

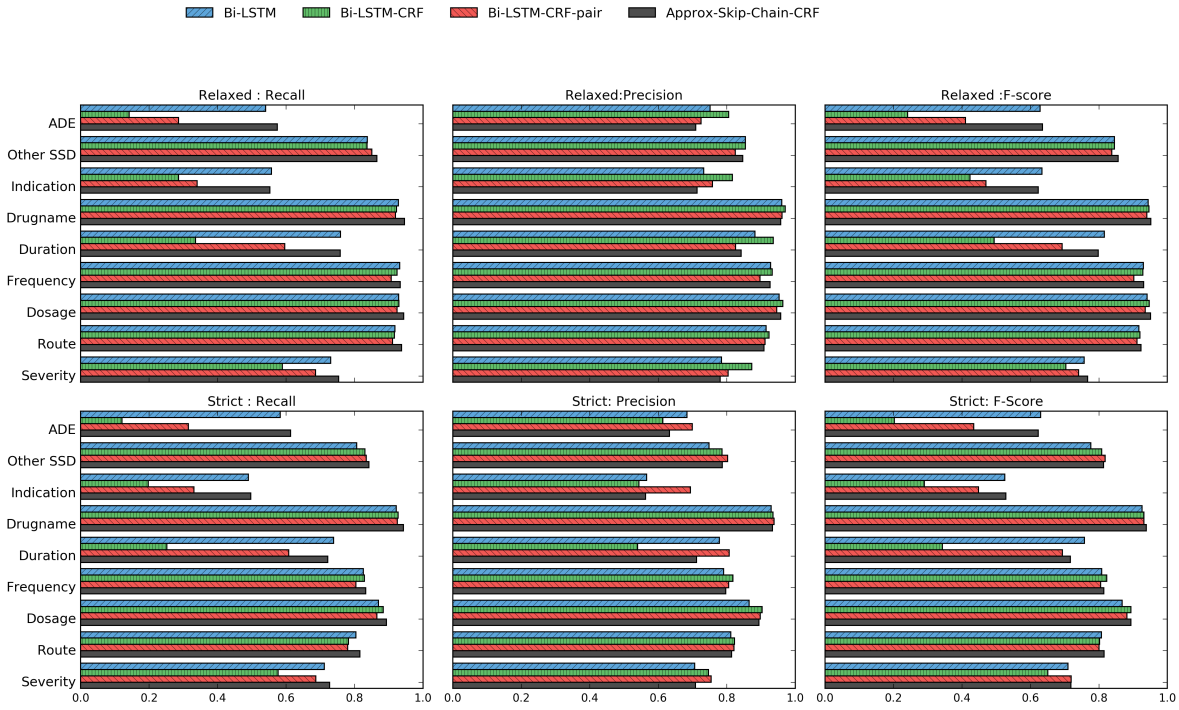

Figure 1: Plots of Recall, Precision and F-score for RNN based methods. The metrics with prefix *Strict* are using phrase based evaluation. *Relaxed* metrics use word based evaluation.Bar-plots are in order with Bi-LSTM on top and Approx-skip-chain-CRF at the bottom.

Clinical Event categories in this corpus are *Adverse Drug Event (ADE)*, *Drugname* , *Indication* and *Other Sign Symptom and Diseases (Other SSD)*. *ADE*, *Indication* and *Other SSD* are events having a common vocabulary of Sign, Symptoms and Diseases (SSD). They can be differentiated based on the context that they are used in. A certain SSD should be labeled as *ADE* if it can be manually identified as a side effect of a drug based on the evidence in the clinical note. It is an *Indication* if it is an affliction that a doctor is actively treating with a medication. Any other SSD that does not fall into the above two categories (for e.g. an SSD in patients history) is labeled as *Other SSD*. *Drugname* event labels any medication or procedure that a physician prescribes.

The attribute categories contain the following properties, *Severity* , *Route*, *Frequency*, *Duration* and *Dosage*. *Severity* is an attribute of the SSD event types , used to label the severity a disease or symptom. *Route*, *Frequency*, *Duration* and *Dosage* are attributes of *Drugname*. They are used to label the medication method, frequency of dosage, duration of dosage, and the dosage quantity respectively. The annotation statistics of the corpus are provided in the Table 1.

5 Experiments

Each document is split into separate sentences and the sentences are tokenized into individual word and special character tokens. The models operate on the tokenized sentences. In order to accelerate the training procedure, all LSTM models use batch-wise training using a batch of 64 sentences. In order to do this, we restricted the sentence length to 50 tokens. All sentences longer than 50 tokens were split into shorter size samples, and shorter sentences were pre-padded with masks. The CRF baseline model(3.5) does not use batch training and so the sentences were used unaltered.

The first layer for all LSTM models was a 200 dimensional word embedding layer. In order to improve performance, we initialized embedding layer values in these models with a skip-gram word embedding (Mikolov et al., 2013). The skip-gram embedding was calculated using a combined corpus

of PubMed open access articles, English Wikipedia and an unlabeled corpus of around hundred thousand Electronic Health Records. The EHRs used in the annotated corpus are not in this unlabeled EHR corpus. This embedding is also used to provide word vector representation to the CRF baseline model.

The bidirectional LSTM layer which outputs $\boldsymbol{\omega}(\mathbf{x})$ contains LSTM neurons with a hidden size ranging from 200 to 250. This hidden size is kept variable in order to control for the number of trainable parameters between different LSTM based models. This helps ensure that the improved performance in these models is only because of the modified model structure, and not an increase in trainable parameters. The hidden size is varied in such a way that the number of trainable parameters are close to 3.55 million parameters. Therefore, the Approx skip chain CRF has 200 hidden layer size, while standard Bi-LSTM model has 250 hidden layer. Since the $\boldsymbol{\omega}(\mathbf{x})$ layer is bidirectional, this effectively means that the Bi-LSTM model has 500 hidden layer size, while Approx skip chain CRF model has 400 dimensional hidden layer.

We use dropout (Srivastava et al., 2014) with a probability of 0.50 in all LSTM models in order to improve regularization performance. We also use batch norm (Ioffe and Szegedy, 2015) between layers wherever possible in order to accelerate training. All RNN models are trained in an end-to-end fashion using Adagrad (Duchi et al., 2011) with momentum. The CRF model was trained using L-BFGS with L2 regularization. We use Begin Inside Outside (BIO) label modifiers for models that use CRF objective.

We use ten-fold cross validation for our results. The documents are divided into training and test documents. From each training set fold, 20% of the sentences form the validation set which is used for model evaluation during training and for early stopping.

We report the word based and exact phrase match based micro-averaged recall, precision and F-score. Exact phrase match based evaluation is calculated on a per phrase basis, and considers a phrase as positively labeled only if the phrase exactly matches the true boundary and label of the reference phrase. Word based evaluation metric is calculated on labels of individual words. A word's predicted label is considered as correct if it matches the reference label, irrespective of whether the remaining words in its phrase are labeled correctly. Word based evaluation is a more relaxed metric than phrase based evaluation.

6 Results

The micro-averaged Precision, Recall and F-score for all five models are shown in Table 2. We report both strict (exact match) and relaxed (word based) evaluation results. As shown in Table 2, the best performance is obtained by Skip-Chain CRF (0.8210 for strict and 0.8632 for relaxed evaluation). All LSTM based models outperform the CRF baseline. Bi-LSTM-CRF and Bi-LSTM-CRF-pair models using exact CRF inference improve the precision of strict evaluation by 2 to 5 percentage points. Bi-LSTM CRF-pair achieved the highest precision for exact-match. However, the recall (both strict and relaxed) for exact CRF-LSTM models is less than Bi-LSTM. This reduction in recall is much less in the Bi-LSTM-pair model. In relaxed evaluation, only the Skip Chain model has a better F-score than the baseline LSTM. Overall, Bi-LSTM-CRF-pair and Approx-Skip-Chain models lead to performance improvements. However, the standard Bi-LSTM-CRF model does not provide an appreciable increase over the baseline.

Figure 1 shows the breakdown of performance for each RNN model with respect to individual clinical entity labels. CRF baseline model performance is not shown in Figure 1, because its performance is consistently lower than Bi-LSTM-CRF model across all label categories. We use pairwise t-test on strict evaluation F-score for each fold in cross validation, to calculate the statistical significance of our scores. The improvement in F-score for Bi-LSTM-CRF-pair and Approx-Skip Chain as compared to Bi-LSTM baseline is statistically significant ($p < 0.01$). The difference in Bi-LSTM-CRF and Bi-LSTM baseline, does not appear to be statistically significant ($p > 0.05$). However, the improvements over CRF baseline for all LSTM models are statistically significant.

7 Discussion

Overall, Approx-Skip-Chain CRF model achieved better F-scores than CRF,Bi-LSTM and Bi-LSTM-

CRF in both strict and relaxed evaluations. The results of strict evaluation, as shown in Figure 1, are our main focus of discussion due to their importance in the clinical domain. As expected, two exact inference-based CRF-LSTM models (Bi-LSTM-CRF and Bi-LSTM-CRF-pair) show the highest precision for all labels. Approx-Skip-Chain CRF's precision is lower(due to approximate inference) but it still mostly outperforms Bi-LSTM. The recall for Skip Chain CRF is almost equal or better than all other models due to its robustness in modeling dependencies between distant labels. The variations in recall contribute to the major differences in F-scores. These variations can be due to several factors including the rarity of that label in the dataset, the complexity of phrases of a particular label, etc.

We believe, exact CRF-LSTM models described here require more training samples than the baseline Bi-LSTM to achieve a comparable recall for labels that are complex or "difficult to detect". For example, as shown in table 1, we can divide the labels into frequent (*Other SSD*, *Indication*, *Severity*, *Drugname*, *Dosage*, and *Frequency*) and rare or sparse (*Duration*, *ADE*, *Route*). We can make a broad generalization, that exact CRF models (especially Bi-LSTM-CRF) have somewhat lower recall for rare labels. This is true for most labels except for *Route*, *Indication*, and *Severity*. The CRF models have very close recall (0.780,0.782) to the baseline Bi-LSTM (0.803) for *Route* even though its number of incidences are lower (2,862 incidences) than *Indication* (3,724 incidences) and *Severity* (3,628 incidences), both of which have lower recall even though their incidences are much higher.

Complexity of each label can explain the aforementioned phenomenon. *Route* for instance, frequently contains unique phrases such as "by mouth" or "p.o.," and is therefore easier to detect. In contrast, *Indication* is ambiguous. Its vocabulary is close to two other labels: *ADE* (1,807 incidences) and the most populous *Other SSD* (40,984 incidences). As a consequence, it is harder to separate the three labels. Models need to learn cues from surrounding context, which is more difficult and requires more samples. This is why the recall for *Indication* is lower for CRF-LSTM models, even though its number of incidences is higher than *Route*. To further support our explanation, our results show that the exact CRF-LSTM models mislabeled around 40% of *Indication* words as *Other SSD*, as opposed to just 20 % in case of the Bi-LSTM baseline. The label *Severity* is a similar case. It contains non-label-specific phrases such as "not terribly", "very rare" and "small area," which may explain why almost 35% of *Severity* words are mislabeled as *Outside* by the bi-LSTM-CRF as opposed to around 20% by the baseline.

It is worthwhile to note that among exact CRF-LSTM models, the recall for Bi-LSTM-CRF-pair is much better than Bi-LSTM-CRF even for sparse labels. This validates our initial hypothesis that Neural Net based pairwise modeling may lead to better detection of rare labels.

8 Conclusion

We have shown that modeling pairwise potentials and using an approximate version of Skip-chain inference increase the performance of the LSTM-CRF models. We also show that these models perform much better than baseline LSTM and CRF models. These results suggest that the structured prediction models are good directions for improving the exact phrase extraction for clinical entities.

Abstract

Review spam detection is a key task in opinion mining. To accomplish this type of detection, previous work has focused mainly on effectively representing fake and non-fake reviews with discriminative features, which are discovered or elaborately designed by experts or developers. This paper proposes a novel review spam detection method that learns the representation of reviews automatically instead of heavily relying on experts' knowledge in a data-driven manner. More specifically, according to 11 relations (generated automatically from two basic patterns) between reviewers and products, we employ tensor decomposition to learn the embeddings of the reviewers and products in a vector space. We collect relations between any two entities (reviewers and products), which results in much useful and global information. We concatenate the review text, the embeddings of the reviewer and the reviewed product as the representation of a review. Based on such representations, the classifier could identify the opinion spam more precisely. Experimental results on an open Yelp dataset show that our method could effectively enhance the spam detection accuracy compared with the state-of-the-art methods.

1 Introduction

With the development of E-commerce, more and more customers share their experiences about products and services by posting reviews on the web. These reviews could heavily guide the purchasing behaviors of customers. The products which receive more positive reviews tend to attract more consumers and result in more profits. Studies on Yelp.com have shown that an extra half-star rating could cause a restaurant to sell out 19% more products (Anderson and Magruder, 2012), and a one-star increase leads to a 5-9% profit increase (Luca, 2011). Therefore, more and more sellers and manufacturers have begun to place emphasis on analyzing reviews. However, the question remains: is every online review trustful? It has been reported that up to 25% of the reviews on Yelp.com could be fraudulent[1]. Due to the great profit or reputation, impostors or spammers energetically post fake reviews on the web to promote or defame targeted products (Jindal and Liu, 2008). Such fake reviews could mislead consumers and damage the online review websites' reputations. Therefore, it is necessary and urgent to detect fake reviews (review spam).

To accomplish this goal, much work has been conducted. They commonly regard this task as a classification task and most efforts are devoted to exploring useful features for representing target reviews. Li et al. (2013) and Kim et al. (2015) represent reviews with linguistic features; Lim et al. (2010) and Mukherjee et al. (2013c) represent reviews with reviewers' behavioral features[2]; Wang et al. (2011) and Akoglu et al. (2013) explore graph structure features[3]; Mukherjee et al. (2013b),

[2] Reviewers' spammer-like behaviors, e.g., if a reviewer continuously posts reviews within a short period of time, (s)he might be a spammer, and her (his) posted reviews could be spam.

[3] A kind of behavioral features which contain much interactions between reviewers and products

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 866–875,
Austin, Texas, November 1-5, 2016.

Rayana and Akoglu (2015) use the combination of aforementioned features. According to the existing studies, reviewers' behavioral features have been proven to be more effective than reviews' linguistic features for detecting review spam (Mukherjee et al., 2013c). It is because that foxy spammers could easily disguise their writing styles and forge reviews, discovering discriminative linguistic features is very difficult. Recently, most of the researchers (Rayana and Akoglu, 2015) have focused on the reviewers' behavioral features, the intuition behind which is to capture the reviewers' actions and supposes that those reviews written with spammer-like behaviors would be spam.

Although, the existing work has made significant progress in combating review spamming, they also have several limitations as follows. (1) The representations of reviews rely heavily on experts' prior knowledge or developers' ingenuity. To discover more discriminative features for representing reviews, previous work (Mukherjee et al., 2013b; Rayana and Akoglu, 2015) have spent lots of manpower and time on the statistics of the review datasets. Besides, experts' prior knowledge or developers' ingenuity is not always reliable with the variations of domains and languages. For example, based on the datasets from Dianping site[4], Li et al. (2015) find that the real users tend to review the restaurants nearby, but the spammers are not restricted to the geographical location, they may come from anywhere. However, it is not true in the Yelp datasets (Mukherjee et al., 2013b). We found that 72% of the Yelp's review spam is posted from the areas near the restaurants, but only 64% of the authentic reviews are near the restaurants. Therefore, how to learn the representations of reviews directly from data instead of heavily relying on the experts' prior knowledge or developers' ingenuity becomes crucial and urgent. (2) Furthermore, limited by the experts' knowledge, previous work only uses partial information of the review system. For example, traditional behavioral features (Lim et al., 2010; Mukherjee et al., 2013c) only utilize the information of individual reviewer. Although the work (Wang et al., 2011; Rayana and Akoglu, 2015) have tried to employ graph structure to consider the interactions among the reviewers and products, it is a kind of local interaction defined within the same product review page. However, the interaction among the reviewers and products from different review pages also provides much useful and global information, which is ignored by the previous work.

To tackle the problems described above, we propose a novel review spam detection method which can learn the representations of reviews instead of heavily relying on the experts' knowledge, developers' ingenuity, or spammer-like assumption, and can reserve the original information with a global manner. Inspired by the work about distributional representation or embedding for text and knowledge base, we propose a tensor factorization-based model to learn the representation of each review automatically. The finally learnt representation of each review is determined by the original data, rather than the features or clues found by experts. More specifically, we defined two basic patterns without any experts' knowledge, developers' ingenuity, or spammer-like assumptions. Based on the two basic patterns, we extended 11 interactive relations between entities (reviewers and products) in terms of time, locations, social contact, etc. Then, we build a 3-mode tensor on these 11 interactive relations between reviewers and products. In order to reserve the original information with a global manner, we collect the relations of any two entities regardless of whether they are from the same review page. In this way, we could reserve the original information of the data as much as possible, which dispenses with human selection. Next, we utilize tensor factorization to perform tensor decomposition, and the representations of reviewers and products are embedded in a latent vector space by collective learning. Afterward, we could obtain vector representations (embeddings) for both the reviewers and products. Then, we concatenate the review text (e.g., bigram), the embedding of a reviewer and the reviewed product as the representation of a review. In this way, the representations of reviews driven by data could be learnt in the entire review system in a global manner. Finally, such representations are fed into a classifier to detect the review spam.

In summary, this paper makes the following contributions:

- It addresses the spam detection issue with a

[4]http://www.dianping.com

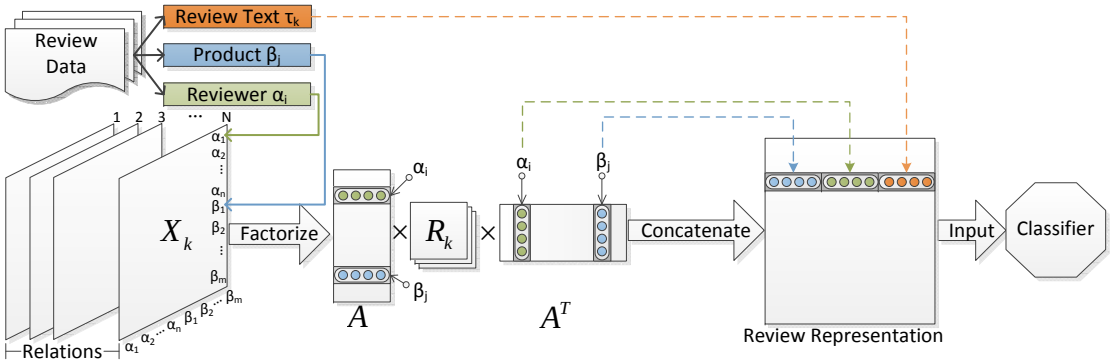

Figure 1: Illustrated of our method. The α_i denotes the i-th reviewer, and the β_j denotes the j-th product.

new perspective. Specifically, it learns the representation of reviews directly from the data. The key advantage is that it can represent the reviews instead of heavily relying on human ingenuity cost, experts' knowledge or any spammer-like assumption.

- It collects the relations between any two entities regardless of whether they are from the same review page, which results in much global information. With the help of tensor factorization, it could collectively embed the information of different relations into the final representations of reviews, and further optimize the representations. Therefore it could faithfully reflect the original characteristics of the entire review system with a global manner.
- An extra advantage is that the learnt representations of reviews are embeddings in a latent space. They are hardly comprehended by human beings included spammers. It's a robust detection method in contrast to the previous methods in which the reviews are represented by the explicit detecting clues and features. Once have realized the explicit features that were captured, experienced spammers could change their spamming strategies.
- The method of this paper renders 89.2% F1-score in detecting restaurant review spam which is higher than the F1-score of 86.1% rendered by the method in (Mukherjee et al., 2013b) (in hotel domain, it's 87.0% vs 84.8%). These experimental results give good confidence to the proposed approach, and the learnt representations of reviews are more robust and effective than in previous methods.

2 The Proposed Method

In this section, we propose our method (shown in Figure 1) in detail. Compared with the previous work, we address the review spam detection issue by learning the representation of the reviews automatically in a latent space without experts' knowledge. First, we extend 11 interactive relations between entities (reviewers and products) from the two basic patterns in terms of time, locations, social contact, etc. Then, our method generates 11 relation matrices of the reviewers (α_i) and products (β_j). After that, we construct a 3-mode tensor $\mathbf{X}$, where each slice X_k in $\mathbf{X}$ denotes the link relationship between the reviewers and products in the relation k. Second, we factorize the tensor $\mathbf{X}$ by employing the algorithm RESCAL (Nickel et al., 2011). In the factorization results, A represents the embeddings of the reviewers (α_i) and products (β_j) in the latent space with the collective learning. Third, we concatenate the review text (bigram), the embedding of its reviewer and the reviewed product together, as the representation of the review. Last, the concatenated embedding of the review is fed into a classifier (e.g., SVM) to detect whether it is a fake or non-fake review.

2.1 Relation Matrices Generation

In the review system, there are two kinds of entities: reviewers and products[5]. Each entity has several attributes, e.g., the attribute 'location' of a restaurant is Chicago (the restaurant is regarded as a product). More details are shown in Table 1.

To learn the representations of reviews directly from the data instead of experts' knowledge, we defined two basic patterns:

[5]The product refers to a hotel/restaurant in our experiments.

Reviewer Attribute	Product Attribute
set of reviewed products	set of reviewers
set of reviews (rating score, time)	set of reviews (rating score, time)
website joining date	average rating
friend count	review count
location	location

Table 1: Entities and Attributes

Pattern 1:Record the relationships between two entities.

Pattern 2:Record the relationships between attributes of two entities.

These patterns do not contain any spammer-like prior assumption, just record the natural relation in the original review system. Based on the two basic patterns, we extended 11 interactive relations between entities and their attributes (showed in Table 1). They will be described in detail as follows. Meanwhile, we define that $avg(a_{k,i}) = \frac{1}{n}\sum_{k=1}^{n} a_{k,i}$.

1. **Have reviewed:** This relation records whether a reviewer has reviewed a product. If reviewer α_i reviewed product β_j, the value $X[i,j,1]$ in this relation matrix $X[:,:,1]$ is 1, otherwise it's 0.

2. **Rating score:** What score (1 to 5 star) a reviewer-rated product receives. The value $X[i,j,2] \in \{1,2,...,5\}$.

3. **Commonly reviewed products:** The number of products that a reviewer commonly reviewed with other reviewers. The value $X[i,j,3] = |P_{ij}|, P_{ij} = P_i \cap P_j$; P_i is the product set reviewed by reviewer α_i.

4. **Commonly reviewed time difference:** The time differences that a reviewer who commonly reviews with other reviewers on the same products. The value $X[i,j,4] = \overline{t_i} - \overline{t_j}$, where $\overline{t_i} = avg(t_{k,i})$; $t_{k,i}$ is the time that the reviewer α_i reviewed the product β_k in the P_{ij} set.

5. **Commonly reviewed rating difference:** The rating differences that a reviewer who commonly reviews with other reviewers on the same products. The value $X[i,j,5] = \overline{r_i} - \overline{r_j}$, where $\overline{r_i} = avg(r_{k,i})$; $r_{k,i}$ is the score of the reviewer α_i rated the product β_k in P_{ij} set.

6. **Date difference of websites joined:** The date differences of joining review websites between a reviewer and others. The value $X[i,j,6] = d_i - d_j$, where d_i is the date on which reviewer α_i joining websites.

7. **Average rating difference:** The differences in the average rating of a reviewer over all his reviews compared with other reviewers. The value $X[i,j,7] = \overline{\gamma_i^r} - \overline{\gamma_j^r}$, where $\overline{\gamma_i^r} = avg(\gamma_{k,i}^r)$; $\gamma_{k,i}^r$ is the score with which the reviewer α_i rated the product β_k in P_i.

   The differences in the average rating of a product over all its reviews compared with other products. $X[i,j,7] = \overline{\gamma_i^p} - \overline{\gamma_j^p}$, where $\overline{\gamma_i^p} = avg(\gamma_{k,i}^p)$; $\gamma_{k,i}^p$ is the score of review k in R_i^β, which is the review set for product β_i.

8. **Friend count difference:** The differences in the friend count of a reviewer compared to others. At the review website, a reviewer can make friends with others. The value $X[i,j,8] = f_i - f_j$; where f_i is the friend count of reviewer α_i.

9. **Have the same location or not:** Whether two reviewers/products are from the same city or whether a reviewer has the same location with a product. If two entities have the same location, the value $X[i,j,9] = 1$, otherwise $X[i,j,9] = 0$.

10. **Common reviewers:** The number of the same reviewers that a product has with other products. The value $X[i,j,10] = |\Theta_{ij}|$, where $\Theta_{ij} = \Theta_i \cap \Theta_j$; Θ_i is the set of reviewers who reviewed product β_i.

11. **Review count difference:** The differences in the reviews count of any two reviewers. The value $X[i,j,11] = |R_i^\alpha| - \left|R_j^\alpha\right|$, where R_i^α is the reviews set of reviewer α_i. Or the differences in the reviews count of any two products, where $X[i,j,11] = \left|R_i^\beta\right| - \left|R_j^\beta\right|$, where R_i^β is the reviews set of product β_i.

According to the relations that we present above, we build 11 relation matrices among the reviewers and products. To unify the values of different matrices to a reference system, we normalize with the

sigmoid function. Thus, the value '0' will be normalized to '0.5'. Moreover, we set the values that make no sense to '0', such as the value between two products in Relation 1: Have reviewed. Then, we unite the 11 matrices to form the adjacent tensor. Each of the matrices is a slice of the tensor. The reviewers and products are regarded as the same entities in the tensor. We build two separate tensors for the hotel domain and restaurant domain respectively. Next, we perform tensor factorization to learn the representations (embeddings) of reviewers and products. Note that the word "relation" is normally used for binary (0/1) relations, but some values of aforementioned relations could be between 0 and 1. However, our experiments show that this type of relation is actually practicable. Besides, there is not any spammer-like assumption in the relations. Namely, the values of relations don't indicate how suspicious the reviewers are. The values faithfully reflect the original characteristics of the entire review system. This can help to reduce the need of carefully designing expert features and the understanding of domains as much as possible.

2.2 Learning to Represent Reviews

In general case, a review contains the text, the reviewer and the reviewed product. We firstly learn to represent reviewers and products. As mentioned above, based on the relations, we could construct an adjacency tensor $\mathbf{X}$. Then, we convert the global relation information related reviewers and products into embeddings through tensor factorization, where an efficient factorization algorithm called RESCAL (Nickel et al., 2011) is employed. First, we introduce it briefly.

To identify latent components in a tensor for collective learning, Nickel et al. (2011) proposed RESCAL, which is a tensor factorization algorithm. Given a tensor $X_{n' \times n' \times m'}$, RESCAL aims to have a rank-r approximation, where each slice X_k is factorized as

$$X_k \approx \boldsymbol{A} R_k \boldsymbol{A}^T, \text{ for all } k = 1...m', \qquad (1)$$

$\mathbf{A}$ is an $n' \times r$ matrix, where the i-th row denotes the i-th entity. R_k is an asymmetric $r \times r$ matrix that describes the interactions of the latent components according to the k-th relation. Note that while R_k differs in each slice, $\mathbf{A}$ remains the same.

$\mathbf{A}$ and R_k are derived by minimizing the loss function below.

$$\min_{\boldsymbol{A}, R_k} f(\boldsymbol{A}, R_k) + \lambda \cdot g(\boldsymbol{A}, R_k), \qquad (2)$$

where $f(\boldsymbol{A}, R_k) = \frac{1}{2}(\sum_k \parallel X_k - \boldsymbol{A} R_k \boldsymbol{A}^T \parallel_F^2)$ is the mean-squared reconstruction error, and $g(\boldsymbol{A}, R_k) = \frac{1}{2}(\parallel \boldsymbol{A} \parallel_F^2 + \sum_k \parallel R_k \parallel_F^2)$ is the regularization term.

In our method, slice X_k is the k-th relation above. The i-th entity is the i-th reviewer or product.

As mentioned in Section 2.1, in order to obtain more useful and global information automatically, we collect the relations of any two entities no matter whether they are from the same review page. Then we could embed the informations over multi-relations into the finally learnt representation by the tensor factorization. As Nickel et al. (2011) proved, all the relations have a determining influence on the learnt latent-component representation of the i-th entity. It removes the noise of the original data by learning through the global loss function. Consequently, we get the representation of reviewers and products with a further optimization by the collective learning.

2.3 Detecting Review Spam in Latent Space

After learning the representations of reviewers and products, we begin to represent the reviews that were written by reviewers for the products. Our final purpose is to detect the review spam. We concatenate the review text (bigram), the embedding of a reviewer and the reviewed product as the representation of a review. The representations of the review text by bigram have been proved to be effective in several previous work (Mukherjee et al., 2013b; Rayana and Akoglu, 2015; Kim et al., 2015). It's also a kind of data-driven representation. Then, we take the embeddings of the reviews as the input to the classifiers. Here, we use the linear kernel SVM model to compare with the experimental results in (Mukherjee et al., 2013b) and (Rayana and Akoglu, 2015).

3 Experiments

3.1 Datasets and Evaluation Metrics

Datasets: To evaluate the proposed method, we conducted experiments on Yelp dataset that was used in

previous studies (Mukherjee et al., 2013b; Mukherjee et al., 2013c; Rayana and Akoglu, 2015). Although there are other datasets for evaluation, such as (Jindal and Liu, 2008), (Lim et al., 2010; Xie et al., 2012) and (Ott et al., 2011), they are generated by human labeling or crowd sourcing and have been proved not to be reliable since human labeling fake reviews is quite poor (Ott et al., 2011). There was lack of real-life and nearly ground truth data, until Mukherjee et al. (2013c) proposed the Yelp review dataset. The statistics of the Yelp dataset are listed in Table 2. The reviewed product here refers to a hotel or restaurant.

Evaluation Metrics: We select precision (P), recall (R), F1-Score (F1) and accuracy (A) as metrics.

Domain	Hotel	Restaurant
fake	802	8368
non-fake	4876	50149
%fake	14.1%	14.3%
#reviews	5678	58517
#reviewers	5124	35593

Table 2: Yelp Labeled Dataset Statistics.

3.2 Our Method vs. The State-of-the-art Methods

To illustrate the effectiveness of the proposed approach, we select several state-of-the-arts for comparison. The first one is SPEAGLE$^+$ (Rayana and Akoglu, 2015), which is a kind of graph-based method. The representations of reviews in (Rayana and Akoglu, 2015) are combined with linguistic features, behavioral features and review graph structure features. It's a semi-supervised method. For a fair comparison with our 5-fold CV classification, we set the ratio of labeled data in SPEAGLE$^+$ to 80%. The second one is Mukherjee et al. (2013b). KC and Mukherjee (2016) also conduct experiments on the restaurant subset in Table 2. But they mainly focus on analyzing the effects of temporal dynamics. It's not our focus. So we didn't take it into comparison. In our experiments, we employ behavioral features (Mukherjee_BF) and both of behavioral and linguistic features (Mukherjee_BF+Bigram) proposed in Mukherjee et al. (2013b), respectively. The parameters used in these compared methods are same as the original papers. For our approach, we set the parameter r to 150, λ to 10, and the iteration number to 100.

The compared results are shown in Table 3. We utilize our learnt embeddings of reviewers (Ours_RE), both of reviewers' embeddings and products' embeddings (Ours_RE+PE), respectively. Moreover, to perform fair comparison, like Mukherjee et al. (2013b), we add representations of the review text in classifier (Ours_RE+PE+Bigram). From the results, we can observe that our method could outperform all state-of-the-arts in both the hotel and restaurant domains. It proves that our method is effective. Furthermore, the improvements in both the hotel and restaurant domains prove that our model possesses preferable domain-adaptability. It could represent the reviews more accurately and globally by learning from the original data, rather than the experts' knowledge or assumption.

3.3 The Effectiveness of Learning to Represent Review

To further prove the representations learnt by our method are effective for detecting review spam, we compare the learnt representation (embeddings) of reviewers (Ours_RE) (Table 3 (a,b) rows 7, 8) with existing behavioral features of reviewers (Mukherjee_BF) (Mukherjee et al., 2013b) (Table 3 (a,b) rows 3, 4). In results, using the learnt reviewers' representations in our method, results in around 2.0% (in 50:50) and 4.0% (in N.D.) improvement in F1 and A in the hotel domain, and results in around 2.1% (in 50:50) and 7.0%(in N.D.) improvement in F1 and A in the restaurant domain. These results show that our data-driven representations of reviewers are more helpful for review spam detection than existing reviewers' behavioral features, and that new method embeds more useful and accurate information from the original data. It isn't limited to experts' knowledge. Moreover, the latent representations are more robust because they are hardly perceived by spammers. Having realized the explicit existing behavioral features, crafty spammers tend to change their spamming strategies. Consider the feature "Review Length", which is used in (Mukherjee et al., 2013b), as an example. They find that the average review length of the spammers is quite short compared with non-spammers. However, once a crafty spammer realizes that he left this type of footprint, he could produce a review that is as long as the non-

spammers to pretend to be a normal reviewer. Besides, as there isn't any spammer-like assumption in our extended relations (Section 2.1), crafty spammers have little influence on them.

We also compared existing behavioral features (BF) (Mukherjee et al., 2013b) with detecting review spam by only employing the 11 generated relations (Rels). We take the relation matrix row of each reviewer as the representations of the reviews. According to the results shown in Figure 2, the 11 generated relations (Rels) results in an obvious improvement than the existing behavioral features (BF) (Mukherjee et al., 2013b) (Table 3 (a,b) row 3) in both the hotel and restaurant domains. It proves that the generated relations could obtain more useful and global informations, as they collect the relations of any entities (reviewers and products) regardless of whether they are from the same review page. Furthermore, Figure 2 also showed that the embeddings of reviewers (RE) learnt by the tensor decomposition perform better than the Rels. As we mentioned in Section 2.2, the tensor decomposition embeds the informations over all the relations collectively, and removes the noise of the original data by learning through the global loss function. Consequently, we get the representations with a further optimization.

3.4 The Effectiveness of Product Embeddings

In general case, a review contains the review text, the reviewer and the reviewed product. But most of the previous work represent the reviews with the reviewers' behavioral features and the reviews' linguistic features. The products are seldom represented. As shown in Table 3 (a,b) rows 9,10 , the representations which added the products embeddings

perform better than just using the reviewer embeddings. Statistics of the datasets suggest that there are about 1% of spammers who not only write fake reviews, but also write non-fake reviews. Liu (2015) also proved that some reviewers have contributed many genuine reviews and have built up their reputation; then they started to spam for some businesses, or even sell their accounts to spammers. Compared with previous work, our method by adding product embeddings could distinguish the reviews of the same reviewer for different products.

3.5 The Effects of Different Relations

We also drop relations of our method with a graceful degradation. Table 4 shows the performances of our method utilizing BF+PE+Bigram for hotel and restaurant domains. We found that dropping Relations 1, 2 and 10 results in a relatively gentle reduction (about 2.2%) in F1-score. According to our survey, the sparseness of the slices generated by Relation 1, 2 and 10 is about 99.9%. For this reason, the result is a relatively gentle reduction. Dropping other relations also result in a 2.5-4.0% performance reduction. It proves that each relation has an influence on the learning to represent reviews.

4 Related Work

Jindal and Liu (2008) first propose the problem of review spam detection. They identify three categories of spam: fake reviews (also called untruthful opinions), reviews on the brand only, and non-reviews.Stepping studies focus on studying fake reviews because of its difficulty to be detected. Most efforts are devoted to represent fake and non-fake reviews with effective features.

Linguistic Features Ott et al. (2011) apply psychological and linguistic clues to identify review spam. They produce the first dataset of gold-standard deceptive review spam, employing crowdsourcing through the Amazon Mechanical Turk. Harris (2012) explores several human- and machine-based assessment methods with writing style features. Feng et al. (2012a) investigate syntactic stylometry for review spam detection. Li et al. (2013) propose a generative LDA-based topic modeling approach for fake review detection. They (Li et al., 2014b) further investigate the general difference of language usage between deceptive and truthful reviews. Li et al. (2014a) propose a positive-unlabeled learning method base on unigrams and bigrams. Kim et al. (2015) carry out a frame-based deep semantic analysis on deceptive opinions.

Behavioral Features Lim et al. (2010) investigate reviewers' rating behavioral features. Jindal et al. (2010) identify unusual review patterns which can represent suspicious behaviors of reviews. Li et al. (2011) provide a two-view semi-supervised method, co-training method base on behavioral features. Feng et al. (2012b) study the distributions of behavioral features. Xie et al. (2012) explore the singleton reviews with abnormal temporal patterns. Mukherjee et al. (2012) study the group spammers' behavioral features. Mukherjee et al. (2013a) propose a principal method which models the spamicity of reviewers. Fei et al. (2013) model the reviewers' co-occurrence in review bursts. Mukherjee et al. (2013c) prove that reviewers' behavioral features are more effective than reviews' linguistic features for detecting review spam. Li et al. (2015) explore the temporal and spatial patterns at Dianping.com. KC and Mukherjee (2016) analyze the temporal dynamics of opinion spamming.

Graph Structure Wang et al. (2011) investigate the review graph features of online store review. Akoglu et al. (2013) exploit the network effect among reviewers and products.

Combined Features There are also some work which explores methods via the combined features referred above. Mukherjee et al. (2013b) prose a method base on the linguistic features and behavioral features. Rayana and Akoglu (2015) propose a model that utilizes clues from review text, reviewers' behaviors and the review graph structure.

5 Conclusion and Future Work

This paper proposes a new review spam detection method that learns the representations of reviews instead of heavily relying on experts' knowledge in a data-driven manner. A 3-mode tensor is built on the relations which are generated from two patterns, and a tensor factorization algorithm is used to automatically learn the vector representations of reviewers and products. Afterwards, we concatenate the review text, the embedding of a reviewer and the

reviewed product as the representation of a review. Then, a classifier is applied to detect the review spam. Experimental results prove the effectiveness of the proposed method, which learns more robust review representations. In future work, we plan to explore a more effective way to learn the embeddings of review text.

Abstract

Stance detection is the task of classifying the attitude Previous work has assumed that either the target is mentioned in the text or that training data for every target is given. This paper considers the more challenging version of this task, where targets are not always mentioned and no training data is available for the test targets. We experiment with conditional LSTM encoding, which builds a representation of the tweet that is dependent on the target, and demonstrate that it outperforms encoding the tweet and the target independently. Performance is improved further when the conditional model is augmented with bidirectional encoding. We evaluate our approach on the SemEval 2016 Task 6 Twitter Stance Detection corpus achieving performance second best only to a system trained on semi-automatically labelled tweets for the test target. When such weak supervision is added, our approach achieves state–of-the-art results.

1 Introduction

The goal of stance detection is to classify the attitude expressed in a text towards a given target, as "positive", "negative", or "neutral". Such information can be useful for a variety of tasks, e.g. Mendoza et al. (2010) showed that tweets stating actual facts were affirmed by 90% of the tweets related to them, while tweets conveying false information were predominantly questioned or denied. In this paper we focus on a novel stance detection task, namely tweet stance detection towards previously unseen targets (mostly entities such as politicians or issues of public interest), as defined in the SemEval Stance Detection for Twitter task (Mohammad et al., 2016). This task is rather difficult, firstly due to not having training data for the targets in the test set, and secondly, due to the targets not always being mentioned in the tweet. For example, the tweet "@realDonaldTrump is the only honest voice of the @GOP" expresses a positive stance towards the target *Donald Trump*. However, when stance is annotated with respect to *Hillary Clinton* as the implicit target, this tweet expresses a negative stance, since supporting candidates from one party implies negative stance towards candidates from other parties.

Thus the challenge is twofold. First, we need to learn a model that interprets the tweet stance towards a target that might not be mentioned in the tweet itself. Second, we need to learn such a model without labelled training data for the target with respect to which we are predicting the stance. In the example above, we need to learn a model for *Hillary Clinton* by only using training data for other targets. While this renders the task more challenging, it is a more realistic scenario, as it is unlikely that labelled training data for each target of interest will be available.

To address these challenges we develop a neural network architecture based on conditional encoding (Rocktäschel et al., 2016). A long-short term memory (LSTM) network (Hochreiter and Schmidhuber, 1997) is used to encode the target, followed by a second LSTM that encodes the tweet using the encoding of the target as its initial state. We show that this approach achieves better F1 than an SVM baseline, or an independent LSTM encoding of the tweet and the target. Results improve fur-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 876–885,
Austin, Texas, November 1-5, 2016.

ther (0.4901 F1) with a bidirectional version of our model, which takes into account the context on either side of the word being encoded. In the context of the shared task, this would have been the second best result, except for an approach which uses automatically labelled tweets for the test targets (F1 of 0.5628). Lastly, when our bidirectional conditional encoding model is trained on such data, it achieves state-of-the-art performance (0.5803 F1).

2 Task Setup

The SemEval 2016 Stance Detection for Twitter shared task (Mohammad et al., 2016) consists of two subtasks, Task A and Task B. In Task A the goal is to detect the stance of tweets towards targets given labelled training data for all test targets (*Climate Change is a Real Concern*, *Feminist Movement*, *Atheism*, *Legalization of Abortion* and *Hillary Clinton*). In Task B, which is the focus of this paper, the goal is to detect stance with respect to an unseen target, *Donald Trump*, for which labeled training/development data is not provided.

Systems need to classify the stance of each tweet as "positive" (FAVOR), "negative" (AGAINST) or "neutral" (NONE) towards the target. The official metric reported for the shared task is F1 macro-averaged over the classes FAVOR and AGAINST. Although the F1 of NONE is not considered, systems still need to predict it to avoid precision errors for the other two classes.

Even though participants were not allowed to manually label data for the test target *Donald Trump*, they were allowed to label data automatically. The two best-performing systems submitted to Task B, pkudblab (Wei et al., 2016) and LitisMind (Zarrella and Marsh, 2016) made use of this, thus changing the task to weakly supervised seen target stance detection, instead of an unseen target task. Although the goal of this paper is to present stance detection methods for targets for which no training data is available, we show that they can also be used successfully in a weakly supervised framework and outperform the state-of-the-art on the SemEval 2016 Stance Detection for Twitter dataset.

3 Methods

A common stance detection approach is to treat it as a sentence-level classification task similar to sentiment analysis (Pang and Lee, 2008; Socher et al., 2013). However, such an approach cannot capture the stance of a tweet with respect to a particular target, unless training data is available for each of the test targets. In such cases, we could learn that a tweet mentioning *Donald Trump* in a positive manner expresses a negative stance towards *Hillary Clinton*. Despite this limitation, we use two such baselines, one implemented with a Support Vector Machine (SVM) classifier and one with an LSTM network, in order to assess whether we are successful in incorporating the target in stance prediction.

A naive approach to incorporate the target in stance prediction would be to generate features concatenating the target with words from the tweet. Ignoring the issue that such features would be rather sparse, a classifier could learn that some words have target-dependent stance weights, but it still assumes that training data is available for each target.

In order to learn how to combine the stance target with the tweet in a way that generalises to unseen targets, we focus on learning distributed representations and ways to combine them. The following sections develop progressively the proposed bidirectional conditional LSTM encoding model, starting from independently encoding the tweet and the target using LSTMs.

3.1 Independent Encoding

Our initial attempt to learn distributed representations for the tweets and the targets is to encode the target and tweet independently as k-dimensional dense vectors using two LSTMs (Hochreiter and Schmidhuber, 1997).

$$
\begin{aligned}
\mathbf{H} &= \begin{bmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{bmatrix} \\
\mathbf{i}_t &= \sigma(\mathbf{W}^i \mathbf{H} + \mathbf{b}^i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}^f \mathbf{H} + \mathbf{b}^f) \\
\mathbf{o}_t &= \sigma(\mathbf{W}^o \mathbf{H} + \mathbf{b}^o) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tanh(\mathbf{W}^c \mathbf{H} + \mathbf{b}^c) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned}
$$

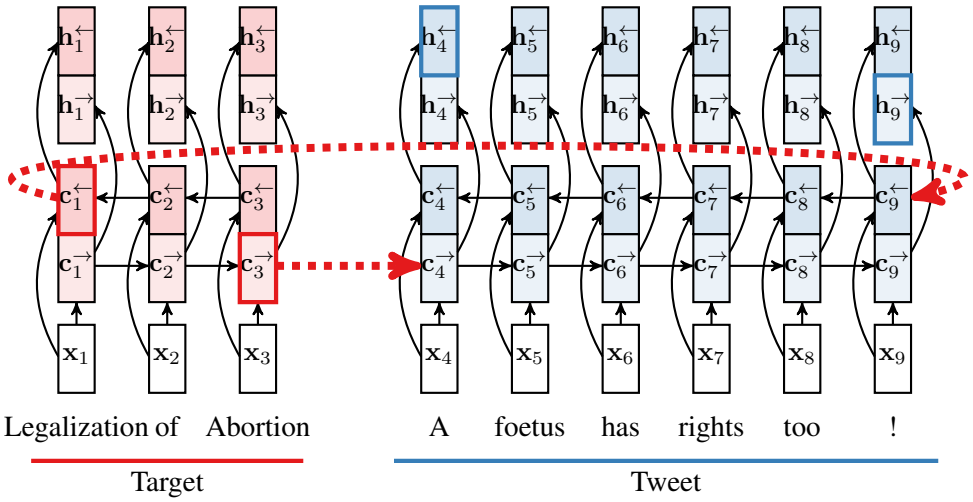

Figure 1: Bidirectional encoding of tweet conditioned on bidirectional encoding of target ($[\mathbf{c}_3^{\rightarrow}\ \mathbf{c}_1^{\leftarrow}]$). The stance is predicted using the last forward and reversed output representations ($[\mathbf{h}_9^{\rightarrow}\ \mathbf{h}_4^{\leftarrow}]$).

Here, $\mathbf{x}_t$ is an input vector at time step t, $\mathbf{c}_t$ denotes the LSTM memory, $\mathbf{h}_t \in \mathbb{R}^k$ is an output vector and the remaining weight matrices and biases are trainable parameters. We concatenate the two output vector representations and classify the stance using the softmax over a non-linear projection

$$\text{softmax}(\tanh(\mathbf{W}^{\text{ta}}\mathbf{h}_{\text{target}} + \mathbf{W}^{\text{tw}}\mathbf{h}_{\text{tweet}} + \mathbf{b}))$$

into the space of the three classes for stance detection where $\mathbf{W}^{\text{ta}}, \mathbf{W}^{\text{tw}} \in \mathbb{R}^{3\times k}$ are trainable weight matrices and $\mathbf{b} \in \mathbb{R}^3$ is a trainable class bias. This model learns target-independent distributed representations for the tweets and relies on the non-linear projection layer to incorporate the target in the stance prediction.

3.2 Conditional Encoding

In order to learn target-dependent tweet representations, we use conditional encoding as previously applied to the task of recognising textual entailment (Rocktäschel et al., 2016). We use one LSTM to encode the target as a fixed-length vector. Then, we encode the tweet with another LSTM, whose state is initialised with the representation of the target. Finally, we use the last output vector of the tweet LSTM to predict the stance of the target-tweet pair.

Formally, let $(\mathbf{x}_1, \ldots, \mathbf{x}_T)$ be a sequence of target word vectors, $(\mathbf{x}_{T+1}, \ldots, \mathbf{x}_N)$ be a sequence of tweet word vectors and $[\mathbf{h}_0\ \mathbf{c}_0]$ be a start state of zeros. The two LSTMs map input vectors and a previous state to a next state as follows:

$$\begin{aligned}
[\mathbf{h}_1\ \mathbf{c}_1] &= \text{LSTM}^{\text{target}}(\mathbf{x}_1, \mathbf{h}_0, \mathbf{c}_0) \\
&\ldots \\
[\mathbf{h}_T\ \mathbf{c}_T] &= \text{LSTM}^{\text{target}}(\mathbf{x}_T, \mathbf{h}_{T-1}, \mathbf{c}_{T-1}) \\
[\mathbf{h}_{T+1}\ \mathbf{c}_{T+1}] &= \text{LSTM}^{\text{tweet}}(\mathbf{x}_{T+1}, \mathbf{h}_0, \mathbf{c}_T) \\
&\ldots \\
[\mathbf{h}_N\ \mathbf{c}_N] &= \text{LSTM}^{\text{tweet}}(\mathbf{x}_N, \mathbf{h}_{N-1}, \mathbf{c}_{N-1})
\end{aligned}$$

Finally, the stance of the tweet w.r.t. the target is classified using a non-linear projection

$$\mathbf{c} = \tanh(\mathbf{W}\mathbf{h}_N)$$

where $\mathbf{W} \in \mathbb{R}^{3\times k}$ is a trainable weight matrix. This effectively allows the second LSTM to read the tweet in a target-specific manner, which is crucial since the stance of the tweet depends on the target (recall the Donald Trump example above).

3.3 Bidirectional Conditional Encoding

Bidirectional LSTMs (Graves and Schmidhuber, 2005) have been shown to learn improved representations of sequences by encoding a sequence from left to right and from right to left. Therefore, we adapt the conditional encoding model from Section 3.2 to use bidirectional LSTMs, which represent the target and the tweet using two vectors for each of them, one obtained by reading the target

and then the tweet left-to-right (as in the conditional LSTM encoding) and one obtained by reading them right-to-left. To achieve this, we initialise the state of the bidirectional LSTM that reads the tweet by the last state of the forward and reversed encoding of the target (see Figure 1). The bidirectional encoding allows the model to construct target-dependent representations of the tweet such that when a word is considered, both its left- and the right-hand side context are taken into account.

3.4 Unsupervised Pretraining

In order to counter-balance the relatively small amount of training data available (5,628 instances in total), we employ unsupervised pre-training by initialising the word embeddings used in the LSTMs with an appropriately trained word2vec model (Mikolov et al., 2013). Note that these embeddings are used only for initialisation, as we allow them to be optimised further during training.

In more detail, we train a word2vec model on a corpus of 395,212 unlabelled tweets, collected with the Twitter Keyword Search API[1] between November 2015 and January 2016, plus all the tweets contained in the official SemEval 2016 Stance Detection datasets (Mohammad et al., 2016). The unlabelled tweets are collected so that they contain the targets considered in the shared task, using up to two keywords per target, namely "hillary", "clinton", "trump", "climate", "femini", "aborti". Note that Twitter does not allow for regular expression search, so this is a free text search disregarding possible word boundaries. We combine this large unlabelled corpus with the official training data and train a skip-gram word2vec model (dimensionality 100, 5 min words, context window of 5).

Tweets and targets are tokenised with the Twitter-adapted tokeniser twokenize[2]. Subsequently, all tokens are lowercased, URLs are removed, and stopword tokens are filtered (i.e. punctuation characters, Twitter-specific stopwords ("rt", "#semst", "via").

As it will be shown in our experiments, unsupervised pre-training is quite helpful, since it is difficult to learn representations for all the words using only the relatively small training datasets available.

Crawled_Unlab*	-	-	-	395,212

Table 1: Data sizes of available corpora. TaskA_Tr+Dv_HC is the part of TaskA_Tr+Dv with tweets for the target Hillary Clinton only, which we use for development. TaskB_Auto-lab is an automatically labelled version of TaskB_Unlab. Crawled_Unlab is an unlabelled tweet corpus collected by us.

Finally, to ensure that the proposed neural network architectures contribute to the performance, we also use the word vectors from word2vec to develop a Bag-of-Word-Vectors baseline (BOWV), in which the tweet and target representations are fed into a logistic regression classifier with L2 regularization (Pedregosa et al., 2011).

4 Experiments

Experiments are performed on the SemEval 2016 Task 6 corpus for Stance Detection on Twitter (Mohammad et al., 2016). We report experiments for two different experimental setups: one is the *unseen target* setup (Section 5), which is the main focus of this paper, i.e. detecting the stance of tweets towards previously unseen targets. We show that conditional encoding, by reading the tweets in a target-specific way, generalises to unseen targets better than baselines which ignore the target. Next, we compare our approach to previous work in a *weakly supervised framework* (Section 6) and show that our approach outperforms the state-of-the-art on the SemEval 2016 Stance Detection Subtask B corpus.

Table 1 lists the various corpora used in the experiments and their sizes. TaskA_Tr+Dv is the official SemEval 2016 Twitter Stance Detection TaskA training and development corpus, which contain instances for the targets *Legalization of Abortion*, *Atheism*, *Feminist Movement*, *Climate Change is a Real Concern* and *Hillary Clinton*. TaskA_Tr+Dv_HC is the part of the corpus which contains only the *Hillary Clinton* tweets, which we use for development purposes. TaskB_Test is the TaskB test corpus on which we report results containing *Donald Trump* testing instances.

TaskB_Unlab is an unlabelled corpus containing *Donald Trump* tweets supplied by the task organisers, and TaskB_Auto-lab* is an automatically labelled version of a small portion of the corpus for the weakly supervised stance detection experiments reported in Section 6. Finally, Crawled_Unlab* is a corpus we collected for unsupervised pre-training (see Section 3.4).

For all experiments, the official task evaluation script is used. Predictions are post processed so that if the target is contained in a tweet, the highest-scoring non-neutral stance is chosen. This was motivated by the observation that in the training data most target-containing tweets express a stance, with only 16% of them being neutral. The code used in our experiments is available from `https://github.com/sheffieldnlp/stance-conditional`.

4.1 Methods

We compare the following baseline methods:

- SVM trained with word and character tweet n-grams features (SVM-ngrams-comb) Mohammad et al. (2016)
- a majority class baseline (Majority baseline), reported in (Mohammad et al., 2016)
- bag of word vectors (BoWV) (see Section 3.4)
- independent encoding of tweet and the target with two LSTMs (Concat) (see Section 3.1)
- encoding of the tweet only with an LSTM (TweetOnly) (see Section 3.1)

to three versions of conditional encoding:

- target conditioned on tweet (TarCondTweet)
- tweet conditioned on target (TweetCondTar)
- a bidirectional encoding model (BiCond)

5 Unseen Target Stance Detection

As explained earlier, the challenge is to learn a model without any manually labelled training data for the test target, but only using the data from the Task A targets. In order to avoid using any labelled data for *Donald Trump*, while still having a (labelled) development set to tune and evaluate our models, we used the tweets labelled for *Hillary Clinton* as a development set and the tweets for the remaining four targets as training. We refer to this as the *development setup*, and all models are tuned using this setup. The labelled *Donald Trump* tweets were only used in reporting our final results.

Table 2: Results for the *unseen target* stance detection development setup.

For the final results we train on all the data from the development setup and evaluate on the official Task B test set, i.e. the *Donald Trump* tweets. We refer to this as our *test setup*.

Based on a small grid search using the development setup, the following settings for LSTM-based models were chosen: input layer size 100 (equal to the word embedding dimension), hidden layer size of 60, training for max 50 epochs with initial learning rate 1e-3 using ADAM (Kingma and Ba, 2014) for optimisation, dropout 0.1. Models were trained using cross-entropy loss. The use of one, relatively small hidden layer and dropout help to avoid overfitting.

5.1 Results and Discussion

Results for the unseen target setting show how well conditional encoding is suited for learning target-dependent representations of tweets, and crucially, how well such representations generalise to unseen targets. The best performing method on both development (Table 2) and test setups (Table 3) is BiCond, which achieves an F1 of 0.4722 and 0.4901 respectively. Notably, Concat, which learns an in-

Table 5: Results for the *unseen target* stance detection development setup for tweets containing the target vs tweets not containing the target.

that learn to condition the encoding of tweets on targets outperform all baselines on the test set.

It is further worth noting that the Bag-of-Word-Vectors baseline achieves results comparable with TweetOnly, Concat and one of the conditional encoding models, TarCondTweet, on the dev set, even though it achieves significantly lower performance on the test set. This indicates that the pre-trained word embeddings on their own are already very useful for stance detection. This is consistent with findings of other works showing the usefulness of such a Bag-of-Word-Vectors baseline for the related tasks of recognising textual entailment Bowman et al. (2015) and sentiment analysis Eisner et al. (2016).

Our best result in the test setup with BiCond is the second highest reported result on the Twitter Stance Detection corpus, however the first, third and fourth best approaches achieved their results by automatically labelling *Donald Trump* training data. BiCond for the unseen target setting outperforms the third and fourth best approaches by a large margin (5 and 7 points in Macro F1, respectively), as can be seen in Table 7. Results for weakly supervised stance detection are discussed in Section 6.

Pre-Training Table 4 shows the effect of unsupervised pre-training of word embeddings with a word2vec skip-gram model, and furthermore, the results of sharing of these representations between the tweets and targets, on the development set. The first set of results is with a uniformly Random embedding initialisation in $[-0.1, 0.1]$. PreFixed uses the pre-trained skip-gram word embeddings, whereas PreCont initialises the word embeddings with ones from SkipGram and continues training them during LSTM training. Our results show that, in the absence of a large labelled training dataset, pre-training of word embeddings is more helpful than random initialisation of embeddings. Sing vs Sep shows the difference between using shared vs two separate embeddings matrices for looking up the word embeddings. Sing means the word representations for tweet and target vocabularies are shared, whereas Sep means they are different. Using shared embeddings performs better, which we hypothesise is because the tweets contain some mentions of targets that are tested.

Target in Tweet vs Not in Tweet Table 5 shows results on the development set for BiCond, compared to the best unidirectional encoding model, TweetCondTar and the baseline model Concat, split by tweets that contain the target and those that do not. All three models perform well when the target is mentioned in the tweet, but less so when the targets are not mentioned explicitly. In the case where the target is mentioned in the tweet, biconditional encoding outperforms unidirectional encoding and unidirectional encoding outperforms Concat. This shows that conditional encoding is able to learn useful dependencies between the tweets and the targets.

6 Weakly Supervised Stance Detection

The previous section showed the usefulness of conditional encoding for unseen target stance detection and compared results against internal baselines. The goal of experiments reported in this section is to compare against participants in the SemEval 2016 Stance Detection Task B. While we consider an *unseen target* setup, most submissions, including the three highest ranking ones for Task B, pkudblab (Wei et al., 2016), LitisMind (Zarrella and Marsh, 2016) and INF-UFRGS (Dias and Becker, 2016) considered a different experimental setup. They automatically annotated training data for the test target *Donald Trump*, thus converting the task into weakly supervised seen target stance detection. The pkudblab system uses a deep convolutional neural network that learns to make 2-way predictions on automatically labelled positive and negative training data for *Donald Trump*. The neutral class is predicted according to rules which are applied at test time.

	Macro			**0.5803**

Table 6: Stance Detection test results for weakly supervised setup, trained on automatically labelled pos+neg+neutral Trump data, and reported on the official test set.

Since the best performing systems which participated in the shared task consider a weakly supervised setup, we further compare our proposed approach to the state-of-the-art using such a weakly supervised setup. Note that, even though pkudblab, LitisMind and INF-UFRGS also use regular expressions to label training data automatically, the resulting datasets were not available to us. Therefore, we had to develop our own automatic labelling method and dataset, which are publicly available from our code repository.

Weakly Supervised Test Setup For this setup, the unlabelled *Donald Trump* corpus TaskB_Unlab is annotated automatically. For this purpose we cre-

ated a small set of regular expressions[3], based on inspection of the TaskB_Unlab corpus, expressing positive and negative stance towards the target. The regular expressions for the positive stance were:

- make(?)america(?)great(?)again
- trump(?)(for|4)(?)president
- votetrump
- trumpisright
- the truth
- #trumprules

The keyphrases for negative stance were: #dumptrump, #notrump, #trumpwatch, racist, idiot, fired

A tweet is labelled as positive if one of the positive expressions is detected, else negative if a negative expressions is detected. If neither are detected, the tweet is annotated as neutral randomly with 2% chance. The resulting corpus size per stance is shown in Table 1. The same hyperparameters for the LSTM-based models are used as for the *unseen target* setup described in the previous section.

6.1 Results and Discussion

Table 6 lists our results in the weakly supervised setting. Table 7 shows all our results, including those using the unseen target setup, compared against the state-of-the-art on the stance detection corpus. Table 7 further lists baselines reported by Mohammad et al. (2016), namely a majority class baseline (Majority baseline), and a method using 1 to 3-gram bag-of-word and character n-gram features (SVM-ngrams-comb), which are extracted from the tweets and used to train a 3-way SVM classifier.

Bag-of-word baselines (BoWV, SVM-ngrams-comb) achieve results comparable to the majority baseline (F1 of 0.2972), which shows how difficult the task is. The baselines which only extract features from the tweets, SVM-ngrams-comb and TweetOnly perform worse than the baselines which also learn representations for the targets (BoWV, Concat). By training conditional encoding models on automatically labelled stance detection data we achieve state-of-the-art results. The best result (F1 of 0.5803) is achieved with the bi-directional conditional encoding model (BiCond). This shows that such models are suitable for unseen, as well as seen target stance detection.

7 Related Work

Stance Detection: Previous work mostly considered target-specific stance prediction in debates (Hasan and Ng, 2013; Walker et al., 2012) or student essays (Faulkner, 2014). The task considered in this paper is more challenging than stance detection in debates because, in addition to irregular language, the Mohammad et al. (2016) dataset is offered without any context, e.g., conversational structure or tweet metadata. The targets are also not always mentioned in the tweets, which is an additional challenge (Augenstein et al., 2016) and distinguishes this task from target-dependent (Vo and Zhang, 2015; Zhang et al., 2016; Alghunaim et al., 2015) and open-domain target-dependent sentiment analysis (Mitchell et al., 2013; Zhang et al., 2015). Related work on rumour stance detection either requires training data from the same ru-

mour (Qazvinian et al., 2011), i.e., target, or is rule-based (Liu et al., 2015) and thus potentially hard to generalise. Finally, the target-dependent stance detection task tackled in this paper is different from that of Ferreira and Vlachos (2016), which while related concerned with the stance of a statement in natural language towards another statement.

Conditional Encoding: Conditional encoding has been applied to the related task of recognising textual entailment (Rocktäschel et al., 2016), using a dataset of half a million training examples (Bowman et al., 2015) and numerous different hypotheses. Our experiments here show that conditional encoding is also successful on a relatively small training set and when applied to an unseen testing target. Moreover, we augment conditional encoding with bidirectional encoding and demonstrate the added benefit of unsupervised pre-training of word embeddings on unlabelled domain data.

8 Conclusions and Future Work

This paper showed that conditional LSTM encoding is a successful approach to stance detection for unseen targets. Our unseen target bidirectional conditional encoding approach achieves the second best results reported to date on the SemEval 2016 Twitter Stance Detection corpus. In the weakly supervised seen target scenario, as considered by prior work, our approach achieves the best results to date on the SemEval Task B dataset. We further show that in the absence of large labelled corpora, unsupervised pre-training can be used to learn target representations for stance detection and improves results on the SemEval corpus. Future work will investigate further the challenge of stance detection for tweets which do not contain explicit mentions of the target.

Abstract

Convolutional neural networks (CNN) have achieved the top performance for event detection due to their capacity to induce the underlying structures of the k-grams in the sentences. However, the current CNN-based event detectors only model the consecutive k-grams and ignore the non-consecutive k-grams that might involve important structures for event detection. In this work, we propose to improve the current CNN models for ED by introducing the non-consecutive convolution. Our systematic evaluation on both the general setting and the domain adaptation setting demonstrates the effectiveness of the non-consecutive CNN model, leading to the significant performance improvement over the current state-of-the-art systems.

1 Introduction

The goal of event detection (ED) is to locate event triggers of some specified types in text. Triggers are generally single verbs or nominalizations that evoke the events of interest. This is an important and challenging task of information extraction in natural language processing (NLP), as the same event might appear in various expressions, and an expression might express different events depending on contexts.

The current state-of-the-art systems for ED have involved the application of convolutional neural networks (CNN) (Nguyen and Grishman, 2015b; Chen et al., 2015) that automatically learn effective feature representations for ED from sentences. This has overcome the two fundamental limitations of the traditional feature-based methods for ED: (i) the complicated feature engineering for rich feature sets and (ii) the error propagation from the NLP toolkits and resources (i.e, parsers, part of speech taggers etc) that generate such features.

The prior CNN models for ED are characterized by the temporal convolution operators that linearly map the vectors for the k-grams in the sentences into the feature space. Such k-gram vectors are obtained by concatenating the vectors of the k consecutive words in the sentences (Nguyen and Grishman, 2015b; Chen et al., 2015). In other words, the previous CNN models for ED only focus on modeling the consecutive k-grams. Unfortunately, such consecutive mechanism is unable to capture the long-range and non-consecutive dependencies that are necessary to the prediction of trigger words. For instance, consider the following sentence with the trigger word "*leave*" from the ACE 2005 corpus:

*The mystery is that she took the job in the first place or didn't **leave** earlier.*

The correct event type for the trigger word "*leave*" in this case is "*End-Org*". However, the previous CNN models might not be able to detect "*leave*" as an event trigger or incorrectly predict its type as "*Movement*". This is caused by their reliance on the consecutive local k-grams such as "*leave earlier*". Consequently, we need to resort to the non-consecutive pattern "*job leave*" to correctly determine the event type of "*leave*" in this case.

Guided by this intuition, we propose to improve the previous CNN models for ED by operating the convolution on all possible non-consecutive k-grams

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 886–891,
Austin, Texas, November 1-5, 2016.

in the sentences. We aggregate the resulting convolution scores via the *max-pooling* function to unveil the most important non-consecutive k-grams for ED. The aggregation over all the possible non-consecutive k-grams is made efficient with dynamic programming.

Note that our work is related to (Lei et al., 2015) who employ the non-consecutive convolution for the sentence and news classification problems. Our work is different from (Lei et al., 2015) in that we model the relative distances of words to the trigger candidates in the sentences via position embeddings, while (Lei et al., 2015) use the absolute distances between words in the k-grams to compute the decay weights for aggregation. To the best of our knowledge, this is the first work on non-consecutive CNN for ED.

We systematically evaluate the proposed model in the general setting as well as the domain adaptation setting. The experiment results demonstrate that our model significantly outperforms the current state-of-the-art models in such settings.

2 Model

We formalize ED as a multi-class classification problem. Given a sentence, for every token in that sentence, we want to predict if the current token is an event trigger of some event in the pre-defined event set or not? The current token along with its context in the sentence constitute an event trigger candidate.

In order to make it compatible with the previous work, we follow the procedure in (Nguyen and Grishman, 2015b) to process the trigger candidates for CNN. In particular, we limit the context of the trigger candidates to a fixed window size by trimming longer sentences and padding shorter sentences with a special token when necessary. Let $2n + 1$ be the fixed window size, and $W = [w_0, w_1, \ldots, w_n, \ldots, w_{2n-1}, w_{2n}]$ be some trigger candidate where the current token is positioned in the middle of the window (token w_n). Before entering CNN, each token w_i is first transformed into a real-valued vector x_i using the concatenation of the following vectors:

1. The word embedding vector of w_i: This is obtained by looking up a pre-trained word embedding table D (Turian et al., 2010; Mikolov et al., 2013a).

2. The position embedding vector of w_i: We obtain this vector by looking up the position embedding table for the relative distance $i - n$ from the token w_i to the current token w_n. The position embedding table is initialized randomly.

3. The real-valued embedding vector for the entity type of w_i: This vector is generated by looking up the entity type embedding table (initialized randomly) for the entity type of w_i. Note that we employ the BIO annotation schema to assign entity type labels to each token in the sentences using the entity mention heads as in (Nguyen and Grishman, 2015b).

The transformation from the token w_i to the vector x_i ($x_i \in \mathbb{R}^d$) essentially converts the input candidate W into a sequence of real-valued vectors $X = (x_0, x_1, \ldots, x_{2n})$. This sequence is used as input in the following CNN models.

2.1 The Traditional CNN

Given the window size k, the traditional CNN models for ED consider the following set of $2n + 1$ consecutive k-gram vectors:

$$C = \{u_i : 0 \leq i \leq 2n\} \quad (1)$$

Vector u_i is the concatenation of the k consecutive vectors preceding position i in the sequence X: $u_i = [x_{i-k+1}, x_{i-k+2}, \ldots, x_i] \in \mathbb{R}^{dk}$ where the out-of-index vectors are simply set to all zeros.

The core of the CNN models is the convolution operation, specified by the filter vector $\mathbf{f} \in \mathbb{R}^{dk}$. In CNN, $\mathbf{f}$ can be seen as a feature extractor for the k-grams that operates via the dot product with each element in C. This produces the following convolution score set: $S(C) = \{\mathbf{f}^T u_i : 0 \leq i \leq 2n\}$.

In the next step, we aggregate the features in S with the $\max$ function, resulting in the aggregation score:

$$p_k^{\mathbf{f}} = \max S(C) = \max\{s_i : 0 \leq i \leq 2n\} \quad (2)$$

Afterward, $p_k^{\mathbf{f}}$ is often transformed by a non-linear function G[1] to generate the transformed score $G(p_k^{\mathbf{f}})$, functioning as the extracted feature for the initial trigger candidate W.

[1] The `tanh` function in this work.

We can then repeat this process for different window sizes k and filters $\mathbf{f}$, generating multiple features $G(p_k^{\mathbf{f}})$ to capture various aspects of the trigger candidate W. Finally, such features are concatenated into a single representation vector for W, to be fed into a feed-forward neural network with a softmax layer in the end to perform classification.

2.2 The Non-consecutive CNN

As mentioned in the introduction, the limitation of the previous CNN models for ED is the inability to encode the non-consecutive k-grams that might be crucial to the trigger prediction. This limitation originates from Equation 1 in which only the consecutive k-gram vectors are considered. In order to overcome such limitation, we propose to model all possible non-consecutive k-grams in the trigger candidate, leading to the following set of non-consecutive k-gram vectors:

$$N = \{v_{i_1 i_2 \ldots i_k} : 0 \leq i_1 < i_2 < \ldots < i_k \leq 2n\}$$

where: $v_{i_1 i_2 \ldots i_k} = [x_{i_1}, x_{i_2}, \ldots, x_{i_k}] \in \mathbb{R}^{dk}$ and the number of elements in N is $|N| = \binom{2n+1}{k}$.

The non-consecutive CNN model then follows the procedure of the traditional CNN model in Section 2.1 to compute the representation vector for classification. The only difference is that the computation is done on the input set N instead of C. In particular, the convolution score set in this case would be $S(N) = \{\mathbf{f}^T v : v \in N\}$, while the aggregating score would be:

$$p_k^{\mathbf{f}} = \max S(N) = \max\{s : s \in S(N)\} \quad (3)$$

2.3 Implementation

Note that the maximum operation in Equation 2 only requires $O(n)$ operations while the naive implementation of Equation 3 would need $O(|N|) = O(n^k)$ operations. In this work, we employ the dynamic programming (DP) procedure below to reduce the computation time for Equation 3.

Assuming the filter vector $\mathbf{f}$ is the concatenation of the k vectors $\mathbf{f}_1, \ldots, \mathbf{f}_k \in \mathbb{R}^d$: $\mathbf{f} = [\mathbf{f}_1, \ldots, \mathbf{f}_k]$, Equation 3 can be re-written by:

$$\begin{aligned} p_k^{\mathbf{f}} = &\max\{\mathbf{f}_1^T x_{i_1} + \ldots + \mathbf{f}_k^T x_{i_k} \\ &: 0 \leq i_1 < i_2 < \ldots < i_k \leq 2n\} \end{aligned}$$

Let D_t^j be the dynamic programming table representing the maximum convolution score for the subfilter $[\mathbf{f}_1, \ldots, \mathbf{f}_j]$ over all possible non-consecutive j-gram vectors in the subsequence $(x_0, x_1, \ldots, x_t)$ of X:

$$\begin{aligned} D_t^j = &\max\{\mathbf{f}_1^T x_{i_1} + \ldots + \mathbf{f}_j^T x_{i_j} \\ &: 0 \leq i_1 < i_2 < \ldots < i_j \leq t\} \end{aligned}$$

where $1 \leq j \leq k$, $j - 1 \leq t \leq 2n$.

Note that $p_k^{\mathbf{f}} = D_{2n}^k$.

We can solve this DP problem by the following recursive formulas[2]:

$$D_t^j = \max\{D_{t-1}^j, D_{t-1}^{j-1} + \mathbf{f}_j^T x_t\}$$

The computation time for this procedure is $O(kn)$ and remains linear in the sequence length.

2.4 Training

We train the networks using stochastic gradient descent with shuffled mini-batches, the AdaDelta update rule, back-propagation and dropout. During the training, we also optimize the embedding tables (i.e, word, position and entity type embeddings) to achieve the optimal states. Finally, we rescale the weights whose l_2-norms exceed a predefined threshold (Nguyen and Grishman (2015a)).

3 Experiments

3.1 Dataset, Parameters and Resources

We apply *the same parameters and resources* as (Nguyen and Grishman, 2015b) to ensure the compatible comparison. Specifically, we employ the window sizes in the set {2, 3, 4, 5} for the convolution operation with 150 filters for each window size. The window size of the trigger candidate is 31 while the dimensionality of the position embeddings and entity type embeddings is 50. We use `word2vec` from (Mikolov et al., 2013b) as the pretrained word embeddings. The other parameters include the dropout rate $\rho = 0.5$, the mini-batch size = 50, the predefined threshold for the l_2 norms = 3.

Following the previous studies (Li et al., 2013; Chen et al., 2015; Nguyen and Grishman, 2015b), we evaluate the models on the ACE 2005 corpus

[2]We ignore the base cases as they are trivial.

with 33 event subtypes. In order to make it compatible, we use the same test set with 40 newswire articles, the same development set with 30 other documents and the same training set with the remaining 529 documents. All the data preprocessing and evaluation criteria follow those in (Nguyen and Grishman, 2015b).

3.2 The General Setting

We compares the non-consecutive CNN model (**NC-CNN**) with the state-of-the-art systems on the ACE 2005 dataset in Table 1. These systems include:

1) The feature-based systems with rich hand-designed feature sets, including: the MaxEnt model with local features in (Li et al., 2013) (**MaxEnt**); the structured perceptron model for joint beam search with local features (**Joint+Local**), and with both local and global features (**Joint+Local+Global**) in (Li et al., 2013); and the sentence-level and cross-entity models in (Hong et al., 2011).

2) The neural network models, i.e, the CNN model in (Nguyen and Grishman, 2015b) (**CNN**), the dynamic multi-pooling CNN model (**DM-CNN**) in (Chen et al., 2015) and the bidirectional recurrent neural networks (**B-RNN**) in (Nguyen et al., 2016a).

3) The probabilistic soft logic based model to capture the event-event correlation in (Liu et al., 2016).

Methods	F
Sentence-level in Hong et al (2011)	59.7
MaxEnt (Li et al., 2013)	65.9
Joint+Local (Li et al., 2013)	65.7
Joint+Local+Global (Li et al., 2013)	67.5
Cross-entity in Hong et al. (2011) †	68.3
Probabilistic soft logic (Liu et al., 2016) †	69.4
CNN (Nguyen and Grishman, 2015b)	69.0
DM-CNN (Chen et al., 2015)	69.1
B-RNN (Nguyen et al., 2016a)	69.3
NC-CNN	**71.3**

Table 1: Performance with Gold-Standard Entity Mentions and Types. † beyond sentence level.

The most important observation from the table is that the non-consecutive CNN model significantly outperforms all the compared models with large margins. In particular, *NC-CNN* is 2% better than B-RNN (Nguyen et al., 2016a), the state-of-the-art system that only relies on the context information within the sentences of the trigger candidates. In addition, although *NC-CNN* only employs the sentence-level information, it is still better than the other models that further exploit the document-level information for prediction (an improvement of 1.9% over the probabilistic soft logic based model in (Liu et al., 2016)). Finally, comparing *NC-CNN* and the CNN model in (Nguyen and Grishman, 2015b), we see that the non-consecutive mechanism significantly improves the performance of the traditional CNN model for ED (up to 2.3% in absolute F-measures with $p < 0.05$).

3.3 The Domain Adaptation Experiments

Previous studies have shown that the NLP models would suffer from a significant performance loss when domains shift (Blitzer et al., 2006; Daume III, 2007; Plank and Moschitti, 2013; Nguyen et al., 2015c). In particular, if a model is trained on some *source domain* and applied to a different domain (*the target domain*), its performance would degrade significantly. The domain adaptation (DA) studies aim to overcome this issue by developing robust techniques across domains.

The best reported system in the DA setting for ED is (Nguyen and Grishman, 2015b), which demonstrated that the CNN model outperformed the feature-based models in the cross-domain setting. In this section, we compare *NC-CNN* with the CNN model in (Nguyen and Grishman, 2015b) (as well as the other models above) in the DA setting to further investigate their effectiveness.

3.3.1 Dataset

This section also uses the ACE 2005 dataset but focuses more on the difference between domains. The ACE 2005 corpus includes 6 different domains: broadcast conversation (*bc*), broadcast news (*bn*), telephone conversation (*cts*), newswire (*nw*), usenet (*un*) and webblogs (*wl*). Following (Nguyen and Grishman, 2015b), we use ***news*** (the union of ***bn*** and ***nw***) as the source domain and ***bc***, ***cts***, ***wl*** and ***un*** as four different target domains[3]. We take half of *bc* as the development set and use the remaining data for testing. Our data split is the same as that in (Nguyen and Grishman, 2015b).

[3]Note that (Nguyen and Grishman, 2015b) does not report the performance on *un* but we include it here for completeness.

System	In-domain(bn+nw)			bc			cts			wl			un		
	P	R	F	P	R	F	P	R	F	P	R	F	P	R	F
MaxEnt	74.5	59.4	66.0	70.1	54.5	61.3	66.4	49.9	56.9	59.4	34.9	43.9	-	-	-
Joint+Local	73.5	62.7	67.7	70.3	57.2	63.1	64.9	50.8	57.0	59.5	38.4	46.7	-	-	-
Joint+Local+Global	72.9	63.2	67.7	68.8	57.5	62.6	64.5	52.3	57.7	56.4	38.5	45.7	-	-	-
B-RNN	71.4	63.5	67.1	70.7	62.1	66.1	70.0	54.4	61.0	52.7	38.3	44.2	66.2	46.0	54.1
DM-CNN	75.9	62.7	68.7	75.3	59.3	66.4	74.8	52.3	61.5	59.2	37.4	45.8	72.2	44.5	55.0
CNN	69.2	67.0	68.0	70.2	65.2	67.6	68.3	58.2	62.8	54.8	42.0	**47.5**	64.6	49.9	56.2
NC-CNN	74.9	66.5	**70.4**†	73.6	64.7	**68.8**†	71.7	57.3	**63.6**	57.8	40.3	47.4	71.7	49.0	**58.1**†

Table 2: Performance on the source domain and on the target domains. Cells marked with †designates that NC-CNN significantly outperforms ($p < 0.05$) all the compared methods on the specified domain.

3.3.2 Performance

Table 2 reports the performance of the systems with 5-fold cross validation. Note that we focus on the systems exploiting only the sentence level information in this section. For each system, we train a model on the training data of the source domain and evaluate this model on the test set of the source domain (in-domain performance) as well as on the four target domains *bc*, *cts*, *wl* and *un*.

We emphasize that the performance of the systems *MaxEnt*, *Joint+Local*, *Joint+Local+Global*, *B-RNN*, and *CNN* is obtained from the actual systems in the original work (Li et al., 2013; Nguyen and Grishman, 2015b; Nguyen et al., 2016a). The performance of *DM-CNN*, on the other hand, is from our re-implementation of the system in (Chen et al., 2015) using the same hyper-parameters and resources as *CNN* and *NC-CNN* for a fair comparison.

From the table, we see that *NC-CNN* is significantly better than the other models on the source domain. This is consistent with the conclusions in Section 3.2 and further confirms the effectiveness of *NC-CNN*. More importantly, *NC-CNN* outperforms *CNN* and the other models on the target domains *bc*, *cts* and *un*, and performs comparably with *CNN* on *wl*. The performance improvement is significant on *bc* and *un* ($p < 0.05$), thereby verifying the robustness of *NC-CNN* for ED across domains.

4 Related Work

There have been three major approaches to event detection in the literature. First, the pattern-based approach explores the application of patterns to identify the instances of events, in which the patterns are formed by predicates, event triggers and constraints on the syntactic context (Grishman et al., 2005; Cao et al., 2015a; Cao et al., 2015b).

Second, the feature-based approach relies on linguistic intuition to design effective feature sets for statistical models for ED, ranging from the local sentence-level representations (Ahn, 2006; Li et al., 2013), to the higher level structures such as the cross-sentence or cross-event information (Ji and Grishman, 2008; Gupta and Ji, 2009; Patwardhan and Riloff, 2009; Liao and Grishman, 2011; Hong et al., 2011; McClosky et al., 2011; Li et al., 2015). Some recent work on the feature-based approach has also investigated event trigger detection in the joint inference with event argument prediction (Riedel et al., 2009; Poon and Vanderwende, 2010; Li et al., 2013; Venugopal et al., 2014) to benefit from their inter-dependencies.

Finally, neural networks have been introduced into ED very recently with the early work on convolutional neural networks (Nguyen and Grishman, 2015b; Chen et al., 2015). The other work includes: (Nguyen et al., 2016a) who employ bidirectional recurrent neural networks to perform event trigger and argument labeling jointly, (Jagannatha and Yu, 2016) who extract event instances from health records with recurrent neural networks and (Nguyen et al., 2016b) who propose a two-stage training algorithm for event extension with neural networks.

5 Conclusion

We present a new CNN architecture for ED that exploits the non-consecutive convolution for sentences. Our evaluation of the proposed model on the general setting and the DA setting demonstrates the effectiveness of the non-consecutive mechanism. We achieve the state-of-the-art performance for ED in both settings. In the future, we plan to investigate the non-consecutive architecture on other problems such as relation extraction or slot filling.

Abstract

Many downstream NLP tasks can benefit from Open Information Extraction (Open IE) as a semantic representation. While Open IE systems are available for English, many other languages lack such tools. In this paper, we present a straightforward approach for adapting PropS, a rule-based predicate-argument analysis for English, to a new language, German. With this approach, we quickly obtain an Open IE system for German covering 89% of the English rule set. It yields 1.6 n-ary extractions per sentence at 60% precision, making it comparable to systems for English and readily usable in downstream applications.[1]

1 Introduction

The goal of Open Information Extraction (Open IE) is to extract coherent propositions from a sentence, each represented as a tuple of a relation phrase and one or more argument phrases (e.g., *born in (Barack Obama; Hawaii)*). Open IE has been shown to be useful for a wide range of semantic tasks, including question answering (Fader et al., 2014), summarization (Christensen et al., 2013) and text comprehension (Stanovsky et al., 2015), and has consequently drawn consistent attention over the last years (Banko et al., 2007; Wu and Weld, 2010; Fader et al., 2011; Akbik and Löser, 2012; Mausam et al., 2012; Del Corro and Gemulla, 2013; Angeli et al., 2015).

Although similar applications of Open IE in other languages are obvious, most previous work focused on English, with only a few recent exceptions (Zhila and Gelbukh, 2013; Gamallo and Garcia, 2015). For most languages, Open IE systems are still missing. While one could create them from scratch, as it was done for Spanish, this can be a very laborious process, as state-of-the-art systems make use of handcrafted, linguistically motivated rules. Instead, an alternative approach is to transfer the rule sets of available systems for English to the new language.

In this paper, we study whether an existing set of rules to extract Open IE tuples from English dependency parses can be ported to another language. We use German, a relatively close language, and the PropS system (Stanovsky et al., 2016) as examples in our analysis. Instead of creating rule sets from scratch, such a transfer approach would simplify the rule creation, making it possible to build Open IE systems for other languages with relatively low effort in a short amount of time. However, challenges we need to address are differences in syntax, dissimilarities in the corresponding dependency representations as well as language-specific phenomena. Therefore, the existing rules cannot be directly mapped to the German part-of-speech and dependency tags in a fully automatic way, but require a careful analysis as carried out in this work. Similar manual approaches to transfer rule-based systems to new languages were shown to be successful, e.g. for temporal tagging (Moriceau and Tannier, 2014), whereas fully automatic approaches led to less competitive systems (Strötgen and Gertz, 2015).

Our analysis reveals that a large fraction of the PropS rule set can be easily ported to German, requiring only small adaptations. With roughly 10%

Extraction 1: liegen (die Orte San Jose und San Andres ; an der nördlichen Küste des Petén-Itzá-Sees)

Extraction 2: sehenswert (die Orte San Jose und San Andres)

Figure 1: PropS representation for *Worth seeing are the towns San Jose and San Andres, which are located on the northern shore of Lake Petén-Itzá.* Grey boxes indicate predicates. Two Open IE tuples, one unary and one binary, are extracted from this sentence.

of the effort that went into the English system, we could build a system for German covering 89% of the rule set. As a result, we present *PropsDE*, the first Open IE system for German. In an intrinsic evaluation, we show that its performance is comparable with systems for English, yielding 1.6 extractions per sentence with an overall precision of 60%.

2 Background

Open Information Extraction Open IE was introduced as an open variant of traditional Information Extraction (Banko et al., 2007). Since its inception, several extractors were developed. The majority of them, namely ReVerb (Fader et al., 2011), KrakeN (Akbik and Löser, 2012), Exemplar (Mesquita et al., 2013) and ClausIE (Del Corro and Gemulla, 2013), successfully used rule-based strategies to extract tuples. Alternative approaches are variants of self-supervision, as in TextRunner (Banko et al., 2007), WOE (Wu and Weld, 2010) and OLLIE (Mausam et al., 2012), and semantically-oriented approaches utilizing semantic role labeling (Open IE-4[2]) or natural logic (Angeli et al., 2015). While TextRunner and ReVerb require only POS tagging as preprocessing to allow a high extraction speed, the other systems rely on dependency parsing to improve the extraction precision.

For non-English Open IE, ExtrHech has been presented for Spanish (Zhila and Gelbukh, 2013). Similar as the English systems, it uses a set of extraction rules, specifically designed for Spanish in this case. More recently, ArgOE (Gamallo and Garcia, 2015) was introduced. It manages to extract tuples in several languages with the same rule set, relying on a dependency parser that uses a common tagset for five European languages. However, an evaluation for English and Spanish revealed that this approach cannot compete with the systems specifically built for those languages. To the best of our knowledge, no work on Open IE for German exists.

Open IE with PropS Stanovsky et al. (2016) recently introduced PropS, a rule-based converter turning dependency graphs for English into typed graphs of predicates and arguments. An example is shown in Figure 1 (in German). Compared to a dependency graph, the representation masks non-core syntactic details, such as tense or determiners, unifies semantically equivalent constructions, such as active/passive, and explicates implicit propositions, such as indicated by possessives or appositions.

The resulting graph can be used to extract Open IE tuples in a straightforward way. Every non-nested predicate node $pred$ in the graph, together with its n argument-subgraphs arg_i, yields a tuple $pred(arg_1; ...; arg_n)$. With this approach, PropS is most similar to KrakeN and ClausIE, applying rules to a dependency parse. However, due to additional nodes for implicit predicates, it can also make extractions that go beyond the scope of other systems, such as *has (Michael; bicycle)* from *Michael's bicycle is red.* In line with more recent Open IE systems, this strategy extracts tuples that are not necessarily binary, but can be unary or of higher arity.

3 Analysis of Portability

Approach For each rule of the converter that transforms a dependency graph to the PropS graph, we assess its applicability for German. A rule is applied to a part of the graph if certain conditions are

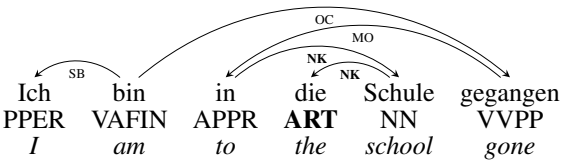
[2] https://github.com/knowitall/openie

fulfilled, expressed using dependency types, POS tags and lemmas. As we already pointed out in the introduction, several differences between the dependency and part-of-speech representations for English and German make a fully automatic translation of these rules impossible. We therefore manually analyzed the portability of each rule and report the findings in the next section.

While using Universal Dependencies (Nivre et al., 2016) could potentially simplify porting the rules, we chose not to investigate this option due to the ongoing nature of the project and focused on the established representations for now. In line with the English system, that works on collapsed Stanford dependencies (de Marneffe and Manning, 2008), we assume a similar input representation for German that can be obtained with a set of collapsing and propagation rules provided by Ruppert et al. (2015) for TIGER dependencies (Seeker and Kuhn, 2012).

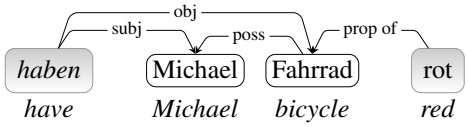
Findings Overall, we find that most rules can be used for German, mainly because syntactic differences, such as freer word order (Kübler, 2008), are already masked by the dependency representation (Seeker and Kuhn, 2012). About **38%** of the rule set can be **directly ported** to German, solely replacing dependency types, POS tags and lemmas with their German equivalents. As an example, the rule removing negation tokens looks for *neg* dependencies in the graph, for which a corresponding type *NG* exists in German. We found similar correspondences to remove punctuation and merge proper noun and number compounds. In addition, we can also handle appositions and existentials with direct mappings.

For **35%** of the English rules, **small changes** are necessary, mainly because no direct mapping to the German tag set is possible or the annotation style differs. For instance, while English has a specific type *det* to link determiners to their governor, a more generic type (*NK*) is used in German. Instead, determiners can be detected by part-of-speech:



Another type of difference exists with regard to the representation of auxiliary verb constructions. In Stanford dependencies, main verbs govern all auxiliaries, whereas in TIGER dependencies, an auxiliary heads the main verb. The above example shows this for *gone* and *am*. Therefore, all rules identifying and removing auxiliaries and modals have to be adapted to account for this difference.

With similar changes as discussed for determiners, we can also handle possessive and copular constructions. The graph for *Michael's bicycle is red*, for example, features an additional predicate *have* to explicate the implicit possessive relation, while *red* becomes an adjectival predicate, omitting *is*:



Moreover, conditional constructions can be processed with slight changes as well. Missing a counterpart for the type *mark*, we instead look for subordinating conjunctions by part-of-speech. In fact, we found conditionals to be represented more consistently across different conjunctions, making their handling in German easier than in English.

More **substantial changes** are necessary for the remaining **27%** of the rules. To represent active and passive in a uniform way, in passive clauses, PropS turns the subject into an object and a potential by-clause into the subject. For English, these cases are indicated by the presence of passive dependencies such as *nsubjpass*. For German, however, no counterparts exist. As an alternative strategy, we instead look for past participle verbs (by POS tag) that are governed by a form of the auxiliary *werden* (Schäfer, 2015). Instances of the German static passive (Zustandspassiv) are, in contrast, handled like copulas. Another deviation from the English system is necessary for relative clauses. PropS heavily relies on the Stanford dependency converter, which propagates dependencies of the relative pronoun to its referent. The German collapser does not have this feature, and we therefore implement it as an additional transformation (see *subj(liegen;Orte)* in Figure 1).

To abstract away from different tenses, PropS represents predicates with their lemma, indicating the original tense as a feature, as detected with a set of rules operating on POS tags. For German, no tense information is contained in POS tags, but instead, a morphological analysis can provide it. Determining

the overall tense of a sentence based on that requires a new set of rules, as the grammatical construction of tenses differs between German and English. PropS also tries to heuristically identify raising constructions, in which syntactic and semantic roles of arguments differ. In German, this phenomenon occurs in similar situations, such as in *Michael scheint zu lächeln* (*Michael seems to smile*), in which *Michael* is not the semantic subject of *scheinen*, though syntactically it is. To determine these cases heuristically, an empirically derived list of common raising verbs, such as done by Chrupała and van Genabith (2007) for English, needs to be created.

An **additional** step that is necessary during the lemmatization of verbs for German is to recover separated particles. For example, a verb like *ankommen* (*arrive*) can be split in a sentence such as *Er kam an* (*He arrived*), moving the particle to the end of the sentence, with a potentially large number of other tokens in between. We can reliably reattach these particles based on the dependency parse. Another addition to the rules that we consider important is to detect subjunctive forms of verbs and indicate the mood with a specific feature for the predicate. A morphological analysis provides the necessary input. Compared to English, the usage of the subjunctive is much more common, usually to indicate either unreality or indirect speech (Thieroff, 2004).

4 German Open IE System

Following our analysis, we implemented a German version of PropS, named PropsDE. It uses matetools for POS tagging, lemmatizing and parsing (Bohnet et al., 2013). Dependencies are collapsed and propagated with JoBimText (Ruppert et al., 2015). The rule set covers 89% of the English rules, lacking only the handling of raising-to-subject verbs and more advanced strategies for coordination constructions and tense detection. To assign confidence scores, PropsDE uses a logistic regression model trained to predict the correctness of extractions. Figure 1 illustrates some extracted tuples. Based on correspondence with the authors of the English system, we conclude that we were able to implement the German version with roughly 10% of the effort they reported. This shows that our approach of manually porting a rule-based system can overcome the lack of a tool for another language with reasonable effort in a short amount of time.

5 Experiments

Experimental Setup Following the common evaluation protocol for Open IE systems, we manually label extractions made by our system. For this purpose, we created a new dataset consisting of 300 German sentences, randomly sampled from three sources of different genres: news articles from TIGER (Brants et al., 2004), German web pages from CommonCrawl (Habernal et al., 2016) and featured Wikipedia articles. For the treebank part, we ran our system using both gold and parsed dependencies to analyze the impact of parsing errors.

Every tuple extracted from this set of 300 sentences was labeled independently by two annotators as correct or incorrect. In line with previous work, they were instructed to label an extraction as incorrect if it has a wrong predicate or argument, including overspecified and incomplete arguments, or if it is well-formed but not entailed by the sentence. Unresolved co-references were not marked as incorrect. We observed an inter-annotator agreement of 85% ($\kappa = 0.63$). For the evaluation, we merged the labels, considering an extraction as correct only if both annotators labeled it as such. Results are measured in terms of precision, the fraction of correct extractions, and yield, the total number of extractions. A precision-yield curve is obtained by decreasing a confidence threshold. The confidence predictor was trained on a separate development set.

Results From the whole corpus of 300 sentences, PropsDE extracted 487 tuples, yielding on average 1.6 per sentence with 2.9 arguments. 60% of them were labeled as correct. Table 1 shows that most extractions are made from Wikipedia articles, whereas the highest precision can be observed for newswire text. According to our expectations, web pages are most challenging, presumably due to noisier language. These differences between the genres can also be seen in the precision-yield curve (Figure 2).

For English, state-of-the-art systems show a similar performance. In a direct comparison of several systems carried out by Del Corro and Gemulla (2013), they observed overall precisions of 58% (Reverb), 57% (ClausIE), 43% (WOE) and 43%

Genre	Sentences	Length	Yield	Precision
News*	100	19.3	142	78.9
News	100	19.3	144	70.8
Wiki	100	21.4	178	61.8
Web	100	19.2	165	49.1
Total	300	20.0	487	60.2

Table 1: Corpus size (length in token) and system performance by genre. News* used gold trees and is not included in total.

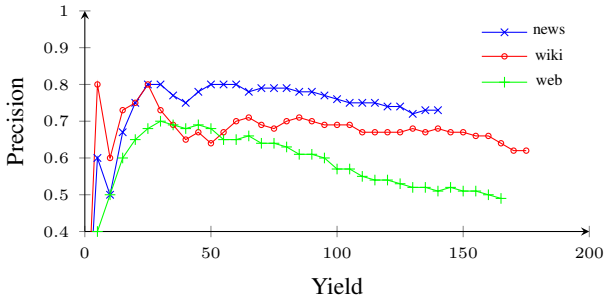


Figure 2: Extraction precision at increasing yield by genre.

(OLLIE) on datasets of similar genre. The reported yield per sentence is higher for ClausIE (4.2), OLLIE (2.6) and WOE (2.1), but smaller for Reverb (1.4). However, we note that in their evaluation, they configured all systems to output only two-argument-extractions. For example, from a sentence such as

> *The principal opposition parties boycotted the polls after accusations of vote-rigging.*

OLLIE can either make two binary extractions

> *boycotted (the principal opposition parties ; the polls)*
> *boycotted the polls after (the principal opposition parties ; accusations of vote-rigging)*

or just a single extraction with three arguments. PropS always extracts the combined tuple

> *boycotted (the principal opposition parties , the polls , after accusations of vote-rigging),*

which is in line with the default configuration of more recent Open IE systems.

For the sake of comparability, we conjecture that the yield of our system would increase if we broke down higher-arity tuples in a similar fashion: Assuming that every extraction with n arguments, $n > 2$, can be split into $n - 1$ separate extractions, our system's yield would increase from 1.6 to 3.0. That is in line with the numbers reported above for the binary configuration for English. Overall, this indicates a reasonable performance of our straightforward porting of PropS to German.

Extractions were most frequently labeled as incorrect due to false relation labels (32%), overspecified arguments (21%) and wrong word order in arguments (19%). Analyzing our system's performance on the treebank, we can see that the usage of gold dependencies increases the precision by 8 percentage points, making parsing errors responsible for about 28% of the incorrect extractions. Since the mate-tools parser is trained on the full TIGER treebank, including our experimental data, its error contribution on unseen data might be even higher.

6 Conclusion

Using PropS and German as examples, we showed that a rule-based Open IE system for English can be ported to another language in a reasonable amount of time. As a result, we presented the first Open IE system for German. In the future, studies targeting less similar languages could further evaluate the portability of PropS. Directions for future work on PropsDE are extensions of the rule set to better cover complex coordination constructions, nested sentences and nominal predicates.

Named Entity Recognition for Novel Types by Transfer Learning

Abstract

In named entity recognition, we often don't have a large in-domain training corpus or a knowledge base with adequate coverage to train a model directly. In this paper, we propose a method where, given training data in a related domain with similar (but not identical) named entity (NE) types and a small amount of in-domain training data, we use transfer learning to learn a domain-specific NE model. That is, the novelty in the task setup is that we assume not just domain mismatch, but also label mismatch.

1 Introduction

There are two main approaches to named entity recognition (NER): (i) build sequence labelling models such as conditional random fields (CRFs) (Lafferty et al., 2001) on a large manually-labelled training corpus (Finkel et al., 2005); and (ii) exploit knowledge bases to recognise mentions of entities in text (Rizzo and Troncy, 2012; Mendes et al., 2011). For many social media-based or security-related applications, however, we cannot assume that we will have access to either of these. An alternative is to have a small amount of in-domain training data and access to large-scale annotated data in a second domain, and perform transfer learning over both the features and label set. This is the problem setting in this paper.

NER of novel named entity (NE) types poses two key challenges. First is the issue of sourcing labelled training data. Handcrafted features play a key role in supervised NER models (Turian et al., 2010), but if we have only limited training amounts of training data, we will be hampered in our ability to reliably learn feature weights. Second, the absence of target NE types in the source domain makes transfer difficult, as we cannot directly apply a model trained over the source domain to the target domain. Alvarado et al. (2015) show that even if the NE label set is identical across domains, large discrepancies in the label distribution can lead to poor performance.

Despite these difficulties, it is possible to transfer knowledge between domains, as related NE types often share lexical and context features. For example, the expressions *give lectures* and *attend tutorials* often occur near mentions of NE types PROFESSOR and STUDENT. If only PROFESSOR is observed in the source domain but we can infer that the two classes are similar, we can leverage the training data to learn an NER model for STUDENT. In practice, differences between NE classes are often more subtle than this, but if we can infer, for example, that the novel NE type STUDENT aligns with NE types PERSON and UNIVERSITY, we can compose the context features of PERSON and UNIVERSITY to induce a model for STUDENT.

In this paper, we propose a transfer learning-based approach to NER in novel domains with label mismatch over a source domain. We first train an NER model on a large source domain training corpus, and then learn the correlation between the source and target NE types. In the last step, we reuse the model parameters of the second step to initialise a linear-chain CRF and fine tune it to learn domain-specific patterns. We show that our methods achieve up to 160% improvement in F-score over a strong baseline, based on only 125 target-domain training sentences.

Austin, Texas, November 1-5, 2016.

2 Related work

The main scenario where transfer learning has been applied to NER is domain adaptation (Arnold et al., 2008; Maynard et al., 2001; Chiticariu et al., 2010), where it is assumed that the label set Y is the same for both the source and target corpora, and only the domain varies. In our case, however, both the domain and the label set differ across datasets.

Similar to our work, Kim et al. (2015) use transfer learning to deal with NER data sets with different label distributions. They use canonical correlation analysis (CCA) to induce label representations, and reduce the problem to one of domain adaptation. This supports two different label mappings: (i) to a coarse label set by clustering vector representations of the NE types, which are combined with mention-level predictions over the target domain to train a target domain model; and (ii) between labels based on the k nearest neighbours of each label type, and from this transferring a pre-trained model from the source to the target domain. They showed their automatic label mapping strategies attain better results than a manual mapping, with the pre-training approach achieving the best results. Similar conclusions were reached by Yosinski et al. (2014), who investigated the transferability of features from a deep neural network trained over the ImageNet data set. Sutton and McCallum (2005) investigated how the target task affects the source task, and demonstrated that decoding for transfer is better than no transfer, and joint decoding is better than cascading decoding.

Another way of dealing with a lack of annotated NER data is to use distant supervision by exploiting knowledge bases to recognise mentions of entities (Ling and Weld, 2012; Dong et al., 2015; Yosef et al., 2013; Althobaiti et al., 2015; Yaghoobzadeh and Schütze, 2015). Having a fine-grained entity typology has been shown to improve other tasks such as relation extraction (Ling and Weld, 2012) and question answering (Lee et al., 2007). Nevertheless, for many social media-based or security-related applications, we don't have access to a high-coverage knowledge base, meaning distant supervision is not appropriate.

3 Transfer Learning for NER

Our proposed approach **TransInit** consists of three steps: (1) we train a linear-chain CRF on a large source-domain corpus; (2) we learn the correlation between source NE types and target NE types using a two-layer neural network; and (3) we leverage the neural network to train a CRF for target NE types.

Given a word sequence $\mathbf{x}$ of length L, an NER system assigns each word x_i a label $y_i \in \mathcal{Y}$, where the label space $\mathcal{Y}$ includes all observed NE types and a special category O for words without any NE type. Let $(\mathbf{x}, \mathbf{y})$ be a sequence of words and their labels. A linear-chain CRF takes the form:

$$\frac{1}{Z}\prod_{l=1}^{L}\exp\Big(\mathbf{W}^f f(y_l, \mathbf{x}) + \mathbf{W}^g g(y_{l-1}, y_l)\Big), \quad (1)$$

where $f(y_l, \mathbf{x})$ is a feature function depending only on $\mathbf{x}$, and the feature function $g(y_{l-1}, y_l)$ captures co-occurrence between adjunct labels. The feature functions are weighted by model parameters $\mathbf{W}$, and Z serves as the partition function for normalisation.

The source domain model is a linear-chain CRF trained on a labelled source corpus. The co-occurrence of target domain labels is easy to learn due to the small number of parameters ($|Y|^2$). Mostly such information is domain specific so that it is unlikely that the co-occurrence of two source types can be matched to the co-occurrence of the two target types. However the feature functions $f(y_l, \mathbf{x})$ capture valuable information about the textual patterns associated with each source NE type. Without $g(y_{l-1}, y_l)$, the linear-chain CRF is reduced to a logistic regression (LR) model:

$$\sigma(y^*, \mathbf{x}_i; \mathbf{W}^f) = \frac{\exp(\mathbf{W}^f_{.y^*} f(y_i^*, \mathbf{x_i}))}{\sum_{y\in\mathcal{Y}} \exp(\mathbf{W}^f_{.y} f(y, \mathbf{x}_i))}. \quad (2)$$

In order to learn the correlation between source and target types, we formulate it as a predictive task by using the unnormalised probability of source types to predict the target types. Due to the simplification discussed above, we are able to extract a linear layer from the source domain, which takes the form $\mathbf{a}_i = \mathbf{W^s}\mathbf{x}_i$, where $\mathbf{W^s}$ denotes the parameters of $f(y_l, \mathbf{x})$ in the source domain model, and each $\mathbf{a}_i$ is the unnormalised probability for each source NE type. Taking $\mathbf{a}_i$ as input, we employ a multi-class LR classifier to predict target types, which is essentially $p(y'|\mathbf{a}) = \sigma(y', \mathbf{a}_i; \mathbf{W^t})$, where y' is the observed type. From another point of view, the whole architecture is a neural network with two linear layers.

We do not add any non-linear layers between these two linear layers because we otherwise end up with saturated activation functions. An activation function is saturated if its input values are its max/min values (Glorot and Bengio, 2010). Taking $\tanh(x)$ as an example, $\frac{\partial tanh(z)}{\partial z} = 1 - \tanh^2(z)$. If z is, for example, larger than 2, the corresponding derivative is smaller than 0.08. Assume that we have a three-layer neural network where z^i denotes the input of layer i, $\tanh(z)$ is the middle layer, and $L(z^{i-2})$ is the loss function. We then have $\frac{\partial L(z^{i-2})}{\partial z^{i-2}} = \frac{\partial L}{\partial z^{i+1}} \frac{\partial \tanh(z^{i-1})}{\partial z^{i-1}} \frac{\partial z^{i-1}}{\partial z^{i-2}}$. If the $\tanh$ layer is saturated, the gradient propagated to the layers below will be small, and no learning based on back propagation will occur.

If no parameter update is required for the bottom linear layer, we will also not run into the issue of saturated activation functions. However, in our experiments, we find that parameter update is necessary for the bottom linear layer because of covariate shift (Sugiyama et al., 2007), which is caused by discrepancy in the distribution between the source and target domains. If the feature distribution differs between domains, updating parameters is a straightforward approach to adapt the model for new domains.

Although the two-layer neural network is capable of recognising target NE types, it has still two drawbacks. First, unlike a CRF, it doesn't include a label transition matrix. Second, the two-layer neural network has limited capacity if the domain discrepancy is large. If we rewrite the two-layer architecture in a compact way, we obtain:

$$p(y'|\mathbf{x}) = \sigma(y', \mathbf{x}_i; \mathbf{W^t W^s}). \quad (3)$$

As the equation suggests, if we minimize the negative log likelihood, the loss function is not convex. Thus, we could land in a non-optimal local minimum using online learning. The pre-trained parameter matrix $\mathbf{W^s}$ imposes a special constraint that the computed scores for each target type are a weighted combination of updated source type scores. If a target type shares nothing in common with source types, the pre-trained $\mathbf{W^s}$ does more harm than good.

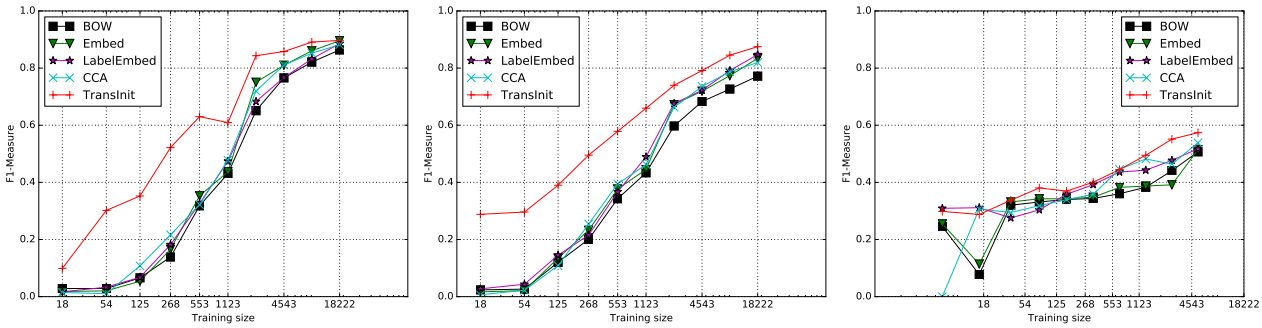
In the last step, we initialise the model parameters of a linear-chain CRF for $f(y_l, \mathbf{x})$ using the model parameters from the previous step. Based on the architecture of the NN model, we can collapse the two linear transformations into one by:

$$\mathbf{W}^f = \mathbf{W^t W^s}, \quad (4)$$

while initialising the other parameters of the CRF to zero. After this transformation, each initialised parameter vector $\mathbf{W}^f_{:y}$ is a weighted linear combination of the updated parameter vectors of the source types. Compared to the second step, the loss function we have now is convex because it is exactly a linear-chain CRF. Our previous steps have provided guided initialization of the parameters by incorporating source domain knowledge. The model also has significantly more freedom to adapt itself to the target types. In other words, collapsing the two matrices simplifies the learning task and removes the constraints imposed by the pre-trained $\mathbf{W^s}$.

Because the tokens of the class O are generally several orders of magnitude more frequent than the tokens of the NE types, and also because of covariate shift, we found that the predictions of the NN models are biased towards the class O (i.e. a non-NE). As a result, the parameters of each NE type will always include or be dominated by the parameters of O after initialisation. To ameliorate this effect, we renormalise $\mathbf{W}^t$ before applying the transformation, as in Equation (4). We do not include the parameters of the source class O when we initialise parameters of the NE types, while copying the parameters of the source class O to the target class O. In particular, let o be the index of source domain class O. For each parameter vector $\mathbf{W}^t_{i*}$ of NE type, we set $W^t_{io} = 0$. For the parameter vector for the target class O, we set only the element corresponding to the weight between source type O and target class O to 1, and other elements to 0.

Finally, we fine-tune the model over the target domain by maximising log likelihood. The training objective is convex, and thus the local optimum is also the global optimum. If we fully train the model, we will achieve the same model as if we trained from scratch over only the target domain. As the knowledge of the source domain is hidden in the initial weights, we want to keep the initial weights as long as they contribute to the predictive task. Therefore, we apply AdaGrad (Rizzo and Troncy, 2012) with early stopping based on development data, so that the knowledge of the source domain is preserved as much as possible.



(a) Target: I2B2, Source: BBN (b) Target: I2B2, Source: CoNLL (c) Target: CADEC, Source: CoNLL

Figure 1: Macro-averaged F1 results across all novel classes on different source/target domain combinations

4 Experimental Setup

4.1 Datasets

We use CADEC (Karimi et al., 2015) and I2B2 (Ben Abacha and Zweigenbaum, 2011) as target corpora with the standard training and test splits. From each training set, we hold out 10% as the development set. As source corpora, we adopt CoNLL (Tjong Kim Sang and De Meulder, 2003) and BBN (Weischedel and Brunstein, 2005).

In order to test the impact of the target domain training data size on results, we split the training set of CADEC and I2B2 into 10 partitions based on a log scale, and created 10 successively larger training sets by merging these partitions from smallest to largest (with the final merge resulting in the full training set). For all methods, we report the macro-averaged F1 over only the NE classes that are novel to the target domain.

4.2 Baselines

We compare our methods with the following two in-domain baselines, one cross-domain data-based method, and three cross-domain transfer-based benchmark methods.

BOW: an in-domain linear-chain CRF with hand-crafted features, from Qu et al. (2015).

Embed: an in-domain linear-chain CRF with hand-crafted features and pre-trained word embeddings, from Qu et al. (2015).

LabelEmbed: take the labels in the source and target domains, and determine the alignment based on the similarity between the pre-trained embeddings for each label.

CCA: the method of Kim et al. (2015), where a one-to-one mapping is generated between source and target NE classes using CCA and k-NN (see Section 2).

TransDeepCRF: A three-layer deep CRF. The bottom layer is a linear layer initialised with $\mathbf{W}^s$ from the source domain-trained CRF. The middle layer is a hard tanh function (Collobert et al., 2011). The top layer is a linear-chain CRF with all parameters initialised to zero.

TwoLayerCRF: A two-layer CRF. The bottom layer is a linear layer initialised with $\mathbf{W}^s$ from the source domain-trained CRF. The top layer is a linear-chain CRF with all parameters initialised to zero.

We compare our method with one variation, which is to freeze the parameters of the bottom linear layer and update only the parameters of the LR classifier while learning the correlation between the source and target types.

4.3 Experimental Results

Figure 1 shows the macro-averaged F1 of novel types between our method **TransInit** and the three baselines on all target corpora. The evaluation results on CADEC with BBN as the source corpus are not reported here because BBN contains all types of CADEC. From the figure we can see that **TransInit** outperforms all other methods with a wide margin on I2B2. When CoNLL is taken as the source corpus, despite not sharing any NE types with I2B2, several target types are subclasses of source types: DOCTOR and PATIENT w.r.t. PERSON, and HOS-

PITAL w.r.t. ORGANIZATION.

In order to verify if **TransInit** is able to capture semantic relatedness between source and target NE types, we inspected the parameter matrix $\mathbf{W}^t$ of the LR classifier in the step of learning type correlations. The corresponding elements in $\mathbf{W}^t$ indeed receive much higher values than the semantically-unrelated NE type pairs. When less than 300 target training sentences are used, these automatically discovered positive correlations directly lead to 10 times higher F1 scores for these types than the baseline **Embed**, which does not have a transfer learning step. Since **TransInit** is able to transfer the knowledge of multiple source types to related target types, this advantage leads to more than 10% improvement in terms of F1 score on these types compared with **LabelEmbed**, given merely 268 training sentences in I2B2. We also observe that, in case of few target training examples, **LabelEmbed** is more robust than **CCA** if the correlation of types can be inferred from their names.

We study the effects of transferring a large number of source types to target types by using BBN, which has 64 types. Here, the novel types of I2B2 w.r.t. BBN are DOCTOR, PATIENT, HOSPITAL, PHONE, and ID. For these types, **TransInit** successfully recognises PERSON as the most related type to DOCTOR, as well as CARDINAL as the most related type to ID. In contrast, **CCA** often fails to identify meaningful type alignments, especially for small training data sizes.

CADEC is definitely the most challenging task when trained on CoNLL, because there is no semantic connection between two of the target NE types (DRUG and DISEASE) and any of the source NE types. In this case, the baseline **LabelEmbed** achieves competitive results with **TransInit**. This suggests that the class names reflect semantic correlations between source and target types, and there are not many shared textual patterns between any pair of source and target NE types in the respective datasets.

Even with a complex model such as a neural network, the transfer of knowledge from the source types to the target types is not an easy task. Figure 2 shows that with a three-layer neural network, the whole model performs poorly. This is due to the fact that the hard tanh layer suffers from saturated function values. We inspected the values of the output hidden units computed by $\mathbf{W}^s\mathbf{x}$ on a random sample of target training examples before training on the target corpora. Most values are either highly positive or negative, which is challenging for online learning algorithms. This is due to the fact that these hidden units are unnormalised probabilities produced by the source domain classifier. Therefore, removing the hidden non-linear-layer layer leads to a dramatic performance improvement. Moreover, Figure 2 also shows that further performance improvement is achieved by reducing the two-layer architecture into a linear chain CRF. And updating the hidden layers leads to up to 27% higher F1 scores than not updating them in the second step of **TransInit**, which indicates that the neural networks need to update lower-level features to overcome the covariate shift problem.

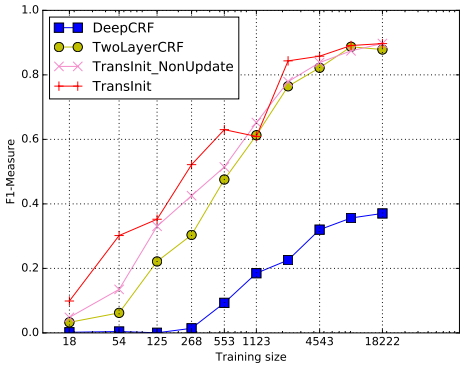


Figure 2: Difficulty of Transfer. The source model is trained on BBN.

5 Conclusion

We have proposed **TransInit**, a transfer learning-based method that supports the training of NER models across datasets where there are mismatches in domain and also possibly the label set. Our method was shown to achieve up to 160% improvement in F1 over competitive baselines, based on a handful of in-domain training instances.

Extracting Subevents via an Effective Two-phase Approach

Allison Badgett and **Ruihong Huang**
Texas A&M University

Abstract

We present our pilot research on automatically extracting subevents from a domain-specific corpus, focusing on the type of subevents that describe physical actions composing an event. We decompose the challenging problem and propose a two-phase approach that effectively captures sentential and local cues that describe subevents. We extracted a rich set of over 600 novel subevent phrases. Evaluation shows the automatically learned subevents help to discover 10% additional main events (of which the learned subevents are a part) and improve event detection performance.

1 Introduction

General and abstract event expressions and event keywords are often used for detecting events. To detect civil unrest events for example, common event expressions "took to the streets" and "staged a protest", and event keywords "rally" and "strike" are usually considered as the first option. Subevents, events that occur as a part of the main event and therefore are useful to instantiate the main event, widely exist in event descriptions but they are rarely used for detecting the main event.

In this paper, we focus on learning subevent phrases that describe physical actions composing an event. Such subevents are the evidence that an event is occurring. For example, if a person were to explain how he knew that the crowd gathered in the street was rioting, he might point to the shouting of political slogans or tires lit on fire. In this instance, the riot would be the event. The slogan-shouting and tire-burning would be the subevents. Because subevent detection requires an understanding of levels of abstraction, this task can even be difficult for humans to perform. Furthermore, subevent phrases and general event phrases often have the same grammatical structure and may share common words, which makes automatically differentiating between event phrases and subevent phrases within a document even more difficult.

Additionally, events and subevents are not disjoint classes. There are some subevents that are unambiguous. For example, "burning tires" is a concrete phrase that would not fall into the category of more abstract events. However, "gathered at site" is certainly more ambiguous. Even human analysts would not necessarily agree on the appropriate class for this phrase. In many cases, the categorization would be context-dependent. Because of this, our research focused on identifying the less ambiguous, and therefore more concrete, cases.

Instead of separating subevent phrases from general event phrases, we explicitly acquire subevent phrases by leveraging both sentential and local cues in describing subevents. We observed that subevents of the type in which we are interested, as important facts presented in news stories, are commonly mentioned in sentences that refer to the source of information or simply in quotation sentences. These sentences usually start or end with characteristic phrases such as "media reports" and "witness said". Furthermore, we observed that subevent phrases often occur in conjunction constructions as a sequence of subevent phrases, as shown in the following examples:

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 906–911,
Austin, Texas, November 1-5, 2016.

(1) *State television broadcast the event live, offering sweeping aerial views that showed the sea of people* **waving banners, blew whistles, and shouted slogans**.

(2) *They also* **set fires, stoned civilian vehicles, taunted the police and hurled stones** *at them, witnesses said.*

where the subevents are shown in bold, and sentential cues are underlined.

Inspired by these observations, we propose a novel two-phase approach to automatically extract subevents, which consists of a sentence classifier that incrementally identifies sentences mentioning subevents and a subevent extractor which looks for a sequence of subevent phrases in a conjunction structure. Our sentence classifier is trained in a weakly supervised manner and only requires a small set of subevent phrases as a guide. The classifier was initially trained with sentences containing eight provided subevent seeds, then it proceeded to label more sentences that mention new subevent phrases.

This two-phase subevent extraction approach can successfully identify 610 diverse subevent phrases from a domain-specific corpus. We evaluate our automatically learned subevent phrases by using them to detect events. Experimental results show that the learned subevent phrases can recover an additional 10% of event articles and improve event detection F-1 score by 3%.

2 Related Work

While it is generally agreed that subevents are an important type of information in event descriptions, they are seldom considered in decades of event extraction research (Appelt et al., 1993; Riloff, 1993; Soderland et al., 1995; Sudo et al., 2003; Li et al., 2005; Yu et al., 2005; Gu and Cercone, 2006; Maslennikov and Chua, 2007; S. and E., 2009; Liao and Grishman, 2010; Huang and Riloff, 2011; Chambers and Jurafsky, 2011; Huang and Riloff, 2012; Huang et al., 2016). Subevents as a theme has been discussed in the past three Event workshops (Eve, 2013), (Eve, 2014), (Eve, 2015). However, despite the great potential of using subevents to improve event detection and extraction (Hakeem and Shah, 2005), and event coreference resolution (Araki et al., 2014), there is little existing research on automatically learning subevent phrases, partially because researchers have not agreed upon the definition of subevents. Much recent research in event timeline generation (Huang and Huang, 2013) suggests the usefulness of subevents in improving quality and completeness of automatically generated event summaries. However, they often focus on a different notion of subevents that broadly covers pre-condition events and consequence events and is temporally-based.

Subevents have been studied for event tracking applications (Shen et al., 2013; Meladianos et al., 2015). However, most current research is specifically related to social media applications, like Twitter, in terms of both its definition of subevents and methodologies. For example, in previous research by (Shen et al., 2013), a subevent is defined as a topic that is discussed intensively in the Twitter stream for a short period of time before fading away. Accordingly, the subevent detection method relies on modeling the "burstiness" and "cohesiveness" properties of tweets in the stream. We instead aim to provide a more general definition of subevents as well as present a method for identifying subevent at the article level.

3 A Two-phase Approach for Subevent Extraction

As illustrated in Figure 1, We use a two-phase algorithm to identify subevent phrases from our domain-specific corpus. For the first stage, we implemented a bootstrapped artificial neural network in order to identify sentences that are likely to contain a subevent phrase. In the second stage, we identify phrases fitting a predetermined conjunction pattern within the sentences classified by the first-stage neural network.

3.1 Phase 1: Identifying Subevent Sentences

3.1.1 Domain-specific Corpus

Thanks to previous research on multi-faceted event recognition by (Huang and Riloff, 2013), we compiled our own domain-specific corpus that describes civil unrest events. Using civil unrest events as an example, (Huang and Riloff, 2013) demon-

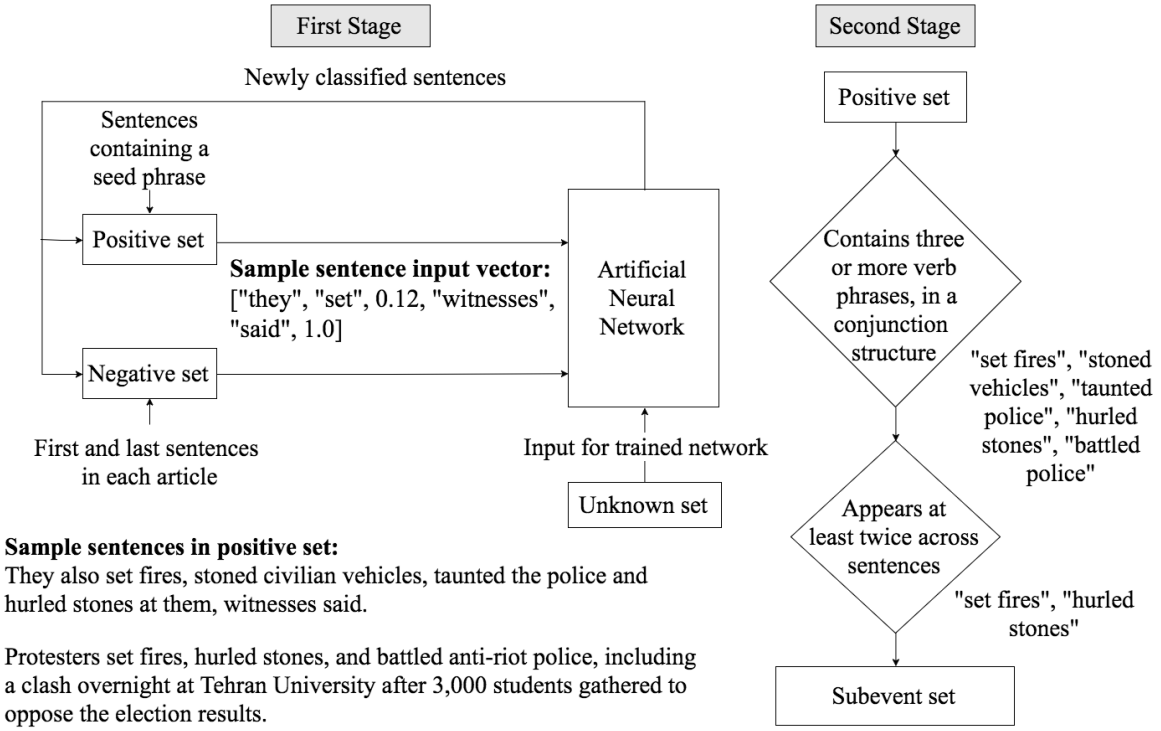

Figure 1: The Two-step Subevent Learning Paradigm

strated that we can use automatically-learned event facet phrases (event agents and purposes) and main event expressions to find event articles with a high accuracy. We first obtained their learned event facet phrases and event expressions, most of which refer to general events. Then we followed their paper and identified two types of news articles that are likely to describe a civil unrest event by matching the obtained phrases to the English Gigaword fifth edition (Parker et al., 2011)

Specifically, we first consider news articles that contain a civil unrest keyword such as "strike" and "protest"[1], then we identify an article as relevant if it contains a sentence where either two types of facet phrases or one facet phrase together with an event expression are found. In addition, we consider news articles that do not contain a civil unrest keyword; we require an article to contain a sentence where three types of event information are matched. Overall, we get a civil unrest corpus containing 232,710 news articles.

[1]We used the same set of keywords as used by (Huang and Riloff, 2013)

3.1.2 Context Feature Selection

We hypothesized that the first and last noun/verb phrases and their positions in the sentence were likely to be good indicators that the sentence might contain a subevent phrase. Because our document corpus was composed of news articles, we determined that concrete subevents would require a level of substantiation that abstract, non-specific events would not. For example, a reporter would not usually cite a source in a sentence informing the reader that a riot occurred but would likely choose to quote a source when reporting that rioters burned tires in the streets. Because of this, sentences containing subevent phrases often begin or end with phrases such as "he witnessed" or "she told the press." To represent the nouns and verbs, we used the 50-dimention Stanford GloVe (Pennington et al., 2014) word embeddings pre-trained on Wikipedia 2014 and Gigaword5 (Parker et al., 2011).

3.1.3 Seeds and Training Sentence Generation

To form a training set for the neural network, we used eight seed subevent phrases (as shown in Table 1) to identify a set of positive sentences that con-

waved banners
shouted slogans
chanted slogans
burned flag
burned flags
blocked road
clashed with police
clashed with government

Table 1: First Stage Classifier Seed Subevent Phrases

tain one of the seed phrases. In total, we obtained around 5000 positive sentences and bounded this to 3500 for use with the classifier. Finding a sufficient number of negative sentences was a more challenging task. After reviewing the corpus, we determined that the first and last sentences of an article are unlikely to contain subevent phrases. These sentences often function as general introductions and conclusions that refer to the main event of the article. We selected 7000 of these sentences to form the negative set. The rest of the sentences not classified as positive or negative remain unknown, amounting to almost 1 million.

3.1.4 Artificial Neural Networks for Sentence Classification

We implemented an artificial neural network with a single hidden layer composed of 500 nodes. In order to facilitate faster training, we used tanh as the activation function of the hidden layer. Softmax was used as the output layer activation function. In order to train the network, we provided an initial set of positive and negative vectors representing sentence data from the corpus as described in Section 3.1.3. These input vectors were then divided into a training set, validation set and testing set. The training set was comprised of 70% of the full dataset, the validation set of 20% and the testing set of 10%. The neural network was trained for 1000 epochs and used the validation set and test set to measure performance in order to avoid overfitting.

Because we began with a limited number of seed phrases to create the positive set, we chose to use a bootstrapping approach to expand our data set and improve the classifier. After training, the entire unknown data set would be classified, and sentences determined to be positive with 0.90 certainty or greater would be added to the positive set. Sentences classified as negative with 0.90 certainty or greater would be added to the negative set. However, in order to maintain the 2:1 ratio of negative to positive vectors, the number of negative vectors that could be added was capped at twice the number of positive additions for each iteration. After the new sentences were added to the positive and negative sets, the neural network was retrained with this data and classified additional previously unknown sentences. The process repeated for five iterations, then bootstrapping ended because not enough newly identified positive sentences were found ($<$3000 in the last iteration). Table 2 shows the number of sentences that were added after each bootstrapping iteration.

Iteration	Positives	Negatives
1	13223	26446
2	12611	25222
3	9411	18822
4	6076	12152
5	2842	5684

Table 2: Number of Sentences Added after Each Iteration

3.2 Phase 2: Subevent Extraction

After accumulating a large set of sentences likely containing subevents from the first phase of the system, the second step identifies the subevent phrases within these sentences. We observe that subevent phrases often occur in lists and we focus on leveraging such local cues to extract subevents. Specifically, we identify conjunction constructions that contain three or more verb phrases, each verb phrase obeys one of the following two forms: verb + direct object or verb + prepositional phrase. We extract the sequence of verb phrases, each as a subevent candidate. We only included subevents with frequency greater than or equal to two in the final evaluation. Through the two-stage extraction procedure, we identified 610 unique subevents. Table 3.2 shows some of the learned subevents.

Clearly, this second phase suffers from low recall. However, because subevents are identified at the corpus level as opposed to the document level, per-sentence recall is not a significant concern as long as a sufficient number of subevents are identi-

threw stones, hurled rocks, pounded in air
smashed through roadblocks, detained people
forced way, fired in air, threw at police
smashed windows, set fire, burned tires
threw bombs, opened fire, blocked road
pelted with stones, appeared on balcony
arrested for vandalism, threw bombs
burned cars, carried banners, lit candles
detained people, planted flag, wore masks
stoned police, converged on highway
chanted against authorities, chanted in city
broke through barricade, blocked traffic
broke windows, screamed outside palace
torched cars, ransacked office, smashed shop
shouted in unison, sang songs, planted flags
runs alongside shrines, chanted for democracy

Table 3: Subset of learned subevents

	Recall	Precision	F1-score
(Huang and Riloff, 2013)	71	**88**	79
+Subevents	**81**	83	**82**

Table 4: Event Recognition Performance Before/After Incorporating Subevents

fied across the whole corpus. As we demonstrate in the evaluation section, corpus-level recall was high enough to produce noticeable results.

4 Evaluation

We show that our acquired subevent phrases are useful to discover articles that describe the main event and therefore improve event detection performance.

For direct comparisons, we tested our subevents using the same test data and the same evaluation setting as the previous multi-faceted event recognition research by (Huang and Riloff, 2013). Specifically, they have annotated 300 new articles that each contains a civil unrest keyword and only 101 of them are actually civil unrest stories. They have shown that the multi-faceted event recognition approach can accurately identify civil unrest documents, by identifying a sentence in the documents where two types of facet phrases or one facet phrase and a main event expression were matched. The first row of Table 4 shows their multi-faceted event recognition performance.

We compared our learned subevent phrases with the event phrases learned by (Huang and Riloff, 2013) and found that 559 out of our 610 unique phrases are not in their list. We augmented their provided event phrase list with our newly acquired subevent phrases and then used the exactly same evaluation procedure. Essentially, we used a longer event phrase dictionary which is a combination of main event expressions resulted from the previous research by (Huang and Riloff, 2013) and our learned subevent phrases. Row 2 shows the event recognition performance using the extended event phrase list. We can see that after incorporating subevent phrases, additional 10% of civil unrest stories were discovered, with a small precision loss, the F1-score on event detection was improved by 3%.

5 Conclusion

We have presented a two-phase approach for identifying a specific type of "subevents", referring to physical actions composing an event. While our approach is certainly tailored to the civil unrest domain, we believe that this method is applicable to many other domains within the scope of news reports, including health, economics and even politics, where reporters overwhelmingly rely on outside opinion to present the facts of the story and provide the summary themselves. However in more casual domains where this is not necessarily the case, this approach will suffer. For instance, in sports writing, a reporter giving a play-by-play of a basketball game will not need to call upon witnesses or field experts to present concrete subevents.

Furthermore, we have shown the great potential of using subevents to improve event detection performance. In addition, distinguishing between events and subevents develops an event hierarchy and can benefit multiple applications such as text summarization and event timeline generation.

Gaussian Visual-Linguistic Embedding for Zero-Shot Recognition

Tanmoy Mukherjee and **Timothy Hospedales**
Queen Mary University of London
School of Electronic Engineering and Computer Science
{k.m.tanmoy,t.hospedales}@qmul.ac.uk

Abstract

An exciting outcome of research at the intersection of language and vision is that of zero-shot learning (ZSL). ZSL promises to scale visual recognition by borrowing distributed semantic models learned from linguistic corpora and turning them into visual recognition models. However the popular word-vector DSM embeddings are relatively impoverished in their expressivity as they model each word as a single vector point. In this paper we explore word-*distribution* embeddings for ZSL. We present a visual-linguistic mapping for ZSL in the case where words and visual categories are both represented by distributions. Experiments show improved results on ZSL benchmarks due to this better exploiting of intra-concept variability in each modality

1 Introduction

Learning vector representations of word meaning is a topical area in computational linguistics. Based on the distributional hypothesis (Harris, 1954) – that words in similar context have similar meanings – distributed semantic models (DSM)s build vector representations based on corpus-extracted context. DSM approaches such as topic models (Blei et al., 2003), and more recently neural networks (Collobert et al., 2011; Mikolov et al., 2013) have had great success in a variety of lexical and semantic tasks (Arora et al., 2015; Schwenk, 2007).

However despite their successes, classic DSMs are severely impoverished compared to humans due to learning solely from word cooccurrence without grounding in the outside world. This has motivated a wave of recent research into multi-modal and cross-modal learning that aims to *ground* DSMs in non-linguistic modalities (Bruni et al., 2014; Kiela and Bottou, 2014; Silberer and Lapata, 2014; **?**). Such multi-modal DSMs are attractive because they learn richer representations than language-only models (e.g., that bananas are *yellow* fruit (Bruni et al., 2012b)), and thus often outperform language only models in various lexical tasks (Bruni et al., 2012a).

In this paper, we focus on a key unique and practically valuable capability enabled by cross-modal DSMs: that of zero-shot learning (ZSL). Zero-shot recognition aims to recognise visual categories in the absence of any training examples by cross-modal transfer from language. The idea is to use a limited set of training data to learn a linguistic-visual mapping and then apply the induced function to map images from novel visual categories (unseen during training) to a linguistic embedding: thus enabling recognition in the absence of visual training examples. ZSL has generated big impact (Lampert et al., 2009; Socher et al., 2013; Lazaridou et al., 2014) due to the potential of leveraging language to help visual recognition scale to many categories without labor intensive image annotation.

DSMs typically generate *vector* embeddings of words, and hence ZSL is typically realised by variants of vector-valued cross-modal regression. However, such vector representations have limited expressivity – each word is represented by a point, with no notion of intra-class variability. In this paper, we consider ZSL in the case where both visual and linguistic concepts are represented by *Gaussian distribution* embeddings. Specifically, our Gaussian-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 912–918,
Austin, Texas, November 1-5, 2016.

embedding approach to ZSL learns concept distributions in both domains: Gaussians representing individual words (as in (Vilnis and McCallum, 2015)) and Gaussians representing visual concepts. Simultaneously, it learns a cross-domain mapping that warps language-domain Gaussian concept representations into alignment with visual-domain concept Gaussians. Some existing vector DSM-based cross-modal ZSL mappings (Akata et al., 2013; Frome et al., 2013) can be seen as special cases of ours where the within-domain model is pre-fixed as vector corresponding to the Gaussian means alone, and only the cross-domain mapping is learned. Our results show that modeling linguistic and visual concepts as Gaussian distributions rather than vectors can significantly improve zero-shot recognition results.

2 Methodology

2.1 Background

Vector Word Embeddings In a typical setup for unsupervised learning of word-vectors, we observe a sequence of tokens $\{w_i\}$ and their context words $\{c(w)_i\}$. The goal is to map each word w to a d-dimensional vector e_w reflecting its distributional properties. Popular skip-gram and CBOW models (Mikolov et al., 2013), learn a matrix $W \in \mathbb{R}^{|V| \times d}$ of word embeddings for each of V vocabulary words ($e_w = W_{(w,:)}$) based on the objective of predicting words given their contexts.

Another way to formalise a word vector representation learning problem is to search for a representation W so that words w have high representational similarity with co-occuring words $c(w)$, and low similarity with representations of non-co-occurring words $\neg c(w)$. This could be expressed as optimisation of max-margin loss J; requiring that each word w's representation e_w is more similar to that of context words e_p than non-context words e_n.

$$J(W) = \sum_{w, w_p \in c(w), w_n \in \neg c(w)} \max(0, \delta - E(e_w, e_{w_p}) + E(e_w, e_{w_n})) \quad (1)$$

where similarity measure $E(\cdot, \cdot)$ is a distance in $\mathbb{R}^d$ space such as cosine or euclidean.

Gaussian Word Embeddings Vector-space models are successful, but have limited expressivity in terms of modelling the variance of a concept, or asymmetric distances between words, etc. This has motivated recent work into *distribution*-based embeddings (Vilnis and McCallum, 2015). Rather than learning word-vectors e_w, the goal here is now to learn a distribution for each word, represented by a per-word mean μ_w and covariance Σ_w.

In order to extend word representation learning approaches such as Eq. (1) to learning Gaussians, we need to replace vector similarity measure $E(\cdot, \cdot)$ with a similarity measure for Gaussians. We follow (Vilnis and McCallum, 2015) in using the inner product between distributions f and g – the probability product kernel (Jebara et al., 2004).

$$E(f, g) = \int_{x \in \mathbb{R}^n} f(x) g(x). \quad (2)$$

The probability product kernel (PPK) has a convenient closed form in the case of Gaussians:

$$\begin{aligned} E(f, g) &= \int_{x \in \mathbb{R}^n} \mathcal{N}(x; \mu_f, \Sigma_f) \mathcal{N}(x; \mu_g, \Sigma_g) dx \\ &= \mathcal{N}(0; \mu_f - \mu_g, \Sigma_f + \Sigma_g) \end{aligned} \quad (3)$$

where μ_f, μ_g are the means and Σ_f, Σ_g are the covariances of the probability distribution f and g.

2.2 Cross-Modal Distribution Mapping

Gaussian models of words can be learned as in the previous section, and that Gaussian models of image categories can be trivially obtained by maximum likelihood. The central task is therefore to establish a mapping between word-and image-Gaussians, which will be of different dimensions d_w and d_x.

We aim to find a projection matrix $A \in \mathbb{R}^{d_x \times d_w}$ such that a word w generates an image vector as $e_x = A e_w$. Working with distributions, this implies that we have $\mu_x = A \mu_w$ and $\Sigma_x = A \Sigma_w A^T$. We can now evaluate the similarity of concept distributions across modalities. The similarity between image-and text-domain Gaussians f and g is:

$$E(f, g) = \mathcal{N}(0; \mu_f - A\mu_g, \Sigma_f + A \Sigma_g A^T) \quad (4)$$

Using this metric, we can train our cross-modal projection A via the cross-domain loss:

$$J(A) = \sum_{f, g \in P,\ h, k \in N} \max(0, \delta - E(f, g) + E(h, k)) \quad (5)$$

where P is the set of matching pairs that should be aligned (e.g., the word Gaussian 'plane' and the Gaussian of plane images) and N is the set of mismatching pairs that should be separated (e.g., 'plane' and images of dogs). This can be optimised with SGD using the gradient:

$$\begin{aligned}\frac{\partial E}{\partial A} &= \frac{1}{2}((\Sigma_f + A\Sigma_g A^T)^{-1}A(\Sigma_g + \Sigma_g^T)) \\ &+ ((\mu_g^T(\Sigma_f + A\Sigma_g A^T)^{-1}(\mu_f - A\mu_g) \\ &+ (\mu_f - A\mu_g)^T(\Sigma_f + A\Sigma_g A^T)^{-1}\mu_g^T \\ &+ (\mu_f - A\mu_g)^T(\Sigma_f + A\Sigma_g A^T)^{-1} \\ &A^T(\Sigma_g + \Sigma_j^T)(\Sigma_f + A\Sigma_g A^T)^{-1}(\mu_f - A\mu_g))\end{aligned}$$

2.3 Joint Representation and Mapping

The cross-domain mapping A can be learned (Eq. 5) for fixed within-domain representations (word and image Gaussians). It is also possible to simultaneously learn the text and image-domain gaussians ($\{\mu_i, \Sigma_i\}^{text}, \{\mu_j, \Sigma_j\}^{img}$) by optimising the sum of three coupled losses: Eq. 1 with Eq. 3, Eq. 5 and max-margin image-classification using Gaussians. We found jointly learning the image-classification Gaussians did not bring much benefit over the MLE Gaussians, so we only jointly learn the text Gaussians and cross-domain mapping.

2.4 Application to Zero-Shot Recognition

Once the text-domain Gaussians and cross-domain mapping have been trained for a set of known words/classes, we can use the learned model to recognise any novel/unseen but name-able visual category w as follows: 1. Get the word-Gaussians of target categories w, $\mathcal{N}(\mu_w, \Sigma_w)$. 2. Project those Gaussians to image modality, $\mathcal{N}(A\mu_w, A\Sigma_w A^T)$. 3. Classify a test image x by evaluating its likelihood under each Gaussian, and picking the most likely Gaussian: $p(w|x) \propto \mathcal{N}(x|A\mu_w, A\Sigma_w A^T)$.

2.5 Contextual Query

To illustrate our approach, we also experiment with a new variant of the ZSL setting. In conventional ZSL, a novel word can be matched against images by projecting it into image space, and sorting images by their distance to the word (vector), or likelihood under the word (Gaussian). However, results may be unreliable when used with polysemous words, or words with large appearance variability. In this case we may wish to enrich the query with contextual words that disambiguate the visual meaning of the query. With regular vector-based queries, the typical approach is to sum the word-vectors. For example: For contextual disambiguation of polysemy, we may hope that vec('bank')+vec('river') may retrieve a very different set of images than vec('bank')+vec('finance'). For specification of a specific subcategory or variant, we may hope that vec('plane')+vec('military') retrieves a different set of images than vec('plane')+vec('passenger'). By using distributions rather than vectors, our framework provides a richer means to make such queries that accounts for the intra-class variability of each concept. When each word is represented by a Gaussian, a two-word query can be represented by their product, which is the new Gaussian $\mathcal{N}(\frac{\Sigma_1^{-1}\mu_1+\Sigma_2^{-1}\mu_2}{\Sigma_1^{-1}+\Sigma_2^{-1}}, (\Sigma_1^{-1} + \Sigma_2^{-1})^{-1})$.

3 Experiments

3.1 Datasets and Settings

Datasets: We evaluate our method [1] using the main Animals with Attributes (**AWA**) and **ImageNet1K** benchmarks. To extract visual features we use the VGG-16 CNN (Simonyan and Zisserman, 2015) to extract a $d_x = 4096$ dimensional feature for each image. To train the word Gaussian representation, we use a combination of UkWAC (Ferraresi et al., 2008) and Wikipedia corpus of 25 million tokens, and learn a $d_w = 100$ dimensional Gaussian representation. We set our margin parameter to $\Delta = 1$.

Settings: Our zero-shot setting involves training a visual recogniser (i.e., our mapping A) on a subset of classes, and evaluating it on a disjoint subset. For AWA, we use the standard 40/10 class split (Lampert et al., 2009), and for ImageNet we use a standard 800/200 class split (Mensink et al., 2012).

Competitors: We implement a set of representative alternatives for direct comparison with ours on the same visual features and text corpus. These include: cross-modal linear regression (LinReg, (Dinu et al., 2015)), non-linear regression (NLinReg, (Lazaridou et al., 2014; Socher et al., 2013)),

Gaussian Embedding	65.4%

Table 2: Comparison of our ZSL results with state of the art.

ES-ZSL (Romera-Paredes and Torr, 2015), and a max-margin cross-modal energy function method (CME, (Akata et al., 2013; Frome et al., 2013)). Note that the CME strategy is the most closely related to ours in that it also trains a $d_x \times d_w$ matrix with max-margin loss, but uses it in a bilinear energy function with vectors $E(x, y) = x^T Ay$; while our energy function operates on Gaussians.

3.2 Results

Table 1 compares our results on the AWA benchmark against alternatives using the same visual features, and word vectors trained on the same corpus. We observe that: (i) Our Gaussian-embedding obtains the best performance overall. (ii) Our method outperforms CME which shares an objective function and optimisation strategy with ours, but operates on vectors rather than Gaussians. This suggests that our new distribution rather than vector-embedding does indeed bring significant benefit.

A comparison to published results obtained by other studies on the same ZSL splits is given in Table 2, where we see that our results are competitive despite exploitation of supervised embeddings such as attributes (Fu et al., 2014), or combinations of embeddings (Akata et al., 2013) by other methods.

We next demonstrate our approach qualitatively by means of the contextual query idea introduced in Sec 2.5. Fig. 1 shows examples of how the top retrieved images differ intuitively when querying ImageNet for zero-shot categories 'plane' and 'horse' with different context words. To ease interpretation, we constrain the retrieval to the true target class, and focus on the effect of the context word. Our learned Gaussian method retrieves more relevant images than the word-vector sum baseline. E.g., with the Gaussian model all of the top-4 retrieved images for Passenger+Plane are relevant, while only two are relevant with the vector model. Similarly, the retrieved black horses are more clearly black.

3.3 Further Analysis

To provide insight into our contribution, we repeat the analysis of the AwA dataset and evaluate several variants of our full method. These use our features, and train the same cross-domain max-margin loss in Eq 5, but vary in the energy function and representa-

AwA	
Bilinear-WordVec	43.1%
Bilinear-MeanVec	52.2%
PPK-MeanVec	52.6%
PPK-Gaussian	65.4%

Table 3: Impact of training and testing with distribution rather than vector-based representations

tions used. Variants include: (i) Bilinear-WordVec: Max-margin training on word vector representations of words and images with a bilinear energy function. (ii) Bilinear-MeanVec: As before, but using our Gaussian means as vector representations in image and text domains. (iii) PPK-MeanVec: Train the max-margin model with Gaussian representation and PPK energy function as in our full model, but treat the resulting means as point estimates for conventional vector-based ZSL matching at testing-time. (v) PPK-Gaussian: Our full model with Gaussian PPK training and testing by Gaussian matching.

From the results in Table 3, we make the observations: (i) Bilinear-MeanVec outperforming Bilinear-WordVec shows that cross-modal (Sec 2.3) training of word Gaussians learns better point estimates of words than conventional word-vector training, since these only differ in the choice of vector representation of class names. (ii) PPK-Gaussian outperforming PPK-MeanVec shows that having a model of intra-class variability (as provided by the word-Gaussians) allows better zero-shot recognition, since these differ only in whether covariance is used at testing time.

3.4 Related Work and Discussion

Our approach models intra-class variability in both images and text. For example, the variability in visual appearance of military versus passenger 'plane's, and the variability in context according to whether a the word 'plane' is being used in a military or civilian sense. Given distribution-based representations in each domain, we find a cross-modal map that warps the two distributions into alignment.

Concurrently with our work, Ren et al (2016) present a related study on distribution-based visual-text embeddings. Methodologically, they benefit from end-to-end learning of deep features as well as cross-modal mapping, but they only discriminatively train word covariances, rather than jointly training both means and covariances as we do.

With regards to efficiency, our model is fast to train if fixing pre-trained word-Gaussians and optimising only the cross-modal mapping A. However, training the mapping jointly with the word-Gaussians comes at the cost of updating the representations of all words in the dictionary, and is thus much slower.

In terms of future work, an immediate improvement would be to generalise our of Gaussian embeddings to model concepts as mixtures of Gaussians or other exponential family distributions (Rudolph et al., 2016; Chen et al., 2015). This would for example, allow polysemy to be represented more cleanly as a mixture, rather than as a wide-covariance Gaussian as happens now. We would also like to explore distribution-based embeddings of sentences/paragraphs for class description (rather than class name) based zero-shot recognition (Reed et al., 2016). Finally, besides end-to-end deep learning of visual features, training non-linear cross-modal mappings is also of interest.

4 Conclusion

In this paper, we advocate using distribution-based embeddings of text and images when bridging the gap between vision and text modalities. This is in contrast to the common practice of point vector-based embeddings. Our distribution-based approach provides a representation of intra-class variability that improves zero-shot recognition, allows more meaningful retrieval by multiple keywords, and also produces better point-estimates of word vectors.

Abstract

Visual Question Answering (VQA) is the task of answering natural-language questions about images. We introduce the novel problem of determining the *relevance of questions to images* in VQA. Current VQA models do not reason about whether a question is even related to the given image (*e.g., What is the capital of Argentina?*) or if it requires information from external resources to answer correctly. This can break the continuity of a dialogue in human-machine interaction. Our approaches for determining relevance are composed of two stages. Given an image and a question, (1) we first determine whether the question is visual or not, (2) if visual, we determine whether the question is relevant to the given image or not. Our approaches, based on LSTM-RNNs, VQA model uncertainty, and caption-question similarity, are able to outperform strong baselines on both relevance tasks. We also present human studies showing that VQA models augmented with such question relevance reasoning are perceived as more intelligent, reasonable, and human-like.

1 Introduction

Visual Question Answering (VQA) is the task of predicting a suitable answer given an image and a question about it. VQA models (*e.g.,* (Antol et al., 2015; Ren et al., 2015)) are typically discriminative models that take in image and question representations and output one of a set of possible answers.

Our work is motivated by the following key observation – all current VQA systems always output an answer *regardless of whether the input question makes any sense for the given image or not*. Fig. 1 shows examples of relevant and irrelevant questions. When VQA systems are fed irrelevant questions as input, they understandably produce nonsensical answers (Q: *"What is the capital of Argentina?"* A: *"fire hydrant"*). Humans, on the other hand, are unlikely to provide such nonsensical answers and will instead answer that this is irrelevant or use another knowledge source to answer correctly, when possible. We argue that this implicit assumption by all VQA systems – that an input question is always relevant for the input image – is simply untenable as VQA systems move beyond standard academic datasets to interacting with real users, who may be unfamiliar, or malicious. The goal of this work is to make VQA systems more human-like by providing them the capability to identify relevant questions.

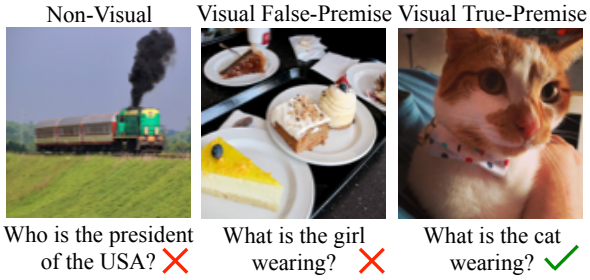

Figure 1: Example irrelevant (non-visual, false-premise) and relevant (visual true-premise) questions in VQA.

While existing work has reasoned about cross-modal similarity, being able to identify whether a question is relevant to a given image is a novel problem with real-world applications. In human-robot interaction, being able to identify questions that are dissociated from the perception data available is important. The robot must decide whether to process the scene it perceives or query external world knowledge resources to provide a response.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 919–924,
Austin, Texas, November 1-5, 2016.

As shown in Fig. 1, we study three types of question-image pairs: **Non-Visual**. These questions are not questions about images at all – they do not require information from *any* image to be answered (*e.g., "What is the capital of Argentina?"*). **Visual False-Premise**. While visual, these questions do not apply to the given image. For instance, the question *"What is the girl wearing?"* makes sense only for images that contain a girl in them. **Visual True-Premise**. These questions are relevant to (*i.e.,* have a premise which is true) the image at hand.

We introduce datasets and train models to recognize both non-visual and false-premise question-image (QI) pairs in the context of VQA. First, we identify whether a question is visual or non-visual; if visual, we identify whether the question has a true-premise for the given image. For visual vs. non-visual question detection, we use a Long Short-Term Memory (LSTM) recurrent neural network (RNN) trained on part of speech (POS) tags to capture visual-specific linguistic structure. For true vs. false-premise question detection, we present one set of approaches that use the uncertainty of a VQA model, and another set that use pre-trained captioning models to generate relevant captions (or questions) for the given image and then compare them to the given question to determine relevance.

Our proposed models achieve accuracies of 92% for detecting non-visual, and 74% for detecting false-premise questions, which significantly outperform strong baselines. We also show through human studies that a VQA system that reasons about question relevance is picked *significantly more often* as being more intelligent, human-like and reasonable than a baseline VQA system which does not. Our code and datasets are publicly available on the authors' webpages.

2 Related Work

There is a large body of existing work that reasons about cross-modal similarity: how well an image matches a query tag (Liu et al., 2009) in text-based image retrieval, how well an image matches a caption (Feng and Lapata, 2013; Xu et al., 2015; Ordonez et al., 2011; Karpathy and Fei-Fei, 2015; Fang et al., 2015), and how well a video matches a description (Donahue et al., 2015; Lin et al., 2014a).

In our work, if a question is deemed irrelevant, the VQA model says so, as opposed to answering the question anyway. This is related to perception systems that do not respond to an input where the system is likely to fail. Such failure prediction systems have been explored in vision (Zhang et al., 2014; Devarakota et al., 2007) and speech (Zhao et al., 2012; Sarma and Palmer, 2004; Choularton, 2009; Voll et al., 2008). Others attempt to provide the most meaningful answer instead of suppressing the output of a model that is expected to fail for a given input. One idea is to avoid a highly specific prediction if there is a chance of being wrong, and instead make a more generic prediction that is more likely to be right (Deng et al., 2012). Malinowski and Fritz (2014) use semantic segmentations in their approach to question answering, where they reason that objects not present in the segmentations should not be part of the answer.

To the best of our knowledge, our work is the first to study the relevance of questions in VQA. Chen et al. (2012) classify users' intention of questions for community question answering services. Most related to our work is Dodge et al. (2012). They extract visual text from within Flickr photo captions to be used as supervisory signals for training image captioning systems. Our motivation is to endow VQA systems the ability to detect non-visual questions to respond in a human-like fashion. Moreover, we also detect a more fine-grained notion of question relevance via true- and false-premise.

3 Datasets

For the task of detecting visual vs. non-visual questions, we assume all questions in the VQA dataset (Antol et al., 2015) are visual, since the Amazon Mechanical Turk (AMT) workers were specifically instructed to ask questions about a displayed image while creating it. We also collected non-visual philosophical and general knowledge questions from the internet (see supplementary material). Combining the two, we have 121,512 visual questions from the validation set of VQA and 9,952[1] generic non-visual questions collected from the internet. We call this dataset Visual vs. Non-

[1]High accuracies on this task in our experiments indicate that this suffices to learn the corresponding linguistic structure.

Visual Questions (VNQ).

We also collect a dataset of true- vs. false-premise questions by showing AMT workers images paired with random questions from the VQA dataset and asking them to annotate whether they are applicable or not. We had three workers annotate each QI pair. We take the majority vote as the final ground truth label.[2] We have 10,793 QI pairs on 1,500 unique images out of which 79% are non-applicable (false-premise). We refer to this visual true- vs. false-premise questions dataset as VTFQ.

Since there is a class imbalance in both of these datasets, we report the average per-class (*i.e.,* normalized) accuracy for all approaches. All datasets are publicly available.

4 Approach

Here we present our approaches for detecting (1) visual vs. non-visual QI pairs, and (2) true- vs. false-premise QI pairs.

4.1 Visual vs. Non-Visual Detection

Recall that the task here is to detect visual questions from non-visual ones. Non-visual questions, such as *"Do dogs fly?"* or *"Who is the president of the USA?"*, often tend to have a difference in the linguistic structure from that of visual questions, such as *"Does this bird fly?"* or *"What is this man doing?"*. We compare our approach (**LSTM**) with a baseline (**RULE-BASED**):

1. **RULE-BASED**. A rule-based approach to detect non-visual questions based on the part of speech (POS)[3] tags and dependencies of the words in the question. *E.g.,* if a question has a plural noun with no determiner before it and is followed by a singular verb (*"Do dogs fly?"*), it is a non-visual question.[4]

2. **LSTM**. We train an LSTM with 100-dim hidden vectors to embed the question into a vector and predict visual vs. not. Instead of feeding question words (['what', 'is', 'the', 'man', 'doing', '?']), the input to our LSTM is embeddings of POS tags of the words (['pronoun', 'verb', 'determiner', 'noun', 'verb']). Embeddings of the POS tags are learnt end-to-end. This captures the structure of image-grounded questions, rather than visual vs. non-visual topics. The latter are less likely to generalize across domains.

[2] 78% of the time all three votes agree.

[3] We use spaCy POS tagger (Honnibal and Johnson, 2015).

[4] See supplement for examples of such hand-crafted rules.

4.2 True- vs. False-Premise Detection

Our second task is to detect whether a question Q entails a false-premise for an image I. We present two families of approaches to measure this QI 'compatibility': (i) using uncertainty in VQA models, and (ii) using pre-trained captioning models.

Using VQA Uncertainty. Here we work with the hypothesis that if a VQA model is uncertain about the answer to a QI pair, the question may be irrelevant for the given image since the uncertainty may mean it has not seen similar QI pairs in the training data. We test two approaches:

1. **ENTROPY**. We compute the entropy of the softmax output from a state-of-the art VQA model (Antol et al., 2015; Lu et al., 2015) for a given QI pair and train a three-layer multilayer perceptron (MLP) on top with 3 nodes in the hidden layer.

2. **VQA-MLP**. We feed in the softmax output to a three-layer MLP with 100 nodes in the hidden layer, and train it as a binary classifier to predict whether a question has a true- or false-premise for the given image.

Using Pre-trained Captioning Models. Here we utilize (a) an image captioning model, and (b) an image question-generation model – to measure QI compatibility. Note that both these models generate natural language capturing the semantics of an image – one in the form of statement, the other in the form of a question. Our hypothesis is that a given question is relevant to the given image if it is similar to the language generated by these models for that image. Specifically:

1. Question-Caption Similarity (**Q-C SIM**). We use NeuralTalk2 (Karpathy and Fei-Fei, 2015) pre-trained on the MSCOCO dataset (Lin et al., 2014b) (images and associated captions) to generate a caption C for the given image, and then compute a learned similarity between Q and C (details below).

2. Question-Question Similarity (**Q-Q' SIM**). We use NeuralTalk2 re-trained (from scratch) on the questions in the VQA dataset to generate a question Q' for the image. Then, we compute a learned similarity between Q and Q'.

Visual vs. Non-Visual		True- vs. False-Premise				
RULE-BASED	LSTM	ENTROPY	VQA-MLP	Q-GEN SCORE	Q-C SIM	Q-Q' SIM
75.68	**92.27**	59.66	64.19	57.41	74.48	**74.58**

Table 1: Normalized accuracy results (averaged over 40 random train/test splits) for visual vs. non-visual detection and true- vs. false-premise detection. **RULE-BASED** and **Q-GEN SCORE** were not averaged because they are deterministic.

We now describe our learned Q-C similarity function (the Q-Q' similarity is analogous). Our Q-C similarity model is a 2-channel LSTM+MLP (one channel for Q, another for C). Each channel sequentially reads word2vec embeddings of the corresponding language via an LSTM. The last hidden state vectors (40-dim) from the 2 LSTMs are concatenated and fed as inputs to the MLP, which outputs a 2-class (relevant vs. not) softmax. The entire model is learned end-to-end on the VTFQ dataset. We also experimented with other representations (*e.g.,* bag of words) for Q, Q', C, which are included in the supplement for completeness.

Finally, we also compare our proposed models above to a simpler baseline (**Q-GEN SCORE**), where we compute the probability of the input question Q under the learned question-generation model. The intuition here is that since the question generation model has been trained only on relevant questions (from the VQA dataset), it will assign a high probability to Q if it is relevant.

5 Experiments and Results

The results for both experiments are presented in Table 1. We present results averaged over 40 random train/test splits. **RULE-BASED** and **Q-GEN SCORE** were not averaged because they are deterministic.

Visual vs. Non-Visual Detection. We use a random set of 100,000 questions from the VNQ dataset for training, and the remaining 31,464 for testing. We see that **LSTM** performs 16.59% (21.92% relative) better than **RULE-BASED**.

True- vs. False-Premise Detection. We use a random set of 7,195 (67%) QI pairs from the VTFQ dataset to train and the remaining 3,597 (33%) to test. While the VQA model uncertainty based approaches (**ENTROPY**, **VQA-MLP**) perform reasonably well (with the MLP helping over raw entropy), the learned similarity approaches perform much better (10.39% gain in normalized accuracy). High uncertainty of the model may suggest that a similar QI pair was not seen during training; however, that does not seem to translate to detecting irrelevance. The language generation models (**Q-C SIM**, **Q-Q' SIM**) seem to work significantly better at modeling the semantic interaction between the question and the image. The generative approach (**Q-GEN SCORE**) is outperformed by the discriminative approaches (**VQA-MLP**, **Q-C SIM**, **Q-Q' SIM**) that are trained explicitly for the task at hand. We show qualitative examples of **Q-Q' SIM** for true- vs. false-premise detection in Fig. 2.

6 Human Qualitative Evaluation

We also perform human studies where we compare two agents: (1) **AGENT-BASELINE**– always answers every question. (2) **AGENT-OURS**– reasons about question relevance before responding. If question is classified as visual true-premise, **AGENT-OURS** answers the question using the same VQA model as **AGENT-BASELINE** (using (Lu et al., 2015)). Otherwise, it responds with a prompt indicating that the question does not seem meaningful for the image.

A total of 120 questions (18.33% relevant, 81.67% irrelevant, mimicking the distribution of the VTFQ dataset) were used. Of the relevant questions, 54% were answered correctly by the VQA model. Human subjects on AMT were shown the response of both agents and asked to pick the agent that sounded more intelligent, more reasonable, and more human-like after every observed QI pair. Each QI pair was assessed by 5 different subjects. Not all pairs were rated by the same 5 subjects. In total, 28 unique AMT workers participated in the study.

AGENT-OURS was picked 65.8% of the time as the winner, **AGENT-BASELINE** was picked only 1.6% of the time, and both considered equally (un)reasonable in the remaining cases. We also measure the percentage of times each robot gets picked

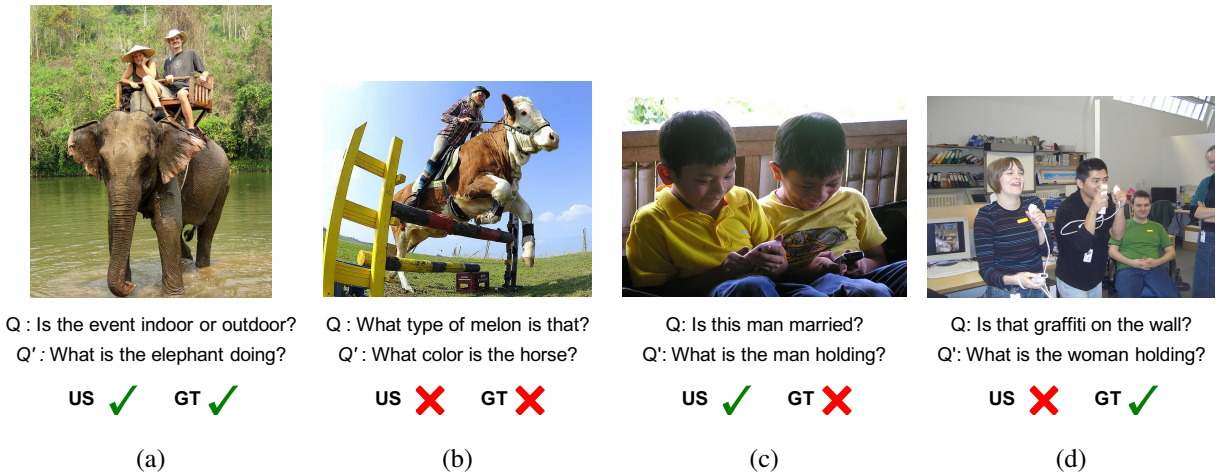

Figure 2: Qualitative examples for **Q-Q' SIM**. (a) and (b) show success cases, and (c) and (d) show failure cases. Our model predicts true-premise in (a) and (c), and false-premise in (b) and (d). In all examples we show the original question Q and the generated question Q'.

by the workers for true-premise, false-premise, and non-visual questions. These percentages are shown in Table 2.

	True-Premise	False-Premise	Non-Visual
AGENT-OURS	22.7	78.2	65.0
AGENT-BASELINE	04.7	01.4	00.0
Both	27.2	03.8	10.0
None	45.4	16.6	25.0

Table 2: Percentage of times each robot gets picked by AMT workers as being more intelligent, more reasonable, and more human-like for true-premise, false-premise, and non-visual questions.

Interestingly, humans often prefer **AGENT-OURS** over **AGENT-BASELINE** even when *both models are wrong* – **AGENT-BASELINE** answers the question incorrectly and **AGENT-OURS** incorrectly predicts that the question is irrelevant and refuses to answer a legitimate question. Users seem more tolerant to mistakes in relevance prediction than VQA.

7 Conclusion

We introduced the novel problem of identifying irrelevant (*i.e.,* non-visual or visual false-premise) questions for VQA. Our proposed models significantly outperform strong baselines on both tasks. A VQA agent that utilizes our detector and refuses to answer certain questions significantly outperforms a baseline (that answers all questions) in human studies. Such an agent is perceived as more intelligent, reasonable, and human-like.

There are several directions for future work. One possibility includes identifying the premise entailed in a question, as opposed to just stating true- or false-premise. Another is determining what external knowledge is needed to answer non-visual questions.

Our system can be further augmented to communicate to users what the assumed premise of the question is that is not satisfied by the image, *e.g.,* respond to *"What is the woman wearing?"* for an image of a cat by saying *"There is no woman."*

Abstract

Temporal common sense has applications in AI tasks such as QA, multi-document summarization, and human-AI communication. We propose the task of *sequencing* – given a jumbled set of aligned image-caption pairs that belong to a story, the task is to sort them such that the output sequence forms a coherent story. We present multiple approaches, via unary (position) and pairwise (order) predictions, and their ensemble-based combinations, achieving strong results on this task. We use both text-based and image-based features, which depict complementary improvements. Using qualitative examples, we demonstrate that our models have learnt interesting aspects of temporal common sense.

1 Introduction

Sequencing is a task for children that is aimed at improving understanding of the temporal occurrence of a sequence of events. The task is, given a jumbled set of images (and maybe captions) that belong to a single story, sort them into the correct order so that they form a coherent story. Our motivation in this work is to enable AI systems to better understand and predict the temporal nature of events in the world. To this end, we train machine learning models to perform the task of "sequencing".

Temporal reasoning has a number of applications such as multi-document summarization of multiple sources of, say, news information where the relative order of events can be useful to accurately merge information in a temporally consistent manner. In question answering tasks (Richardson et al., 2013; Fader et al., 2014; Weston et al., 2015; Ren et al., 2015), answering questions related to when an event occurs, or what events occurred prior to a particular event require temporal reasoning. A good temporal model of events in everyday life, i.e., a "temporal common sense", could also improve the quality of communication between AI systems and humans.

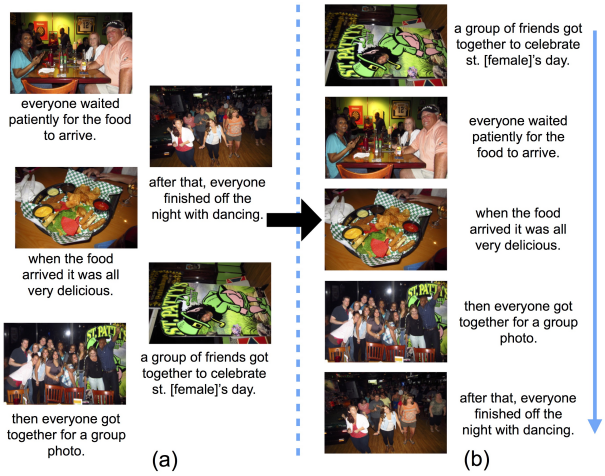

Figure 1: (a) The input is a jumbled set of aligned image-caption pairs. (b) Actual output of the system – an ordered sequence of image-caption pairs that form a coherent story.

Stories are a form of narrative sequences that have an inherent temporal common sense structure. We propose the use of visual stories depicting personal events to learn temporal common sense. We use stories from the Sequential Image Narrative Dataset (SIND) (Ting-Hao Huang, 2016) in which a set of 5 aligned image-caption pairs together form a coherent story. Given an input story that is jumbled (Fig. 1(a)), we train machine learning models to sort them into a coherent story (Fig. 1(b)).[1]

[*]Denotes equal contribution.
[†]Part of this work was done during an internship at TTIC.

[1]Note that 'jumbled' here refers to the loss of temporal ordering; image-caption pairs are still aligned.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 925–931,
Austin, Texas, November 1-5, 2016.

Our contributions are as follows:
– We propose the task of visual story sequencing.
– We implement two approaches to solve the task: one based on individual story elements to predict position, and the other based on pairwise story elements to predict relative order of story elements. We also combine these approaches in a voting scheme that outperforms the individual methods.
– As features, we represent a story element as both text-based features from the caption and image-based features, and show that they provide complementary improvements. For text-based features, we use both sentence context and relative order based distributed representations.
– We show qualitative examples of our models learning temporal common sense.

2 Related Work

Temporal ordering has a rich history in NLP research. Scripts (Schank and Abelson, 2013), and more recently, narrative chains (Chambers and Jurafsky, 2008) contain information about the participants and causal relationships between events that enable the understanding of stories. A number of works (Mani and Schiffman, 2005; Mani et al., 2006; Boguraev and Ando, 2005) learn temporal relations and properties of news events from the dense, expert-annotated TimeBank corpus (Pustejovsky et al., 2003). In our work, however, we use multi-modal story data that has no temporal annotations.

A number of works also reason about temporal ordering by using manually defined linguistic cues (Webber, 1988; Passonneau, 1988; Lapata and Lascarides, 2006; Hitzeman et al., 1995; Kehler, 2000). Our approach uses neural networks to avoid feature design for learning temporal ordering.

Recent works (Modi and Titov, 2014; Modi, 2016) learn distributed representations for predicates in a sentence for the tasks of event ordering and cloze evaluation. Unlike their work, our approach makes use of multi-modal data with *free-form* natural language text to learn event embeddings. Further, our models are trained end-to-end while their pipelined approach involves parsing and extracting verb frames from each sentence, where errors may propagate from one module to the next (as discussed in Section 4.3).

Chen et al. (2009) use a generalized Mallows model for modeling sequences for coherence within single documents. Their approach may also be applicable to our task. Recently, Mostafazadeh et al. (2016) presented the "ROCStories" dataset of 5-sentence stories with stereotypical causal and temporal relations between events. In our work though, we make use of a multi-modal story-dataset that contains *both* images and associated story-like captions.

Some works in vision (Pickup et al., 2014; Basha et al., 2012) also temporally order images; typically by finding correspondences between multiple images of the same scene using geometry-based approaches. Similarly, Choi et al. (2016) compose a story out of multiple short video clips. They define metrics based on scene dynamics and coherence, and use dense optical flow and patch-matching. In contrast, our work deals with stories containing potentially visually dissimilar but *semantically* coherent set of images and captions.

A few other recent works (Kim et al., 2015; Kim et al., 2014; Kim and Xing, 2014; Sigurdsson et al., 2016; Bosselut et al., 2016; Wang et al., 2016) summarize hundreds of individual streams of information (images, text, videos) from the web that deal with a single concept or event, to learn a common theme or *storyline* or for *timeline summarization*. Our task, however, is to predict the correct sorting of a given story, which is different from summarization or retrieval. Ramanathan et al. (2015) attempt to learn temporal embeddings of video frames in complex events. While their motivation is similar to ours, they deal with sampled frames from a video while we attempt to learn temporal common sense from *multi-modal* stories consisting of a sequence of aligned image-caption pairs.

3 Approach

In this section, we first describe the two components in our approach: unary scores that do not use context, and pairwise scores that encode relative orderings of elements. Next, we describe how we combine these scores through a voting scheme.

3.1 Unary Models

Let $\sigma \in \Sigma_n$ denote a permutation of n elements (image-caption pairs). We use σ_i to denote the position of element i in the permutation σ. A unary score

$S_u(\sigma)$ captures the appropriateness of each story element i in position σ_i:

$$S_u(\sigma) = \sum_{i=1}^{n} P(\sigma_i|i) \quad (1)$$

where $P(\sigma_i|i)$ denotes the probability of the element i being present in position σ_i, which is the output from an n-way softmax layer in a deep neural network. We experiment with 2 networks –
(1) A language-alone unary model (Skip-Thought+MLP) that uses a Gated Recurrent Unit (GRU) proposed by Cho et al. (2014) to embed a caption into a vector space. We use the Skip-Thought (Kiros et al., 2015) GRU, which is trained on the BookCorpus (Zhu et al., 2015) to predict the context (preceding and following sentences) of a given sentence. These embeddings are fed as input into a Multi-Layer Perceptron (MLP).
(2) A language+vision unary model (Skip-Thought+CNN+MLP) that embeds the caption as above and embeds the image via a Convolutional Neural Network (CNN). We use the activations from the penultimate layer of the 19-layer VGG-net (Simonyan and Zisserman, 2014), which have been shown to generalize well. Both embeddings are concatenated and fed as input to an MLP.

In both cases, the best ordering of the story elements (optimal permutation) $\sigma^* = \arg\max_{\sigma \in \Sigma_n} S_u(\sigma)$ can be found efficiently in $O(n^3)$ time with the Hungarian algorithm (Munkres, 1957). Since these unary scores are not influenced by other elements in the story, they capture the semantics and linguistic structures associated with specific positions of stories *e.g.*, the beginning, the middle, and the end.

3.2 Pairwise Models

Similar to learning to rank approaches (Hang, 2011), we develop pairwise scoring models that given a pair of elements (i, j), learn to assign a score:
$S([\![\sigma_i < \sigma_j]\!] \mid i, j)$ indicating whether element i should be placed before element j in the permutation σ. Here, $[\![\cdot]\!]$ indicates the Iverson bracket (which is 1 if the input argument is true and 0 otherwise). We develop and experiment with the following 3 pairwise models:
(1) A language-alone pairwise model (Skip-Thought+MLP) that takes as input a pair of Skip-Thought embeddings and trains an MLP (with hinge-loss) that outputs $S([\![\sigma_i < \sigma_j]\!] \mid i, j)$, the score for placing i before j.
(2) A language+vision pairwise model (Skip-Thought+CNN+MLP) that concatenates the Skip-Thought and CNN embeddings for i and j and trains a similar MLP as above.
(3) A language-alone neural position embedding (NPE) model. Instead of using frozen Skip-Thought embeddings, we learn a task-aware ordered distributed embedding for sentences. Specifically, each sentence in the story is embedded $X = (\mathbf{x}_1, \ldots, \mathbf{x}_n)$, $\mathbf{x}_i \in \mathbb{R}^d_+$, via an LSTM (Hochreiter and Schmidhuber, 1997) with ReLU non-linearities. Similar to the max-margin loss that is applied to negative examples by Vendrov et al. (2016), we use an asymmetric penalty that encourages sentences appearing early in the story to be placed closer to the origin than sentences appearing later in the story.

$$\begin{aligned} L_{ij} &= \Big\| \max(0, \alpha - (\mathbf{x}_j - \mathbf{x}_i)) \Big\|^2 \\ Loss &= \sum_{1<=i<j=n} L_{ij} \end{aligned} \quad (2)$$

At train time, the parameters of the LSTM are learned end-to-end to minimize this asymmetric ordered loss (as measured over the gold-standard sequences). At test time, we use $S([\![\sigma_i < \sigma_j]\!] \mid i, j) = L_{ij}$. Thus, as we move away from the origin in the embedding space, we traverse through the sentences in a story. Each of these three pairwise approaches assigns a score $S(\sigma_i, \sigma_j | i, j)$ to an ordered pair of elements (i,j), which is used to construct a pairwise scoring model:

$$S_p(\sigma) = \sum_{1<=i<j<=n} \Big\{ S([\![\sigma_i < \sigma_j]\!]) - S([\![\sigma_j < \sigma_i]\!]) \Big\}, \quad (3)$$

by summing over the scores for all possible ordered pairs in the permutation. This pairwise score captures local contextual information in stories. Finding the best permutation $\sigma^* = \arg\max_{\sigma \in \Sigma_n} S_p(\sigma)$ under this pairwise model is NP-hard so approximations will be required. In our experiments, we study short sequences ($n = 5$), where the space of permutations is easily enumerable ($5! = 120$). For longer sequences, we can utilize integer programming methods or well-studied spectral relaxations for this problem.

3.3 Voting-based Ensemble

To combine the complementary information captured by the unary (S_u) and pairwise models (S_p), we use a voting-based ensemble. For each method in the ensemble, we find the top three permutations. Each of these permutations (σ^k) then vote for a particular element to be placed at a particular position. Let V be a vote matrix such that V_{ij} stores the number of votes for i^{th} element to occur at j^{th} position, *i.e.* $V_{ij} = \sum_k [\![\sigma_i^k == j]\!]$). We use the Hungarian algorithm to find the optimal permutation that maximizes the votes assigned, *i.e.* $\sigma^*_{\text{vote}} = \arg\max_{\sigma \in \Sigma_n} \sum_{i=1}^{n} \sum_{j=1}^{n} V_{ij} \cdot [\![\sigma_i == j]\!]$. We experimented with a number of model voting combinations and found the combination of pairwise Skip-Thought+CNN+MLP and neural position embeddings to work best (based on a validation set).

4 Experiments

4.1 Data

We train and evaluate our model on personal multimodal stories from the SIND (Sequential Image Narrative Dataset) (Ting-Hao Huang, 2016), where each story is a sequence of 5 images and corresponding story-like captions. The narrative captions in this dataset, e.g., "friends having a good time" (as opposed to "people sitting next to each other") capture a sequential, conversational language, which is characteristic of stories. We use 40,155 stories for training, 4990 for validation and 5055 stories for testing.

4.2 Metrics

We evaluate the performance of our model at correctly ordering a jumbled set of story elements using the following 3 metrics:

Spearman's rank correlation (Sp.) (Spearman, 1904) measures if the ranking of story elements in the predicted and ground truth orders are monotonically related (higher is better).

Pairwise accuracy (Pairw.) measures the fraction of pairs of elements whose predicted relative ordering is the same as the ground truth order (higher is better).

Average Distance (Dist.) measures the average change in position of all elements in the predicted story from their respective positions in the ground truth story (lower is better).

Method	Features	Sp.	Pairw.	Dist.
Random Order		0.000	0.500	1.601
Unary	SkipThought	0.508	0.718	1.373
	SkipThought + Image	0.532	0.729	1.352
Pairwise	SkipThought	0.546	0.732	0.923
	SkipThought + Image	0.565	0.740	0.897
Pairwise Order	NPE	0.480	0.704	1.010
Voting	SkipThought + Image (Pairwise) + NPE	**0.675**	**0.799**	**0.724**

Table 1: Performance of our different models and features at the sequencing task.

4.3 Results

Pairwise Models vs Unary Models As shown in Table 1, the pairwise models based on Skip-Thought features outperform the unary models in our task. However, the Pairwise Order Model performs worse than the unary Skip-Thought model, suggesting that the Skip-Thought features, which encode context of a sentence, also provide a crucial signal for temporal ordering of story sentences.

Contribution of Image Features Augmenting the text features with image features results in a visible performance improvement of both the model trained with unary features and the model trained with pairwise features. While image features by themselves result in poor performance on this task, they seem to capture temporal information that is complementary to the text features.

Ensemble Voting To exploit the fact that unary and pairwise models, as well as text and image features, capture different aspects of the story, we combine them using a voting ensemble. Based on the validation set, we found that combining the Pairwise Order model and the Pairwise model with both Skip-Thought and Image (CNN) features performs the best. This voting based method achieves the best performance on all three metrics. This shows that our different approaches indeed capture complementary information regarding feasible orderings of caption-image pairs to form a coherent story.

For comparison to existing related work, we tried

(d) Fourth Position (e) Fifth Position

Figure 2: Word cloud corresponding to most discriminative words for each position.

to duplicate the pipelined approach of Modi and Titov (2014). For this, we first parse our story sentences to extract SVO (subject, verb, object) tuples (using the Stanford Parser (Chen and Manning, 2014)). However, this step succeeds for only 60% of our test data. Now even if we consider a *perfect* downstream algorithm that *always* makes the correct position prediction given SVO tuples, the overall performance is still a Spearman correlation of just 0.473, i.e., the *upper bound* performance of this pipelined approach is *lower* than the performance of our text-only end-to-end model (correlation of 0.546) in Table 1.

4.4 Qualitative Analysis

Visualizations of position predictions from our model demonstrate that it has learnt the *three act structure* (Trottier, 1998) in stories – the setup, the middle and the climax. We also present success and failure examples of our sorting model's predictions. See the supplementary for more details and figures.

We visualize our model's *temporal common sense*, in Fig. 2. The word clouds show *discriminative words* – the words that the model believes are indicative of sentence positions in a story. The size of a word is proportional to the ratio of its frequency of occurring in that position to other positions. Some words like 'party', 'wedding', etc., probably because our model believes that the start the story describes the setup – the occasion or event. People often tend to describe meeting friends or family members which probably results in the discriminative words such as 'people', 'friend', 'everyone' in the second and the third sentences. Moreover, the model believes that people tend to conclude the stories using words like 'finally', 'afterwards', tend to talk about 'great day', group 'pictures' with everyone, etc.

5 Conclusion

We propose the task of "sequencing" in a set of image-caption pairs, with the motivation of learning temporal common sense. We implement multiple neural network models based on individual and pairwise element-based predictions (and their ensemble), and utilize both image and text features, to achieve strong performance on the task. Our best system, on average, predicts the ordering of sentences to within a distance error of 0.8 (out of 5) positions. We also analyze our predictions and show qualitative examples that demonstrate temporal common sense.

Human Attention in Visual Question Answering: Do Humans and Deep Networks Look at the Same Regions?

Abstract

We conduct large-scale studies on 'human attention' in Visual Question Answering (VQA) to understand where humans choose to look to answer questions about images. We design and test multiple game-inspired novel attention-annotation interfaces that require the subject to sharpen regions of a blurred image to answer a question. Thus, we introduce the VQA-HAT (Human ATtention) dataset. We evaluate attention maps generated by state-of-the-art VQA models against human attention both qualitatively (via visualizations) and quantitatively (via rank-order correlation). Overall, our experiments show that current VQA attention models do not seem to be looking at the same regions as humans.

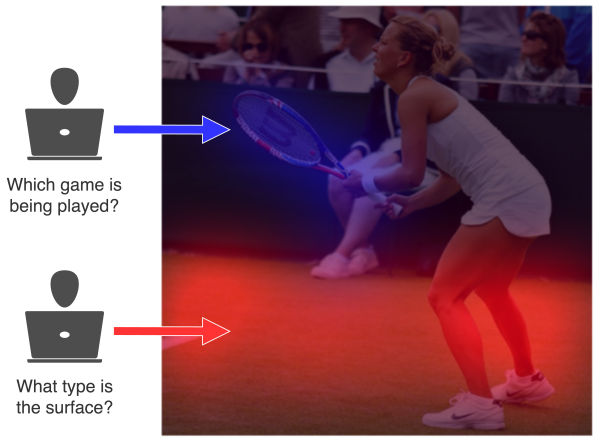

Figure 1: Different human attention regions based on question. (best viewed in color)

1 Introduction

It helps to pay attention. Humans have the ability to quickly perceive a scene by selectively attending to parts of the image instead of processing the whole scene in its entirety (Rensink, 2000). Inspired by human attention, a recent trend in computer vision and deep learning is to build computational models of attention. Given an input signal, these models learn to attend to parts of it for further processing and have been successfully applied in machine translation (Bahdanau et al., 2015; Firat et al., 2016), object recognition (Ba et al., 2015; Mnih et al., 2014; Sermanet et al., 2014), image captioning (Xu et al., 2015; Cho et al., 2015) and visual question answering (Yang et al., 2016; Lu et al., 2016; Xu and Saenko, 2015; Xiong et al., 2016).

In this work, we study attention for the task of Visual Question Answering (VQA). Unlike image captioning, where a coarse understanding of an image is often sufficient for producing generic descriptions (Devlin et al., 2015), visual questions selectively target different areas of an image including background details and underlying context. This suggests that a VQA model may benefit from an explicit or implicit attention mechanism to answer a question correctly. In this work, we are interested in the following questions: 1) Which image regions do humans choose to look at in order to answer questions about images? 2) Do deep VQA models with attention mechanisms attend to the same regions as humans?

We design and conduct studies to collect "human attention maps". Figure 1 shows human attention maps on the same image for two different questions. When asked 'What type is the surface?', humans choose to look at the floor, while attention for 'Which game is being played?' is concentrated around the player and racket.

These human attention maps can be used both for evaluating machine-generated attention maps and for explicitly training attention-based models.

[*]Denotes equal contribution.

Figure 2: (a-c): Column 1 shows deblurred image, and column 2 shows human attention map.

Contributions. First, we design game-inspired novel interfaces for collecting human attention maps of where humans choose to look to answer questions from the large-scale VQA dataset (Antol et al., 2015); this VQA-HAT (Human ATtention) dataset is publicly available at our project webpage[1] Second, we perform qualitative and quantitative comparison of the maps generated by state-of-the-art attention-based VQA models (Yang et al., 2016; Lu et al., 2016) and a task-independent saliency baseline (Judd et al., 2009) against our human attention maps through visualizations and rank-order correlation. We find that machine-generated attention maps from the most accurate VQA model have a mean rank-correlation of 0.26 with human attention maps, which is worse than task-independent saliency maps that have a mean rank-correlation of 0.49. It is well understood that task-independent saliency maps have a 'center bias' (Tatler, 2007; Judd et al., 2009). After we control for this center bias, we find that the correlation of task-independent saliency is poor (as expected), while trends for machine-generated VQA-attention maps remain the same, which confirms our key finding that current VQA attention models do not seem to be looking at the same regions as humans.

2 Related Work

Our work draws on recent work in attention-based VQA and human studies in saliency prediction. We work with the free-form and open-ended VQA dataset released by (Antol et al., 2015).

VQA Models. Attention-based models for VQA typically use convolutional neural networks to highlight relevant regions of image given a question. Stacked Attention Networks (SAN) proposed in (Yang et al., 2016) use LSTM encodings of question words to produce a spatial attention distribution over the convolutional layer features of the image. Hierarchical Co-Attention Network (Lu et al., 2016) generates multiple levels of image attention based on words, phrases and complete questions, and is the top entry on the VQA Challenge[2] as of the time of this submission. Another interesting approach uses question parsing to compose the neural network from modules, attention being one of the sub-tasks addressed by these modules (Andreas et al., 2016). Note that all these works are *unsupervised* attention models, where "attention" is simply an intermediate variable (a spatial distribution) that is produced by the model to optimize downstream loss (VQA cross-entropy). The fact that some (it's unclear how many) of these spatial distributions end up being interpretable is simply fortuitous. In contrast, we study where humans choose to look to answer visual questions. These human attention maps can be used to evaluate unsupervised maps.

Human Studies. There's a rich history of work in collecting eye tracking data from human subjects to gain an understanding of image saliency and visual perception (Jiang et al., 2014; Judd et al., 2009; Fei-Fei et al., 2007; Yarbus, 1967). Eye tracking data to study natural visual exploration (Jiang et al., 2014; Judd et al., 2009) is useful but difficult and expensive to collect on a large scale. (Jiang et al., 2015) established mouse tracking as an accurate alternative to eye tracking for collecting attention maps. They collected large-scale attention annotations for MS COCO (Lin et al., 2014) on Ama-

[1] http://computing.ece.vt.edu/~abhshkdz/vqa-hat

[2] http://visualqa.org/challenge.html

zon Mechanical Turk (AMT). While (Jiang et al., 2015) studies natural exploration and collects task-independent human annotations by asking subjects to freely move the mouse cursor to anywhere they wanted to look on a blurred image, our approach is task-driven. (Jia Deng and Jonathan Krause and Li Fei-Fei, 2013; Deng et al., 2015) leverage crowdsourcing to help computers select discriminative features for fine-grained recognition. They introduce a novel gamified setting where the humans can reveal regions with certain penalty which ensures discriminative regions with assured quality. Related to this is the work of (von Ahn and Dabbish, 2004) who explore gamification to locate objects in an image. To the best of our knowledge, this is the first work to collect human attention maps for VQA.

Specifically, as described in Section 3, we collect ground truth attention annotations by instructing subjects to sharpen parts of a blurred image that are important for answering the questions accurately. Section 4 covers evaluation of unsupervised attention maps generated by VQA models against our human attention maps.

3 VQA-HAT (Human ATtention) Dataset

We design and test multiple game-inspired novel interfaces for conducting large-scale human studies on AMT. Our basic interface design consists of a "deblurring" exercise for answering visual questions. Specifically, we present subjects with a blurred image and a question about the image, and ask subjects to sharpen regions of the image that will help them answer the question correctly, in a smooth, click-and-drag, 'coloring' motion with the mouse. The sharpening is gradual: successively scrubbing the same region progressively sharpens it.

We experiment with multiple variants of the data collection interface. Analysis of the interfaces as well as details of the human evaluation studies conducted to converge on the final interface used for results in this main document have been included in the supplement. The human evaluation studies consisted of showing these attention-sharpened images to humans and asking them to answer the question. Based on these human studies, we pick the "Blurred Image with Answer" interface, where subjects were shown the correct answer in addition to the question and blurred image, and asked to deblur as few regions as possible such that someone can answer the question just by looking at the sharpened regions. Since the payment structure on AMT encourage completing tasks as quickly as possible, this implicitly incentivizes subjects to deblur as few regions as possible. Our followup human studies on these collected maps show that other subjects are able to answer questions based on these collected maps (details in supplement). Thus, overall we achieve a balance between highlighting too little or too much.

Note that the "Blurred Image with Answer" interface used to collect attention maps is a verification task as opposed to actual question answering. We show subjects an answer and ask them to sharpen regions that will help them answer the question correctly, as opposed to showing them just the question and asking them for the answer as well as relevant sharpened regions in the image ("Blurred Image without Answer" interface). Attention maps collected via this verification task "Blurred Image with Answer" are more informative (in terms of human VQA accuracy) than those collected for "Blurred Image without Answer" – 78.7% vs. 75.2%.

We collected human attention maps for 58475 train (out of 248349 total) and 1374 val (out of 121512 total) question-image pairs from the VQA dataset. This dataset is publicly available[1]. Overall, we conducted approximately 20000 Human Intelligence Tasks (HITs) on AMT, among 800 unique workers. Figure 2 shows examples of collected human attention maps.

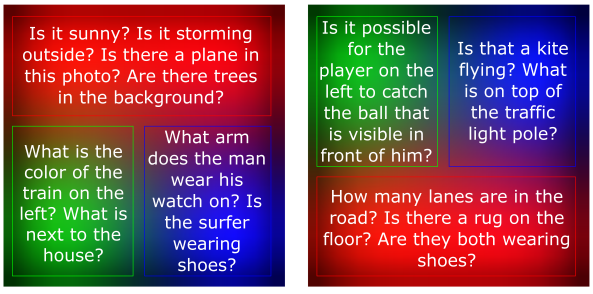

Figure 3

To visualize the collected dataset, we cluster the human attention maps and visualize the average attention map and example questions falling in each of them for 6 selected clusters in Figure 3.

4 Human Attention Maps vs Unsupervised Attention Models

Now that we have collected these human attention maps, we can ask the following question – do unsupervised attention models learn to predict attention maps that are similar to human attention maps? To rephrase, *do neural networks look at the same regions as humans to answer a visual question?*

VQA Attention Models. We evaluate maps generated by the following unsupervised models:

- Stacked Attention Network (SAN) (Yang et al., 2016) with two attention layers (SAN-2)[3].
- Hierarchical Co-Attention Network (HieCoAtt) (Lu et al., 2016) with word-level (HieCoAtt-W), phrase-level (HieCoAtt-P) and question-level (HieCoAtt-Q) attention maps; we evaluate all three maps[4].

Comparison Metric: Rank Correlation. We first scale both the machine-generated and human attention maps to 14x14, rank the pixels according to their spatial attention and then compute correlation between these two ranked lists. We choose an order-based metric so as to make the evaluation invariant to absolute spatial probability values which can be made peaky or diffuse by tweaking a 'temperature' parameter.

Table 1 shows rank-order correlation averaged over all image-question pairs on the validation set. We compare with random attention maps and task-independent saliency maps generated by a model trained to predict human eye fixation locations where subjects are asked to freely view an image for 3 seconds (Judd et al., 2009). Both SAN-2 and HieCoAtt attention maps are positively correlated with human attention maps, but not as strongly as task-independent Judd saliency maps. Our findings lead to two take-away messages with significant potential impact on future research in this active field. First, current VQA attention models do not seem to be 'looking' at the same regions as humans to produce an answer. Second, as attention-based VQA models become more accurate (58.9% SAN $\rightarrow$ 62.1% HieCoAtt), they seem to be (slightly) better correlated with humans in terms of where they look. Our dataset will allow for a more thorough validation of this observation as future attention-based VQA models are proposed. Figure 4 shows examples of human and machine-generated attention maps with their rank-correlation coefficients.

Model	Rank-correlation
SAN-2 (Yang et al., 2016)	0.249 ± 0.004
HieCoAtt-W (Lu et al., 2016)	0.246 ± 0.004
HieCoAtt-P (Lu et al., 2016)	0.256 ± 0.004
HieCoAtt-Q (Lu et al., 2016)	0.264 ± 0.004
Random	0.000 ± 0.001
Judd et al. (Judd et al., 2009)	0.497 ± 0.004
Human	0.623 ± 0.003

Table 1: Mean rank-correlation coefficients (higher is better); error bars show standard error of means. We can see that both SAN-2 and HieCoAtt attention maps are positively correlated with human attention maps, but not as strongly as task-independent Judd saliency maps.

Model	Rank-correlation
SAN-2 (Yang et al., 2016)	0.038 ± 0.011
HieCoAtt-W (Lu et al., 2016)	0.062 ± 0.012
HieCoAtt-P (Lu et al., 2016)	0.048 ± 0.010
HieCoAtt-Q (Lu et al., 2016)	0.114 ± 0.012
Judd et al. (Judd et al., 2009)	-0.063 ± 0.009

Table 2: Correlation on the reduced set without center bias goes down significantly for Judd saliency since they have a strong center bias. Relative trends among SAN-2 & HieCoAtt are similar to those over the whole validation set (reported in Table 1).

To put these numbers in perspective, we computed inter-human agreement on the validation set by collecting 3 human attention maps per image-question pair and computing mean rank-correlation, which is 0.623. Lastly, all reported correlations are averaged over 3 trials by adding random noise (order of 10^{-14}) to human attention maps to account for ranking variations in case of uniformly weighted regions.

Center Bias. Judd saliency maps aim to predict human eye fixations during natural visual exploration. These tend to have a strong center bias (Tatler, 2007; Judd et al., 2009). Although our human attention maps dataset is not an eye tracking study, the cen-

[3] https://github.com/zcyang/imageqa-san

[4] https://github.com/jiasenlu/HieCoAttenVQA

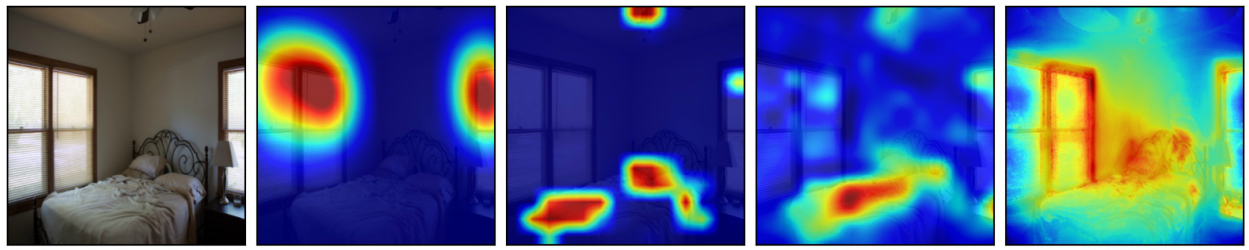

Figure 4: Random example of human attention (column 2) v/s machine-generated attention (columns 3-5)

ter bias still exists albeit not as severely as in eye-tracking. A potential source of center bias is the fact that the VQA dataset was human-generated by subjects looking at images. Thus, salient objects in the center of the image are likely to be potential subjects of questions. We compute rank-correlation of a synthetically generated central attention map with Judd saliency and human attention maps. Judd saliency maps have a mean rank-correlation of 0.877 and human attention maps have a mean rank-correlation of 0.458 on the validation set.

To eliminate the effect of center bias in this evaluation, we removed human attention maps that have positive rank-correlation with the center attention map. We compute rank-correlation of machine-generated attention with human attention on this reduced set. See Table 2. Mean correlation goes down significantly for Judd saliency maps since they have a strong center bias. Relative trends among SAN-2 & HieCoAtt are similar to those over the whole validation set (reported in Table 1). HieCoAtt-Q now has higher correlation with human attention maps than Judd saliency. Thus discounting the center bias, VQA-specific machine attention maps correlate better with VQA-specific human attention maps than task-independent machine saliency maps.

5 Conclusion & Discussion

We introduce and release the VQA-HAT dataset[1]. This dataset can be used to evaluate attention maps generated in an unsupervised manner by attention-based VQA models, or to explicitly train models with attention supervision for VQA. We quantify whether current attention-based VQA models are 'looking' at the same regions of the image as humans do to produce an answer.

Necessary vs Sufficient Maps. Are human attention maps 'necessary' and/or 'sufficient'? If regions highlighted by the human attention maps are sufficient to answer the question accurately, then so is any region that is a superset. For example, if attention mass is concentrated on a 'cat' for 'What animal is present in the picture?', then an attention map that assigns weights to any arbitrary-sized region that includes the 'cat' is sufficient as well. On the contrary, a *necessary* and sufficient attention map would be the smallest visual region sufficient for answering the question accurately. It is an ill-posed problem to define a necessary attention map in the space of pixels; random pixels can be blacked out and chances are that humans would still be able to answer the question given the resulting subset attention map. Our work thus poses an interesting question for future work – what is the right *semantic* space in which it is meaningful to talk about necessary and sufficient attention maps for humans?

Abstract

In this paper, we explore the possibility of leveraging Residual Networks (ResNet), a powerful structure in constructing extremely deep neural network for image understanding, to improve recurrent neural networks (RNN) for modeling sequential data. We show that for sequence classification tasks, incorporating residual connections into recurrent structures yields similar accuracy to Long Short Term Memory (LSTM) RNN with much fewer model parameters. In addition, we propose two novel models which combine the best of both residual learning and LSTM. Experiments show that the new models significantly outperform LSTM.

1 Introduction

Recurrent Neural Networks (RNNs) are powerful tools to model sequential data. Among various RNN models, Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) is one of the most effective structures. In LSTM, gating mechanism is used to control the information flow such that gradient vanishing problem in vanilla RNN is better handled, and long range dependency is better captured. However, as empirically verified by previous works and our own experiments, to obtain fairly good results, training LSTM RNN needs carefully designed optimization procedure (Hochreiter et al., 2001; Pascanu et al., 2013; Dai and Le, 2015; Laurent et al., 2015; He et al., 2016; Arjovsky et al., 2015), especially when faced with unfolded very deep architectures for fairly long sequences (Dai and Le, 2015).

From another perspective, for constructing very deep neural networks, recently Residual Networks (ResNet) (He et al., 2015) have shown their effectiveness in quite a few computer vision tasks. By learning a residual mapping between layers with identity skip connections (Jaeger et al., 2007), ResNet ensures a fluent information flow, leading to efficient optimization for very deep structures (e.g., with hundreds of layers). In this paper, we explore the possibilities of leveraging residual learning to improve the performances of recurrent structures, in particular, LSTM RNN, in modeling fairly long sequences (i.e., whose lengths exceed 100). To summarize, our main contributions include:

1. We introduce residual connecting mechanism into the recurrent structure and propose recurrent residual networks for sequence learning. Our model achieves similar performances to LSTM in text classification tasks, whereas the number of model parameters is greatly reduced.

2. We present in-depth analysis of the strengths and limitations of LSTM and ResNet in respect of sequence learning.

3. Based on such analysis, we further propose two novel models that incorporate the strengths of the mechanisms behind LSTM and ResNet. We demonstrate that our models outperform LSTM in many sequence classification tasks.

2 Background

RNN models sequences by taking sequential input $x = \{x_1, \cdots, x_T\}$ and generating T step hidden states $h = \{h_1, \cdots, h_T\}$. At each time step t, RNN takes the input vector $x_t \in \mathcal{R}^n$ and the previous hidden state vector $h_{t-1} \in \mathcal{R}^m$ to produce the next hidden state h_t.

Based on this basic structure, LSTM avoids gradient vanishing in RNN training and thus copes better with long range dependencies, by further augmenting vanilla RNN with a memory cell vector $c_t \in \mathcal{R}^m$ and multiplicative gate units that regulate the information flow. To be more specific, at each time step t, an LSTM unit takes x_t, c_{t-1}, h_{t-1} as input, generates the input, output and forget gate signals (denoted as i_t, o_t and f_t respectively), and produces the next cell state c_t and hidden state h_t:

$$\begin{aligned} \tilde{c}_t &= tanh(W_c[h_{t-1}, x_t] + b_c) \\ i_t &= \sigma(W_i[h_{t-1}, x_t] + b_i) \\ f_t &= \sigma(W_f[h_{t-1}, x_t] + b_f) \\ o_t &= \sigma(W_o[h_{t-1}, x_t] + b_o) \\ c_t &= f_t \otimes C_{t-1} + i_t \otimes \tilde{c}_t \\ h_t &= o_t \otimes tanh(c_t) \end{aligned} \tag{1}$$

where $\otimes$ refers to element-wise product. $\sigma(x)$ is the sigmoid function $\sigma(x) = 1/(1+\exp(-x))$. $W_j (j \in \{i, o, f, c\})$ are LSTM parameters. In the following part, such functions generating h_t and c_t are denoted as $h_t, c_t = LSTM(x_t, h_{t-1}, c_{t-1})$.

Residual Networks (ResNet) are among the pioneering works (Szegedy et al., 2015; Srivastava et al., 2015) that utilize extra identity connections to enhance information flow such that very deep neural networks can be effectively optimized. ResNet (He et al., 2015) is composed of several stacked residual units, in which the l^{th} unit takes the following transformation:

$$h_{l+1} = f(g(h_l) + \mathcal{F}(h_l; W_l)) \tag{2}$$

where h_l and h_{l+1} are the input and output for the l^{th} unit respectively. $\mathcal{F}$ is the residual function with weight parameters W_l. f is typically the ReLU function (Nair and Hinton, 2010). g is set as identity function, i.e., $g(h_l) = h_l$. Such an identity connection guarantees the direct propagation of signals among different layers, thereby avoids gradient vanishing. The recent paper (Liao and Poggio, 2016) talks about the possibility of using shared weights in ResNet, similar to what RNN does.

3 Recurrent Residual Learning

The basic idea of recurrent residual learning is to force a direct information flow in different time steps of RNNs by identity (skip) connections. In this section, we introduce how to leverage residual learning to 1) directly construct recurrent neural network in subsection 3.1; 2) improve LSTM in subsection 3.2.

3.1 Recurrent Residual Networks (RRN)

The basic architecture of Recurrent Residual Network (**RRN** for short) is illustrated in Figure 1, in which orange arrows indicate the identity connections from each h_{t-1} to h_t, and blue arrows represent the recurrent transformations taking both h_t and x_t as input. Similar to equation (2), the recurrent transformation in RRN takes the following form (denoted as $h_t = RRN(x_t, h_{t-1})$ in the following sections):

$$h_t = f(g(h_{t-1}) + \mathcal{F}(h_{t-1}, x_t; W)), \tag{3}$$

where g is still the identity function s.t. $g(h_{t-1}) = h_{t-1}$, corresponding to the orange arrows in Figure 1. f is typically set as *tanh*. For function $\mathcal{F}$ with weight parameters W (corresponding to the blue arrows in Figure 1), inspired by the observation that higher recurrent depth tends to lead to better performances (Zhang et al., 2016), we impose K deep transformations in $\mathcal{F}$:

$$\begin{aligned} y_1^t &= \sigma(x_t W_1 + h_{t-1} U_1 + b_1) \\ y_2^t &= \sigma(x_t W_2 + y_1^t U_2 + b_2) \\ &\cdots \\ y_K^t &= \sigma(x_t W_K + y_{K-1}^t U_K + b_K) \\ \mathcal{F}(h_{t-1}, x_t) &= y_K^t \end{aligned} \tag{4}$$

where x_t is taken at every layer such that the input information is better captured, which works similarly to the mechanism of highway network (Srivastava et al., 2015). K is the recurrent depth defined in (Zhang et al., 2016). The weights W_m ($m \in \{1, \cdots, K\}$) are shared across different time steps t.

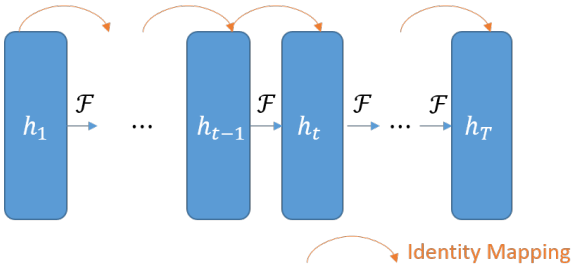

Figure 1: The basic structure of Recurrent Residual Networks.

RRN forces the direct propagation of hidden state signals between every two consecutive time steps with identity connections g. In addition, the multiple non-linear transformations in $\mathcal{F}$ guarantees its capability in modelling complicated recurrent relationship. In practice, we found that $K = 2$ yields fairly good performances, meanwhile leads to half of LSTM parameter size when model dimensions are the same.

3.2 Gated Residual RNN

Identity connections in ResNet are important for propagating the single input image information to higher layers of CNN. However, when it comes to sequence classification, the scenario is quite different in that there is a new input at every time step. Therefore, a forgetting mechanism to "forget" less critical historical information, as is employed in LSTM (controlled by the forget gate f_t), becomes necessary. On the other hand, while LSTM benefits from the flexible gating mechanism, its parametric nature brings optimization difficulties to cope with fairly long sequences, whose long range information dependencies could be better captured by identity connections.

Inspired by the success of the gating mechanism of LSTM and the residual connecting mechanism with enhanced information flow of ResNet, we further propose two Gated Residual Recurrent models leveraging the strengths of the two mechanisms.

3.2.1 Model 1: Skip-Connected LSTM (SC-LSTM)

Skip-Connected LSTM (**SC-LSTM** for short) introduces identity connections into standard LSTM to enhance the information flow. Note that in Figure 1, a straightforward approach is to replace $\mathcal{F}$ with an LSTM unit. However, our preliminary experiments do not achieve satisfactory results. Our conjecture is that identity connections between consecutive memory cells, which are already sufficient to maintain short-range memory, make the unregulated information flow overly strong, and thus compromise the merit of gating mechanism.

To reasonably enhance the information flow for LSTM network while keeping the advantage of gating mechanism, starting from equation (1), we propose to add skip connections between two LSTM hidden states with a wide range of distance L (e.g., $L = 20$), such that $\forall t = \{1, 1+L, 1+2L, \cdots, 1+\lfloor\frac{T-L-1}{L}\rfloor L\}$:

$$h_{t+L} = tanh(c_{t+L}) \otimes o_{t+L} + \alpha h_t \tag{5}$$

Here α is a scalar that can either be fixed as 1 (i.e., identity mapping) or be optimized during training process as a model parameter (i.e., parametric skip connection). We refer to these two variants as **SC-LSTM-I** and **SC-LSTM-P** respectively. Note that in SC-LSTM, the skip connections only exist in time steps $1, 1+L, 1+2L, \cdots, 1+\lfloor\frac{T-L-1}{L}\rfloor L$. The basic structure is shown in Figure 2.

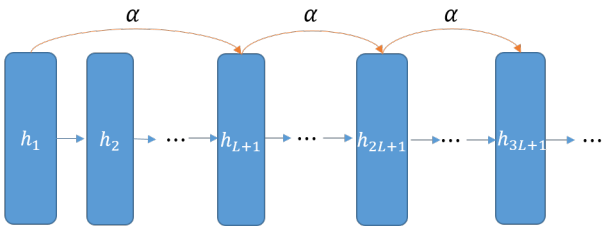

Figure 2: The basic structure of Skip-Connected LSTM.

3.2.2 Model 2: Hybrid Residual LSTM (HRL)

Since LSTM generates sequence representations out of flexible gating mechanism, and RRN generates representations with enhanced residual historical information, it is a natural extension to combine the two representations to form a signal that benefits from both mechanisms. We denote this model as Hybrid Residual LSTM (**HRL** for short).

In HRL, two independent signals, h_t^{LSTM} generated by LSTM (equation (1)) and h_t^{RRN} generated by RRN (equation (3)), are propagated through LSTM and RRN respectively:

$$\begin{aligned} h_t^{LSTM}, c_t &= LSTM(x_t, h_{t-1}^{LSTM}, c_{t-1}) \\ h_t^{RRN} &= RRN(x_t, h_{t-1}^{RRN}) \end{aligned} \tag{6}$$

The final representation h_T^{HRL} is obtained by the mean pooling of the two "sub" hidden states:

$$h_T^{HRL} = \frac{1}{2}(h_T^{LSTM} + h_T^{RRN}) \quad (7)$$

h_T^{HRL} is then used for higher level tasks such as predicting the sequence label. Acting in this way, h_T^{HRL} contains both the *statically* forced and *dynamically* adjusted historical signals, which are respectively conveyed by h_t^{RRN} and h_t^{LSTM}.

4 Experiments

We conduct comprehensive empirical analysis on sequence classification tasks. Listed in the ascending order of average sequence lengths, several public datasets we use include:

1. **AG's news corpus**[1],a news article corpus with categorized articles from more than $2,000$ news sources. We use the dataset with 4 largest classes constructed in (Zhang et al., 2015).

2. **IMDB movie review dataset**[2], a binary sentiment classification dataset consisting of movie review comments with positive/negative sentiment labels (Maas et al., 2011).

3. **20 Newsgroups** (**20NG** for short), an email collection dataset categorized into 20 news groups. Simiar to (Dai and Le, 2015), we use the post-processed version[3], in which attachments, PGP keys and some duplicates are removed.

4. **Permuted-MNIST** (**P-MNIST** for short). Following (Le et al., 2015; Arjovsky et al., 2015), we shuffle pixels of each MNIST image (LeCun et al., 1998) with a fixed random permutation, and feed all pixels sequentially into recurrent network to predict the image label. Permuted-MNIST is assumed to be a good testbed for measuring the ability of modeling very long range dependencies (Arjovsky et al., 2015).

[1] http://www.di.unipi.it/~gulli/AG_corpus_of_news_articles.html

[2] http://ai.stanford.edu/~amaas/data/sentiment/

[3] http://ana.cachopo.org/datasets-for-single-label-text-categorization

Detailed statistics of each dataset are listed in Table 1. For all the text datasets, we take every word as input and feed word embedding vectors pre-trained by Word2Vec (Mikolov et al., 2013) on Wikipedia into the recurrent neural network. The top most frequent words with 95% total frequency coverage are kept, while others are replaced by the token "UNK". We use the standard training/test split along with all these datasets and randomly pick 15% of training set as dev set, based on which we perform early stopping and for all models tune hyper-parameters such as dropout ratio (on non-recurrent layers) (Zaremba et al., 2014), gradient clipping value (Pascanu et al., 2013) and the skip connection length L for SC-LSTM (cf. equation (5)). The last hidden states of recurrent networks are put into logistic regression classifiers for label predictions. We use Adadelta (Zeiler, 2012) to perform parameter optimization. All our implementations are based on Theano (Theano Development Team, 2016) and run on one K40 GPU. All the source codes and datasets can be downloaded at `https://publish.illinois.edu/yirenwang/emnlp16source/`.

We compare our proposed models mainly with the state-of-art standard LSTM RNN. In addition, to fully demonstrate the effects of residual learning in our HRL model, we employ another hybrid model as baseline, which combines LSTM and GRU (Cho et al., 2014), another state-of-art RNN variant, in a similar way as HRL. We use **LSTM+GRU** to denote such a baseline. The model sizes (word embedding size $\times$ hidden state size) configurations used for each dataset are listed in Table 2. In Table 2, "Non-Hybrid" refers to LSTM, RRN and SC-LSTM models, while "Hybrid" refers to two methods that combines two basic models: HRL and LSTM+GRU. The model sizes of all hybrid models are smaller than the standard LSTM. All models have only one recurrent layer.

4.1 Experimental Results

All the classification accuracy numbers are listed in Table 3. From this table, we have the following observations and analysis:

1. RRN achieves similar performances to standard LSTM in all classification tasks with only

Dataset	Ave. Len	Max Len	#Classes	#Train : #Test
AG's News	34	211	4	$120,000 : 7,600$
IMDB	281	$2,956$	2	$25,000 : 25,000$
20NG	267	$11,924$	20	$11,293 : 7,528$
P-MNIST	784	784	10	$60,000 : 10,000$

Table 1: Classification Datasets.

	AG's News	*IMDB*	*20NG*	*P-MNIST*
Non-Hybird	256×512	256×512	500×768	1×100
Hybrid	256×384	256×384	256×512	1×80

Table 2: Model Sizes on Different Dataset.

Model/Task	*AG's News*	*IMDB*	*20NG*	*P-MNIST*
LSTM	91.76%	88.88%	79.21%	90.64%
RRN	91.19%	89.13%	79.76%	88.63%
SC-LSTM-P	92.01%	90.74%	**82.98%**	94.46%
SC-LSTM-I	**92.05%**	90.67%	81.85%	**94.80%**
LSTM+GRU	91.05%	89.23%	80.12%	90.28%
HRL	91.90%	**90.92%**	81.73%	90.33%

Table 3: Classification Results (Test Accuracy).

half of the model parameters, indicating that residual network structure, with connecting mechanism to enhance the information flow, is also an effective approach for sequence learning. However, the fact that it fails to significantly outperform other models (as it does in image classification) implies that forgetting mechanism is desired in recurrent structures to handle multiple inputs.

2. Skip-Connected LSTM performs much better than standard LSTM. For tasks with shorter sequences such as AG's News, the improvement is limited. However, the improvements get more significant with the growth of sequence lengths among different datasets[4], and the performance is particularly good in P-MNIST with very long sequences. This reveals the importance of skip connections in carrying on historical information through a long range of time steps, and demonstrates the effectiveness of our approach that adopts the residual connecting mechanism to improve LSTM's capability of handling long-term dependency. Furthermore, SC-LSTM is robust with different hyperparameter values: we test $L = 10, 20, 50, 75$ in P-MNIST and find the performance is not sensitive w.r.t. these L values.

3. HRL also outperforms standard LSTM with fewer model parameters[5]. In comparison, the hybrid model of LSTM+GRU cannot achieve such accuracy as HRL. As we expected, the additional long range historical information propagated by RRN is proved to be good assistance to standard LSTM.

5 Conclusion

In this paper, we explore the possibility of leveraging residual network to improve the performance of LSTM RNN. We show that direct adaptation of ResNet performs well in sequence classification. In addition, when combined with the gating mechanism in LSTM, residual learning significantly improve LSTM's performance. As to future work, we plan to apply residual learning to other sequence tasks such as language modeling, and RNN based neural machine translation (Sutskever et al., 2014) (Cho et al., 2014).

[4]t-test on SC-LSTM-P and SC-LSTM-I with $p\_value < 0.001$.

[5]t-test on HRL with $p\_value < 0.001$.

Abstract

In this work we present a generalisation of the Modified Kneser-Ney interpolative smoothing for richer smoothing via additional discount parameters. We provide mathematical underpinning for the estimator of the new discount parameters, and showcase the utility of our rich MKN language models on several European languages. We further explore the interdependency among the training data size, language model order, and number of discount parameters. Our empirical results illustrate that larger number of discount parameters, i) allows for better allocation of mass in the smoothing process, particularly on small data regime where statistical sparsity is severe, and ii) leads to significant reduction in perplexity, particularly for out-of-domain test sets which introduce higher ratio of out-of-vocabulary words.[1]

1 Introduction

Probabilistic language models (LMs) are the core of many natural language processing tasks, such as machine translation and automatic speech recognition. m-gram models, the corner stone of language modeling, decompose the probability of an utterance into conditional probabilities of words given a fixed-length context. Due to sparsity of the events in natural language, smoothing techniques are critical for generalisation beyond the training text when estimating the parameters of m-gram LMs. This is particularly important when the training text is small, e.g. building language models for translation or speech recognition in low-resource languages.

A widely used and successful smoothing method is interpolated Modified Kneser-Ney (MKN) (Chen and Goodman, 1999). This method uses a linear interpolation of higher and lower order m-gram probabilities by preserving probability mass via absolute discounting. In this paper, we extend MKN by introducing additional discount parameters, leading to a richer smoothing scheme. This is particularly important when statistical sparsity is more severe, i.e., in building high-order LMs on small data, or when out-of-domain test sets are used.

Previous research in MKN language modeling, and more generally m-gram models, has mainly dedicated efforts to make them faster and more compact (Stolcke et al., 2011; Heafield, 2011; Shareghi et al., 2015) using advanced data structures such as succinct suffix trees. An exception is Hierarchical Pitman-Yor Process LMs (Teh, 2006a; Teh, 2006b) providing a rich Bayesian smoothing scheme, for which Kneser-Ney smoothing corresponds to an approximate inference method. Inspired by this work, we directly enrich MKN smoothing realising some of the reductions while remaining more efficient in learning and inference.

We provide estimators for our additional discount parameters by extending the discount bounds in MKN. We empirically analyze our enriched MKN LMs on several European languages in in- and out-of-domain settings. The results show that our discounting mechanism significantly improves the perplexity compared to MKN and offers a more elegant

way of dealing with out-of-vocabulary (OOV) words and domain mismatch.

2 Enriched Modified Kneser-Ney

Interpolative Modified Kneser-Ney (MKN) (Chen and Goodman, 1999) smoothing is widely accepted as a state-of-the-art technique and is implemented in leading LM toolkits, e.g., SRILM (Stolcke, 2002) and KenLM (Heafield, 2011).

MKN uses lower order k-gram probabilities to smooth higher order probabilities. $P(w|\mathbf{u})$ is defined as,

$$\frac{c(\mathbf{u}w) - \mathbb{D}^m(c(\mathbf{u}w))}{c(\mathbf{u})} + \frac{\gamma(\mathbf{u})}{c(\mathbf{u})} \times \bar{P}(w|\pi(\mathbf{u}))$$

where $c(\mathbf{u})$ is the frequency of the pattern $\mathbf{u}$, $\gamma(.)$ is a constant ensuring the distribution sums to one, and $\bar{P}(w|\pi(\mathbf{u}))$ is the smoothed probability computed recursively based on a similar formula[2] conditioned on the suffix of the pattern $\mathbf{u}$ denoted by $\pi(\mathbf{u})$. Of particular interest are the discount parameters $\mathbb{D}^m(.)$ which remove some probability mass from the maximum likelihood estimate for each event which is redistributed over the smoothing distribution. The discounts are estimated as

$$\mathbb{D}^m(i) = \begin{cases} 0, & \text{if } i = 0 \\ 1 - 2\frac{n_2[m]}{n_1[m]}\frac{n_1[m]}{n_1[m]+2n_2[m]}, & \text{if } i = 1 \\ 2 - 3\frac{n_3[m]}{n_2[m]}\frac{n_1[m]}{n_1[m]+2n_2[m]}, & \text{if } i = 2 \\ 3 - 4\frac{n_4[m]}{n_3[m]}\cdot\frac{n_1[m]}{n_1[m]+2n_2[m]}, & \text{if } i \geq 3 \end{cases}$$

where $n_i(m)$ is the number of unique m-grams[3] of frequency i. This effectively leads to three discount parameters $\{\mathbb{D}^m(1), \mathbb{D}^m(2), \mathbb{D}^m(3+)\}$ for the distributions on a particular context length, m.

2.1 Generalised MKN

Ney et al. (1994) characterized the data sparsity using the following empirical inequalities,

$$3n_3[m] < 2n_2[m] < n_1[m] \quad \text{for} \quad m \leq 3$$

It can be shown (see Appendix A) that these empirical inequalities can be extended to higher frequencies and larger contexts $m > 3$,

$$\begin{aligned}(N-m)n_{N-m}[m] < ... < 2n_2[m] \\ < n_1[m] < \sum_{i>0} n_i[m] \ll n_0[m] < \sigma^m\end{aligned}$$

where σ^m is the possible number of m-grams over a vocabulary of size σ, $n_0[m]$ is the number of m-grams that never occurred, and $\sum_{i>0} n_i[m]$ is the number of m-grams observed in the training data.

We use these inequalities to extend the discount depth of MKN, resulting in new discount parameters. The additional discount parameters increase the flexibility of the model in altering a wider range of raw counts, resulting in a more elegant way of assigning the mass in the smoothing process. In our experiments, we set the number of discounts to 10 for all the levels of the hierarchy, (compare this to these in MKN).[4] This results in the following estimators for the discounts,

$$\mathbb{D}^m(i) = \begin{cases} 0, & \text{if } i = 0 \\ i - (i+1)\frac{n_{i+1}[m]}{n_i[m]}\frac{n_1[m]}{n_1[m]+2n_2[m]}, & \text{if } i < 10 \\ 10 - 11\frac{n_{11}[m]}{n_{10}[m]}\cdot\frac{n_1[m]}{n_1[m]+2n_2[m]}, & \text{if } i \geq 10 \end{cases}$$

It can be shown that the above estimators for our discount parameters are derived by maximizing a lower bound on the leave-one-out likelihood of the training set, following (Ney et al., 1994; Chen and Goodman, 1999) (see Appendix B for the proof sketch).

3 Experiments

We compare the effect of using different numbers of discount parameters on perplexity using the Finnish (FI), Spanish (ES), German (DE), English (EN) portions of the Europarl v7 (Koehn, 2005) corpus. For each language we excluded the first 10K sentences and used it as the in-domain test set (denoted as EU), skipped the second 10K sentences, and used the rest as the training set. The data was tokenized, sentence split, and the XML markup discarded. We tested the effect of domain mismatch, under two settings for out-of-domain test sets: i) *mild* using the Spanish section of news-test 2013, the German, English sections of news-test 2014, and the Finnish section

[2]Note that in all but the top layer of the hierarchy, *continuation counts*, which count the number of unique contexts, are used in place of the frequency counts (Chen and Goodman, 1999).

[3]Continuation counts are used for the lower layers.

[4]We have selected the value of 10 arbitrarily; however our approach can be used with larger number of discount parameters, with the caveat that we would need to handle sparse counts in the higher orders.

Table 1: Perplexity for various m-gram orders $m \in 2, 3, 10$ and training languages from Europarl, using different numbers of discount parameters for MKN. **MKN ($D_{[1...3]}$)**, **MKN ($D_{[1...4]}$)**, **MKN ($D_{[1...10]}$)** represent vanilla MKN, MKN with 1 more discounts, and MKN with 7 more discount parameters, respectively. Test sets sources EU, NT, TW, MED are Europarl, news-test, Twitter, and medical patent descriptions, respectively. OOV is reported as the ratio $\frac{|\{OOV \in \text{test-set}\}|}{|\{w \in \text{test-set}\}|}$.

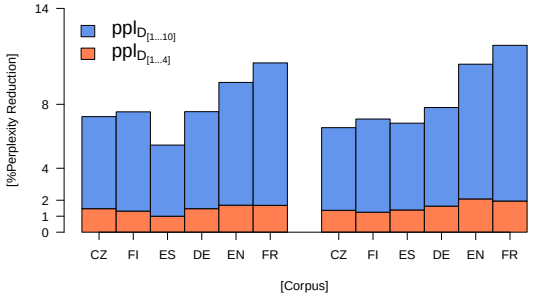

Figure 1: Percentage of perplexity reduction for pplx$_{D_{[1...4]}}$ and pplx$_{D_{[1...10]}}$ compared with pplx$_{D_{[1...3]}}$ on different training corpora (Europarl CZ, FI, ES, DE, EN, FR) and on news-test sets (NT) for $m = 2$ (left), and $m = 10$ (right).

of news-test 2015 (all denoted as NT)[5], and ii) *extreme* using a 24 hour period of streamed Finnish, and Spanish tweets[6] (denoted as TW), and the German and English sections of the patent description of medical translation task[7] (denoted as MED). See Table 1 for statistics of the training and test sets.

3.1 Perplexity

Table 1 shows substantial reduction in perplexity on all languages for out-of-domain test sets when expanding the number of discount parameters from 3 in vanilla MKN to 4 and 10. Consider the English news-test (NT), in which even for a 2-gram language model a single extra discount parameter ($m = 2$, $D_{[1...4]}$) improves the perplexity by 18 points and this improvement quadruples to 77 points when using 10 discounts ($m = 2$, $D_{[1...10]}$). This effect is consistent across the Europarl corpora, and for all LM orders. We observe a substantial improvements even for $m = 10$-gram models (see Figure 1). On the medical test set which has 9 times higher OOV ratio, the perplexity reduction shows a similar trend. However, these reductions vanish when an in-domain test set is used. Note that we use the same treatment of OOV words for computing the perplexities which is used in KenLM (Heafield, 2013).

3.2 Analysis

Out-of-domain and Out-of-vocabulary We selected the Finnish language for which the number and ratio of OOVs are close on its out-of-domain and in-domain test sets (NT and EU), while showing substantial reduction in perplexity on out-of-domain test set, see FI bars on Figure 1. Figure 2 (left), shows the full perplexity results for Finnish for vanilla MKN, and our extensions when tested on in-domain (EU) and out-of-domain (NT) test sets. The discount plot, Figure 2 (middle) illustrates the behaviour of the various discount parameters. We also measured the average hit length for queries by varying m on in-domain and out-of-domain test sets. As illustrated in Figure 2 (right) the in-domain test set allows for longer matches to the training data as

[5] http://www.statmt.org/{wmt13,14,15}/test.tgz
[6] Streamed via Twitter API on 17/05/2016.
[7] http://www.statmt.org/wmt14/medical-task/

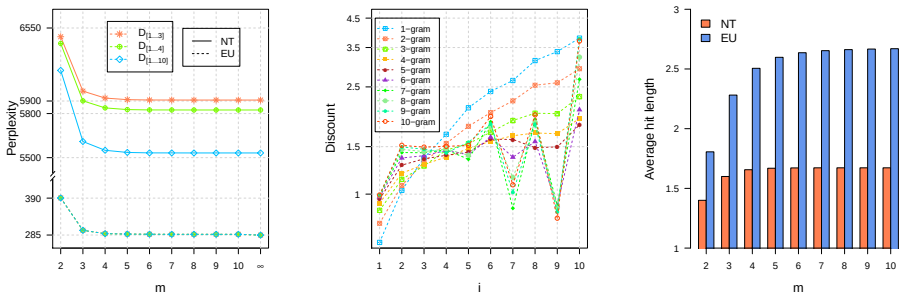

Figure 2: Statistics for the Finnish section of Europarl. The left plot illustrates the perplexity when tested on an out-of-domain (NT) and in-domain (EU) test sets varying LM order, m. The middle plot shows the discount parameters $D_{i\in[1...10]}$ for different m-gram orders. The right plot correspond to average hit length on EU and NT test sets.

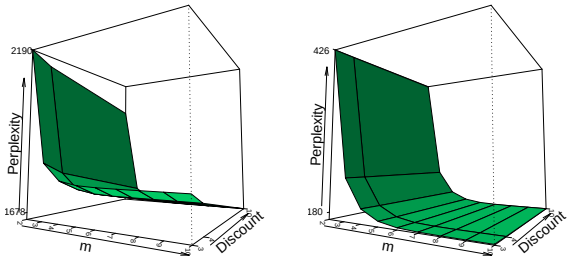

Figure 3: Perplexity (z-axis) vs. $m \in [2...10]$ (x-axis) vs. number of discounts $D_{i\in3,4,10}$ (y-axis) for German language trained on Europarl (left), and CommonCrawl2014 (right) and tested on news-test. Arrows show the direction of the increase.

m grows. This indicates that having more discount parameters is not only useful for test sets with extremely high number of OOV, but also allows for a more elegant way of assigning mass in the smoothing process when there is a domain mismatch.

Interdependency of m, data size, and discounts To explore the correlation between these factors we selected the German and investigated this correlation on two different training data sizes: Europarl (61M words), and CommonCrawl 2014 (984M words). Figure 3 illustrates the correlation between these factors using the same test set but with small and large training sets. Considering the slopes of the surfaces indicates that the small training data regime (left) which has higher sparsity, and more OOV in the test time benefits substantially from the more accurate discounting compared to the large training set (right) in which the gain from discounting is slight.[8]

[8]Nonetheless, the improvement in perplexity consistently grows with introducing more discount parameters even under the large training data regime, which suggests that more discount parameters, e.g., up to D_{30}, may be required for larger training corpus to reflect the fact that even an event with frequency of 30 might be considered rare in a corpus of nearly 1 billion words.

4 Conclusions

In this work we proposed a generalisation of Modified Kneser-Ney interpolative language modeling by introducing new discount parameters. We provide the mathematical proof for the discount bounds used in Modified Kneser-Ney and extend it further and illustrate the impact of our extension empirically on different Europarl languages using in-domain and out-of-domain test sets.

The empirical results on various training and test sets show that our proposed approach allows for a more elegant way of treating OOVs and mass assignments in interpolative smoothing. In future work, we will integrate our language model into the Moses machine translation pipeline to intrinsically measure its impact on translation qualities, which is of particular use for out-of-domain scenario.

A. Inequalities

We prove that these inequalities hold in expectation by making the reasonable assumption that events in

the natural language follow the power law (Clauset et al., 2009), $p\big(C(\mathbf{u}) = f\big) \propto f^{-1-\frac{1}{s_m}}$, where s_m is the parameter of the distribution, and $C(\mathbf{u})$ is the random variable denoting the frequency of the m-grams pattern $\mathbf{u}$. We now compute the expected number of unique patterns having a specific frequency $E[n_i[m]]$. Corresponding to each m-grams pattern $\mathbf{u}$, let us define a random variable $X_\mathbf{u}$ which is 1 if the frequency of $\mathbf{u}$ is i and zero otherwise. It is not hard to see that $n_i[m] = \sum_\mathbf{u} X_\mathbf{u}$, and

$$\begin{aligned}E\big[n_i[m]\big] &= E\big[\sum_\mathbf{u} X_\mathbf{u}\big] = \sum_\mathbf{u} E[X_\mathbf{u}] = \sigma^m E[X_\mathbf{u}] \\ &= \sigma^m\Big(p\big(C(\mathbf{u}) = i\big) \times 1 + p\big(C(\mathbf{u}) \neq i\big) \times 0\Big) \\ &\propto \sigma^m i^{-1-\frac{1}{s_m}}.\end{aligned}$$

We can verify that

$$\begin{aligned}(i+1)E\big[n_{i+1}[m]\big] < iE\big[n_i[m]\big] \Leftrightarrow \\ (i+1)\sigma^m(i+1)^{-1-\frac{1}{s_m}} < i\sigma^m i^{-1-\frac{1}{s_m}} \Leftrightarrow \\ i^{\frac{1}{s_m}} < (i+1)^{\frac{1}{s_m}}.\end{aligned}$$

which completes the proof of the inequalities.

B. Discount bounds proof sketch

The leave-one-out (leaving those m-grams which occurred only once) log-likelihood function of the interpolative smoothing is lower bounded by backoff model's (Ney et al., 1994), hence the estimated discounts for later can be considered as an approximation for the discounts of the former. Consider a backoff model with absolute discounting parameter D, were $P(w_i|w_{i-m+1}^{i-1})$ is defined as:

$$\begin{cases} \frac{c(w_{i-m+1}^i)-D}{c(w_{i-m+1}^{i-1})} & \text{if } c(w_{i-m+1}^i) > 0 \\ \frac{Dn_{1+}(w_{i-m+1}^{i-1}\,\bullet)}{c(w_{i-m+1}^{i-1})}\bar{P}(w^i|w_{i-m+2}^{i-1}) & \text{if } c(w_{i-m+1}^i) = 0 \end{cases}$$

where $n_{1+}(w_{i-m+1}^{i-1}\,\bullet)$ is the number of unique right contexts for the w_{i-m+1}^{i-1} pattern. Assume that for any choice of $0 < D < 1$ we can define $\bar{P}$ such that $P(w_i|w_{i_m+1}^{i-1})$ sums to 1. For readability we use the $\lambda(w_{i-m+1}^{i-1}) = \frac{n_{1+}(w_{i-m+1}^{i-1}\,\bullet)}{c(w_{i-m+1}^{i-1})-1}$ replacement. Following (Chen and Goodman, 1999), rewriting the leave-one-out log-likelihood for KN (Ney et al., 1994) to include more discounts (in this proof up to D_4), results in:

$$\begin{aligned}&\sum_{\substack{w_{i-m+1}^i \\ c(w_{i-m+1}^i)>4}} c(w_{i-m+1}^i)\log\frac{c(w_{i-m+1}^i)-1-D_4}{c(w_{i-m+1}^{i-1})-1} + \\ &\sum_{j=2}^{4}\Big(\sum_{\substack{w_{i-m+1}^i \\ c(w_{i-m+1}^i)=j}} c(w_{i-m+1}^i)\log\frac{c(w_{i-m+1}^i)-1-D_{j-1}}{c(w_{i-m+1}^{i-1})-1}\Big) + \\ &\sum_{\substack{w_{i-m+1}^i \\ c(w_{i-m+1}^i)=1}}\Big(c(w_{i-m+1}^i)\log(\sum_{j=1}^{4} n_j[m]D_j)\lambda(w_{i-m+1}^{i-1})\bar{P}\Big)\end{aligned}$$

which can be simplified to,

$$\begin{aligned}&\sum_{\substack{w_{i-m+1}^i \\ c(w_{i-m+1}^i)>4}} c(w_{i-m+1}^i)\log(c(w_{i-m+1}^i)-1-D_4) + \\ &\sum_{j=2}^{4}\Big(jn_j[m]\log(j-1-D_{j-1})\Big) + \\ &n_1[m]\log(\sum_{j=1}^{4} n_j[m]D_j) + \text{const}\end{aligned}$$

To find the optimal D_1, D_2, D_3, D_4 we set the partial derivatives to zero. For D_3,

$$\begin{aligned}&\frac{\partial}{\partial D_3} = n_1[m]\frac{n_3[m]}{\sum_{j=1}^4 n_j[m]D_j} - \frac{4n_4[m]}{3-D_3} = 0 \Rightarrow \\ &n_1[m]n_3[m](3-D_3) = 4n_4[m]\sum_{j=1}^{4} n_j[m]D_j \Rightarrow \\ &3n_1[m]n_3[m] - D_3 n_1[m]n_3[m] - 4n_4[m]n_1[m]D_1 > 0 \\ &\Rightarrow 3 - 4\frac{n_4[m]}{n_3[m]}D_1 > D_3 \quad \blacksquare\end{aligned}$$

And after taking $c(w_{i-m+1}^i) = 5$ out of the summation, for D_4:

$$\begin{aligned}&\frac{\partial}{\partial D_4} = \sum_{c(w_{i-m+1}^i)>5}\frac{-c(w_{i-m+1}^i)}{c(w_{i-m+1}^i)-1-D} - \frac{5n_5[m]}{4-D_4} \\ &+ n_1[m]\frac{n_4[m]}{\sum_{j=1}^4 n_j[m]D_j} = 0 \Rightarrow -\frac{5n_5[m]}{4-D_4} \\ &+ n_1[m]\frac{n_4[m]}{\sum_{j=1}^4 n_j[m]D_j} > 0 \Rightarrow n_1[m]n_4[m](4-D_4) \\ &> 5n_5[m]\sum_{j=1}^{4} n_j[m]D_j \Rightarrow 4 - 5\frac{n_5[m]}{n_4[m]}D_1 > D_4 \quad \blacksquare\end{aligned}$$

Abstract

We propose a domain adaptation framework, and formally prove that it generalizes the feature augmentation technique in (Daumé III, 2007) and the multi-task regularization framework in (Evgeniou and Pontil, 2004). We show that our framework is strictly more general than these approaches and allows practitioners to tune hyper-parameters to encourage transfer between close domains and avoid negative transfer between distant ones.

1 Introduction

Domain adaptation (DA) is an important problem that has received substantial attention in natural language processing (Blitzer et al., 2006; Daumé III, 2007; Finkel and Manning, 2009; Daumé III et al., 2010). In this paper, we propose a novel regularization framework which allows DA practitioners to tune hyper-parameters to encourage transfer between close domains, and avoid negative transfer (Rosenstein et al., 2005) between distant ones. In our framework, model parameters in multiple domains are learned jointly and constrained to remain close to one another. In the transfer learning taxonomy (Pan and Yang, 2010), our framework falls under the parameter-transfer category for multi-task inductive learning. We show that our framework generalizes the frustratingly easy domain adaptation (FEDA) in Daumé III (2007), Finkel and Manning (2009), and the regularised multi-task learning of Evgeniou and Pontil (2004). At the same time, it provides us with hyper-parameters to control the amount of transfer between domains.

2 Domain Adaptation Framework

Given labeled data from N domains, $\mathbf{D}^1, \ldots, \mathbf{D}^N$, traditional machine learning maximizes the following objective function for each domain $\mathbf{D}^i$:

$$\mathcal{O}(\mathbf{D}^i; \mathbf{w}_i) = \mathcal{L}_i(\mathbf{D}^i; \mathbf{w}_i) - \lambda_i ||\mathbf{w}_i||^2, \quad (1)$$

and we maximize $\mathcal{L}_i$ by tuning the parameter vector $\mathbf{w}_i$. For example, $\mathcal{L}_i$ can be the log-likelihood or the negative hinge loss. The term $\lambda_i ||\mathbf{w}_i||^2$ is the L_2-regularization term where λ_i is a positive scalar. In our framework, we propose to maximize

$$\sum_{i=1}^{N} \mathcal{L}_i(\mathbf{D}^i; \mathbf{w}_i) - \sum_{i=1}^{N} \eta_{0,i} ||\mathbf{w}_i||^2 - \sum\nolimits_{1 \le j < k \le N} \eta_{j,k} ||\mathbf{w}_j - \mathbf{w}_k||^2, \quad (2)$$

where $\eta_{j,k}$ are parameters controlling the transfer between domains. In the next sections, we show how our framework generalizes existing works.

2.1 Frustratingly Easy DA

The FEDA approach was introduced by Daumé III (2007) and later formalized by Finkel and Manning (2009) within a hierarchical Bayesian DA framework. While simple, the approach has often been shown to be effective. In this section, we show that our framework generalizes the FEDA approach.

The FEDA approach defines a new augmented feature space by duplicating each feature in $\mathbf{D}^i$ to a "general" domain. Therefore each parameter in $\mathbf{w}_i$ has a corresponding parameter in $\mathbf{w}_0$, and:

$$\mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}_i, \mathbf{w}_0) = \mathcal{L}_i(\mathbf{D}^i; \mathbf{w}_i + \mathbf{w}_0) \quad (3)$$

This directly leads to the following remark:

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 950–954,
Austin, Texas, November 1-5, 2016.

Remark For all i, for any $\mathbf{w}_i, \mathbf{w}_0, \mathbf{d} \in \mathbf{R}^m$:

$$\mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}_i + \mathbf{d}, \mathbf{w}_0 - \mathbf{d}) = \mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}_i, \mathbf{w}_0)$$

The complete objective function involving N ($N \geq 2$) domains is defined as follows:

$$\mathcal{O}'(\mathbf{D}; , \mathbf{w}_0, \mathbf{w}_1, \ldots, \mathbf{w}_N) = \sum_{i=1}^{N} \mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}_i, \mathbf{w}_0) - \sum_{i=0}^{N} \lambda_i ||\mathbf{w}_i||^2$$

We first prove the following relation:

Lemma 2.1 *Assume*

$$(\mathbf{w}_0^*, ..., \mathbf{w}_N^*) = \arg\max_{\mathbf{w}_1, ..., \mathbf{w}_N, \mathbf{w}_0} \left[\sum_{i=1}^{N} \mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}_i, \mathbf{w}_0) - \left(\lambda_0 ||\mathbf{w}_0||^2 + \sum_{i=1}^{N} \lambda_i ||\mathbf{w}_i||^2 \right) \right],$$

where $\lambda_0, \lambda_1, \ldots, \lambda_N > 0$*, then:*

$$\lambda_0 \mathbf{w}_0^* = \sum_{i=1}^{N} \lambda_i \mathbf{w}_i^* \tag{4}$$

Proof Let's introduce the vector $\mathbf{d}$ as follows:

$$\mathbf{d} = \frac{1}{\sum_{i=0}^{N} \lambda_i} \left(\lambda_0 \mathbf{w}_0^* - \sum_{i=1}^{N} \lambda_i \mathbf{w}_i^* \right) \tag{5}$$

Denote $(\mathbf{w}'_0, \ldots, \mathbf{w}'_N)$ such that $\forall\ 0 \leq i \leq N$,

$$\mathbf{w}'_i = \mathbf{w}_i^* + \mathbf{d}, \text{ and } \mathbf{w}'_0 = \mathbf{w}_0^* - \mathbf{d}.$$

Based on the remark, $\mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}'_i, \mathbf{w}'_0) = \mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}_i^*, \mathbf{w}_0^*)$. Let $\Delta = \mathcal{O}'(\mathbf{D}; \mathbf{w}'_0, \ldots, \mathbf{w}'_N) - \mathcal{O}'(\mathbf{D}; \mathbf{w}_0^*, \ldots, \mathbf{w}_N^*)$. Since $(\mathbf{w}_0^*, \ldots, \mathbf{w}_N^*)$ is optimal, $\Delta \leq 0$. Moreover,

$$\begin{aligned}
\Delta &= \sum_{i=1}^{N} \mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}'_i, \mathbf{w}'_0) - \sum_{i=0}^{N} \lambda_i ||\mathbf{w}'_i||^2 \\
&\quad - \sum_{i=1}^{N} \mathcal{L}'_i(\mathbf{D}^i; \mathbf{w}_i^*, \mathbf{w}_0^*) + \sum_{i=0}^{N} \lambda_i ||\mathbf{w}_i^*||^2 \\
&= \lambda_0 ||\mathbf{w}_0^*||^2 - \lambda_0 ||\mathbf{w}_0^* - \mathbf{d}||^2 \\
&\quad + \sum_{i=1}^{N} \lambda_i ||\mathbf{w}_i^*||^2 - \sum_{i=1}^{N} \lambda_i ||\mathbf{w}_i^* + \mathbf{d}||^2 \\
&= -\left(\sum_{i=0}^{N} \lambda_i \right) ||\mathbf{d}||^2 + \\
&\quad 2\mathbf{d} \cdot \left(\lambda_0 \mathbf{w}_0^* - \sum_{i=1}^{N} \lambda_i \mathbf{w}_i^* \right) \\
&= -\left(\sum_{i=0}^{N} \lambda_i \right) ||\mathbf{d}||^2 + 2\mathbf{d} \cdot \left(\sum_{i=0}^{N} \lambda_i \right) \mathbf{d} \\
&= \left(\sum_{i=0}^{N} \lambda_i \right) ||\mathbf{d}||^2 \geq 0
\end{aligned}$$

Hence, $\Delta = 0$ implying $||\mathbf{d}|| = 0$ and so $\mathbf{d} = \mathbf{0}$. From the definition of $\mathbf{d}$, Equation 4 holds. ∎

Next we state the following lemma (see supplementary material for the proof).

Lemma 2.2 *For any vectors* $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_N \in \mathbf{R}^m$*, any scalars* $\lambda_0, \lambda_1, \ldots, \lambda_N \in \mathbf{R}^+$*, let* $\mathbf{v}_0 = (\sum_{i=1}^{N} \lambda_i \mathbf{v}_i)/\lambda_0$*, then the following always holds:*

$$\lambda_0 ||\mathbf{v}_0||^2 + \sum_{i=1}^{N} \lambda_i ||\mathbf{v}_i||^2 = \sum_{i=1}^{N} \eta_{0,i} ||\mathbf{v}_i + \mathbf{v}_0||^2 + \sum_{1 \leq j < k \leq N} \eta_{j,k} ||\mathbf{v}_j - \mathbf{v}_k||^2,$$

$$\text{where} \quad \eta_{i,j} = \frac{\lambda_i \lambda_j}{\sum_{l=0}^{N} \lambda_l},\ \forall\ 0 \leq i < j \leq N.$$

Now we state and prove the following theorem, which shows our framework generalizes FEDA.

Theorem 2.3 *For* $\lambda_0, \lambda_1, \ldots, \lambda_N \in \mathbf{R}^+$*, define*

$$\forall 0 \leq i < j \leq N, \quad \eta_{i,j} = \frac{\lambda_i \lambda_j}{\sum_{l=0}^{N} \lambda_l},$$

the following holds:

$$\max_{\mathbf{w}_1,\mathbf{w}_2,\ldots,\mathbf{w}_N,\mathbf{w}_0} \left[\sum_{i=1}^{N} \mathcal{L}'_i(\mathbf{D}^i;\mathbf{w}_i,\mathbf{w}_0) - \left(\lambda_0||\mathbf{w}_0||^2 + \sum_{i=1}^{N}\lambda_i||\mathbf{w}_i||^2\right)\right]$$
$$= \max_{\mathbf{w}_1,\mathbf{w}_2,\ldots,\mathbf{w}_N} \left[\sum_{i=1}^{N} \mathcal{L}_i(\mathbf{D}^i;\mathbf{w}_i) - \left(\sum_{i=1}^{N}\eta_{0,i}||\mathbf{w}_i||^2 + \sum_{1\le j<k\le N}\eta_{j,k}||\mathbf{w}_j-\mathbf{w}_k||^2\right)\right]$$

Proof Let $(\mathbf{w}_0^*,\ldots,\mathbf{w}_N^*)$ be a solution to the first optimization problem. We have:

$$\mathbf{LHS} = \sum_{i=1}^{N} \mathcal{L}'_i(\mathbf{D}^i;\mathbf{w}_i^*,\mathbf{w}_0^*) - \left(\lambda_0||\mathbf{w}_0^*||^2 + \sum_{i=1}^{N}\lambda_i||\mathbf{w}_i^*||^2\right) \quad (6)$$

Lemma 2.1 gives $\mathbf{w}_0^* = \left(\sum_{i=1}^{N}\lambda_i\mathbf{w}_i^*\right)/\lambda_0$. Introduce $\mathbf{w}'_i = \mathbf{w}_i^* + \mathbf{w}_0^*$. Using Lemma 2.2, we have:

$$\mathbf{LHS} = \sum_{i=1}^{N} \mathcal{L}'_i(\mathbf{D}^i;\mathbf{w}_i^*,\mathbf{w}_0^*) - \left(\sum_{i=1}^{N}\eta_{0,i}||\mathbf{w}_i^*+\mathbf{w}_0^*||^2 + \sum_{1\le j<k\le N}\eta_{j,k}||\mathbf{w}_j^*-\mathbf{w}_k^*||^2\right)$$
$$= \sum_{i=1}^{N} \mathcal{L}_i(\mathbf{D}^i;\mathbf{w}'_i) - \left(\sum_{i=1}^{N}\eta_{0,i}||\mathbf{w}'_i||^2 + \sum_{1\le j<k\le N}\eta_{j,k}||\mathbf{w}'_j-\mathbf{w}'_k||^2\right) \le \mathbf{RHS}$$

Now, let $(\mathbf{w}_1^*,\mathbf{w}_2^*,\ldots,\mathbf{w}_N^*)$ be an optimal solution to the second problem. Given the relation between $\eta_{i,j}$ and $\lambda_0,\lambda_1,\ldots,\lambda_N$, let $\mathbf{w}'_0 = \left(\sum_{i=1}^{N}\lambda_i\mathbf{w}_i^*\right)/\left(\sum_{l=0}^{N}\lambda_l\right)$, and $\mathbf{w}'_i = \mathbf{w}_i^* - \mathbf{w}'_0$. We show in the supplementary material that

$$\mathbf{w}'_0 = \frac{1}{\lambda_0}\left(\sum_{i=1}^{N}\lambda_i\mathbf{w}'_i\right) \quad (7)$$

Based on these and Lemma 2.2, we have:

$$\mathbf{RHS} = \sum_{i=1}^{N} \mathcal{L}_i(\mathbf{D}^i;\mathbf{w}_i^*) - \left(\sum_{i=1}^{N}\eta_{0,i}||\mathbf{w}_i^*||^2 + \sum_{1\le j<k\le N}\eta_{j,k}||\mathbf{w}_j^*-\mathbf{w}_k^*||^2\right)$$
$$= \sum_{i=1}^{N} \mathcal{L}_i(\mathbf{D}^i;\mathbf{w}'_i+\mathbf{w}'_0) - \left(\sum_{i=1}^{N}\eta_{0,i}||\mathbf{w}'_i+\mathbf{w}'_0||^2 + \sum_{1\le j<k\le N}\eta_{j,k}||\mathbf{w}'_j-\mathbf{w}'_k||^2\right)$$
$$= \sum_{i=1}^{N} \mathcal{L}'_i(\mathbf{D}^i;\mathbf{w}'_i,\mathbf{w}'_0) - \left(\lambda_0||\mathbf{w}'_0||^2 + \sum_{i=1}^{N}\lambda_i||\mathbf{w}'_i||^2\right) \le \mathbf{LHS}$$

Therefore we must have $\mathbf{LHS} = \mathbf{RHS}$. ∎

This formally shows that FEDA is equivalent to solving the objective function given in Equation 2. In this new optimization problem, if we drop the terms involving $\eta_{j,k}$ for $j \neq 0$, we have:

$$\sum_{i=1}^{N}\left(\mathcal{L}_i(\mathbf{D}^i;\mathbf{w}_i) - \eta_{0,i}||\mathbf{w}_i||^2\right) \quad (8)$$

This is learning without domain adaptation. The additional regularization terms allow us keep the parameters from different domains close to one other. In the special case with two domains, if we use the same λ for all regularization terms, we have the following corollary:

Corollary 2.4 *For any $\lambda > 0$:*

$$\max_{\mathbf{w}_1,\mathbf{w}_2,\mathbf{w}_0}\left[\mathcal{L}'_1(\mathbf{D}^1;\mathbf{w}_1,\mathbf{w}_0) + \mathcal{L}'_2(\mathbf{D}^2;\mathbf{w}_2,\mathbf{w}_0) - \lambda\left(||\mathbf{w}_1||^2 + ||\mathbf{w}_2||^2 + ||\mathbf{w}_0||^2\right)\right]$$
$$= \max_{\mathbf{w}_1,\mathbf{w}_2}\left[\mathcal{L}_1(\mathbf{D}^1;\mathbf{w}_1) + \mathcal{L}_2(\mathbf{D}^2;\mathbf{w}_2) - \frac{1}{3}\lambda\left(||\mathbf{w}_1||^2 + ||\mathbf{w}_2||^2 + ||\mathbf{w}_1-\mathbf{w}_2||^2\right)\right]$$

Hence, the FEDA feature augmentation technique indirectly introduces a regularization term that pushes the source and target parameters as close

as possible. This is related to the technique of Chelba and Acero (2006) where they regularize the model parameters for the target domain using the term $\lambda||\mathbf{w} - \mathbf{w}^s||$, where $\mathbf{w}^s$ is the parameter vector learned from the source domain. The difference here is, in their work the parameters for the source domain are learned first and then fixed. The relation between their work and the feature augmentation technique was also briefly discussed in the paper of Daumé III (2007). We formally showed a precise relation here in this paper.

2.2 Regularized Multi-task Learning

Evgeniou and Pontil (2004) proposed multi-task regularized learning using support vector machines (SVM). They decomposed the model weight vector as a sum of domain-specific vectors and a general vector, in much the same way as FEDA[1]. Hence, both Lemma 2.1 and Theorem 2.3 of this paper apply, and our framework also generalizes multi-task regularized learning.

3 Experimental Results

In this section we apply our framework to both structured and un-structured tasks. For structured prediction, we use the named-entity recognition (NER) ACE-2005 dataset with 7 classes and 6 domains. We apply the linear chain CRF (Lafferty et al., 2001), and show results using standard and softmax-margin CRF (SM-CRF) (Gimpel and Smith, 2010), with features consisting of word shape features, neighboring words, previous prediction and prefixes/suffixes. The second task is sentiment classification on the Amazon review data set (Blitzer et al., 2007) from 4 domains, labeled positive or negative. We apply logistic regression (LR) and SVM using unigram and bigram features. All the models used in this section are implemented on top of a common framework, which was also used to implement various structured prediction models previously (Lu, 2015; Lu and Roth, 2015; Muis and Lu, 2016). For each task we compare:

TGT Trained only on the specific domain data,
ALL Trained on the data from all domains,

[1]They proved in Lemma 2.1 in their paper a similar relationship to Equation 4, but their proof assumes a SVM framework, and that λ_1=λ_2=. . . =λ_N.

AUG The FEDA approach, and
RF Our proposed regularization framework.

We use a 40/30/30 train-development-test split and report the results on the test set. The regularization parameters were tuned on the development set over a logarithmic scale between 10^{-3} to 10^3. For our framework, we used random search to tune the parameters, since an exhaustive search is too expensive (21 parameters for 6 domains). We choose the within-domain $\eta_{0,i}$ to be close to those used for the *ALL* and *AUG* model, while choosing the other $\eta_{j,k}$ to be 1-2 orders of magnitude higher. A good model could quickly be found that generally beats the baselines on the development set and also generalizes well to the test set. We show the results for NER in Table 1 and the sentiment task in Table 2.

4 Discussion

Our proof did not require any assumption about $\mathcal{L}$, as long as L_2 regularization is used. This means our result is applicable to a variety of models such as SVM, LR, and CRF (where L_2 regularization is used for the latter two models). Theoretically, we have shown the equivalence of DA optimization problems. Empirically, for non-convex objectives, different approaches may arrive at different solutions. However, for convex loss functions, our objective (Equation 2) is also convex, and all approaches should share the same solution.

We have shown that we can map the FEDA optimization problem to our framework. The converse is false: for any problem in this family (with arbitrary choices of η), we can only solve it using FEDA if there are only 2 domains, or if all regularization hyper-parameters are equal. Some parameter configurations in this family are "unreachable" by the feature augmentation technique. This is because in Theorem 2.3, the values of η's are defined based on λ's and therefore possess certain properties. For example, they must at least satisfy such constraints as $\eta_{i,k}\eta_{k,j} = \eta_{i,l}\eta_{l,j}$ for any $i \leq k, l \leq j$. We have seen that some of those unreachable problems could give us better empirical results. Can we find an alternative simple adaptation method such that all problems in this family are "reachable"? This is a question that needs to be addressed in future research.

5 Conclusion

In this paper, we presented a framework for domain adaptation that generalizes several previous works (Daumé III, 2007; Finkel and Manning, 2009; Evgeniou and Pontil, 2004). Our approach allows practitioners to specify the amount of transfer between domains via regularization hyper-parameters. These parameters could be tuned based on intuition or using held-out data. In future work we could also seek to find methods that can automatically optimize these parameters. The supplementary material of this paper is available at `http://statnlp.org/research/ml/`.

Abstract

In this paper, we enhance the attention-based neural machine translation (NMT) by adding explicit coverage embedding models to alleviate issues of repeating and dropping translations in NMT. For each source word, our model starts with a *full* coverage embedding vector to track the *coverage* status, and then keeps updating it with neural networks as the translation goes. Experiments on the large-scale Chinese-to-English task show that our enhanced model improves the translation quality significantly on various test sets over the strong large vocabulary NMT system.

1 Introduction

Neural machine translation (NMT) has gained popularity in recent years (e.g. (Bahdanau et al., 2014; Jean et al., 2015; Luong et al., 2015; Mi et al., 2016b; Li et al., 2016)), especially for the attention-based models of Bahdanau et al. (2014). The attention at each time step shows which source word the model should focus on to predict the next target word. However, the attention in each step only looks at the previous hidden state and the previous target word, there is no history or coverage information typically for each source word. As a result, this kind of model suffers from issues of repeating or dropping translations.

The traditional statistical machine translation (SMT) systems (e.g. (Koehn, 2004)) address the above issues by employing a source side "coverage vector" for each sentence to indicate explicitly which words have been translated, which parts have not yet. A coverage vector starts with all zeros, meaning no word has been translated. If a source word at position j got translated, the coverage vector sets position j as 1, and they won't use this source word in future translation. This mechanism avoids the repeating or dropping translation problems.

However, it is not easy to adapt the "coverage vector" to NMT directly, as attentions are soft probabilities, not 0 or 1. And SMT approaches handle one-to-many fertilities by using phrases or hiero rules (predict several words in one step), while NMT systems only predict one word at each step.

In order to alleviate all those issues, we borrow the basic idea of "coverage vector", and introduce a coverage embedding vector for each source word. We keep updating those embedding vectors at each translation step, and use those vectors to track the *coverage* information.

Here is a brief description of our approach. At the beginning of translation, we start from a *full* coverage embedding vector for each source word. This is different from the "coverage vector" in SMT in following two aspects:

- each source word has its own coverage embedding vector, instead of 0 or 1, a scalar, in SMT,
- we start with a *full* embedding vector for each word, instead of 0 in SMT.

After we predict a translation word y_t at time step t, we need to update each coverage embedding vector accordingly based on the attentions in the current step. Our motivation is that if we observe a very high attention over x_i in this step, there is a high chance that x_i and y_t are translation equivalent. So the embedding vector of x_i should come to *empty* (a zero vector) in a one-to-one translation case, or subtract the embedding of y_t for the one-to-many translation case. An *empty* coverage embedding of a word x_i indicates this word is translated, and we can not translate x_i again in future. Empirically, we model this procedure by using neural networks (gated recurrent unit (GRU) (Cho et al., 2014) or direct subtraction).

Large-scale experiments over Chinese-to-English on various test sets show that our method improves the translation quality significantly over the large vocabulary NMT system (Section 5).

*Work done while at IBM. To contact Abe, aittycheriah@google.com.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 955–960,
Austin, Texas, November 1-5, 2016.

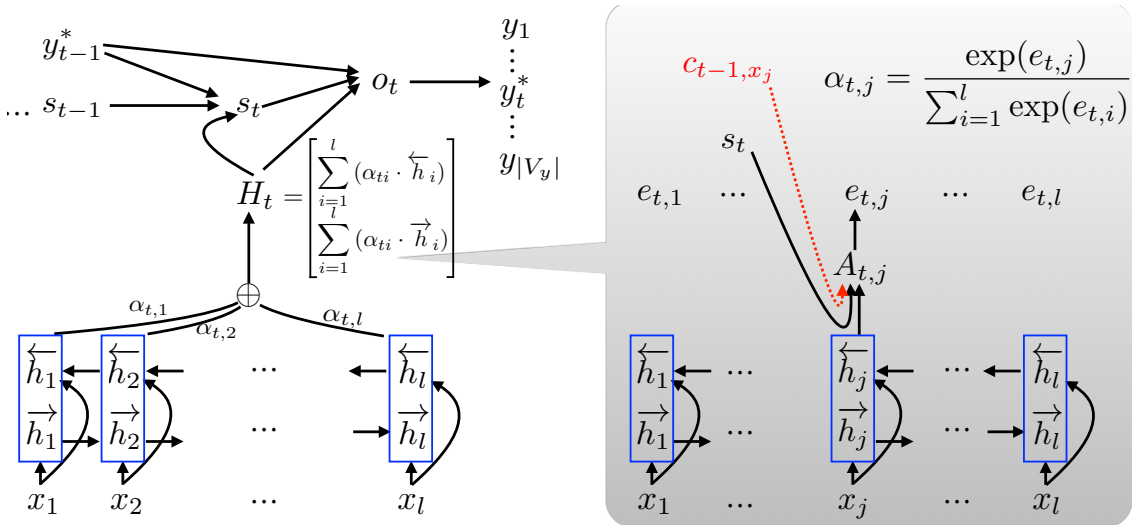

Figure 1: The architecture of attention-based NMT.The source sentence is $\mathbf{x} = (x_1, ..., x_l)$ with length l, the translation is $\mathbf{y}^* = (y_1^*, ..., y_m^*)$ with length m. $\overleftarrow{h_i}$ and $\overrightarrow{h_i}$ are bi-directional encoder states. $\alpha_{t,j}$ is the attention probability at time t, position j. H_t is the weighted sum of encoding states. s_t is a hidden state. o_t is an output state. Another one layer neural network projects o_t to the target output vocabulary, and conducts softmax to predict the probability distribution over the output vocabulary. The attention model (in right gray box) is a two layer feedforward neural network, $A_{t,j}$ is an intermediate state, then another layer converts it into a real number $e_{t,j}$, the final attention probability at position j is $\alpha_{t,j}$. We plug coverage embedding models into NMT model by adding an input c_{t-1,x_j} to $A_{t,j}$ (the red dotted line).

2 Neural Machine Translation

As shown in Figure 1, attention-based neural machine translation (Bahdanau et al., 2014) is an encoder-decoder network. the encoder employs a bi-directional recurrent neural network to encode the source sentence $\mathbf{x} = (x_1, ..., x_l)$, where l is the sentence length, into a sequence of hidden states $\mathbf{h} = (h_1, ..., h_l)$, each h_i is a concatenation of a left-to-right $\overrightarrow{h_i}$ and a right-to-left $\overleftarrow{h_i}$,

$$h_i = \begin{bmatrix} \overleftarrow{h}_i \\ \overrightarrow{h}_i \end{bmatrix} = \begin{bmatrix} \overleftarrow{f}(x_i, \overleftarrow{h}_{i+1}) \\ \overrightarrow{f}(x_i, \overrightarrow{h}_{i-1}) \end{bmatrix},$$

where $\overleftarrow{f}$ and $\overrightarrow{f}$ are two GRUs.

Given the encoded $\mathbf{h}$, the decoder predicts the target translation by maximizing the conditional log-probability of the correct translation $\mathbf{y}^* = (y_1^*, ...y_m^*)$, where m is the sentence length. At each time t, the probability of each word y_t from a target vocabulary V_y is:

$$p(y_t|\mathbf{h}, y_{t-1}^*..y_1^*) = g(s_t, y_{t-1}^*), \quad (1)$$

where g is a two layer feed-forward neural network (o_t is a intermediate state) over the embedding of the previous word y_{t-1}^*, and the hidden state s_t. The s_t is computed as:

$$s_t = q(s_{t-1}, y_{t-1}^*, H_t) \quad (2)$$

$$H_t = \begin{bmatrix} \sum_{i=1}^{l} (\alpha_{t,i} \cdot \overleftarrow{h}_i) \\ \sum_{i=1}^{l} (\alpha_{t,i} \cdot \overrightarrow{h}_i) \end{bmatrix}, \quad (3)$$

where q is a GRU, H_t is a weighted sum of $\mathbf{h}$, the weights, α, are computed with a two layer feed-forward neural network r:

$$\alpha_{t,i} = \frac{\exp\{r(s_{t-1}, h_i, y_{t-1}^*)\}}{\sum_{k=1}^{l} \exp\{r(s_{t-1}, h_k, y_{t-1}^*)\}} \quad (4)$$

3 Coverage Embedding Models

Our basic idea is to introduce a coverage embedding for each source word, and keep updating this embedding at each time step. Thus, the coverage embedding for a sentence is a matrix, instead of a vector in SMT. As different words have different fertilities (one-to-one, one-to-many, or one-to-zero), similar to word embeddings, each source word has its own coverage embedding vector. For simplicity, the number of coverage embedding vectors is the same as the source word vocabulary size.

At the beginning of our translation, our coverage embedding matrix $(c_{0,x_1}, c_{0,x_2}, ...c_{0,x_l})$ is initialized with the coverage embedding vectors of all the source words.

Then we update them with neural networks (a GRU (Section 3.1.1) or a subtraction (Section 3.1.2))

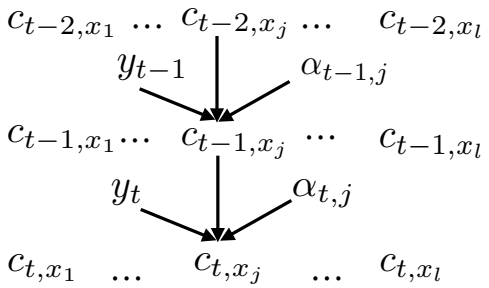

Figure 2: The coverage embedding model with a GRU at time step $t-1$ and t. $c_{0,1}$ to $c_{0,l}$ are initialized with the word coverage embedding matrix

until we translation all the source words.

In the middle of translation, some coverage embeddings should be close to *zero*, which indicate those words are covered or translated, and can not be translated in future steps. Thus, in the end of translation, the embedding matrix should be close to zero, which means all the words are covered.

In the following part, we first show two updating methods, then we list the NMT objective that takes into account the embedding models.

3.1 Updating Methods

3.1.1 Updating with a GRU

Figure 2 shows the updating method with a GRU. Then, at time step t, we feed y_t and $\alpha_{t,j}$ to the coverage model (shown in Figure 2),

$$z_{t,j} = \sigma(W^{zy} y_t + W^{z\alpha}\alpha_{t,j} + U^z c_{t-1,x_j})$$
$$r_{t,j} = \sigma(W^{ry} y_t + W^{r\alpha}\alpha_{t,j} + U^r c_{t-1,x_j})$$
$$\tilde{c}_{t,x_j} = \tanh(W y_t + W^{\alpha}\alpha_{t,j} + r_{t,j} \circ U c_{t-1,x_j})$$
$$c_{t,x_j} = z_{t,j} \circ c_{t-1,x_j} + (1 - z_{t,j}) \circ \tilde{c}_{t,x_j},$$

where, z_t is the update gate, r_t is the reset gate, $\tilde{c}_t$ is the new memory content, and c_t is the final memory. The matrix W^{zy}, $W^{z\alpha}$, U^z, W^{ry}, $W^{r\alpha}$, U^r, W^y, W^{α} and U are shared across different position j. $\circ$ is a pointwise operation.

3.1.2 Updating as Subtraction

Another updating method is to subtract the embedding of y_t directly from the coverage embedding c_{t,x_j} with a weight $\alpha_{t,j}$ as

$$c_{t,x_j} = c_{t-1,x_j} - \alpha_{t,j} \circ (W^{y\to c} y_t), \qquad (5)$$

where $W^{y\to c}$ is a matrix that coverts word embedding of y_t to the same size of our coverage embedding vector c.

3.2 Objectives

We integrate our coverage embedding models into the attention NMT (Bahdanau et al., 2014) by adding c_{t-1,x_j} to the first layer of the attention model (shown in the red dotted line in Figure 1).

Hopefully, if y_t is partial translation of x_j with a probability $\alpha_{t,j}$, we only remove partial information of c_{t-1,x_j}. In this way, we enable coverage embedding c_{0,x_j} to encode fertility information of x_j.

As we have mentioned, in the end of translation, we want all the coverage embedding vectors to be close to *zero*. So we also minimize the absolute values of embedding matrixes as

$$\theta^* = \arg\max_{\theta} \sum_{n=1}^{N} \Bigg\{ \sum_{t=1}^{m} \log p(y_t^{*n} | \mathbf{x}^n, y_{t-1}^{*n} .. y_1^{*n}) - \lambda \sum_{i=1}^{l} ||c_{m,x_i}|| \Bigg\}, \qquad (6)$$

where λ is the coefficient of our coverage model.

As suggested by Mi et al. (2016a), we can also use some supervised alignments in our training. Then, we know exactly when each c_{t,x_j} should become close to *zero* after step t. Thus, we redefine Equation 6 as:

$$\theta^* = \arg\max_{\theta} \sum_{n=1}^{N} \Bigg\{ \sum_{t=1}^{m} \log p(y_t^{*n} | \mathbf{x}^n, y_{t-1}^{*n} .. y_1^{*n}) - \lambda \sum_{i=1}^{l} (\sum_{j=a_{x_i}}^{m} ||c_{j,x_i}||) \Bigg\}, \qquad (7)$$

where a_{x_i} is the maximum index on the target sentence x_i can be aligned to.

4 Related Work

There are several parallel and independent related work (Tu et al., 2016; Feng et al., 2016; Cohn et al., 2016). Tu et al. (2016) is the most relevant one. In their paper, they also employ a GRU to model the coverage vector. One main difference is that our model introduces a specific coverage embedding vector for each source word, in contrast, their work initializes the word coverage vector with a scalar with a uniform distribution. Another difference lays in the fertility part, Tu et al. (2016) add an accumulate operation and a fertility function to simulate

the process of one-to-many alignments. In our approach, we add fertility information directly to coverage embeddings, as each source word has its own embedding. The last difference is that our baseline system (Mi et al., 2016b) is an extension of the large vocabulary NMT of Jean et al. (2015) with candidate list decoding and UNK replacement, a much stronger baseline system.

Cohn et al. (2016) augment the attention model with well-known features in traditional SMT, including positional bias, Markov conditioning, fertility and agreement over translation directions. This work is orthogonal to our work.

5 Experiments

5.1 Data Preparation

We run our experiments on Chinese to English task. We train our machine translation systems on two training sets. The first training corpus consists of approximately 5 million sentences available within the DARPA BOLT Chinese-English task. The second training corpus adds HK Law, HK Hansard and UN data, the total number of training sentence pairs is 11 million. The Chinese text is segmented with a segmenter trained on CTB data using conditional random fields (CRF).

Our development set is the concatenation of several tuning sets (GALE Dev, P1R6 Dev, and Dev 12) released under the DARPA GALE program. The development set is 4491 sentences in total. Our test sets are NIST MT06, MT08 news, and MT08 web.

For all NMT systems, the full vocabulary sizes for thr two training sets are $300k$ and $500k$ respectively. The coverage embedding vector size is 100. In the training procedure, we use AdaDelta (Zeiler, 2012) to update model parameters with a mini-batch size 80. Following Mi et al. (2016b), the output vocabulary for each mini-batch or sentence is a sub-set of the full vocabulary. For each source sentence, the sentence-level target vocabularies are union of top $2k$ most frequent target words and the top 10 candidates of the word-to-word/phrase translation tables learned from 'fast_align' (Dyer et al., 2013). The maximum length of a source phrase is 4. In the training time, we add the reference in order to make the translation reachable.

Following Jean et al. (2015), We dump the alignments, attentions, for each sentence, and replace UNKs with the word-to-word translation model or the aligned source word.

Our traditional SMT system is a hybrid syntax-based tree-to-string model (Zhao and Al-onaizan, 2008), a simplified version of Liu et al. (2009) and Cmejrek et al. (2013). We parse the Chinese side with Berkeley parser, and align the bilingual sentences with GIZA++. Then we extract Hiero and tree-to-string rules on the training set. Our two 5-gram language models are trained on the English side of the parallel corpus, and on monolingual corpora (around 10 billion words from Gigaword (LDC2011T07)), respectively. As suggestion by Zhang (2016), NMT systems can achieve better results with the help of those monolingual corpora. We tune our system with PRO (Hopkins and May, 2011) to minimize (TER- BLEU)/2 on the development set.

5.2 Translation Results

Table 1 shows the results of all systems on 5 million training set. The traditional syntax-based system achieves 9.45, 12.90, and 17.72 on MT06, MT08 News, and MT08 Web sets respectively, and 13.36 on average in terms of (TER- BLEU)/2. The large-vocabulary NMT (LVNMT), our baseline, achieves an average (TER- BLEU)/2 score of 15.74, which is about 2 points worse than the hybrid system.

We test four different settings for our coverage embedding models:

- $\mathbf{U}_{GRU}$: updating with a GRU;
- $\mathbf{U}_{Sub}$: updating as a subtraction;
- $\mathbf{U}_{GRU}$ + $\mathbf{U}_{Sub}$: combination of two methods (do not share coverage embedding vectors);
- **+Obj.**: $\mathbf{U}_{GRU}$ + $\mathbf{U}_{Sub}$ plus an additional objective in Equation 6[1].

$\mathbf{U}_{GRU}$ improves the translation quality by 1.3 points on average over LVNMT. And $\mathbf{U}_{GRU}$ + $\mathbf{U}_{Sub}$ achieves the best average score of 13.14, which is about 2.6 points better than LVNMT. All the improvements of our coverage embedding models over LVNMT are statistically significant with the sign-test of Collins et al. (2005). We believe that we need to explore more hyper-parameters of **+Obj.** in order to get even better results over $\mathbf{U}_{GRU}$ + $\mathbf{U}_{Sub}$.

[1]We use two λs for $\mathbf{U}_{GRU}$ and $\mathbf{U}_{Sub}$ separately, and we test $\lambda_{GRU} = 1 \times 10^{-4}$ and $\lambda_{Sub} = 1 \times 10^{-2}$ in our experiments.

LVNMT		0.96	34.53	12.25	0.93	28.86	17.40	0.97	26.78	17.57	15.74
Ours	$\mathbf{U}_{GRU}$	0.92	35.59	10.71	0.89	30.18	15.33	0.97	27.48	16.67	14.24
	$\mathbf{U}_{Sub}$	0.91	35.90	10.29	0.88	30.49	15.23	0.96	27.63	16.12	13.88
	$\mathbf{U}_{GRU}$+$\mathbf{U}_{Sub}$	0.92	36.60	9.36	0.89	31.86	13.69	0.95	27.12	16.37	13.14
	+Obj.	0.93	36.80	9.78	0.90	31.83	14.20	0.95	28.28	15.73	13.24

Table 1: Single system results in terms of (TER-BLEU)/2 (the lower the better) on 5 million Chinese to English training set. NMT results are on a large vocabulary ($300k$) and with UNK replaced. $\mathbf{U}_{GRU}$: updating with a GRU; $\mathbf{U}_{Sub}$: updating as a subtraction; $\mathbf{U}_{GRU}$ + $\mathbf{U}_{Sub}$: combination of two methods (do not share coverage embedding vectors); **+Obj.**: $\mathbf{U}_{GRU}$ + $\mathbf{U}_{Sub}$ with an additional objective in Equation 6, we have two λs for $\mathbf{U}_{GRU}$ and $\mathbf{U}_{Sub}$ separately, and we test $\lambda_{GRU} = 1 \times 10^{-4}$ and $\lambda_{Sub} = 1 \times 10^{-2}$.

single system	MT06		MT08				avg.
			News		Web		
	BP	T-B	BP	T-B	BP	T-B	T-B
Tree-to-string	0.90	8.70	0.84	12.65	0.84	17.00	12.78
LVNMT	0.96	9.78	0.94	14.15	0.97	15.89	13.27
$\mathbf{U}_{GRU}$	0.97	8.62	0.95	12.79	0.97	15.34	12.31

Table 2: Single system results in terms of (TER-BLEU)/2 on 11 million set. NMT results are on a large vocabulary ($500k$) and with UNK replaced. Due to the time limitation, we only have the results of $\mathbf{U}_{GRU}$ system.

Table 2 shows the results of 11 million systems, LVNMT achieves an average (TER-BLEU)/2 of 13.27, which is about 2.5 points better than 5 million LVNMT. The result of our $\mathbf{U}_{GRU}$ coverage model gives almost 1 point gain over LVNMT. Those results suggest that the more training data we use, the stronger the baseline system becomes, and the harder to get improvements. In order to get a reasonable or strong NMT system, we have to conduct experiments over a large-scale training set.

5.3 Alignment Results

Table 3 shows the F1 scores on the alignment test set (447 hand aligned sentences). The MaxEnt model is trained on $67k$ hand-aligned data, and achieves an F1 score of 75.96. For NMT systems, we dump alignment matrixes, then, for each target word we only add the highest probability link if it is higher than 0.2. Results show that our best coverage model, $\mathbf{U}_{GRU}$ + $\mathbf{U}_{Sub}$, improves the F1 score by 2.2 points over the sorce of LVNMT.

We also check the repetition statistics of NMT outputs. We simply compute the number of repeated phrases (length longer or equal than 4 words) for each sentence. On MT06 test set, the 5 million LVNMT has 209 repeated phrases, our $\mathbf{U}_{GRU}$ system reduces it significantly to 79, $\mathbf{U}_{GRU}$+$\mathbf{U}_{Sub}$ and **+Obj.** only have 50 and 47 repeated phrases, respectively. The 11 million LVNMT gets 115 repeated phrases, and $\mathbf{U}_{GRU}$ reduces it further down to 16. Those trends hold across other test sets. Those statistics show that a larger training set or coverage embedding models alleviate the repeating problem in NMT.

system		pre.	rec.	F1
MaxEnt		74.86	77.10	75.96
LVNMT		47.88	41.06	44.21
Ours	$\mathbf{U}_{GRU}$	51.11	41.42	45.76
	$\mathbf{U}_{Sub}$	49.07	42.49	45.55
	$\mathbf{U}_{GRU}$+$\mathbf{U}_{Sub}$	49.46	43.83	46.47
	+Obj.	49.78	41.73	45.40

Table 3: Alignment F1 scores of different models.

6 Conclusion

In this paper, we propose simple, yet effective, coverage embedding models for attention-based NMT. Our model learns a special coverage embedding vector for each source word to start with, and keeps updating those coverage embeddings with neural networks as the translation goes. Experiments on the large-scale Chinese-to-English task show significant improvements over the strong LVNMT system.

Abstract

Canonical morphological segmentation aims to divide words into a sequence of standardized segments. In this work, we propose a character-based neural encoder-decoder model for this task. Additionally, we extend our model to include morpheme-level and lexical information through a neural reranker. We set the new state of the art for the task improving previous results by up to 21% accuracy. Our experiments cover three languages: English, German and Indonesian.

1 Introduction

Morphological segmentation aims to divide words into morphemes, meaning-bearing sub-word units. Indeed, segmentations have found use in a diverse set of NLP applications, e.g., automatic speech recognition (Afify et al., 2006), keyword spotting (Narasimhan et al., 2014), machine translation (Clifton and Sarkar, 2011) and parsing (Seeker and Çetinoğlu, 2015). In the literature, most research has traditionally focused on *surface segmentation*, whereby a word w is segmented into a sequence of substrings whose concatenation is the entire word; see Ruokolainen et al. (2016) for a survey. In contrast, we consider *canonical segmentation*: w is divided into a sequence of standardized segments. To make the difference concrete, consider the following example: the surface segmentation of the complex English word *achievability* is *achiev+abil+ity*, whereas its canonical segmentation is *achieve+able+ity*, i.e., we restore the alterations made during word formation.

Canonical versions of morphological segmentation have been introduced multiple times in the literature (Kay, 1977; Naradowsky and Goldwater, 2009; Cotterell et al., 2016). Canonical segmentation has several representational advantages over surface segmentation, e.g., whether two words share a morpheme is no longer obfuscated by orthography. However, it also introduces a hard algorithmic challenge: in addition to segmenting a word, we must reverse orthographic changes, e.g., mapping *achievability*↦*achieveableity*.

Computationally, canonical segmentation can be seen as a sequence-to-sequence problem: we must map a word form to a canonicalized version with segmentation boundaries. Inspired by the recent success of neural encoder-decoder models (Sutskever et al., 2014) for sequence-to-sequence problems in NLP, we design a neural architecture for the task. However, a naïve application of the encoder-decoder model ignores much of the linguistic structure of canonical segmentation—it cannot directly model the individual canonical segments, e.g., it cannot easily produce segment-level embeddings. To solve this, we use a neural reranker on top of the encoder-decoder, allowing us to embed both characters and entire segments. The combined approach outperforms the state of the art by a wide margin (up to 21% accuracy) in three languages: English, German and Indonesian.

2 Neural Canonical Segmentation

We begin by formally describing the canonical segmentation task. Given a discrete alphabet Σ (e.g., the 26 letters of the English alphabet),

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 961–967,
Austin, Texas, November 1-5, 2016.

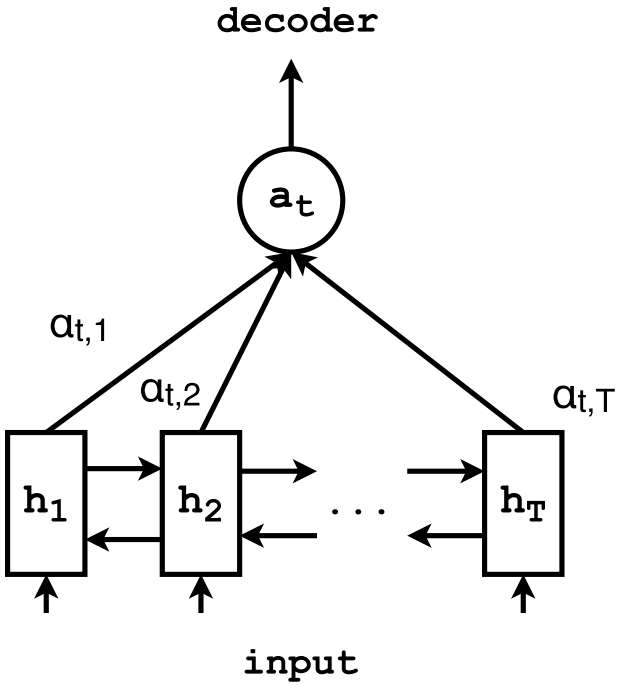

Figure 1: Detailed view of the attention mechanism of the neural encoder-decoder.

our goal is to map a word $w \in \Sigma^*$ (e.g., w=*achievability*), to a canonical segmentation $c \in \Omega^*$ (e.g., c=*achieve+able+ity*). We define $\Omega = \Sigma \cup \{+\}$, where $+$ is a distinguished separation symbol. Additionally, we will write the segmented form as $c=\sigma_1+\sigma_2+\ldots+\sigma_n$, where each segment $\sigma_i \in \Sigma^*$ and n is the number of canonical segments.

We take a probabilistic approach and, thus, attempt to learn a distribution $p(c \mid w)$. Our model consists of two parts. First, we apply an encoder-decoder recurrent neural network (RNN) (Bahdanau et al., 2014) to the sequence of characters of the input word to obtain candidate canonical segmentations. Second, we define a neural reranker that allows us to embed individual morphemes and chooses the final answer from within a set of candidates generated by the encoder-decoder.

2.1 Neural Encoder-Decoder

Our encoder-decoder is based on Bahdanau et al. (2014)'s neural machine translation model.[1] The **encoder** is a bidirectional gated RNN (GRU) (Cho et al., 2014b). Given a word $w \in \Sigma^*$, the input to the encoder is the sequence of characters of w, represented as one-hot vectors. The **decoder** defines a conditional probability distribution over $c \in \Omega^*$ given w:

$$\begin{aligned} p_{\text{ED}}(c \,|\, w) &= \prod_{t=1}^{|c|} p(c_t | c_1, \ldots, c_{t-1}, w) \\ &= \prod_{t=1}^{|c|} g(c_{t-1}, s_t, a_t) \end{aligned}$$

where g is a nonlinear activation function, s_t is the state of the decoder at t and a_t is a weighted sum of the $|w|$ states of the encoder. The state of the encoder for w_i is the concatenation of forward and backward hidden states $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$ for w_i. An overview of how the attention weight and the weighted sum a_t are included in the architecture can be seen in Figure 1. The attention weights $\alpha_{t,i}$ at each timestep t are computed based on the respective encoder state and the decoder state s_t. See Bahdanau et al. (2014) for further details.

2.2 Neural Reranker

The encoder-decoder, while effective, predicts each output character in Ω sequentially. It does not use explicit representations for entire segments and is incapable of incorporating simple lexical information, e.g., does this canonical segment occur as an independent word in the lexicon? Therefore, we extend our model with a reranker.

The reranker rescores canonical segmentations from a candidate set, which in our setting is sampled from p_{ED}. Let the sample set be $\mathcal{S}_w = \{k^{(i)}\}_{i=1}^{N}$ where $k^{(i)} \sim p_{\text{ED}}(c \mid w)$. We define the neural reranker as

$$p_\theta(c \,|\, w) = \frac{\exp\Big(u^\top \tanh(W v_c) + \tau \log p_{\text{ED}}(c \,|\, w)\Big)}{Z_\theta}$$

where $v_c = \sum_{i=1}^{n} v_{\sigma_i}$ (recall $c = \sigma_1+\sigma_2+\ldots+\sigma_n$) and v_{σ_i} is a one-hot morpheme embedding of σ_i with an additional binary dimension marking if σ_i occurs independently as a word in the language.[2] The partition function is $Z_\theta(w)$ and the parameters are $\theta = \{u, W, \tau\}$. The parameters W and u

[1] github.com/mila-udem/blocks-examples/tree/master/machine_translation

[2] To determine if a canonical segment is in the lexicon, we check its occurrence in ASPELL. Alternatively, one could ask whether it occurs in a large corpus, e.g., Wikipedia.

are projection and hidden layers, respectively, of a multi-layered perceptron and τ can be seen as a temperature parameter that anneals the encoder-decoder model p_{ED} (Kirkpatrick, 1984). We define the partition function over the sample set $\mathcal{S}_w$:

$$Z_\theta = \sum_{k \in \mathcal{S}_w} \exp\left(u^\top \tanh(W v_k) + \tau \log p_{\text{ED}}(k \mid w)\right).$$

The reranking model's ability to embed morphemes is important for morphological segmentation since we often have strong corpus-level signals. The reranker also takes into account the character-level information through the score of the encoder-decoder model. Due to this combination we expect stronger performance.

3 Related Work

Various approaches to morphological segmentation have been proposed in the literature. In the unsupervised realm, most work has been based on the principle of minimum description length (Cover and Thomas, 2012), e.g., LINGUISTICA (Goldsmith, 2001; Lee and Goldsmith, 2016) or MORFESSOR (Creutz and Lagus, 2002; Creutz et al., 2007; Poon et al., 2009). MORFESSOR was later extended to a semi-supervised version by Kohonen et al. (2010). Supervised approaches have also been considered. Most notably, Ruokolainen et al. (2013) developed a supervised approach for morphological segmentation based on conditional random fields (CRFs) which they later extended to work also in a semi-supervised way (Ruokolainen et al., 2014) using letter successor variety features (Hafer and Weiss, 1974). Similarly, Cotterell et al. (2015) improved performance with a semi-Markov CRF.

More recently, Wang et al. (2016) achieved state-of-the-art results on surface morphological segmentation using a window LSTM. Even though Wang et al. (2016) also employ a recurrent neural network, we distinguish our approach, in that we focus on *canonical* morphological segmentation, rather than *surface* morphological segmentation.

Naturally, our approach is also relevant to other applications of recurrent neural network transduction models (Sutskever et al., 2014; Cho et al., 2014a). In addition to machine translation (Bahdanau et al., 2014), these models have been successfully applied to many areas of NLP, including parsing (Vinyals et al., 2015), morphological reinflection (Kann and Schütze, 2016) and automatic speech recognition (Graves and Schmidhuber, 2005; Graves et al., 2013).

4 Experiments

To enable comparison to earlier work, we use a dataset that was prepared by Cotterell et al. (2016) for canonical segmentation.[3]

4.1 Languages

The dataset we work on covers 3 languages: English, German and Indonesian. English and German are West Germanic Languages, with the former being an official languages in nearly 60 different states and the latter being mainly spoken in Western Europe. Indonesian — or *Bahasa Indonesia*— is the official language of Indonesia.

Cotterell et al. (2016) report the best experimental results for Indonesian, followed by English and finally German. The high error rate for German might be caused by it being rich in orthografic changes. In contrast, Indonesian morphology is comparatively simple.

4.2 Corpora

The data for the English language was extracted from segmentations derived from the CELEX database (Baayen et al., 1993). The German data was extracted from DerivBase (Zeller et al., 2013), which provides a collection of derived forms together with the transformation rules, which were used to create the canonical segmentations. Finally, the data for Bahasa Indonesia was collected by using the output of the MORPHIND analyzer (Larasati et al., 2011), together with an open-source corpus of Indonesian. For each language we used the 10,000 forms that were selected at random by Cotterell et al. (2016) from a uniform distribution over types to form the corpus. Following them, we perform our experiments on 5 splits of the data into 8000 training forms, 1000 development forms and 1000 test forms and report averages.

[3] ryancotterell.github.io/canonical-segmentation

4.3 Training

We train an ensemble of five encoder-decoder models. The encoder and decoder RNNs each have 100 hidden units. Embedding size is 300. We use ADADELTA (Zeiler, 2012) with a minibatch size of 20. We initialize all weights (encoder, decoder, embeddings) to the identity matrix and the biases to zero (Le et al., 2015). All models are trained for 20 epochs. The hyperparameter values are taken from Kann and Schütze (2016) and kept unchanged for the application to canonical segmentation described here.

To train the reranking model, we first gather the sample set $\mathcal{S}_w$ on the training data. We take 500 individual samples, but (as we often sample the same form multiple times) $|\mathcal{S}_w| \approx 5$. We optimize the log-likelihood of the training data using ADADELTA. For generalization, we employ L_2 regularization and we perform grid search to determine the coefficient $\lambda \in \{0.0, 0.1, 0.2, 0.3, 0.4, 0.5\}$. To decode the model, we again take 500 samples to populate $\mathcal{S}_w$ and select the best segmentation.

Baselines. Our first baseline is the joint transduction and segmentation model (**JOINT**) of Cotterell et al. (2016). It is the current state of the art on the datasets we use and the task of canonical segmentation in general. This model uses a jointly trained, separate transduction and segmentation component. Importantly, the joint model of Cotterell et al. (2016) *already contains segment-level features*. Thus, reranking this baseline would not provide a similar boost.

Our second baseline is a weighted finite-state transducer (**WFST**) (Mohri et al., 2002) with a log-linear parameterization (Dreyer et al., 2008), again, taken from Cotterell et al. (2016). The WFST baseline is particularly relevant because, like our encoder-decoder, it formulates the problem directly as a string-to-string transduction.

Evaluation Metrics. We follow Cotterell et al. (2016) and use the following evaluation measures: error rate, edit distance and morpheme F_1. Error rate is defined as 1 minus the proportion of guesses that are completely correct. Edit distance is the Levenshtein distance between guess and gold standard. For this, guess and gold are each represented as one string with a distinguished character denoting the segment boundaries. Morpheme F_1 compares the morphemes in guess and gold. Precision (resp. recall) is the proportion of morphemes in guess (resp. gold) that occur in gold (resp. guess).

Table 1: Error rate (top), edit distance (middle), F_1 (bottom) for canonical segmentation. Each double column gives the measure and its standard deviation. Best result on each line (excluding UB) in bold. RR: encoder-decoder+reranker. ED: encoder-decoder. JOINT, WFST: baselines (see text). UB: upper bound, the maximum score our reranker could obtain, i.e., considering the best sample in the predictions of ED.

5 Results

The results of the canonical segmentation experiment in Table 1 show that both of our models improve over all baselines. The encoder-decoder alone has a .02 (English), .15 (German) and .01 (Indonesion) lower error rate than the best baseline. The encoder-decoder improves most for the language for which the baselines did worst. This suggests that, for more complex languages, a neural network model might be a good choice.

The reranker achieves an additional improvement of .04 to .06. for the error rate. This is likely due to the additional information the reranker has access to: morpheme embeddings and existing words.

Important is also the upper bound we report. It shows the maximum performance the reranker could achieve, i.e., evaluates the best solution that appears in the set of candidate answers for the reranker. The right answer is contained in $\geq 94\%$ of samples. Note that, even though the upper bound goes up with the number of samples we take, there is no guarantee for any finite number of samples that they will contain the true answer. Thus, we would need to take an infinite number of samples to get a perfect upper bound. However, as the current upper bound is quite high, the encoder-decoder proves to be an appropri-

ate model for the task. Due to the large gap between the performance of the encoder-decoder and the upper bound, a better reranker could further increase performance. We will investigate ways to improve the reranker in future work.

Error analysis. We give for representative samples the error (E for the segmentation produced by our method) and the correct analysis (G for gold).

We first analyze cases in which the right answer does not appear at all in the samples drawn from the encoder-decoder. Those include problems with umlauts in German (G: *verflüchtigen*↦ *ver+flüchten+ig*, E: *verflucht+ig*) and orthographic changes at morpheme boundaries (G:*cutter*↦*cut+er*, E: *cutter* or *cutt+er*, sampled with similar frequency). There are also errors that are due to problems with the annotation, e.g., the following two gold segmentations are arguably incorrect: *tec*↦*detective* and *syrerin*↦*syr+er+in* (*syr* is neither a word nor an affix in German).

In other cases, the encoder-decoder does find the right solution (G), but gives a higher probability to an incorrect analysis (E). Examples are a wrong split into adjectives or nouns instead of verbs (G: *fügsamkeit*↦*fügen+sam+keit*, E: *fügsam+keit*), the other way around (G: *zähler*↦*zahl+er*, E: *zählen+er*), cases where the wrong morphemes are chosen (G: *precognition*↦*pre+cognition*, E: *precognit+ion*), difficult cases where letters have to be inserted (G: *redolence*↦*redolent+ence*, E: *re+dolence*) or words the model does not split up, even though they should be (G: *additive*↦ *addition+ive*, E: *additive*).

Based on its access to lexical information and morpheme embeddings, the reranker is able to correct some of the errors made by the encoder-decoder. Samples are G: *geschwisterpärchen*↦ *geschwisterpaar+chen*, E: *geschwisterpar+chen* (*geschwisterpaar* is a word in German but *geschwisterpar* is not) or G: *zickig*↦ *zicken+ig*, E: *zick+ig* (with *zicken*, but not *zick*, being a German word).

Finally, we want to know if segments that appear in the test set without being present in the training set are a source of errors. In order to investigate that, we split the test samples into two groups: The first group contains the samples for which our system finds the right answer. The second one contains all other samples. We compare the percentage of samples that do not appear in the training data for both groups. We exemplarily use the German data and the results results are shown in Table 2. First, it can be seen that very roughly about a third of all segments does not appear in the training data. This is mainly due to unseen lemmas as their stems are naturally unknown to the system. However, the correctly solved samples contain nearly 10% more unseen segments. As the average number of segments per word for wrong and right solutions — 2.44 and 2.11, respectively — does not differ by much, it seems unlikely that many errors are caused by unknown segments.

wrong samples	right samples
27.33 (.02)	36.60 (.01)

Table 2: Percentage of segments in the solutions for the test data that do not appear in the training set - split by samples that our system does or does not get right. We use the German data and average over the 5 splits. Standard deviation in parenthesis.

6 Conclusion and Future Work

We developed a model consisting of an encoder-decoder and a neural reranker for the task of canonical morphological segmentation. Our model combines character-level information with features on the morpheme level and external information about words. It defines a new state of the art, improving over baseline models by up to .21 accuracy, 16 points F_1 and .77 Levenshtein distance.

We found that $\geq 94\%$ of correct segmentations are in the sample set drawn from the encoder-decoder model, demonstrating the upper bound on the performance of our reranker is quite high; in future work, we hope to develop models to exploit this.

Exploiting Mutual Benefits between Syntax and Semantic Roles using Neural Network

Abstract

We investigate mutual benefits between syntax and semantic roles using neural network models, by studying a parsing→SRL pipeline, a SRL→parsing pipeline, and a simple joint model by embedding sharing. The integration of syntactic and semantic features gives promising results in a Chinese Semantic Treebank, demonstrating large potentials of neural models for joint parsing and semantic role labeling.

1 Introduction

The correlation between syntax and semantics has been a fundamental problem in natural language processing (Steedman, 2000). As a shallow semantic task, semantic role labeling (SRL) models have traditionally been built upon syntactic parsing results (Gildea and Jurafsky, 2002; Gildea and Palmer, 2002; Punyakanok et al., 2005). It has been shown that parser output features play a crucial role for accurate SRL (Pradhan et al., 2005; Surdeanu et al., 2007).

On the reverse direction, semantic role features have been used to improve parsing (Boxwell et al., 2010). Existing methods typically use semantic features to rerank n-best lists of syntactic parsing models (Surdeanu et al., 2008; Hajič et al., 2009). There has also been attempts to learn syntactic parsing and semantic role labeling models jointly, but most such efforts have led to negative results (Sutton and McCallum, 2005; Van Den Bosch et al., 2012; Boxwell et al., 2010).

With the rise of deep learning, neural network models have been used for semantic role labeling (Collobert et al., 2011). Recently, it has been shown that a neural semantic role labeler can give state-of-the-art accuracies without using parser output features, thanks to the use of recurrent neural network structures that automatically capture syntactic information (Zhou and Xu, 2015; Wang et al., 2015). In the parsing domain, neural network models have also been shown to give state-of-the-art results recently (Dyer et al., 2015; Weiss et al., 2015; Zhou et al., 2015).

The availability of parser-independent neural SRL models allows parsing and SRL to be performed by both parsing→SRL and SRL→parsing pipelines, and gives rise to the interesting research question whether mutual benefits between syntax and semantic roles can be better exploited under the neural setting. Different from traditional models that rely on manual feature combinations for joint learning tasks (Sutton and McCallum, 2005; Zhang and Clark, 2008a; Finkel and Manning, 2009; Lewis et al., 2015), neural network models induce non-linear feature combinations automatically from input word and Part-of-Speech (POS) embeddings. This allows more complex feature sharing between multiple tasks to be achieved effectively (Collobert et al., 2011).

We take a first step[1] in such investigation by cou-

[*]Work done while the first author was visiting SUTD.

[1]Recently, Swayamdipta et al. (2016) independently proposed a similar idea to perform joint syntactic and semantic dependency parsing. Their work mainly focuses on extending actions of a greedy transition-based parser to support the joint task, achieving good performance on an English shared task, while we use a neural network for multi-task learning and we

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 968–974,
Austin, Texas, November 1-5, 2016.

pling a state-of-the-art neural semantic role labeler (Wang et al., 2015) and a state-of-the-art neural parser (Dyer et al., 2015). First, we propose a novel parsing→SRL pipeline using a tree Long Short-Term Memory (LSTM) model (Tai et al., 2015) to represent parser outputs, before feeding them to the neural SRL model as inputs. Second, we investigate a SRL→parsing pipeline, using semantic role label embeddings to enrich parser features. Third, we build a joint training model by embedding sharing, which is the most shallow level of parameter sharing between deep neural networks. This simple strategy is immune to significant differences between the network structures of the two models, which prevent direct sharing of deeper network parameters. We choose a Chinese semantic role treebank (Qiu et al., 2016) for preliminary experiments, which offers consistent dependency between syntax and semantic role representations, thereby facilitates the application of standard LSTM models. Results show that the methods give improvements to both parsing and SRL accuracies, demonstrating large potentials of neural networks for the joint task.

Our contributions can be summarized as:

• We show that the state-of-the-art LSTM semantic role labeler of Zhou and Xu (2015), which has been shown to be able to induce syntactic features automatically, can still be improved using parser output features via tree LSTM (Tai et al., 2015);

• We show that state-of-the-art neural parsing can be improved by using semantic role features;

• We show that parameter sharing between neural parsing and SRL improves both sub tasks, which is in line with the observation of Collobert et al. (2011) between POS tagging, chunking and SRL.

• Our code and all models are released at https://github.com/ShiPeng95/ShallowJoint.

2 Models

2.1 Semantic Role Labeler

We employ the SRL model of Wang et al. (2015), which uses a bidirectional Long Short-term Memory (Hochreiter and Schmidhuber, 1997; Graves and Schmidhuber, 2005; Graves et al., 2013) for sequential labeling.

work on a Chinese dataset.

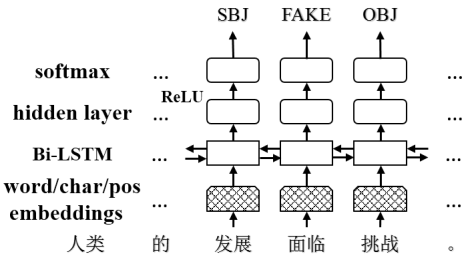

Figure 1: Bi-LSTM Semantic Role Labeler

Given the sentence "人类(human) 的(de) 发展(development) 面临(face) 挑战(challenge)", the structure of the model is shown in Figure 1. For each word w_t, the LSTM model uses a set of vectors to control information flow: an input gate i_t, a forget gate f_t, a memory cell c_t, an output gate o_t, and a hidden state h_t. The computation of each vector is as follows:

$$i_t = \sigma(W^{(i)}x_t + U^{(i)}h_{t-1} + V^{(i)}c_{t-1} + b^{(i)})$$
$$f_t = 1.0 - i_t$$
$$c_t = f_t \odot c_{t-1} + i_t \odot \tanh(W^{(u)}x_t + U^{(u)}h_{t-1} + b^{(u)})$$
$$o_t = \sigma(W^{(o)}x_t + U^{(o)}h_{t-1} + V^{(o)}c_t + b^{(o)})$$
$$h_t = o_t \odot \tanh(c_t)$$

Here σ denotes component-wise sigmoid function and $\odot$ is component-wise multiplication.

The representation of x_t is from four sources: an embedding for the word w_t, two hidden states of the last LSTM cells in a character-level bidirectional LSTM (Ballesteros et al., 2015) (denoted as $\overrightarrow{ch_t}$ and $\overleftarrow{ch_t}$, respectively), and a learned vector Part-of-Speech (POS) representation (pos_t). A linear transformation is applied to the vector representations before feeding them into a component-wise ReLU (Nair and Hinton, 2010) function.

$$x_t = \max\{0, V^{(x)}[w_t; \overrightarrow{ch_t}; \overleftarrow{ch_t}; pos_t] + b^{(x)}\}$$

The hidden state vectors at the t-th word from both directions (denote as $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$, respectively) are passed through the ReLU function, before a softmax layer for semantic role detection.

2.2 Stack-LSTM Dependency Parser

We employ the Stack-LSTM model of Dyer et al. (2015) for dependency parsing. As shown in Figure 2, it uses a buffer (B) to order input words, a stack (S) to store partially constructed syntactic trees, and

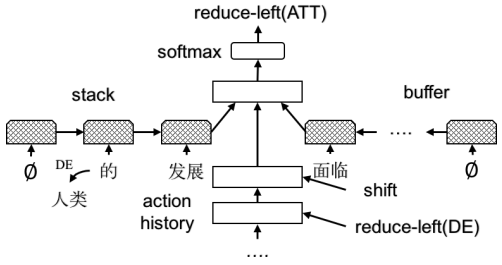

Figure 2: Stack-LSTM Parser

takes the following types of actions to build trees from input.

• **SHIFT**, which pops the top element off the buffer, pushing it into stack.

• **REDUCE-LEFT/REDUCE-RIGHT**, which pop the top two elements off the stack, pushing back the composition of the two elements with a dependent relation.

The parser is initialized by pushing input embeddings into the buffer in the reverse order. The representation of the token is same as the previous bidirectional LSTM (Bi-LSTM) model. The buffer (B), stack (S) and action history sequence (A) are all represented by LSTMs, with S being represented by a novel stack LSTM. At a time step t, the parser predicts an action according to current parser state p_t:

$$p_t = \max\{0, W^{(parser)}[s_t; b_t; a_t] + d^p\},$$
$$y_t^{(parser)} = softmax(V^{(parser)} p_t + d^y)$$

W, V and d are model parameters.

2.3 DEP→SRL Pipeline

In this pipeline model, we apply Stack-LSTM parsing first and feed the results as additional features for SRL. For each word w_t to the SRL system, the corresponding input becomes,

$$x_t^{(dep)} = \max\{0, V^{(dep)}[w_t; \overrightarrow{ch}_t; \overleftarrow{ch}_t; pos_t; \mathbf{dep_t}]\}$$

where dep_t is the t-th word's dependency information from parser output and $V^{(dep)}$ is a weight matrix. There are multiple ways to define dep_t. A simple method is to use embeddings of the dependency label at w_t. However, this input does not embody full arc information.

We propose a novel way of defining $dep_{\bar{t}}$, by using hidden vector $h_{\bar{t}}$ of a dependency tree LSTM (Tai et al., 2015) at $w_{\bar{t}}$ as $dep_{\bar{t}}$. Given a dependency tree output, we define tree LSTM inputs $x_{\bar{t}}$ in the same way as Section 2.1. The tree LSTM is a bottom-up generalization of the sequence LSTM, with a node $h_{\bar{t}}$ having multiple predecessors $h_{\bar{t}-1}^k$, which corresponding to the syntactic dependents of the word $w_{\bar{t}}$. The computation of $h_{\bar{t}}$ for each $w_{\bar{t}}$ is (unlike t, which is a left-to-right index, $\bar{t}$ is a bottom-up index, still with one $h_{\bar{t}}$ being computed for each $w_{\bar{t}}$):

$$\widetilde{h}_{\bar{t}-1} = \sum_k h_{\bar{t}-1}^k$$
$$i_{\bar{t}} = \sigma(W^{(i)} x_{\bar{t}} + U^{(i)} \widetilde{h}_{\bar{t}-1} + b^{(i)})$$
$$f_{\bar{t}^k = \sigma(W^{(f)} x_{\bar{t}} + U^{(f)} h_{\bar{t}-1}^k + b^{(f)})}$$
$$c_{\bar{t}=\sum_k f_{\bar{t}}^k \odot c_{\bar{t}-1}^k + i_{\bar{t}} \odot \tanh(W^{(u)} x_{\bar{t}} + U^{(u)} \widetilde{h}_{\bar{t}-1} + b^{(u)})}$$
$$o_{\bar{t}=\sigma(W^{(o)} x_{\bar{t}} + U^{(o)} \widetilde{h}_{\bar{t}-1} + b^{(o)})}$$
$$h_{\bar{t}=o_{\bar{t}} \odot \tanh(c_{\bar{t}})}$$

For training, we construct a corpus with all words being associated with automatic dependency labels by applying 10-fold jackknifing.

2.4 SRL→DEP Pipeline

In this pipeline model, we conduct SRL first, and feed the output semantic roles to the Stack-LSTM parser in the token level. The representation of a token becomes:

$$x_t^{(srl)} = \max\{0, V^{(srl)}[w_t; \overrightarrow{ch}_t; \overleftarrow{ch}_t; pos_t; \mathbf{srl_t}]\}$$

where srl_t is the t-th word's predicted semantic role embedding and $V^{(srl)}$ is a weight matrix.

For training, we construct a training corpus with automatically tagged semantic role labels by using 10-fold jackknifing.

2.5 Joint Model by Parameter Sharing

The structure of the joint system is shown in Figure 3. Here the parser and semantic role labeler are coupled in the embedding layer, sharing the vector lookup tables for characters, words and POS. More specifically, the Bi-LSTM model of Section 2.1 and the Stack-LSTM model of Section 2.2 are used for the SRL task and the parsing task, respectively. The Bi-LSTM labeler and Stack-LSTM parser share the embedding layer. During training, we maximize the

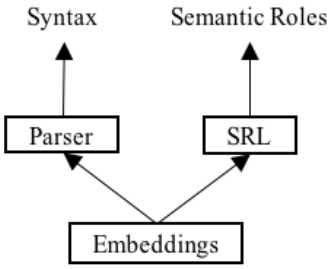

Figure 3: Joint Multi-task Model

sum of log-likelihood for the two different tasks. The loss from the semantic role labeler and the parser both propagate to the embedding layer, resulting in a better vector representation of each token, which benefits both tasks at the same time. On the other hand, due to different neural structures, there is no sharing of other parameters. The joint model offers the simplest version of *shared training* (Collobert et al., 2011), but does not employ shared decoding (Sutton and McCallum, 2005; Zhang and Clark, 2008b). Syntax and semantic roles are assigned separately, avoiding error propagation.

3 Experiments

3.1 Experimental Settings

Datasets We choose Chinese Semantic Treebank (Qiu et al., 2016) for our experiments. Similar to the CoNLL corpora (Surdeanu et al., 2008; Hajič et al., 2009) and different from PropBank (Kingsbury and Palmer, 2002; Xue and Palmer, 2005), it is a dependency-based corpus rather than a constituent-based corpus. The corpus contains syntactic dependency arc and semantic role annotations in a consistent form, hence facilitating the joint task. We follow the standard split for the training, development and test sets, as shown in Table 1.

Training Details. There is a large number of singletons in the training set and a large number of out-of-vocabulary (OOV) words in the development set. We use the mechanism of Dyer et al. (2015) to stochastically set singletons as *UNK* token in each training iteration with a probability p_{unk}. The hyper-parameter p_{unk} is set to 0.2.

For parameters used in Stack-LSTM, we follow Dyer et al. (2015). We set the number of embeddings by intuition, and decide to have the size of word embedding twice as large as that of character embedding, and the size of character embedding larger than the size of POS embedding. More specifically, we fix the size of word embeddings n_w to 64, character embeddings n_{char} to 32, POS embeddings n_{pos} to 30, action embeddings n_{dep} to 30, and semantic role embeddings n_{srl} to 30. The LSTM input size is set to 128 and the LSTM hidden size to 128.

Dataset	Words	**Types**	**Singletons**	**OOV**
Train	280,043	24,866	12,012	-
Dev	23,724	5,492	-	1,505
Test	32,326	6,989	-	1,893

Table 1: Statistics of Chinese Semantic Treebank.

We randomly initialize each parameter to a real value in $[-\sqrt{\frac{6}{r+c}}, \sqrt{\frac{6}{r+c}}]$, where r is the number of input unit and c is the number of output unit (Glorot and Bengio, 2010). To minimize the influence of external information, we did not pretrain the embedding values. In addition, we apply a Gaussian noise $N(0, 0.2)$ to word embeddings during training to prevent overfitting.

We optimize model parameters using stochastic gradient descent with momentum. The same learning rate decay mechanism of Dyer et al. (2015) is used. The best model parameters are selected according to a score metric on the development set. For different tasks, we use different score metrics to evaluate the parameters. Since there are there metrics, F1, UAS and LAS, possibly reported at the same time, we use the weighted average to consider the effect of all metrics when choosing the best model on the dev set. In particular, we use F_1 for SRL, $0.5 \times LAS + 0.5 \times UAS$ for parsing, and $0.5 \times F_1 + 0.25 \times UAS + 0.25 \times LAS$ for the joint task.

3.2 Results

The final results are shown in Table 2, where F_1 represents the F_1-score of semantic roles, and UAS and LAS represent parsing accuracies. The **Bi-LSTM** row represents the bi-directional semantic role labeler, the **S-LSTM** row represents the Stack-LSTM parser, the **DEP→SRL** row represents the dependency parsing → SRL pipeline, the **SRL→DEP** row represents the SRL → dependency parsing pipeline, and the **Joint** row represents the parameter-shared model. For the DEP→SRL pipeline, *lab* and *lstm*

Model	F_1	UAS	LAS
Bi-LSTM	72.71	-	-
S-LSTM	-	84.33	82.10
DEP→SRL(*lab*/*lstm*)	73.00/**74.18**	84.33	82.10
SRL→DEP	72.71	84.75	82.62
Joint	73.84	**85.15**	**82.91**

Table 2: Results. Bi-LSTM and S-LSTM are two baseline models for SRL and parsing, respectively. DEP→SRL and SRL→DEP are two pipeline models. 'Joint' denotes the proposed model for joint parsing and semantic role labeling. *lab* uses only the dependency label as features, while *lstm* applies features extracted from dependency trees using tree LSTMs.

represents the use of dependency label embeddings and tree LSTM hidden vectors for the additional SRL features dep_t, respectively.

Comparison between Bi-LSTM and DEP→SRL shows that slight improvement is brought by introducing dependency label features to the semantic role labeler (72.71→73.00). By introducing full tree information, the *lstm* integration leads to much higher improvements (72.71→74.18). This demonstrates that the LSTM SRL model of Zhou and Xu (2015) can still benefit from parser outputs, despite that it can learn syntactic information independently.

In the reverse direction, comparison between S-LSTM and SRL→DEP shows improvement to UAS/LAS by integrating semantic role features (82.10→82.62). This demonstrates the usefulness of semantic roles to parsing and is consistent with observations on discrete models (Boxwell et al., 2010). To our knowledge, we are the first to report results using a SRL → Parsing pipeline, which is enabled by the neural SRL model.

Using shared embeddings, the joint model gives improvements on both SRL and parsing. The most salient difference between the joint model and the two pipelines is the shared parameter space.

These results are consistent with the finds of Collobert et al. (2011) who show that POS, chunking and semantic role information can bring benefit to each other in joint neural training. In contrast to their results (SRL 74.15→74.29, POS 97.12→97.22, CHUNK 93.37→93.75), we find that parsing and SRL benefit relatively more from each other (SRL 72.72→73.84, DEP 84.33→85.15). This is intuitive because parsing offers deeper syntactic information compared to POS and shallow syntactic chunking.

4 Conclusion

We investigated the mutual benefits between dependency syntax and semantic roles using two state-of-the-art LSTM models, finding that both can be further improved. In addition, simple multitask learning is also effective. These results demonstrate potentials for deeper joint neural models between these tasks.

Abstract

This paper investigates the effects of data size and frequency range on distributional semantic models. We compare the performance of a number of representative models for several test settings over data of varying sizes, and over test items of various frequency. Our results show that neural network-based models underperform when the data is small, and that the most reliable model over data of varying sizes and frequency ranges is the inverted factorized model.

1 Introduction

Distributional Semantic Models (DSMs) have become a staple in natural language processing. The various parameters of DSMs — e.g. size of context windows, weighting schemes, dimensionality reduction techniques, and similarity measures — have been thoroughly studied (Weeds et al., 2004; Sahlgren, 2006; Riordan and Jones, 2011; Bullinaria and Levy, 2012; Levy et al., 2015), and are now well understood. The impact of various processing models — matrix-based models, neural networks, and hashing methods — have also enjoyed considerable attention lately, with at times conflicting conclusions (Baroni et al., 2014; Levy et al., 2015; Schnabel et al., 2015; Österlund et al., 2015; Sahlgren et al., 2016). The consensus interpretation of such experiments seems to be that the choice of processing model is less important than the parameterization of the models, since the various processing models all result in more or less equivalent DSMs (provided that the parameterization is comparable).

One of the least researched aspects of DSMs is the effect on the various models of data size and frequency range of the target items. The only previous work in this direction that we are aware of is Asr et al. (2016), who report that on small data (the CHILDES corpus), simple matrix-based models outperform neural network-based ones. Unfortunately, Asr et al. do not include any experiments using the same models applied to bigger data, making it difficult to compare their results with previous studies, since implementational details and parameterization will be different.

There is thus still a need for a consistent and fair comparison of the performance of various DSMs when applied to data of varying sizes. In this paper, we seek an answer to the question: **which DSM should we opt for if we only have access to limited amounts of data?** We are also interested in the related question: **which DSM should we opt for if our target items are infrequent?** The latter question is particularly crucial, since one of the major assets of DSMs is their applicability to create semantic representations for ever-expanding vocabularies from text feeds, in which new words may continuously appear in the low-frequency ranges.

In the next section, we introduce the contending DSMs and the general experiment setup, before turning to the experiments and our interpretation of the results. We conclude with some general advice.

2 Distributional Semantic Models

One could classify DSMs in many different ways, such as the type of context and the method to build distributional vectors. Since our main goal here is

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 975–980,
Austin, Texas, November 1-5, 2016.

to gain an understanding of the effect of data size and frequency range on the various models, we focus primarily on the differences in processing models, hence the following typology of DSMs.

Explicit matrix models

We here include what could be referred to as *explicit* models, in which each vector dimension corresponds to a specific context (Levy and Goldberg, 2014). The baseline model is a simple co-occurrence matrix F (in the following referred to as CO for Co-Occurrence). We also include the model that results from applying Positive Pointwise Mutual Information (PPMI) to the co-occurrence matrix. PPMI is defined as simply discarding any negative values of the PMI, computed as:

$$\text{PMI}(a, b) = \log \frac{f_{ab} \times T}{f_a f_b} \quad (1)$$

where f_{ab} is the co-occurrence count of word a and word b, f_a and f_b are the individual frequencies of the words, and T is the number of tokens in the data.[1]

Factorized matrix models

This type of model applies an additional factorization of the weighted co-occurrence counts. We here include two variants of applying Singular Value Decomposition (SVD) to the PPMI-weighting co-occurrence matrix; one version that discards all but the first couple of hundred latent dimensions (TSVD for *truncated* SVD), and one version that instead *removes* the first couple of hundred latent dimensions (ISVD for *inverted* SVD). SVD is defined in the standard way:

$$F = U\Sigma V^T \quad (2)$$

where U holds the eigenvectors of F, Σ holds the eigenvalues, and $V \in U(w)$ is a unitary matrix mapping the original basis of F into its eigenbasis. Since V is redundant due to invariance under unitary transformations, we can represent the factorization of $\hat{F}$ in its most compact form $\hat{F} \equiv U\Sigma$.

[1]We also experimented with *smoothed* PPMI, which raises the context counts to the power of α and normalizes them (Levy et al., 2015), thereby countering the tendency of mutual information to favor infrequent events: $f(b) = \frac{\#(b)^\alpha}{\sum_b \#(b)^\alpha}$, but it did not lead to any consistent improvements compared to PPMI.

Hashing models

A different approach to reduce the dimensionality of DSMs is to use a hashing method such as Random Indexing (RI) (Kanerva et al., 2000), which accumulates distributional vectors $\vec{d}(a)$ in an online fashion:

$$\vec{d}(a) \leftarrow \vec{d}(a_i) + \sum_{j=-c, j\neq 0}^{c} w(x^{(i+j)})\pi^j \vec{r}(x^{(i+j)}) \quad (3)$$

where c is the extension of the context window, $w(b)$ is a weight that quantifies the importance of context term b,[2] $\vec{r}_d(b)$ is a *sparse random index vector* that acts as a fingerprint of context term b, and π^j is a permutation that rotates the random index vectors one step to the left or right, depending on the position of the context items within the context windows, thus enabling the model to take word order into account (Sahlgren et al., 2008).

Neural network models

There are many variations of DSMs that use neural networks as processing model, ranging from simple recurrent networks (Elman, 1990) to more complex deep architectures (Collobert and Weston, 2008). The incomparably most popular neural network model is the one implemented in the `word2vec` library, which uses the softmax for predicting b given a (Mikolov et al., 2013):

$$p(b|a) = \frac{\exp(\vec{b} \cdot \vec{a})}{\sum_{b' \in C} \exp(\vec{b'} \cdot \vec{a})} \quad (4)$$

where C is the set of context words, and $\vec{b}$ and $\vec{a}$ are the vector representations for the context and target words, respectively. We include two versions of this general model; Continuous Bag of Words (CBOW) that predicts a word based on the context, and Skip-Gram Negative Sampling (SGNS) that predicts the context based on the current word.

3 Experiment setup

Since our main focus in this paper is the performance of the above-mentioned DSMs on data of

[2]We use $w(b) = e^{-\lambda \cdot \frac{f(b)}{V}}$ where $f(b)$ is the frequency of context item b, V is the total number of unique context items seen thus far (i.e. the current size of the growing vocabulary), and λ is a constant that we set to 60 (Sahlgren et al., 2016).

varying sizes, we use one big corpus as starting point, and split the data into bins of varying sizes. We opt for the ukWaC corpus (Ferraresi et al., 2008), which comprises some 1.6 billion words after tokenization and lemmatization. We produce subcorpora by taking the first 1 million, 10 million, 100 million, and 1 billion words.

Since the co-occurrence matrix built from the 1 billion-word ukWaC sample is very big (more than 4,000,000 $\times$ 4,000,000), we prune the co-occurrence matrix to 50,000 dimensions before the factorization step by simply removing infrequent context items.[3] As comparison, we use 200 dimensions for TSVD, 2,800 (3,000-200) dimensions for ISVD, 2,000 dimensions for RI, and 200 dimensions for CBOW and SGNS. These dimensionalities have been reported to perform well for the respective models (Landauer and Dumais, 1997; Sahlgren et al., 2008; Mikolov et al., 2013; Österlund et al., 2015). All DSMs use the same parameters as far as possible with a narrow context window of ± 2 words, which has been shown to produce good results in semantic tasks (Sahlgren, 2006; Bullinaria and Levy, 2012).

We use five standard benchmark tests in these experiments; two multiple-choice vocabulary tests (the TOEFL synonyms and the ESL synonyms), and three similarity/relatedness rating benchmarks (SimLex-999 (SL) (Hill et al., 2015), MEN (Bruni et al., 2014), and Stanford Rare Words (RW) (Luong et al., 2013)). The vocabulary tests measure the synonym relation, while the similarity rating tests measure a broader notion of semantic similarity (SL and RW) or relatedness (MEN).[4] The results for the vocabulary tests are given in accuracy (i.e., percentage of correct answers), while the results for the similarity tests are given in Spearman rank correlation.

4 Comparison by data size

Table 1 summarizes the results over the different test settings. The most notable aspect of these results is that the neural networks models do not produce competitive results for the smaller data, which corroborates the results by Asr et al. (2016). The best results for the smallest data are produced by the factorized models, with both TSVD and ISVD producing top scores in different test settings. It should be noted, however, that even the top scores for the smallest data set are substandard; only two models (PPMI and TSVD) manage to beat the random baseline of 25% for the TOEFL tests, and none of the models manage to beat the random baseline for the ESL test.

The ISVD model produces consistently good results; it yields the best overall results for the 10 mil-

lion and 100 million-word data, and is competitive with SGNS on the 1 billion word data. Figure 1 shows the average results and their standard deviations over all test settings.[5] It is obvious that there are no huge differences between the various models, with the exception of the baseline CO model, which consistently underperforms. The TSVD and RI models have comparable performance across the different data sizes, which is systematically lower than the PPMI model. The ISVD model is the most consistently good model, with the neural network-based models steadily improving as data becomes bigger.

Looking at the different datasets, SL and RW are the hardest ones for all the models. In the case of SL, this confirms the results in (Hill et al., 2015), and might be due to the general bias of DSMs towards semantic relatedness, rather than genuine semantic similarity, as represented in SL. The substandard performance on RW might instead be due to the low frequency of the target items. It is interesting to note that these are benchmark tests in which neural models perform the worst even when trained on the largest data.

5 Comparison by frequency range

In order to investigate how each model handles different frequency ranges, we split the test items into three different classes that contain about a third of the frequency mass of the test items each. This split was produced by collecting all test items into a common vocabulary, and then sorting this vocabulary by its frequency in the ukWaC 1 billion-word corpus. We split the vocabulary into 3 equally large parts; the HIGH range with frequencies ranging from 3,515,086 ("do") to 16,830 ("organism"), the MEDIUM range with frequencies ranging between 16,795 ("desirable") and 729 ("prickly"), and the LOW range with frequencies ranging between 728 ("boardwalk") to hapax legomenon. We then split each individual test into these three ranges, depending on the frequencies of the test items. Test pairs were included in a given frequency class if and only if both the target and its relatum occur in the frequency range for that class. For the constituent words in the test item that belong to different frequency ranges, which is the most common case, we use a separate MIXED class. The resulting four classes contain 1,387 items for the HIGH range, 656 items for the MEDIUM range, 350 items for the LOW range, and 3,458 items for the MIXED range.[6]

Table 2 (next side) shows the average results over the different frequency ranges for the various DSMs trained on the 1 billion-word ukWaC data. We also include the highest and lowest individual test scores (signified by ↑ and ↓), in order to get an idea about the consistency of the results. As can be seen in the table, the most consistent model is ISVD, which produces the best results in both the MEDIUM and MIXED frequency ranges. The neural network models SGNS and CBOW produce the best results in the HIGH and LOW range, respectively, with CBOW clearly outperforming SGNS in the latter case. The major difference between these models is that CBOW predicts a word based on a context, while SGNS predicts a context based on a word. Clearly, the former approach is more beneficial for low-frequent items.

The PPMI, TSVD and RI models perform similarly across the frequency ranges, with RI producing somewhat lower results in the MEDIUM range, and TSVD producing somewhat lower results in the LOW range. The CO model underperforms in all frequency ranges. Worth noting is the fact that all models that are based on an explicit matrix (i.e. CO,

[5] Although rank correlation is not directly comparable with accuracy, they are both bounded between zero and one, which means we can take the average to get an idea about overall performance.

[6] 233 test terms did not occur in the 1 billion-word corpus.

DSM	HIGH	MEDIUM	LOW	MIXED
CO	32.61 (↑62.5,↓04.6)	35.77 (↑66.6,↓21.2)	12.57 (↑35.7,↓00.0)	27.14 (↑56.6,↓07.9)

CBOW	62.73 (↑81.2,↓31.9)	59.50 (↑83.3,↓32.4)	**27.13** (↑78.5,↓00.0)	52.21 (↑76.6,↓25.9)

Table 2: Average results for DSMs over four different frequency ranges for the items in the TOEFL, ESL, SL, MEN, and RW tests. All DSMs are trained on the 1 billion words data.

PPMI, TSVD and ISVD) produce better results in the MEDIUM range than in the HIGH range.

The arguably most interesting results are in the LOW range. Unsurprisingly, there is a general and significant drop in performance for low frequency items, but with interesting differences among the various models. As already mentioned, the CBOW model produces the best results, closely followed by PPMI and RI. It is noteworthy that the low-dimensional embeddings of the CBOW model only gives a modest improvement over the high-dimensional explicit vectors of PPMI. The worst results are produced by the ISVD model, which scores even lower than the baseline CO model. This might be explained by the fact that ISVD removes the latent dimensions with largest variance, which are arguably the most important dimensions for very low-frequent items. Increasing the number of latent dimensions with high variance in the ISVD model improves the results in the LOW range (16.59 when removing only the top 100 dimensions).

6 Conclusion

Our experiments confirm the results of Asr et al. (2016), who show that neural network-based models are suboptimal to use for smaller amounts of data. On the other hand, our results also show that none of the standard DSMs work well in situations with small data. It might be an interesting novel research direction to investigate how to design DSMs that are applicable to small-data scenarios.

Our results demonstrate that the inverted factorized model (ISVD) produces the most robust results over data of varying sizes, and across several different test settings. We interpret this finding as further corroborating the results of Bullinaria and Levy (2012), and Österlund et al. (2015), with the conclusion that the inverted factorized model is a robust competitive alternative to the widely used SGNS and CBOW neural network-based models.

We have also investigated the performance of the various models on test items in different frequency ranges, and our results in these experiments demonstrate that all tested models perform optimally in the medium-to-high frequency ranges. Interestingly, all models based on explicit count matrices (CO, PPMI, TSVD and ISVD) produce somewhat better results for items of medium frequency than for items of high frequency. The neural network-based models and ISVD, on the other hand, produce the best results for high-frequent items.

None of the tested models perform optimally for low-frequent items. The best results for low-frequent test items in our experiments were produced using the CBOW model, the PPMI model and the RI model, all of which uses weighted context items without any explicit factorization. By contrast, the ISVD model underperforms significantly for the low-frequent items, which we suggest is an effect of removing latent dimensions with high variance.

This interpretation suggests that it might be interesting to investigate *hybrid models* that use different processing models — or at least different parameterizations — for different frequency ranges, and for different data sizes. We leave this as a suggestion for future research.

Abstract

This paper considers the problem of learning Chinese word embeddings. In contrast to English, a Chinese word is usually composed of characters, and most of the characters themselves can be further divided into components such as radicals. While characters and radicals contain rich information and are capable of indicating semantic meanings of words, they have not been fully exploited by existing word embedding methods. In this work, we propose *multi-granularity embedding* (MGE) for Chinese words. The key idea is to make full use of such word-character-radical composition, and enrich word embeddings by further incorporating finer-grained semantics from characters and radicals. Quantitative evaluation demonstrates the superiority of MGE in word similarity computation and analogical reasoning. Qualitative analysis further shows its capability to identify finer-grained semantic meanings of words.

1 Introduction

Word embedding, also known as distributed word representation, is to represent each word as a real-valued low-dimensional vector, through which the semantic meaning of the word can be encoded. Recent years have witnessed tremendous success of word embedding in various NLP tasks (Bengio et al., 2006; Mnih and Hinton, 2009; Collobert et al., 2011; Zou et al., 2013; Kim, 2014; Liu et al., 2015; Iyyer et al., 2015). The basic idea behind is to learn the distributed representation of a word using its context. Among existing approaches, the continuous bag-of-words model (CBOW) and Skip-Gram model are simple and effective, capable of learning word embeddings efficiently from large-scale text corpora (Mikolov et al., 2013a; Mikolov et al., 2013b).

Besides the success in English, word embedding has also been demonstrated to be extremely useful for Chinese language processing (Xu et al., 2015; Yu et al., 2015; Zhou et al., 2015; Zou et al., 2013). The work on Chinese generally follows the same idea as on English, i.e., to learn the embedding of a word on the basis of its context. However, in contrast to English where words are usually taken as basic semantic units, Chinese words may have a complicated composition structure of their semantic meanings. More specifically, a Chinese word is often composed of several characters, and most of the characters themselves can be further divided into components such as radicals (部首).[1] Both characters and radicals may suggest the semantic meaning of a word, regardless of its context. For example, the Chinese word "吃饭 (have a meal)" consists of two characters " 吃 (eat)" and "饭 (meal)", where " 吃 (eat)" has the radical of "口 (mouth)", and "饭 (meal)" the radical of " 饣 (food)". The semantic meaning of "吃饭" can be revealed by the constituent characters as well as their radicals.

Despite being the linguistic nature of Chinese and containing rich semantic information, such word-character-radical composition has not been fully exploited by existing approaches. Chen et al. (2015) introduced a character-enhanced word embedding model (CWE), which learns embeddings jointly for words and characters but ignores radicals. Sun et al. (2014) and Li et al. (2015) utilized radical information to learn better character embeddings. Similarly, Shi et al. (2015) split characters into small components based on the Wubi method,[2] and took into account those components during the learning process. In their work, however, embeddings are learned only for characters. For a word, the embedding is generated by simply combining the embeddings of the constituent characters. Since not all Chinese word-

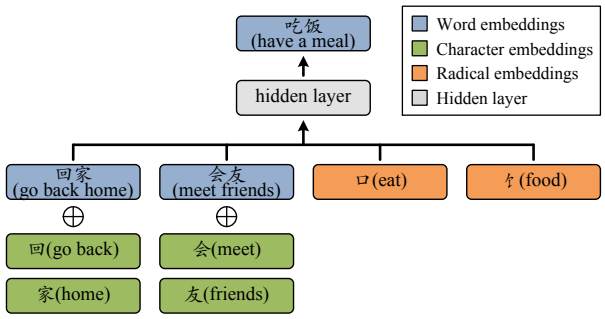

Figure 1: A simple illustration of MGE, where embeddings are learned jointly for words, characters, and radicals. Given a sequence of words {" 回家 (go back home)", " 吃饭 (have a meal)", " 会友 (meet friends)"}, MGE predicts the central word "吃饭" by using 1) the embedding composed by each context word and its constituent characters, and 2) the embedding associated with each radical detected in the target word.

s are semantically compositional (e.g., transliterated words such as "苏打 (soda)"), embeddings obtained in this way may be of low quality for these words.

In this paper, aiming at making full use of the semantic composition in Chinese, we propose *multi-granularity embedding* (MGE) which learns embeddings jointly for words, characters, and radicals. The framework of MGE is sketched in Figure 1. Given a word, we learn its embedding on the basis of 1) the context words (blue bars in the figure), 2) their constituent characters (green bars), and 3) the radicals found in the target word (orange bars). Compared to utilizing context words alone, MGE enriches the embeddings by further incorporating finer-grained semantics from characters and radicals. Similar ideas of adaptively using multiple levels of embeddings have also been investigated in English recently (Kazuma and Yoshimasa, 2016; Miyamoto and Cho, 2016).

We evaluate MGE with the benchmark tasks of word similarity computation and analogical reasoning, and demonstrate its superiority over state-of-the-art metods. A qualitative analysis further shows the capability of MGE to identify finer-grained semantic meanings of words.

2 Multi-Granularity Word Embedding

This section introduces MGE based on the continuous bag-of-words model (CBOW) (Mikolov et al., 2013b) and the character-enhanced word embedding model (CWE) (Chen et al., 2015).

MGE aims at improving word embedding by leveraging both characters and radicals. We denote the Chinese word vocabulary as $\mathcal{W}$, the character vocabulary as $\mathcal{C}$, and the radical vocabulary as $\mathcal{R}$. Each word $w_i \in \mathcal{W}$ is associated with a vector embedding $\mathbf{w}_i$, each character $c_i \in \mathcal{C}$ a vector embedding $\mathbf{c}_i$, and each radical $r_i \in \mathcal{R}$ a vector embedding $\mathbf{r}_i$. Given a sequence of words $\mathcal{D} = \{w_1, \cdots, w_N\}$, MGE predicts each word $w_i \in \mathcal{D}$ conditioned on 1) context words in a sliding window with size ℓ, denoted as $\mathcal{W}_i = \{w_{i-\ell}, ...w_{i-1}, w_{i+1}, ..., w_{i+\ell}\}$, 2) characters in each context word $w_j \in \mathcal{W}_i$, denoted as $\mathcal{C}_j$, and 3) radicals in the target word w_i, denoted as $\mathcal{R}_i$. See Figure 1 for a simple illustration.

More specifically, given the corpus $\mathcal{D}$, MGE maximizes the overall log likelihood as follows:

$$L(\mathcal{D}) = \sum_{w_i \in \mathcal{D}} \log p(\mathbf{w}_i | \mathbf{h}_i). \quad (1)$$

Here $\mathbf{h}_i$ is a hidden vector composed by the embeddings of context words, constituent characters, and radicals, defined as:

$$\mathbf{h}_i = \frac{1}{2}\Big[\frac{1}{|\mathcal{W}_i|}\sum_{w_j \in \mathcal{W}_i}\Big(\mathbf{w}_j \oplus \frac{1}{|\mathcal{C}_j|}\sum_{c_k \in \mathcal{C}_j}\mathbf{c}_k\Big) + \frac{1}{|\mathcal{R}_i|}\sum_{r_k \in \mathcal{R}_i}\mathbf{r}_k\Big]. \quad (2)$$

For each context word $w_j \in \mathcal{W}_i$, a word-character composition $(\mathbf{w}_j \oplus \frac{1}{|\mathcal{C}_j|}\sum_{c \in \mathcal{C}_j}\mathbf{c})$ is first generated by the embeddings of w_j and its constituent characters $\mathcal{C}_j$. These word-character compositions are then combined with the radical embeddings in $\mathcal{R}_i$ to predict the target word. $|\mathcal{W}_i|$/$|\mathcal{R}_i|$/$|\mathcal{C}_j|$ is the cardinality of $\mathcal{W}_i$/$\mathcal{R}_i$/$\mathcal{C}_j$, and $\oplus$ is the composition operation.[3] Given $\mathbf{h}_i$, the conditional probability $p(\mathbf{w}_i|\mathbf{h}_i)$ is defined by a softmax function:

$$p(\mathbf{w}_i|\mathbf{h}_i) = \frac{\exp(\mathbf{h}_i^\top \mathbf{w}_i)}{\sum_{w_{i'} \in \mathcal{W}} \exp(\mathbf{h}_i^\top \mathbf{w}_{i'})}. \quad (3)$$

We use negative sampling and stochastic gradient descent to solve the optimization problem.

Note that 1) Not all Chinese words are semantically compositional, e.g., transliterated words and entity names. For such words we use neither characters nor radicals. 2) A Chinese character usually plays

[3]There are a variety of options for $\oplus$, e.g., addition and concatenation. This paper follows (Chen et al., 2015) and uses the addition operation.

different roles when it appears at different positions within a word. We follow (Chen et al., 2015) and design a position-based MGE model (MGE+P). The key idea of MGE+P is to keep three embeddings for each character, corresponding to its appearance at the positions of "begin", "middle", and "end". For details, please refer to (Chen et al., 2015).

3 Experiments

We evaluate MGE with the tasks of word similarity computation and analogical reasoning.

3.1 Experimental Setups

We select the Chinese Wikipedia Dump[4] for embedding learning. In preprocessing, we use the THULAC tool[5] to segment the corpus. Pure digit words, non-Chinese words, and words whose frequencies are less than 5 in the corpus are removed. We further crawl from an online Chinese dictionary[6] and build a character-radical index with 20,847 characters and 269 radicals. We use this index to detect the radical of each character in the corpus. As such, we get a training set with 72,602,549 words, 277,200 unique words, 8,410 unique characters, and 256 unique radicals. Finally, we use THULAC to perform Chinese POS tagging on the training set and identify all entity names. For these entity names, neither characters nor radicals are considered during learning. Actually, Chen et al. (2015) categorized non-compositional Chinese words into three groups, i.e., transliterated words, single-morpheme multi-character words, and entity names. In their work, they used a human-annotated corpus, manually determining each word to be split or not. Since human annotation could be time-consuming and labor intensive, we just consider automatically identified entity names.

We compare MGE with CBOW (Mikolov et al., 2013b)[7] and CWE (Chen et al., 2015)[8]. Both CWE and MGE are extensions of CBOW, with the former taking into account characters and the latter further incorporating radical information. We further consider position-based CWE and MGE, denoted as CWE+P and MGE+P, respectively.We follow (Chen et al., 2015) and use the same hyperparameter setting. For all the methods, we set the context window size to 3, and select the embedding dimension k in $\{100, 200\}$. During optimization, we use 10-word negative sampling and fix the initial learning rate to 0.025.

Method	WordSim-239		WordSim-293	
	$k=100$	$k=200$	$k=100$	$k=200$
CBOW	0.4917	0.4971	**0.5667**	**0.5723**
CWE	0.5121	0.5197	0.5511	0.5655
CWE+P	0.4989	0.5026	0.5427	0.5545
MGE	**0.5670**	**0.5769**	0.5555	0.5659
MGE+P	0.5511	0.5572	0.5530	0.5692

Table 1: Results on word similarity computation.

3.2 Word Similarity Computation

This task is to evaluate the effectiveness of embeddings in preserving semantic relatedness between two words. We use the WordSim-240 and WordSim-296 datasets[9] provided by Chen et al. (2015) for evaluation, both containing Chinese word pairs with human-labeled similarity scores. On WordSim-240 there is a pair containing new words (i.e., words that have not appeared in the training set), and on WordSim-296 there are 3 such pairs. We remove these pairs from both datasets, and accordingly get WordSim-239 and WordSim-293.

We compute the Spearman correlation coefficient (Myers et al., 2010) between the similarity scores given by the embedding models and those given by human annotators. For the embedding models, the similarity score between two words is calculated as the cosine similarity between their embeddings. The Spearman correlation coefficient is a nonparametric measure of rank correlation, assessing how well the relationship between two variables can be described. The results are shown in Table 1.
