From the results, we can see that 1) On WordSim-239, MGE(+P) performs significantly better than CWE(+P), which in turn outperforms CBOW. This observation demonstrates the superiority of incorporating finer-grained semantics, particularly from radicals. For example, MGE performs much better on word pairs such as "银行 (bank)" and " 钱 (money)", in which the two words share the same radical of "钅 (gold)". 2) On WordSim-293, MGE(+P)

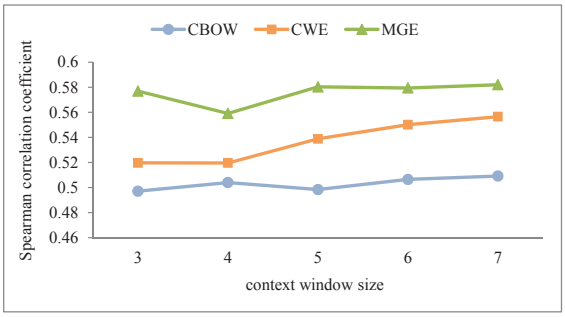

Figure 2: Word similarity computation results with different context window sizes on WordSim-239 ($k = 200$).

performs equally well as CWE(+P), but both are slightly worse than CBOW. The reason may be that WordSim-293 contains a great many of word pairs in which the two words belonging to different domains, e.g., "公鸡 (rooster)" and "航程 (flying range)". These pairs usually get low human-labeled similarity scores. However, splitting the words in such pairs into characters, and further the characters into radicals will not help to effectively identify the *dissimilarity* between them.[10]

We further investigate the influence of the context window size in word similarity computation. Figure 2 gives the results of CBOW, CWE, and MGE on WordSim-239, with the context window size set in $\{3, 4, 5, 6, 7\}$. The results indicate that MGE performs consistently better than CBOW and CWE on this dataset, unaffected by varying the context window size.

3.3 Word Analogical Reasoning

This task evaluates the effectiveness of embeddings in capturing linguistic regularities between pairs of words, in the form of " 伦敦 (London) : 英国 (England) ≈ 巴黎 (Paris) : 法国 (France)". We use the dataset provided by Chen et al. (2015) for evaluation. It contains 1,124 analogies categorized into 3 types: 1) capitals of countries (677 groups); 2) states/provinces of cities (175 groups); and 3) family relations (272 groups). All the words in this dataset are covered by the training set.

Method	Total	Capital	State	Family
CBOW	0.7498	0.8109	0.8400	**0.5294**
CWE	0.7248	0.8375	0.8541	0.3566
CWE+P	0.7391	0.8065	0.8114	0.5147
MGE	0.7524	**0.8804**	0.8686	0.3529
MGE+P	**0.7720**	0.8685	**0.8857**	0.4485

Table 2: Results on word analogical reasoning ($k = 200$).

For each analogy "$a : b \approx c : d$", we create a question "$a : b \approx c :$? ", and predict the answer as: $d^* = \arg\max_{w \in \mathcal{W}} \cos(\mathbf{b} - \mathbf{a} + \mathbf{c}, \mathbf{w})$. Here $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$, $\mathbf{w}$ are the word embeddings, and $\cos(\cdot, \cdot)$ the cosine similarity. The question is considered to be correctly answered if $d^* = d$. We use accuracy as the evaluation metric, and report the results in Table 2.

The results indicate that 1) MGE(+P) substantially outperforms the baseline methods on almost all types of analogies (except for the Family type). This again demonstrates the superiority of incorporating radical information. 2) For the Capital and State types, all the words are entity names for which neither characters nor radicals are used. MGE(+P) still outperforms the baselines on these two types, showing its capability to learn better embeddings even for non-compositional words. 3) On the Family type, both MGE(+P) and CWE(+P) perform worse than CBOW. This may be caused by the inappropriate decomposition of family words into characters. Consider, for example, the question " 叔叔 (uncle) : 阿姨 (aunt) ≈ 王子 (prince) : ? ". If we split " 王子" into "王 (king)" and "子 (son)", we will more likely to predict " 女王 (queen)" rather than the correct answer "公主 (princess)", since "女王" contains the character " 女 (daughter)" which is usually the antonym of " 子 (son)".

3.4 Case Study

Besides quantitative evaluation, this section further provides qualitative analysis to show in what manner the semantic meaning of a radical, character and word can be captured by their embeddings.

Take the word "游泳 (swimming)" as an example. Table 3 presents the words that are most similar to it (with the highest cosine similarity between their embeddings), discovered by MGE, CWE, and CBOW. The results show that 1) By incorporating the character information, MGE and CWE are capable of

[10] This observation is inconsistent with that reported in (Chen et al., 2015), which shows that CWE outperforms CBOW on WordSim-296. The reason may be that Chen et al. (2015) used a human-annotated corpus for embedding learning, and manually determined each word to be split or not. In contrast, we use the publicly available Chinese Wikipedia data, and automatically segment the corpus and identify entity names (words that are not to be split), without human annotation.

MGE	潜泳(underwater swimming), 畅泳(swimming happily) 爬泳(front crawl swimming), 泳手(swimmer) 泳术(swimming skill), 冬泳(winter swimming) 裸泳(swimming skill), 田径(track and field)
CWE	潜泳(underwater swimming), 畅泳(swimming happily) 爬泳(front crawl swimming), 田径(track and field) 泳手(swimmer), 习泳(learn to swim) 冬泳(winter swimming), 泳术(swimming skill)
CBOW	田径(track and field), 跳高(high jump) 跳水(diving), 跳绳(rope skipping) 划船(boating), 撑竿跳(pole vaulting) 皮划艇(canoeing), 体操(gymnastics)

Table 3: The most similar words to "游泳 (swimming)".

Radical	疒(illness)
Closest characters	佝(rickets) 痫(chronic disease) 偻(bending one's back) 疬(epidemic disease) 痨(tuberculosis) 淬(quenching) 疥(scabies) 痔(hemorrhoids)
Closest words	佝偻(rickets) 癣疥(ringworm scabies) 痘疤(pock) 瘴疬(communicable subtropical disease) 疮痍(traumata) 疮疤(scar) 痲疹(measles) 疱疮(pemphigus)

Table 4: The most similar characters/words to "疒 (illness)".

capturing finer-grained semantics that are more specific to the word. The top words discovered by them are semantically related to "游泳 (swimming)" itself, e.g., "潜泳 (underwater swimming)" and "爬泳 (front crawl swimming)". But the top words discovered by CBOW are just other types of sports in parallel with " 游泳 (swimming)", e.g., " 跳高 (high jump)" and " 跳水 (diving)". 2) MGE performs even better than CWE by further incorporating the radical information. The less relevant word " 田径 (track and field)" is ranked 4th by CWE. But after introducing the radical "氵 (water)", MGE can successfully rank "泳手 (swimmer)", "泳术 (swimming skill)", and " 冬泳 (winter swimming)" before it. All these words contain the radical "氵 (water)" and are more relevant to "游泳 (swimming)".

We further take the radical "疒 (illness)" as an example, and list the most similar characters and words discovered by MGE in Table 4. The similarity between a radical and a character/word is also defined as the cosine similarity between their embeddings. From the results, we can see that almost all the characters and words are disease-related, e.g., "佝 (rickets)", "痨 (tuberculosis)", and "癣疥 (ringworm scabies)", and most of them share the same radical "疒 (illness)". This observation demonstrates the rationality of embedding Chinese words, characters, and radicals into the same vector space, and measuring their similarities directly in that space. Note that this operation might be problematic for English. For example, it could be hard to figure out what kind of similarity there is between the character "i" and the word "ill". But for Chinese, this problem might be alleviated since characters and radicals themselves contain rich semantic information.

4 Conclusion and Future Work

In this paper we propose a new approach to Chinese word embedding, referred to as *multi-granularity embedding* (MGE). MGE improves word embedding by further leveraging both characters and radicals, and hence makes full use of the word-character-radical semantic composition. Experimental results on word similarity computation and analogical reasoning demonstrate the superiority of MGE over state-of-the-art methods. A qualitative analysis further shows that by incorporating radical information MGE can identify finer-grained semantic meanings of words.

As future work, we would like to 1) Investigate more complicate composition manners among radicals, characters, and words, e.g., a hierarchical structure of them. 2) Explore the semantic composition of higher level language units such as phrases, sentences, and even documents.

Numerically Grounded Language Models for Semantic Error Correction

Georgios P. Spithourakis and **Isabelle Augenstein** and **Sebastian Riedel**

Abstract

Semantic error detection and correction is an important task for applications such as fact checking, speech-to-text or grammatical error correction. Current approaches generally focus on relatively shallow semantics and do not account for numeric quantities. Our approach uses language models grounded in numbers within the text. Such groundings are easily achieved for recurrent neural language model architectures, which can be further conditioned on incomplete background knowledge bases. Our evaluation on clinical reports shows that numerical grounding improves perplexity by 33% and F1 for semantic error correction by 5 points when compared to ungrounded approaches. Conditioning on a knowledge base yields further improvements.

1 Introduction

In many real world scenarios it is important to detect and potentially correct semantic errors and inconsistencies in text. For example, when clinicians compose reports, some statements in the text may be inconsistent with measurements taken from the patient (Bowman, 2013). Error rates in clinical data range from 2.3% to 26.9% (Goldberg et al., 2008) and many of them are number-based errors (Arts et al., 2002). Likewise, a blog writer may make statistical claims that contradict facts recorded in databases (Munger, 2008). Numerical concepts constitute 29% of contradictions in Wikipedia and GoogleNews (De Marneffe et al., 2008) and 8.8% of contradictory pairs in entailment datasets (Dagan et al., 2006).

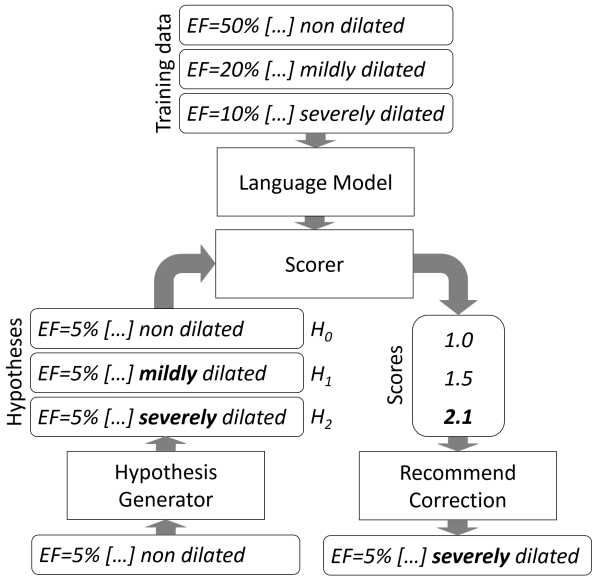

Figure 1: Semantic error correction using language models. "EF" is a clinical term and stands for "ejection fraction".

These inconsistencies may stem from oversight, lack of reporting guidelines or negligence. In fact they may not even be errors at all, but point to interesting outliers or to errors in a reference database. In all cases, it is important to spot and possibly correct such inconsistencies. This task is known as semantic error correction (*SEC*) (Dahlmeier and Ng, 2011).

In this paper, we propose a SEC approach to support clinicians with writing patient reports. A SEC system reads a patient's structured background information from a knowledge base (*KB*) and their clinical report. Then it recommends improvements to the text of the report for semantic consistency. An example of an inconsistency is shown in Figure 1.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 987–992,
Austin, Texas, November 1-5, 2016.

The SEC system has been trained on a dataset of records and learnt that the phrases "non dilated" and "severely dilated" correspond to high and low values for "EF" (abbreviation for "ejection fraction", a clinical measurement), respectively. If the system is then presented with the phrase "non dilated" in the context of a low value, it will detect a semantic inconsistency and correct the text to "severely dilated".

Our contributions are: 1) a straightforward extension to recurrent neural network (RNN) language models for *grounding* them in numbers available in the text; 2) a simple method for modelling text *conditioned on* an incomplete KB by lexicalising it; 3) our evaluation on a semantic error correction task for clinical records shows that our method achieves F1 improvements of 5 and 6 percentage points with grounding and KB conditioning, respectively, over an ungrounded approach (F1 of 49%).

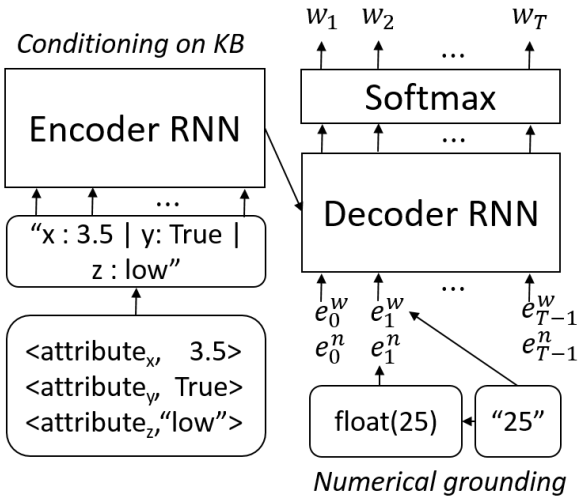

Figure 2: A language model that is numerically grounded and conditioned on a lexicalised KB. Examples of data in rounded rectangles.

2 Methodology

Our approach to semantic error correction (Figure 1) starts with training a language model (LM), which can be grounded in numeric quantities mentioned inline with text (Subsection 2.1) and/or conditioned on a potentially incomplete KB (Subsection 2.2). Given a document for semantic checking, a hypothesis generator proposes corrections, which are then scored using the trained language model (Subsection 2.3). A final decision step involves accepting the best scoring hypothesis.

2.1 Numerically grounded language modelling

Let $\{w_1, ..., w_T\}$ denote a document, where w_t is the one-hot representation of the t-th token and V is the vocabulary size. A neural LM uses a matrix, $E_{in} \in \mathbb{R}^{D \times V}$, to derive word embeddings, $e^w_t = E_{in} w_t$. A hidden state from the previous time step, h_{t-1}, and the current word embedding, e^w_t, are sequentially fed to an RNN's recurrence function to produce the current hidden state, $h_t \in \mathbb{R}^D$. The conditional probability of the next word is estimated as $\mathrm{softmax}(E_{out} h_t)$, where $E_{out} \in \mathbb{R}^{V \times D}$ is an output embeddings matrix.

We propose concatenating a representation, e^n_t, of the numeric value of w_t to the inputs of the RNN's recurrence function at each time step. Through this numeric representation, the model can generalise to out-of-vocabulary numbers. A straightforward representation is defining $e^n_t = \mathrm{float}(w_t)$, where $\mathrm{float}(.)$ is a numeric conversion function that returns a floating point number constructed from the string of its input. If conversion fails, it returns zero.

The proposed mechanism for *numerical grounding* is shown in Figure 2. Now the probability of each next word depends on numbers that have appeared earlier in the text. We treat numbers as a separate modality that happens to share the same medium as natural language (text), but can convey exact measurements of properties of the real world. At training time, the numeric representations mediate to ground the language model in the real world.

2.2 Conditioning on incomplete KBs

The proposed extension can also be used in *conditional language modelling* of documents given a knowledge base. Consider a set of KB tuples accompanying each document and describing its attributes in the form $< attribute, value >$, where attributes are defined by a KB schema. We can *lexicalise* the KB by converting its tuples into textual statements of the form "$attribute$: $value$". An example of how we lexicalise the KB is shown in Figure 2. The generated tokens can then be interpreted for their word embeddings and numeric representations. This

		words	3.4%	3.5%	3.5%
		numeric	40.4%	40.8%	41.8%

Table 1: Statistics for clinical dataset. Counts for non-numeric (*words*) and *numeric* tokens reported as percentage of counts for *all* tokens. Out-of-vocabulary (OOV) rates are for vocabulary of 1000 most frequent words in the train data.

approach can incorporate KB tuples flexibly, even when values of some attributes are missing.

2.3 Semantic error correction

A statistical model chooses the most likely correction from a set of possible correction choices. If the model scores a corrected hypothesis higher than the original document, the correction is accepted.

A *hypothesis generator function*, G, takes the original document, H_0, as input and generates a set of candidate corrected documents $G(H_0) = \{H_1, ..., H_M\}$. A simple hypothesis generator uses confusion sets of semantically related words to produce all possible substitutions.

A *scorer model*, s, assigns a score $s(H_i) \in \mathbb{R}$ to a hypothesis H_i. The scorer is based on a likelihood ratio test between the original document (null hypothesis, H_0) and each candidate correction (alternative hypotheses, H_i), i.e. $s(H_i) = \frac{p(H_i)}{p(H_0)}$. The assigned score represents how much more probable a correction is than the original document.

The probability of observing a document, $p(H_i)$, can be estimated using language models, or grounded and conditional variants thereof.

3 Data

Our dataset comprises 16,003 clinical records from the London Chest Hospital (Table 1). Each patient record consists of a text report and accompanying structured KB tuples. The latter describe 20 possible numeric attributes (age, gender, etc.), which are also partly contained in the report. On average, 7.7 tuples are completed per record. Numeric tokens constitute only a small proportion of each sentence (4.3%), but account for a large part of the unique tokens vocabulary (>40%) and suffer from high OOV rates.

description	confusion set

Table 2: Confusion sets.

To evaluate SEC, we generate a "corrupted" dataset of semantic errors from the test part of the "trusted" dataset (Table 1, last column). We manually build confusion sets (Table 2) by searching the development set for words related to numeric quantities and grouping them if they appear in similar contexts. Then, for each document in the trusted test set we generate an erroneous document by sampling a substitution from the confusion sets. Documents with no possible substitution are excluded. The resulting "corrupted" dataset is balanced, containing 2,926 correct and 2,926 incorrect documents.

4 Results and discussion

Our *base LM* is a single-layer long short-term memory network (LSTM, Hochreiter and Schmidhuber (1997) with all latent dimensions (internal matrices, input and output embeddings) set to $D = 50$. We extend this baseline to a *conditional* variant by conditioning on the lexicalised KB (see Section 2.2). We also derive a numerically *grounded* model by concatenating the numerical representation of each token to the inputs of the base LM model (see Section 2.1). Finally, we consider a model that is both grounded and conditional (*g-conditional*).

The vocabulary contains the $V = 1000$ most frequent tokens in the training set. Out-of-vocabulary tokens are substituted with *<num_unk>*, if numeric, and *<unk>*, otherwise. We extract the numerical representations before masking, so that the grounded models can generalise to out-of-vocabulary numbers. Models are trained to minimise token cross-entropy, with 20 epochs of back-

propagation and adaptive mini-batch gradient descent (AdaDelta) (Zeiler, 2012).

For SEC, we use an oracle hypothesis generator that has access to the groundtruth confusion sets (Table 2). We estimate the scorer (Section 2.3) using the trained *base*, *conditional*, *grounded* or *g-conditional* LMs. As additional baselines we consider a scorer that assigns *random* scores from a uniform distribution and *always* (*never*) scorers that assign the lowest (highest) score to the original document and uniformly random scores to the corrections.

4.1 Experiment 1: Numerically grounded LM

We report perplexity and adjusted perplexity (Ueberla, 1994) of our LMs on the test set for all tokens and token classes (Table 3). Adjusted perplexity is not sensitive to OOV-rates and thus allows for meaningful comparisons across token classes. Perplexities are high for numeric tokens because they form a large proportion of the vocabulary. The *grounded* and *g-conditional* models achieved a 33.3% and 36.9% improvement in perplexity, respectively, over the *base LM* model. Conditioning without grounding yields only slight improvements, because most of the numerical values from the lexicalised KB are out-of-vocabulary.

The qualitative example in Figure 3 demonstrates how numeric values influence the probability of tokens given their history. We select a document from the development set and substitute its numeric values as we vary EF (the rest are set by solving a known system of equations). The selected exact values were unseen in the training data. We calculate the probabilities for observing the document with different word choices {"non", "mildly", "severely"} under the *grounded* LM and find that "non dilated" is associated with higher EF values. This shows that it has captured semantic dependencies on numbers.

4.2 Experiment 2: Semantic error correction

We evaluate SEC systems on the corrupted dataset (Section 3) for detection and correction.

For detection, we report precision, recall and F1 scores in Table 4. Our *g-conditional* model achieves the best results, a total F1 improvement of 2 points over the *base LM* model and 7 points over the best baseline. The conditional model without grounding performs slightly worse in the F1 metric than the *base LM*. Note that with more hypotheses the *random* baseline behaves more similarly to *always*. Our hypothesis generator generated on average 12 hypotheses per document. The results of *never* are zero as it fails to detect any error.

For correction, we report mean average precision (MAP) in addition to the same metrics as for detection (Table 5). The former measures the position of the ranking of the correct hypothesis. The *always* (*never*) baseline ranks the correct hypothesis at the top (bottom). Again, the *g-conditional* model

model	P	R	F1
random	50.27	90.29	64.58
always	50.00	100.0	66.67
never	0.0	0.0	0.0
base LM	57.51	94.05	71.38
conditional	56.86	94.43	70.98
grounded	58.87	94.70	72.61
g-conditional	**60.48**	**95.25**	**73.98**

Table 4: Error detection results on the test set. We report precision (P), recall (R) and F1. Best results in **bold**.

Table 5: Error correction results on the test set. We report mean average precision (MAP), precision (P), recall (R) and F1. Best results in **bold**.

yields the best results, achieving an improvement of 6 points in F1 and 5 points in MAP over the *base LM* model and an improvement of 47 points in F1 and 9 points in MAP over the best baseline. The *conditional* model without grounding has the worst performance among the LM-based models.

5 Related Work

Grounded language models represent the relationship between words and the non-linguistic context they refer to. Previous work grounds language on vision (Bruni et al., 2014; Socher et al., 2014; Silberer and Lapata, 2014), audio (Kiela and Clark, 2015), video (Fleischman and Roy, 2008), colour (McMahan and Stone, 2015), and olfactory perception (Kiela et al., 2015). However, no previous approach has explored in-line numbers as a source of grounding.

Our language modelling approach to SEC is inspired by LM approaches to grammatical error detection (GEC) (Ng et al., 2013; Felice et al., 2014). They similarly derive confusion sets of semantically related words, substitute the target words with alternatives and score them with an LM. Existing semantic error correction approaches aim at correcting word error choices (Dahlmeier and Ng, 2011), collocation errors (Kochmar, 2016), and semantic anomalies in adjective-noun combinations (Vecchi et al., 2011). So far, SEC approaches focus on short distance semantic agreement, whereas our approach can detect errors which require to resolve long-range dependencies. Work on GEC and SEC shows that language models are useful for error correction, however they neither ground in numeric quantities nor incorporate background KBs.

6 Conclusion

In this paper, we proposed a simple technique to model language in relation to numbers it refers to, as well as conditionally on incomplete knowledge bases. We found that the proposed techniques lead to performance improvements in the tasks of language modelling, and semantic error detection and correction. Numerically grounded models make it possible to capture semantic dependencies of content words on numbers.

In future work, we will plan to apply numerically grounded models to other tasks, such as numeric error correction. We will explore alternative ways for deriving the numeric representations, such as accounting for verbal descriptions of numbers. For SEC, a trainable hypothesis generator can potentially improve the coverage of the system.

Abstract

Annotation projection based on parallel corpora has shown great promise in inexpensively creating Proposition Banks for languages for which high-quality parallel corpora and syntactic parsers are available. In this paper, we present an experimental study where we apply this approach to three languages that lack such resources: *Tamil*, *Bengali* and *Malayalam*. We find an average quality difference of 6 to 20 absolute F-measure points vis-a-vis high-resource languages, which indicates that annotation projection alone is insufficient in low-resource scenarios. Based on these results, we explore the possibility of using annotation projection as a starting point for inexpensive data curation involving both experts and non-experts. We give an outline of what such a process may look like and present an initial study to discuss its potential and challenges.

1 Introduction

Creating syntactically and semantically annotated NLP resources for low-resource languages is known to be immensely costly. For instance, the Proposition Bank (Palmer et al., 2005) was created by annotating predicate-argument structures in the Penn Treebank (Marcus et al., 1993) with shallow semantic labels: *frame* labels for verbal predicates and *role* labels for arguments. Similarly, the SALSA (Burchardt et al., 2006) resource added FrameNet-style annotations to the TIGER Treebank (Brants et al., 2002), the Chinese Propbank (Xue, 2008) is built on the Chinese Treebank (Xue et al., 2005), and so forth. Since each such layer of annotation typically requires years of manual work, the accumulated costs can be prohibitive for low-resource languages.

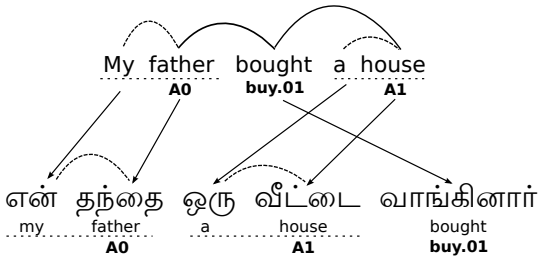

Figure 1: Annotation projection on a pair of very simple sentences. English Propbank frame (**buy.01**) and role (**A0**, **A1**) labels are projected onto aligned Tamil words. Furthermore, the typed dependencies between the words "my father" and "a house" (dotted lines) are projected onto their Tamil equivalents.

Recent work on **annotation projection** offers a way to inexpensively label a target language corpus with linguistic annotation (Padó and Lapata, 2009). This only requires a word-aligned parallel corpus of labeled English sentences and their translations in the target language. English labels are then automatically projected onto the aligned target language words. Refer to Figure 1 for an example.

Low-resource languages. However, previous work that investigated Propbank annotation projection has focused only on languages for which treebanks - and therefore syntactic parsers - already exist. Since syntactic information is typically used to increase projection accuracy (Padó and Lapata, 2009; Akbik et al., 2015), we must expect this approach to work less well for low-resource languages. In addition, low-resource languages have fewer sources of high-

Austin, Texas, November 1-5, 2016.

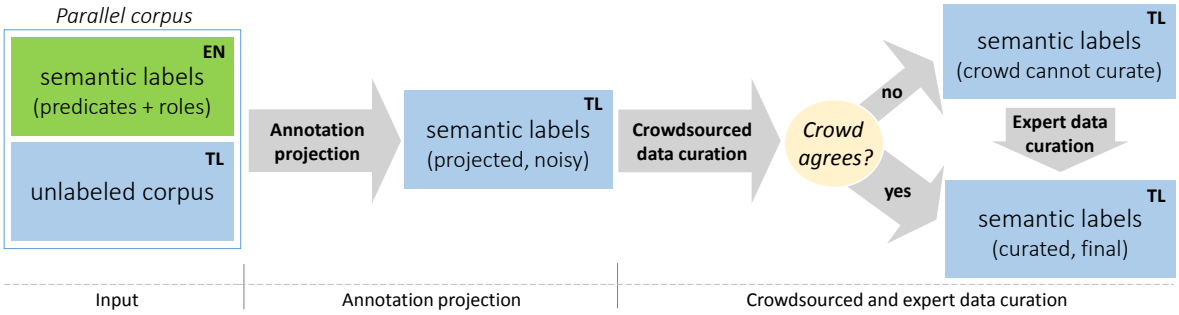

Figure 2: Proposed process of using annotation projection in a parallel corpus from English (EN) to a target language (TL) as basis for crowdsourced data curation. Experts are only involved in cases where the crowd cannot agree on a label.

quality parallel data available, further complicating annotation projection.

Contributions. In this paper, we present a study in which we apply annotation projection to three low-resource languages in order to quantify the difference in precision and recall vis-a-vis high-resource languages. Our study finds overall F1-measure of generated Proposition Banks to be significantly below state-of-the-art results, leading us to conclude that annotation projection may at best be a *starting point* for the generation of semantic resources for low-resource languages. To explore this idea, we outline a potential semi-automatic process in which we use crowdsourced data curation and limited expert involvement to confirm and correct automatically projected labels. Based on this initial study, we discuss the potential and challenges of the proposed approach.

2 Annotation Projection

Annotation projection takes as input a word-aligned parallel corpus of sentences in a source language (usually English) and their target language translations. A syntactic parser and a semantic role labeler produce labels for the English sentences, which are then projected onto aligned target language words. The underlying theory is that parallel sentences share a degree of syntactic and, in particular, semantic similarity, making such projection possible (Padó and Lapata, 2009).

State-of-the-art. Previous work analyzed errors in annotation projection and found that they are often caused by non-literal translations (Akbik et al., 2015). For this reason, previous work defined lexical and syntactic constraints to increase projection quality. These include verb filters to allow only verbs to be labeled as frames (Van der Plas et al., 2011), heuristics to ensure that only heads of syntactic constituents are labeled as arguments (Padó and Lapata, 2009) and the use of verb translation dictionaries (Akbik et al., 2015) to constrain frame mappings.

Adaptation to low-resource languages. Low-resource languages, however, lack syntactic parsers to identify target language predicate-argument structures. This requires us to make the following modifications to the approach:

Target language predicates We define lexical constraints using verb translation dictionaries. This ensures that only target language verbs that are aligned to literal source language translations are labeled as frames.

Target language arguments To identify arguments, we project not only the role label of source language arguments heads, but the entire argument dependency structure. This is illustrated in Figure 1: Two dependency arcs are projected from English onto Tamil, giving evidence that arguments **A0** and **A1** in the Tamil sentence each consist of two words.

This step produces a target language corpus with semantically annotated predicate-argument structure.

3 Outline of a Data Curation Process

As confirmed in the experiments section of this paper, the quality of the Proposition Banks generated using annotation projection is significantly lower for low-resource languages. We therefore propose to use this approach only as a starting point for an inexpensive curation process as illustrated in Figure 2:

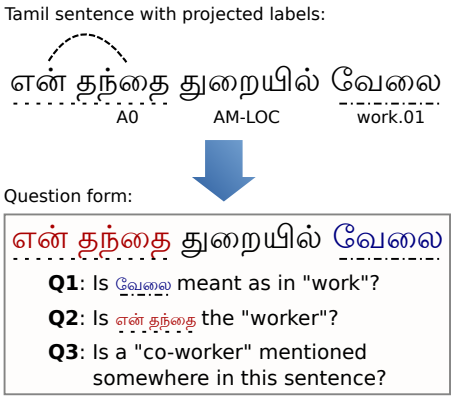

Figure 3: Example of how data curation questions may be formulated for the labels projected onto Tamil in Figure 1.

Step 1: Crowdsourced data curation. Previous work has experimented with different approaches in crowdsourcing to generate frame-semantic annotations over text (Hong and Baker, 2011), including selection tasks (selecting one answer from a list of options) (Fossati et al., 2013) and marking tasks (marking text passages that evoke a certain semantic role) (Feizabadi and Padó, 2014). While these studies only report moderate results on annotator correctness and agreement, our goal is different from these works in that we only wish to curate projected labels, not generate SRL annotations from scratch. A related project in extending FrameNet with paraphrases (Pavlick et al., 2015) has shown that the crowd can effectively curate wrong paraphrases by answering a series of confirm-or-reject questions.

For our initial study, we generate human readable question-answer pairs (He et al., 2015) using the label descriptions of the English Propbank (see Figure 3). We generate two types of questions:

Label confirmation questions are confirm-or-reject questions on whether projected labels are correct (e.g. **Q1** and **Q2** in Figure 3). Workers further qualify their answers to indicate whether a sequence of words marked as an argument is incomplete.

Missing label questions are marking tasks which ask whether any core role labels of a frame are missing. For example, the BUY.01 frame has 5 core roles (labeled **A0** to **A4**), one of which is the ”price” (**A3**). Since no ”price” is labeled in the Tamil sentence in Figure 3, question **Q3** asks users to add this label if a ”price” is mentioned.

DATA SET	Bengali	Malayalam	Tamil
OPENSUBTITLES2016	75K	224K	21K
SPOKENTUTORIALS	31K	17K	32K
Total # sentences	106K	241K	53K

Table 1: Parallel data sets and number of parallel sentences used for each language.

Our goal is to effectively distribute a large part of the curation workload. In cases where the crowd unanimously agrees, we remove labels judged to be incorrect and add labels judged to be missing.

Step 2: Expert data curation. We also expect a percentage of questions for which non-experts will give conflicting answers[1]. As Figure 2 shows, such cases will be passed to experts for further curation. However, for the purpose of scalability, we aim to keep expert involvement to a minimum.

4 Experimental Study

We report our initial investigations over the following questions: (1) What are the differences in annotation projection quality between low- and high-resource languages?; and (2) Can non-experts be leveraged to at least partially curate projected labels?

4.1 Experimental Setup

Languages. We evaluate three low-resource languages, namely *Bengali*, an Indo-Aryan language, as well as *Tamil* and *Malayalam*, two South Dravidian languages. Between them, they are estimated to have more than 300 million first language speakers, yet there are few NLP resources available.

Data sets. We use two parallel corpora (see Table 1): OPENSUBTITLES2016 (Tiedemann, 2012), a corpus automatically generated from movie subtitles, and SPOKENTUTORIALS, a corpus of technical-domain tutorial translations.

Evaluation. For the purpose of comparison to previous work on high-resource languages, we replicate

[1]Common problems for non-experts that we observe in our initial experiments involve ambiguities caused by implicit or causal role-predicate relationships, as well as figurative usage and hypotheticals.

		PRED.	ARGUMENT

Table 2: Estimated precision and recall for Tamil, Bengali and Malayalam before and after non-expert curation. We list state-of-the-art results for German and Hindi for comparison.

earlier evaluation practice and English preprocessing steps (Akbik et al., 2015). After projection, we randomly select 100 sentences for each target language and pass them to a curation step by 2 non-experts. We then measure the inter-annotator agreement and the quality of the generated Proposition Banks in terms of predicate precision[2] and argument F1-score before and after crowdsourced curation[3].

4.2 Results

The evaluation results are listed in Table 2. For comparison, we include evaluation results reported for three high-resource languages: German and Chinese, representing average high-resource results, as well as Hindi, a below-average outlier. We make the following observations:

Lower annotation projection quality. We find that the F1-scores of Bengali, Malayalam and Tamil are 6, 11 and 31 pp below that of an average high-resource language (as exemplified by German in Table 2). Bengali and Malayalam, however, do surpass Hindi, for which only a relatively poor dependency parser was used. This suggests that syntactic annotation projection may be a better method for identifying predicate-argument structures in languages that lack fully developed dependency parsers.

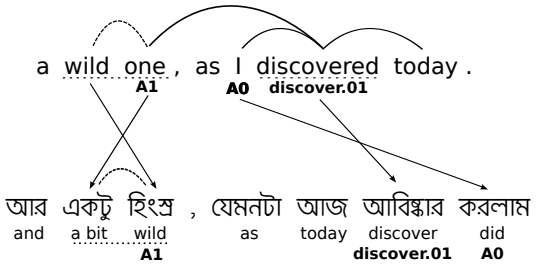

Figure 4: Example of a projection error. The verb *discover* in Bengali is a light verb construction. In addition, the pronoun *I* is not explicitly mentioned in the Bengali target sentence. This causes the pronoun *I* to be mistakenly aligned to the auxiliary of the light verb, causing it to be falsely labeled as **A0**.

Impact of parallel data. We note a significant impact of the size and quality of available parallel data on overall quality. For instance, the lowest-scoring language in our experiments, Tamil, use the smallest amount parallel data (see Table 1), most of which was from the SPOKENTUTORIALS corpus. This data is specific to the technical domain and seems less suited for annotation projection than the more general OPENSUBTITLES2016 corpus.

A qualitative inspection of projection errors points to a large portion of errors stemming from translation shifts. For instance, refer to Figure 4 for an English-Bengali example of the impact of even slight differences in translation: The English verb *discover* is expressed in Bengali as a light verb, while the pronoun *I* is dropped in the Bengali sentence (it is still implicitly evoked through the verb being in first person form). This causes the word alignment to align the English *I* to the Bengali auxiliary, onto which the role label **A0** is then incorrectly projected.

5 Discussion

In all three languages, we note improvements through curation. Argument F1-score improves to 77% (↑2 pp) for Bengali, to 74% (↑4 pp) for Malay-

[2]Since we do not ask missing label questions for predicates, we cannot estimate predicate recall.

[3]Following (Akbik et al., 2015), in the *exact* evaluation scheme, labels marked as correct and complete count as true positives. In *partial*, incomplete correct labels also count as true positives.

alam, and to 61% (↑11 pp) for Tamil on exact matches. Especially Tamil improves drastically, albeit from a much lower initial score than the other languages. This supports our general observation that crowd workers are good at spotting obvious errors, while they often disagree about more subtle differences in semantics. These results indicate that a curation process can at least be partially crowdsourced. An interesting question for further investigation is to what degree this is possible. As Table 2 shows, non-expert agreement in our initial study was far below reported expert agreement, with 25% to 35% of all questions problematic for non-experts.

A particular focus of our future work is therefore to quantify to which extent crowd-feedback can be valuable and how far the involvement of experts can be minimized for cost-effective resource generation. However, a Proposition Bank generated through this process would be peculiar in several ways:

Crowd semantics. First, generated Proposition Banks would be created in a drastically different way than current approaches that rely on experts to create and annotate frames. Effectively, the non-expert crowd would, to a large degree, shape the selection and annotation of English frame and role annotation for new target languages. An important question therefore is to what degree an auto-generated Propbank would differ from an expertly created one. In a related line of work (Akbik et al., 2016), we have conducted a preliminary comparison of an auto-generated Proposition Bank for Chinese and the manually created Chinese Proposition Bank (Xue and Palmer, 2005). Encouragingly, we find a significant overlap between both versions. Future work will further explore the usefulness of auto-generated Propbanks to train a semantic role labeler (Akbik and Li, 2016) and their usefulness for downstream applications in low-resource languages.

Partial syntactic annotation. Second, while curation of semantically labeled predicate-argument structure can be formulated as human intelligence tasks, this will not in all likelihood be possible for full parse trees. These Propbanks would therefore lack a treebank-style syntactic layer of annotation. Would an existing Propbank facilitate the future task of creating treebanks for low-resource languages? In other words, could the traditional order of first creating treebanks and then Propbanks be reversed?

PROPBANK	#SENTENCES	#LABELS	#FRAMES
Bengali	5,757	17,899	88
Malayalam	10,579	26,831	95
Tamil	3,486	11,765	68

Table 3: Number of labeled sentences, semantic labels and distinct frames of each auto-generated Propbank (*before* non-expert curation).

6 Conclusion and Outlook

We applied annotation projection to low-resource languages and found a significant drop in quality vis-a-vis high-resource languages. We then proposed and outlined a curation process for semi-automatically generating Proposition Banks and noted encouraging results in an initial study. To encourage discussion within the research community, we make our generated Proposition Banks for Bengali, Malayalam and Tamil (see Table 3 for an overview) publicly available[4].

A Hierarchical Model of Reviews for Aspect-based Sentiment Analysis

Abstract

Opinion mining from customer reviews has become pervasive in recent years. Sentences in reviews, however, are usually classified independently, even though they form part of a review's argumentative structure. Intuitively, sentences in a review build and elaborate upon each other; knowledge of the review structure and sentential context should thus inform the classification of each sentence. We demonstrate this hypothesis for the task of aspect-based sentiment analysis by modeling the interdependencies of sentences in a review with a hierarchical bidirectional LSTM. We show that the hierarchical model outperforms two non-hierarchical baselines, obtains results competitive with the state-of-the-art, and outperforms the state-of-the-art on five multilingual, multi-domain datasets without any hand-engineered features or external resources.

1 Introduction

Sentiment analysis (Pang and Lee, 2008) is used to gauge public opinion towards products, to analyze customer satisfaction, and to detect trends. With the proliferation of customer reviews, more fine-grained aspect-based sentiment analysis (ABSA) has gained in popularity, as it allows aspects of a product or service to be examined in more detail.

Reviews – just with any coherent text – have an underlying structure. A visualization of the discourse structure according to Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) for the example review in Figure 1 reveals that sentences and clauses are connected via different rhetorical relations, such as *Elaboration* and *Background*.

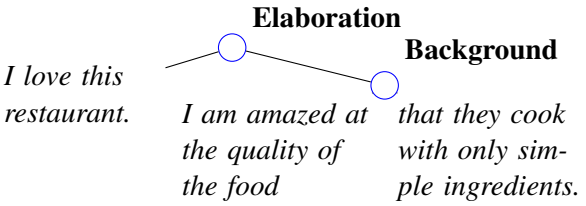

Figure 1: RST structure of an example review.

Intuitively, knowledge about the relations and the sentiment of surrounding sentences should inform the sentiment of the current sentence. If a reviewer of a restaurant has shown a positive sentiment towards the quality of the food, it is likely that his opinion will not change drastically over the course of the review. Additionally, overwhelmingly positive or negative sentences in the review help to disambiguate sentences whose sentiment is equivocal.

Neural network-based architectures that have recently become popular for sentiment analysis and ABSA, such as convolutional neural networks (Severyn and Moschitti, 2015), LSTMs (Vo and Zhang, 2015), and recursive neural networks (Nguyen and Shirai, 2015), however, are only able to consider intra-sentence relations such as *Background* in Figure 1 and fail to capture inter-sentence relations, e.g. *Elaboration* that rely on discourse structure and provide valuable clues for sentiment prediction.

We introduce a hierarchical bidirectional long short-term memory (H-LSTM) that is able to leverage both intra- and inter-sentence relations. The sole dependence on sentences and their structure

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 999–1005,
Austin, Texas, November 1-5, 2016.

within a review renders our model fully language-independent. We show that the hierarchical model outperforms strong sentence-level baselines for aspect-based sentiment analysis, while achieving results competitive with the state-of-the-art and outperforming it on several datasets without relying on any hand-engineered features or sentiment lexica.

2 Related Work

Aspect-based sentiment analysis. Past approaches use classifiers with expensive hand-crafted features based on n-grams, parts-of-speech, negation words, and sentiment lexica (Pontiki et al., 2014; Pontiki et al., 2015). The model by Zhang and Lan (2015) is the only approach we are aware of that considers more than one sentence. However, it is less expressive than ours, as it only extracts features from the preceding and subsequent sentence without any notion of structure. Neural network-based approaches include an LSTM that determines sentiment towards a target word based on its position (Tang et al., 2015) as well as a recursive neural network that requires parse trees (Nguyen and Shirai, 2015). In contrast, our model requires no feature engineering, no positional information, and no parser outputs, which are often unavailable for low-resource languages. We are also the first – to our knowledge – to frame sentiment analysis as a sequence tagging task.

Hierarchical models. Hierarchical models have been used predominantly for representation learning and generation of paragraphs and documents: Li et al. (2015) use a hierarchical LSTM-based autoencoder to reconstruct reviews and paragraphs of Wikipedia articles. Serban et al. (2016) use a hierarchical recurrent encoder-decoder with latent variables for dialogue generation. Denil et al. (2014) use a hierarchical ConvNet to extract salient sentences from reviews, while Kotzias et al. (2015) use the same architecture to learn sentence-level labels from review-level labels using a novel cost function. The model of Lee and Dernoncourt (2016) is perhaps the most similar to ours. While they also use a sentence-level LSTM, their class-level feed-forward neural network is only able to consider a limited number of preceding texts, while our review-level bidirectional LSTM is (theoretically) able to consider an unlimited number of preceding *and* successive sentences.

3 Model

In the following, we will introduce the different components of our hierarchical bidirectional LSTM architecture displayed in Figure 2.

3.1 Sentence and Aspect Representation

Each review consists of sentences, which are padded to length l by inserting padding tokens. Each review in turn is padded to length h by inserting sentences containing only padding tokens. We represent each sentence as a concatentation of its word embeddings $x_{1:l}$ where $x_t \in \mathbb{R}^k$ is the k-dimensional vector of the t-th word in the sentence.

Every sentence is associated with an aspect. Aspects consist of an entity and an attribute, e.g. `FOOD#QUALITY`. Similarly to the entity representation of Socher et al. (2013), we represent every aspect a as the average of its entity and attribute embeddings $\frac{1}{2}(x_e + x_a)$ where $x_e, x_a \in \mathbb{R}^m$ are the m-dimensional entity and attribute embeddings respectively[1].

3.2 LSTM

We use a Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), which adds input, output, and forget gates to a recurrent cell, which allow it to model long-range dependencies that are essential for capturing sentiment.

For the t-th word in a sentence, the LSTM takes as input the word embedding x_t, the previous output h_{t-1} and cell state c_{t-1} and computes the next output h_t and cell state c_t. Both h and c are initialized with zeros.

3.3 Bidirectional LSTM

Both on the review and on the sentence level, sentiment is dependent not only on preceding but also successive words and sentences. A Bidirectional LSTM (Bi-LSTM) (Graves et al., 2013) allows us to look ahead by employing a forward LSTM, which processes the sequence in chronological order, and a backward LSTM, which processes the sequence in reverse order. The output h_t at a given time step is then the concatenation of the corresponding states of the forward and backward LSTM.

[1] Averaging embeddings produced slightly better results than using a separate embedding for every aspect.

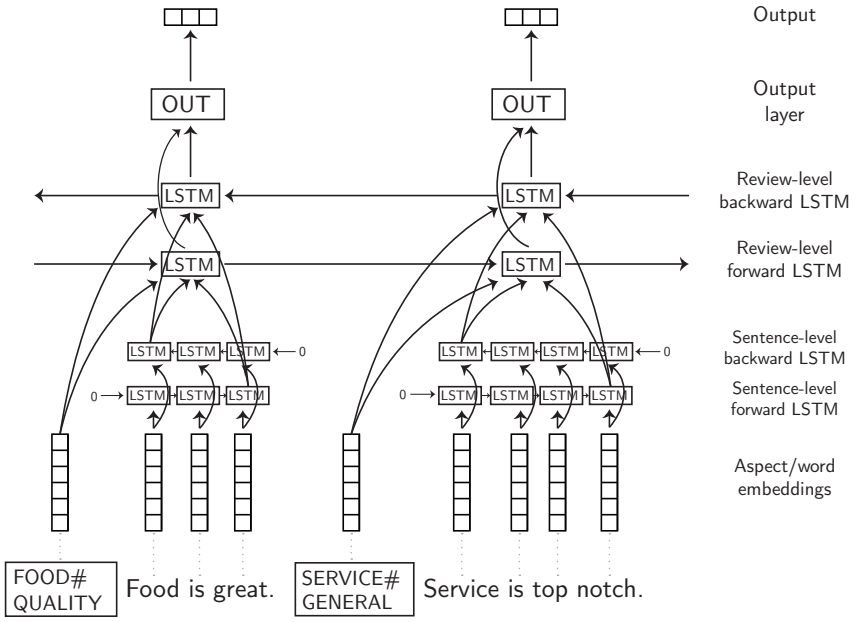

Figure 2: The hierarchical bidirectional LSTM (H-LSTM) for aspect-based sentiment analysis. Word embeddings are fed into a sentence-level bidirectional LSTM. Final states of forward and backward LSTM are concatenated together with the aspect embedding and fed into a bidirectional review-level LSTM. At every time step, the output of the forward and backward LSTM is concatenated and fed into a final layer, which outputs a probability distribution over sentiments.

3.4 Hierarchical Bidirectional LSTM

Stacking a Bi-LSTM on the review level on top of sentence-level Bi-LSTMs yields the hierarchical bidirectional LSTM (H-LSTM) in Figure 2.

The sentence-level forward and backward LSTMs receive the sentence starting with the first and last word embedding x_1 and x_l respectively. The final output h_l of both LSTMs is then concatenated with the aspect vector a[2] and fed as input into the review-level forward and backward LSTMs. The outputs of both LSTMs are concatenated and fed into a final softmax layer, which outputs a probability distribution over sentiments[3] for each sentence.

4 Experiments

4.1 Datasets

For our experiments, we consider datasets in five domains (restaurants, hotels, laptops, phones, cameras) and eight languages (English, Spanish, French, Russian, Dutch, Turkish, Arabic, Chinese) from the recent SemEval-2016 Aspect-based Sentiment Analysis task (Pontiki et al., 2016), using the provided train/test splits. In total, there are 11 domain-language datasets containing 300-400 reviews with 1250-6000 sentences[4]. Each sentence is annotated with none, one, or multiple domain-specific aspects and a sentiment value for each aspect.

4.2 Training Details

Our LSTMs have one layer and an output size of 200 dimensions. We use 300-dimensional word embeddings. We use pre-trained GloVe (Pennington et al., 2014) embeddings for English, while we train embeddings on `frWaC`[5] for French and on the Leipzig Corpora Collection[6] for all other languages.[7] Entity

[2]We experimented with other interactions, e.g. rescaling the word embeddings by their aspect similarity, an attention-like mechanism, as well as summing and multiplication, but found that simple concatenation produced the best results.

[3]The sentiment classes are *positive*, *negative*, and *neutral*.

[4]Exact dataset statistics can be seen in (Pontiki et al., 2016).

[5]`http://wacky.sslmit.unibo.it/doku.php?id=corpora`

[6]`http://corpora2.informatik.uni-leipzig.de/download.html`

[7]Using 64-dimensional Polyglot embeddings (Al-Rfou et al., 2013) yielded generally worse performance.

Language	Domain	Best	XRCE	IIT-TUDA	CNN	LSTM	H-LSTM	HP-LSTM
English	Restaurants	**88.1**	**88.1**	86.7	82.1	81.4	83.0	85.3
Spanish	Restaurants	**83.6**	-	**83.6**	79.6	75.7	79.5	81.8
French	Restaurants	**78.8**	**78.8**	72.2	73.2	69.8	73.6	75.4
Russian	Restaurants	77.9	-	73.6	75.1	73.9	**78.1**	77.4
Dutch	Restaurants	77.8	-	77.0	75.0	73.6	82.2	**84.8**
Turkish	Restaurants	**84.3**	-	**84.3**	74.2	73.6	76.7	79.2
Arabic	Hotels	82.7	-	81.7	82.7	80.5	82.8	**82.9**
English	Laptops	**82.8**	-	**82.8**	78.4	76.0	77.4	80.1
Dutch	Phones	83.3	-	82.6	83.3	81.8	81.3	**83.6**
Chinese	Cameras	**80.5**	-	-	78.2	77.6	78.6	78.8
Chinese	Phones	73.3	-	-	72.4	70.3	**74.1**	73.3

Table 1: Results of our system with randomly initialized word embeddings (H-LSTM) and with pre-trained embeddings (HP-LSTM) for ABSA for each language and domain in comparison to the best system for each pair (Best), the best two single systems (XRCE, IIT-TUDA), a sentence-level CNN (CNN), and our sentence-level LSTM (LSTM).

and attribute embeddings of aspects have 15 dimensions and are initialized randomly. We use dropout of 0.5 after the embedding layer and after LSTM cells, a gradient clipping norm of 5, and no l_2 regularization.

We unroll the aspects of every sentence in the review, e.g. a sentence with two aspects occurs twice in succession, once with each aspect. We remove sentences with no aspect[8] and ignore predictions for all sentences that have been added as padding to a review so as not to force our model to learn meaningless predictions, as is commonly done in sequence-to-sequence learning (Sutskever et al., 2014). We segment Chinese data before tokenization.

We train our model to minimize the cross-entropy loss, using stochastic gradient descent, the Adam update rule (Kingma and Ba, 2015), mini-batches of size 10, and early stopping with a patience of 10.

4.3 Comparison models

We compare our model using random (H-LSTM) and pre-trained word embeddings (HP-LSTM) against the best model of the SemEval-2016 Aspect-based Sentiment Analysis task (Pontiki et al., 2016) for each domain-language pair (Best) as well as against the two best single models of the competition: IIT-TUDA (Kumar et al., 2016), which uses large sentiment lexicons for every language, and XRCE (Brun et al., 2016), which uses a parser augmented with hand-crafted, domain-specific rules. In order to ascertain that the hierarchical nature of our model is the deciding factor, we additionally compare against the sentence-level convolutional neural network of Ruder et al. (2016) (CNN) and against a sentence-level Bi-LSTM (LSTM), which is identical to the first layer of our model.[9]

5 Results and Discussion

We present our results in Table 1. Our hierarchical model achieves results superior to the sentence-level CNN and the sentence-level Bi-LSTM baselines for almost all domain-language pairs by taking the structure of the review into account. We highlight examples where this improves predictions in Table 2.

In addition, our model shows results competitive with the best single models of the competition, while requiring no expensive hand-crafted features or external resources, thereby demonstrating its language and domain independence. Overall, our model compares favorably to the state-of-the-art, particularly for low-resource languages, where few hand-engineered features are available. It outperforms the state-of-the-art on four and five datasets using randomly initialized and pre-trained embeddings respectively.

[8] Labeling them with a NONE aspect and predicting *neutral* slightly decreased performance.

[9] To ensure that the additional parameters do not account for the difference, we increase the number of layers and dimensions of LSTM, which does not impact the results.

Id	Sentence	LSTM	H-LSTM
1.1	No Comparison	*negative*	*positive*
1.2	It has great sushi and even better service.	*positive*	*positive*
2.1	Green Tea creme brulee is a must!	*positive*	*positive*
2.2	Don't leave the restaurant without it.	*negative*	*positive*

Table 2: Example sentences where knowledge of other sentences in the review (not necessarily neighbors) helps to disambiguate the sentiment of the sentence in question. For the aspect in 1.1, the sentence-level LSTM predicts *negative*, while the context of the service and food quality in 1.2 allows the H-LSTM to predict *positive*. Similarly, for the aspect in 2.2, knowledge of the quality of the green tea crème brulée helps the H-LSTM to predict the correct sentiment.

5.1 Pre-trained embeddings

In line with past research (Collobert et al., 2011), we observe significant gains when initializing our word vectors with pre-trained embeddings across almost all languages. Pre-trained embeddings improve our model's performance for all languages except Russian, Arabic, and Chinese and help it achieve state-of-the-art in the Dutch phones domain. We release our pre-trained multilingual embeddings so that they may facilitate future research in multilingual sentiment analysis and text classification[10].

5.2 Leveraging additional information

As annotation is expensive in many real-world applications, learning from only few examples is important. Our model was designed with this goal in mind and is able to extract additional information inherent in the training data. By leveraging the structure of the review, our model is able to inform and improve its sentiment predictions as evidenced in Table 2.

The large performance differential to the state-of-the-art for the Turkish dataset where only 1104 sentences are available for training and the performance gaps for high-resource languages such as English, Spanish, and French, however, indicate the limits of an approach such as ours that only uses data available at training time.

While using pre-trained word embeddings is an effective way to mitigate this deficit, for high-resource languages, solely leveraging unsupervised language information is not enough to perform on-par with approaches that make use of large external resources (Kumar et al., 2016) and meticulously hand-crafted features (Brun et al., 2016).

Sentiment lexicons are a popular way to inject additional information into models for sentiment analysis. We experimented with using sentiment lexicons by Kumar et al. (2016) but were not able to significantly improve upon our results with pre-trained embeddings[11]. In light of the diversity of domains in the context of aspect-based sentiment analysis and many other applications, domain-specific lexicons (Hamilton et al., 2016) are often preferred. Finding better ways to incorporate such domain-specific resources into models as well as methods to inject other forms of domain information, e.g. by constraining them with rules (Hu et al., 2016) is thus an important research avenue, which we leave for future work.

6 Conclusion

In this paper, we have presented a hierarchical model of reviews for aspect-based sentiment analysis. We demonstrate that by allowing the model to take into account the structure of the review and the sentential context for its predictions, it is able to outperform models that only rely on sentence information and achieves performance competitive with models that leverage large external resources and hand-engineered features. Our model achieves state-of-the-art results on 5 out of 11 datasets for aspect-based sentiment analysis.

Are Word Embedding-based Features Useful for Sarcasm Detection?

Abstract

This paper makes a simple increment to state-of-the-art in sarcasm detection research. Existing approaches are unable to capture subtle forms of context incongruity which lies at the heart of sarcasm. We explore if prior work can be enhanced using semantic similarity/discordance between word embeddings. We augment word embedding-based features to four feature sets reported in the past. We also experiment with four types of word embeddings. We observe an improvement in sarcasm detection, irrespective of the word embedding used or the original feature set to which our features are augmented. For example, this augmentation results in an improvement in F-score of around 4% for three out of these four feature sets, and a minor degradation in case of the fourth, when Word2Vec embeddings are used. Finally, a comparison of the four embeddings shows that Word2Vec and dependency weight-based features outperform LSA and GloVe, in terms of their benefit to sarcasm detection.

1 Introduction

Sarcasm is a form of verbal irony that is intended to express contempt or ridicule. Linguistic studies show that the notion of context incongruity is at the heart of sarcasm (Ivanko and Pexman, 2003). A popular trend in automatic sarcasm detection is semi-supervised extraction of patterns that capture the underlying context incongruity (Davidov et al., 2010; Joshi et al., 2015; Riloff et al., 2013). However, techniques to extract these patterns rely on sentiment-bearing words and may not capture nuanced forms of sarcasm. Consider the sentence '*With a sense of humor like that, you could make a living as a garbage man anywhere in the country.*[1]' The speaker makes a subtle, contemptuous remark about the sense of humor of the listener. However, absence of sentiment words makes the sarcasm in this sentence difficult to capture as features for a classifier.

In this paper, we explore use of word embeddings to capture context incongruity in the absence of sentiment words. The intuition is that **word vector-based similarity/discordance is indicative of semantic similarity which in turn is a handle for context incongruity**. In the case of the 'sense of humor' example above, the words 'sense of humor' and 'garbage man' are semantically dissimilar and their presence together in the sentence provides a clue to sarcasm. Hence, our set of features based on word embeddings aim to capture such semantic similarity/discordance. Since such semantic similarity is but one of the components of context incongruity **and** since existing feature sets rely on sentiment-based features to capture context incongruity, it is imperative that the two be combined for sarcasm detection. Thus, our paper deals with the question:

Can word embedding-based features when augmented to features reported in prior work improve the performance of sarcasm detection?

To the best of our knowledge, this is the first attempt that uses word embedding-based features to detect sarcasm. In this respect, the paper makes a simple increment to state-of-the-art but opens up a new direction in sarcasm detection research. We establish our hypothesis in case of four past works and four types of word embeddings, to show that the benefit of using word embedding-based features holds across multiple feature sets and word embeddings.

2 Motivation

In our literature survey of sarcasm detection (Joshi et al., 2016), we observe that a popular trend is semi-supervised extraction of patterns with implicit sentiment. One such work is by Riloff et al. (2013) who give a bootstrapping algorithm that discovers a set of positive verbs and

[1]All examples in this paper are actual instances from our dataset.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1006–1011,
Austin, Texas, November 1-5, 2016.

negative/undesirable situations. However, this simplification (of representing sarcasm merely as positive verbs followed by negative situation) may not capture difficult forms of context incongruity. Consider the sarcastic sentence 'A woman needs a man like a fish needs bicycle'[2]. The sarcasm in this sentence is understood from the fact that a fish does not need bicycle - and hence, the sentence ridicules the target 'a man'. However, this sentence does not contain any sentiment-bearing word. Existing sarcasm detection systems relying on sentiment incongruity (as in the case of our past work reported as Joshi et al. (2015)) may not work well in such cases of sarcasm.

To address this, we use semantic similarity as a handle to context incongruity. To do so, we use word vector similarity scores. Consider similarity scores (as given by Word2Vec) between two pairs of words in the sentence above:

similarity(man,woman) = 0.766
similarity(fish,bicycle) = 0.131

Words in one part of this sentence ('man' and 'woman') are lot more similar than words in another part of the sentence ('fish' and 'bicycle'). This semantic discordance can be a clue to presence of context incongruity. Hence, we propose features based on similarity scores between word embeddings of words in a sentence. In general, we wish to capture the most similar and most dissimilar word pairs in the sentence, and use their scores as features for sarcasm detection.

3 Background: Features from prior work

We augment our word embedding-based features to the following four feature sets that have been reported:

1. **Liebrecht et al. (2013)**: They consider unigrams, bigrams and trigrams as features.
2. **González-Ibánez et al. (2011a)**: They propose two sets of features: unigrams and dictionary-based. The latter are words from a lexical resource called LIWC. We use words from LIWC that have been annotated as emotion and psychological process words, as described in the original paper.
3. **Buschmeier et al. (2014)**: In addition to unigrams, they propose features such as: (a) Hyperbole (captured by three positive or negative words in a row), (b) Quotation marks and ellipsis, (c) Positive/Negative Sentiment words followed by an exclamation mark or question mark, (d) Positive/Negative Sentiment Scores followed by ellipsis (represented by a '...'), (e) Punctuation, (f) Interjections, and (g) Laughter expressions.
4. **Joshi et al. (2015)**: In addition to unigrams, they use features based on implicit and explicit incongruity. Implicit incongruity features are patterns with implicit sentiment as extracted in a pre-processing step. Explicit incongruity features consist of number of sentiment flips, length of positive and negative subsequences and lexical polarity.

4 Word Embedding-based Features

In this section, we now describe our word embedding-based features. We reiterate that these features will be augmented to features from prior works (described in Section 3).

As stated in Section 2, our word embedding-based features are based on similarity scores between word embeddings. The similarity score is the cosine similarity between vectors of two words. To illustrate our features, we use our example '*A woman needs a man like a fish needs a bicycle*'. The scores for all pairs of words in this sentence are given in Table 1.

	man	**woman**	**fish**	**needs**	**bicycle**
man	-	**0.766**	**0.151**	**0.078**	**0.229**
woman	0.766	-	0.084	0.060	0.229
fish	0.151	0.084	-	0.022	0.130
needs	0.078	0.060	0.022	-	0.060
bicycle	0.229	0.229	0.130	0.060	-

Table 1: Similarity scores for all pairs of content words in 'A woman needs a man like a fish needs bicycle'

Using these similarity scores, we compute two sets of features:

1. **Unweighted similarity features (S)**: We first compute similarity scores for all pairs of words (except stop words). We then return four feature values per sentence.[3]:
   - Maximum score of most *similar* word pair
   - Minimum score of most *similar* word pair
   - Maximum score of most *dissimilar* word pair
   - Minimum score of most *dissimilar* word pair

   For example, in case of the first feature, we consider the most similar word to every word in the sentence, and the corresponding similarity scores. These most similar word scores for each word are indicated in bold in Table 1. Thus, the first feature in case of our example would have the value 0.766 derived from the man-woman pair and the second feature would take the value 0.078 due to the needs-man pair. The other features are computed in a similar manner.

[2]This quote is attributed to Irina Dunn, an Australian writer (https://en.wikipedia.org/wiki/Irina_Dunn

[3]These feature values consider all words in the sentence, *i.e.*, the 'maximum' is computed over all words

2. **Distance-weighted similarity features (WS)**: Like in the previous case, we first compute similarity scores for all pairs of words (excluding stop-words). For all similarity scores, we divide them by square of distance between the two words. Thus, the similarity between terms that are close in the sentence is weighted higher than terms which are distant from one another. Thus, for all possible word pairs, we compute four features:

   - Maximum distance-weighted score of most *similar* word pair
   - Minimum distance-weighted score of most *similar* word pair
   - Maximum distance-weighted score of most *dissimilar* word pair
   - Minimum distance-weighted score of most *dissimilar* word pair

   These are computed similar to unweighted similarity features.

5 Experiment Setup

We create a dataset consisting of quotes on GoodReads [4]. GoodReads describes itself as '*the world's largest site for readers and book recommendations.*' The website also allows users to post quotes from books. These quotes are snippets from books labeled by the user with tags of their choice. We download quotes with the tag 'sarcastic' as sarcastic quotes, and the ones with 'philosophy' as non-sarcastic quotes. Our labels are based on these tags given by users. We ensure that no quote has both these tags. This results in a dataset of 3629 quotes out of which 759 are labeled as sarcastic. This skew is similar to skews observed in datasets on which sarcasm detection experiments have been reported in the past (Riloff et al., 2013).

We report five-fold cross-validation results on the above dataset. We use SVM_{perf} by Joachims (2006) with c as 20, w as 3, and loss function as F-score optimization. This allows SVM to be learned while optimizing the F-score.

As described above, we compare features given in prior work alongside the augmented versions. This means that for each of the four papers, we experiment with four configurations:

1. Features given in paper X
2. Features given in paper X + unweighted similarity features (S)
3. Features given in paper X + weighted similarity features (WS)
4. Features given in paper X + S+WS (*i.e.*, weighted and unweighted similarity features)

Features	P	R	F
Baseline			
Unigrams	67.2	78.8	72.53
S	64.6	75.2	69.49
WS	67.6	51.2	58.26
Both	67	52.8	59.05

Table 2: Performance of unigrams versus our similarity-based features using embeddings from Word2Vec

We experiment with four types of word embeddings:

1. **LSA**: This approach was reported in Landauer and Dumais (1997). We use pre-trained word embeddings based on LSA[5]. The vocabulary size is 100,000.
2. **GloVe**: We use pre-trained vectors avaiable from the GloVe project[6]. The vocabulary size in this case is 2,195,904.
3. **Dependency Weights**: We use pre-trained vectors[7] weighted using dependency distance, as given in Levy and Goldberg (2014). The vocabulary size is 174,015.
4. **Word2Vec**: use pre-trained Google word vectors. These were trained using Word2Vec tool [8] on the Google News corpus. The vocabulary size for Word2Vec is 3,000,000. To interact with these pre-trained vectors, as well as compute various features, we use gensim library (Řehůřek and Sojka, 2010).

To interact with the first three pre-trained vectors, we use scikit library (Pedregosa et al., 2011).

6 Results

Table 2 shows performance of sarcasm detection when our word embedding-based features are used on their own *i.e*, not as augmented features. The embedding in this case is Word2Vec. The four rows show baseline sets of features: unigrams, unweighted similarity using word embeddings (S), weighted similarity using word embeddings (WS) and both (*i.e.*, unweighted plus weighted similarities using word embeddings). Using only unigrams as features gives a F-score of 72.53%, while only unweighted and weighted features gives F-score of 69.49% and 58.26% respectively. This **validates our intuition**

Table 3: Performance obtained on augmenting word embedding features to features from four prior works, for four word embeddings; L: Liebrecht et al. (2013), G: González-Ibánez et al. (2011a), B: Buschmeier et al. (2014) , J: Joshi et al. (2015)

that word embedding-based features alone are not sufficient, and should be augmented with other features.

Following this, we show performance using features presented in four prior works: Buschmeier et al. (2014), Liebrecht et al. (2013), Joshi et al. (2015) and González-Ibánez et al. (2011a), and compare them with augmented versions in Table 3.

Table 3 shows results for four kinds of word embeddings. All entries in the tables are **higher than the simple unigrams baseline**, *i.e.*, F-score for each of the four is higher than unigrams - highlighting that these are better features for sarcasm detection than simple unigrams. Values in bold indicate the best F-score for a given prior work-embedding type combination. In case of Liebrecht et al. (2013) for Word2Vec, the overall improvement in F-score is 4%. Precision increases by 8% while recall remains nearly unchanged. For features given in González-Ibánez et al. (2011a), there is a negligible degradation of 0.91% when word embedding-based features based on Word2Vec are used. For Buschmeier et al. (2014) for Word2Vec, we observe an improvement in F-score from 76.61% to 78.09%. Precision remains nearly unchanged while recall increases. In case of Joshi et al. (2015) and Word2Vec, we observe a slight improvement of 0.20% when unweighted (S) features are used. This shows that word embedding-based features are useful, across four past works for Word2Vec.

Table 3 also shows that the improvement holds across the four word embedding types as well. The maximum improvement is observed in case of Liebrecht et al. (2013). It is around 4% in case of LSA, 5% in case of GloVe, 6% in case of Dependency weight-based and 4% in case of Word2Vec. These improvements are not directly comparable because the four embeddings have different vocabularies (since they are trained on different datasets) and vocabulary sizes, their results cannot be directly compared.

Therefore, we take an intersection of the vocabulary (*i.e.*, the subset of words present in all four embeddings) and repeat all our experiments using these intersection files. The vocabulary size of these intersection files (for all four embeddings) is 60,252. Table 4 shows the average increase in F-score when a given word embedding and a word embedding-based feature is used, with the intersection file as described above. These gain values are lower than in the previous case. This is because these are the values in case of the intersection versions - which are subsets of the complete embeddings. Each gain value is averaged over the four prior works. Thus, when unweighted similarity (+S) based features computed using LSA are augmented to features from prior work, an average increment of 0.835% is obtained over the four prior works. The values allow us to compare the benefit of using these four kinds of embeddings. In case of unweighted similarity-based features, dependency-based weights give the maximum gain (0.978%). In case of weighted similarity-based features and '+S+WS', Word2Vec gives the maximum gain (1.411%). Table 5 averages these values over the

	Word2Vec	LSA	GloVe	Dep. Wt.
+S	0.835	0.86	0.918	**0.978**
+WS	**1.411**	0.255	0.192	1.372
+S+WS	**1.182**	0.24	0.845	0.795

Table 4: Average gain in F-Scores obtained by using intersection of the four word embeddings, for three word embedding feature-types, augmented to four prior works; Dep. Wt. indicates vectors learned from dependency-based weights

Word Embedding	Average F-score Gain
LSA	0.452
Glove	0.651
Dependency	1.048
Word2Vec	1.143

Table 5: Average gain in F-scores for the four types of word embeddings; These values are computed for a subset of these embeddings consisting of words common to all four

three types of word embedding-based features. Using Dependency-based and Word2Vec embeddings results in a higher improvement in F-score (1.048% and 1.143% respectively) as compared to others.

7 Error Analysis

Some categories of errors made by our system are:

1. **Embedding issues due to incorrect senses**: Because words may have multiple senses, some embeddings lead to error, as in '*Great. Relationship advice from one of America's most wanted.*'.
2. **Contextual sarcasm**: Consider the sarcastic quote '*Oh, and I suppose the apple ate the cheese*'. The similarity score between 'apple' and 'cheese' is 0.4119. This comes up as the maximum similar pair. The most dissimilar pair is 'suppose' and 'apple' with similarity score of 0.1414. The sarcasm in this sentence can be understood only in context of the complete conversation that it is a part of.
3. **Metaphors in non-sarcastic text**: Figurative language may compare concepts that are not directly related but still have low similarity. Consider the non-sarcastic quote '*Oh my love, I like to vanish in you like a ripple vanishes in an ocean - slowly, silently and endlessly*'. Our system incorrectly predicts this as sarcastic.

8 Related Work

Early sarcasm detection research focused on speech (Tepperman et al., 2006) and lexical features (Kreuz and Caucci, 2007). Several other features have been proposed (Kreuz and Caucci, 2007; Joshi et al., 2015; Khattri et al., 2015; Liebrecht et al., 2013; González-Ibánez et al., 2011a; Rakov and Rosenberg, 2013; Wallace, 2015; Wallace et al., 2014; Veale and Hao, 2010; González-Ibánez et al., 2011b; Reyes et al., 2012). Of particular relevance to our work are papers that aim to first extract patterns relevant to sarcasm detection. Davidov et al. (2010) use a semi-supervised approach that extracts sentiment-bearing patterns for sarcasm detection. Joshi et al. (2015) extract phrases corresponding to implicit incongruity i.e. the situation where sentiment is expressed without use of sentiment words. Riloff et al. (2013) describe a bootstrapping algorithm that iteratively discovers a set of positive verbs and negative situation phrases, which are later used in a sarcasm detection algorithm. Tsur et al. (2010) also perform semi-supervised extraction of patterns for sarcasm detection. The only prior work which uses word embeddings for a related task of sarcasm detection is by Ghosh et al. (2015). They model sarcasm detection as a word sense disambiguation task, and use embeddings to identify whether a word is used in the sarcastic or non-sarcastic sense. Two sense vectors for every word are created: one for literal sense and one for sarcastic sense. The final sense is determined based on the similarity of these sense vectors with the sentence vector.

9 Conclusion

This paper shows the benefit of features based on word embedding for sarcasm detection. We experiment with four past works in sarcasm detection, where we augment our word embedding-based features to their sets of features. Our features use the similarity score values returned by word embeddings, and are of two categories: similarity-based (where we consider maximum/minimum similarity score of most similar/dissimilar word pair respectively), and weighted similarity-based (where we weight the maximum/minimum similarity scores of most similar/dissimilar word pairs with the linear distance between the two words in the sentence). We experiment with four kinds of word embeddings: LSA, GloVe, Dependency-based and Word2Vec. In case of Word2Vec, for three of these past feature sets to which our features were augmented, we observe an improvement in F-score of at most 5%. Similar improvements are observed in case of other word embeddings. A comparison of the four embeddings shows that Word2Vec and dependency weight-based features outperform LSA and GloVe.

This work opens up avenues for use of word embeddings for sarcasm classification. Our word embedding-based features may work better if the similarity scores are computed for a subset of words in the sentence, or using weighting based on syntactic distance instead of linear distance as in the case of our weighted similarity-based features.

Weakly Supervised Tweet Stance Classification by Relational Bootstrapping

Javid Ebrahimi and **Dejing Dou** and **Daniel Lowd**
Department of Computer and Information Science, University of Oregon
Eugene, Oregon 97403, USA
{javid,dou,lowd}@cs.uoregon.edu

Abstract

Supervised stance classification, in such domains as Congressional debates and online forums, has been a topic of interest in the past decade. Approaches have evolved from text classification to structured output prediction, including collective classification and sequence labeling. In this work, we investigate collective classification of stances on Twitter, using hinge-loss Markov random fields (HL-MRFs). Given the graph of all posts, users, and their relationships, we constrain the predicted post labels and latent user labels to correspond with the network structure. We focus on a weakly supervised setting, in which only a small set of hashtags or phrases is labeled. Using our relational approach, we are able to go beyond the stance-indicative patterns and harvest more stance-indicative tweets, which can also be used to train any linear text classifier when the network structure is not available or is costly.

1 Introduction

Stance classification is the task of determining from text whether the author of the text is in favor of, against, or neutral towards a target of interest. This is an interesting task to study on social networks due to the abundance of personalized and opinionated language. Studying stance classification can be beneficial in identifying electoral issues and understanding how public stance is shaped (Mohammad et al., 2015).

Twitter provides a wealth of information: public tweets by individuals, their profile information, whom they follow, and more. Exploiting all these pieces of information, in addition to the text, could help build better NLP systems. Examples of this approach include user preference modeling (Li et al., 2014), stance classification (Rajadesingan and Liu, 2014), and geolocation identification (Jurgens, 2013; Rahimi et al., 2015). For stance classification, knowing the author's past posting behavior, or her friends' stances on issues, could improve the stance classifier. These are inherently structured problems, and they demand structured solutions, such as Statistical Relational Learning (SRL) (Getoor, 2007). In this paper, we use hinge-loss Markov random fields (HL-MRFs) (Bach et al., 2015), a recent development in the SRL community.

SemEval 2016 Task 6 organizers (Mohammad et al., 2016) released a dataset with Donald Trump as the target, without stance annotation. The goal of the task was to evaluate stance classification systems, which used minimal labeling on phrases. This scenario is becoming more and more relevant due to the vast amount of data and ever-changing nature of the language on social media. This is critical in applications in which a timely detection is highly desired, such as violence detection (Cano Basave et al., 2013) and disaster situations.

Our work is the first to use SRL for stance classification on Twitter. We formulate the weakly supervised stance classification problem as a bi-type collective classification problem: We start from a small set of stance-indicative patterns and label the tweets as positive and negative, accordingly. Then, our relational learner uses these noisy-labeled tweets, as well as the network structure, to classify the stance

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1012–1017,
Austin, Texas, November 1-5, 2016.

of other tweets and authors. Our goal will be to constrain pairs of similar tweets, pairs of tweets and their authors, and pairs of neighboring users to have similar labels. We do this through hinge-loss feature functions that encode our background knowledge about the domain: (1) A person is pro/against Trump if she writes a tweet with such stance; (2) Friends in a social network often agree on their stance toward Trump; (3) similar tweets express similar stances.

2 Related Work

Stance classification is related to sentiment classification with a major difference that the target of interest may not be explicitly mentioned in the text and it may not be the target of opinion in the text (Mohammad et al., 2016). Previous work has focused on Congressional debates (Thomas et al., 2006; Yessenalina et al., 2010), company-internal discussions (Agrawal et al., 2003), and debates in online forums (Anand et al., 2011; Somasundaran and Wiebe, 2010). Stance classification has newly been posed as structured output prediction. For example, citation structure (Burfoot et al., 2011) or rebuttal links (Walker et al., 2012) are used as extra information to model agreements or disagreements in debate posts and to infer their labels. Arguments and counter-arguments occur in sequences; Hasan and Ng (2014) used this observation and posed stance classification in debate forums as a sequence labeling task, and used a global inference method to classify the posts.

Sridhar et al. (2015) use HL-MRFs to collectively classify stance in online debate forums. We address a weakly supervised problem, which makes our approach different as we do not rely on local text classifiers. Rajadesingan et al. (2014) propose a retweet-based label propagation method which starts from a set of known opinionated users and labels the tweets posted by the people who were in the retweet network.

3 Stance Classification on Twitter

3.1 Markov Random Fields

Markov random fields (MRFs) are widely used in machine learning and statistics. Discriminative Markov random fields such as conditional random fields (Lafferty et al., 2001) are defined by a joint distribution over random variables $Y_1, ..., Y_m$ conditioned on $X_1, ..., X_n$ that is specified by a vector of d real-valued potential functions $\phi_l(\boldsymbol{y}, \boldsymbol{x})$ for $l = 1, ..., d$, and a parameter (weight) vector $\boldsymbol{\theta} \in \mathbb{R}^d$:

$$\mathrm{P}(\boldsymbol{y}|\boldsymbol{x};\boldsymbol{\theta}) = \frac{1}{Z(\boldsymbol{\theta}, \boldsymbol{x})} \exp\Big(\langle \boldsymbol{\theta}, \phi(\boldsymbol{y}, \boldsymbol{x}) \rangle\Big)$$

where $\langle \boldsymbol{\theta}, \phi(\boldsymbol{y}, \boldsymbol{x}) \rangle$ denotes the dot product of the parameters and the potential functions, and $Z(\boldsymbol{\theta}, \boldsymbol{x})$ is the partition function.

3.2 HL-MRFs for Tweet Stance Classification

Finding the *maximum a posteriori* (MAP) state is a difficult discrete optimization problem and, in general, is NP-hard. One particular class of MRFs that allows for convex inference is hinge-loss Markov random fields (HL-MRFs) (Bach et al., 2015). In this graphical model, each potential function is a hinge-loss function, and instead of discrete variables, MAP inference is performed over relaxed continuous variables with domain $[0, 1]^n$. These hinge-loss functions, multiplied by the corresponding model parameters (weights), act as penalizers for soft linear constraints in the graphical model.

Consider $\boldsymbol{t}_i$, $\boldsymbol{u}_j$ as the random variables denoting the ith tweet and the jth user. The potential function, $\phi(\boldsymbol{t}_i, \boldsymbol{u}_j)$, relating a user and her tweet is as follows,

$$\max(0, t_{ik} - u_{jk}) \tag{1}$$

where t_{ik} and u_{jk} denote the respective assertions that $\boldsymbol{t}_i$ has label k, and $\boldsymbol{u}_j$ has label k . The function captures the distance between the label for a user and her tweet. In other words, this function measures the penalty for dissimilar labels for a user and her tweet.

For users who are "friends" (i.e., who "follow" each other on Twitter), we add this potential function,

$$\max(0, u_{ik} - u_{jk}) \tag{2}$$

and for the tweet-tweet relations,

$$s_{ij} \max(0, t_{ik} - t_{jk}) \tag{3}$$

where s_{ij} measures the similarity between two tweets. This scalar helps penalize violations in proportion to the similarity between the tweets. For the similarity measure, we simply used the cosine similarity between the n-gram (1-4-gram) representation of the tweets and set 0.7 as the cutoff threshold.

Finally, two hard linear constraints are added, to ensure that $\boldsymbol{t}_i$, and $\boldsymbol{u}_j$ are each assigned a single label, or in other words, are fractionally assigned labels with weights that sum to one.

$$\sum_k t_{ik} = 1 \ , \ \sum_k u_{ik} = 1 \tag{4}$$

Weight learning is performed by an improved structured voted perceptron (Lowd and Domingos, 2007), at every iteration of which we estimate the labels of the users by hard EM. This formulation can work in weakly supervised settings, because the constraints simply dictate similar/neighboring nodes to have similar labels.

In the language of Probabilistic Soft Logic (PSL) (Bach et al., 2015), the constraints can be defined by the following rules:

PSL Rules:

tweet-label(T, L) $\wedge$ tweet-user(T, U) $\Rightarrow$ user-label(U, L)
user-label(U_1, L) $\wedge$ friend(U_1, U_2) $\Rightarrow$ user-label(U_2, L)
tweet-label(T_1, L) $\wedge$ similar(T_1, T_2) $\Rightarrow$ tweet-label(T_2, L)
PredicateConstraint.Functional , on : user-label
PredicateConstraint.Functional , on : tweet-label

Our post-similarity constraint implementation is different from the original PSL implementation due to the *multiplicative* similarity scalar[1].

This work is a first step toward relational stance classification on Twitter. Incorporating other relational features, such as mention networks and retweet networks can potentially improve our results. Similarly, employing textual entailment techniques for tweet similarity will most probably improve our results.

4 Experiments and Results

4.1 Data

SemEval-2016 Task 6.b (Mohammad et al., 2016) provided 78,000+ tweets associated with "Donald Trump". The protocol of the task only allowed minimal manual labeling, i.e. "tweets or sentences that are manually labeled for stance" were not allowed, but "manually labeling a handful of hashtags" was permitted. Additionally, using Twitter's API, we collected each user's follower list and their profile information. This often requires a few queries per user. We only considered the tweets which contain no URL, are not retweets, and have at most three hashtags and three mentions.

[1]The original implementation would result in the function, max(0, $t_{ik} + s_{ij} - t_{jk} - 1$), which is less intuitive than ours.

Algorithm Relational Bootstrapping

Input:
Unlabeled pairs of tweets and authors ($\mathbf{t}_i$, $\mathbf{u}_i$).
Friendship pairs ($\mathbf{u}_i$, $\mathbf{u}_j$) between users.
Similarity triplets ($\mathbf{t}_i$, $\mathbf{t}_j$, s_{ij}) between tweets.
Stance-indicative regexes **R**.
// Create an initial dataset.
Training set **X** = $\{\}$.
Harvest positive and negative tweets based on **R**.
Add the harvested tweets to **X**.
// Augment the dataset by the relational classifier.
Learning & inference over $P(\mathbf{U}, \mathbf{T}|\mathbf{X})$ by our HL-MRF.
Add some classified tweets to training set: **X** = **X** + **T**.
Output: X.

Table 1: Patterns to collect pro-Trump and anti-Trump tweets.

This task's goal was to test stance towards the target in 707 tweets. The authors in the test set are not identified, which prevents us from pursuing a fully relational approach. Thus, we adopt a two-phase approach: First, we predict the stance of the training tweets using our HL-MRF. Second, we use the labeled instances as training for a linear text classifier. This dataset-augmenting procedure is summarized in the Algorithm *Relational Bootstrapping*.

4.2 Experimental Setup

We pick the pro-Trump and anti-Trump indicative regular expressions and hashtags, which are shown in Table 1. Tweets that have at least one positive or one negative pattern, and do not have both positive and negative patterns, are considered as our initial positive and negative instances. This gives us a dataset with noisy labels; for example, the tweet "*his #MakeAmericaGreatAgain #Tag is a bummer.*" is against Donald Trump, incorrectly labeled favorable. A quantitative analysis of the impact of noise, and the goodness of initial patterns, can be pursued in the future through a supervised approach.

Tweets in the "neither" class range from news about the target of interest, to tweets totally irrele-

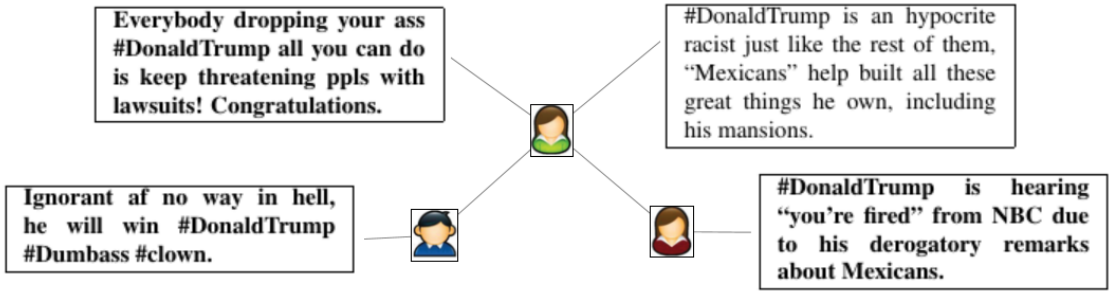

Figure 1: An example of the output of our relational bootstrapper. A small excerpt of the network, consisting of three users, four tweets and two friendship links. The tweet in regular type face is labeled as anti-Trump in the first phase, because of the word "racist" in the tweet. The other tweets, which are in boldface, are found through SRL harvesting, and are automatically labeled as anti-Trump tweets correctly.

vant to him. This makes it difficult to collect neutral tweets, and we will classify tweets to be in that class based on a heuristic described in the next subsection.

Given the limited number of seeds, we need to collect more training instances to build a stance classifier. Because of the original noise in the labels and the imposed fragmentary view of data, *self-learning* would perform poorly. Instead, we augment the dataset with tweets that our relational model classifies as positive or negative with a minimum confidence (class value 0.52 for pro-Trump and 0.56 for anti-Trump). The hyper-parameters were found through experimenting on a development set, which was the stance-annotated dataset of SemEval Task 6.a. The targets of that dataset include Hillary Clinton, Abortion, Climate Change, and Athesim. Since there are more anti-Trump tweets than pro-Trump (Mohammad et al., 2016), for our grid search we prefer a higher confidence threshold for the anti-Trump class, making it harder for the class bias to adversely impact the quality of harvested tweets. We also exclude the tweets that were sent by a user with no friends in the network. An example which showcases relational harvesting of tweets can be seen in Figure 1, wherein given the evidence, some of which is shown, three new tweets are found.

4.3 Classification

We convert the tweets to lowercase, and we remove stopwords and punctuation marks. For tweet classification, we use a linear-kernel SVM, which has proven to be effective for text classification and robust in high-dimensional spaces. We use the implementation of Pedregosa et al. (2011), and we employ the features below, which are normalized to unit length after conjoinment.

No. total tweets	21,000
No. initial pro tweets	1,100
No. initial anti tweets	1,490
No. relational-harvested pro tweets	960
No. relational-harvested anti tweets	780
No. edges in tweet similarity network	7,400
No. edges in friend network	131,000

Table 2: Statistics of the data

N-grams: `tf-idf` of binary representation of word n-grams (1–4 gram) and character n-grams (2–6 gram). After normalization, we only pick the top 5% most frequent grams.

Lexicon: Binary indicators of positive-emotion and negative-emotion words in LIWC2007 categories (Tausczik and Pennebaker, 2010).

Sentiment: Sentiment distribution, based on a sentiment analyzer for tweets, VADER (Hutto and Gilbert, 2014).

Table 3 demonstrates the results of stance classification. The metrics used are the macro-average of the F1-score for favor, against, and average of these two. The best competing system for the task used a deep convolutional neural network to train on pro and against instances, which were collected through linguistic patterns. At test time, they randomly assigned the instances, about which the classifier was less confident, to the "neither" class. Another base-

Method	F_{favor}	$F_{against}$	F_{avg}
SVM-ngrams-comb	18.42	38.45	28.43
best-system	**57.39**	55.17	56.28
SVM-IN	30.43	59.52	44.97
SVM-NB	47.67	57.53	52.60
SVM-RB	52.14	59.26	55.70
SVM-RB-N	54.27	**60.77**	**57.52**

Table 3: Evaluation on SemEval-2016 Task 6.b.

line is an SVM, trained on another stance classification dataset (Task 6.a), using a combination of n-gram features (SVM-ngrams-comb).

SVM-IN is trained on the initial dataset created by linguistic patterns, SVM-RB is trained on the relational-augmented dataset, and SVM-NB is a naive bootstrapping method that simply adds more instances, from the users in the initial dataset, with the same label as their tweets in the initial dataset, and for those who have both positive and negative tweets, does not add more of their tweets.

At test time, we could predict an instance to be of the "neither" class if it contains none of our stance-indicative patterns, nor any of the top 100 word grams that have the highest `tf-idf` weight in the training set. SVM-RB-N follows this heuristic for the "neither" class, while SVM-RB ignores this class altogether.

4.4 Demographics of the Users

As an application of stance classification, we analyze the demographics of the users based on their profile information. Due to the demographics of Twitter users, one has to be cautious about drawing generalizing conclusions from the analysis of Twitter data. We pick a balanced set of 1000 users with the highest degree of membership to any of the two groups. In Figure 2, we plot states represented by at least 50 users in the dataset. We can see that the figure correlates with US presidential electoral politics; supporters of Trump dominate Texas, and they are in the clear minority in California.

5 Conclusions and Future Work

In this paper, we propose a weakly supervised stance classifier that leverages the power of relational learning to incorporate extra features that are generally present on Twitter and other social media, i.e., authorship and friendship information. HL-MRFs enables us to use a set of hard and soft linear constraints to employ both the noisy-labeled instances and background knowledge in the form of soft constraints for stance classification on Twitter.

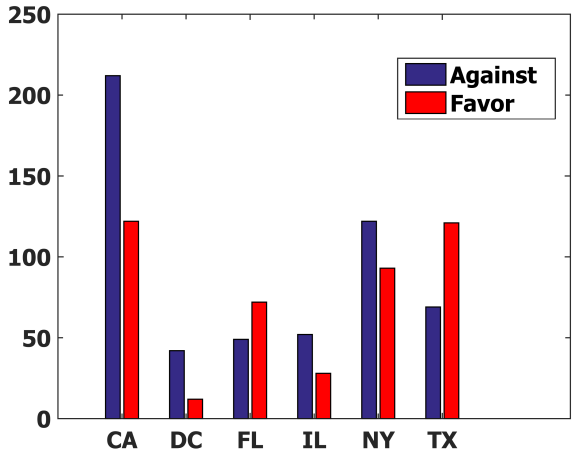

Figure 2: Distribution of Twitter users in a number of states.

While the relational learner tends to smooth out the incorrectly labeled instances, this model still suffers from noise in the labels. Labeling features and enforcing model expectation can be used to alleviate the impact of noise; currently, the initial linguistic patterns act as hard constraints for the label of the tweets, which can be relaxed by techniques such as generalized expectation (Druck et al., 2008).

The SemEval dataset has only one target of interest, Donald Trump. But the target of the opinion in the tweet may not necessarily be him, but related targets, such as Hillary Clinton and Ted Cruz. Thus, automatic detection of targets and inferring the stance towards all of the targets is the next step toward creating a practical weakly-supervised stance classifier.

The Gun Violence Database: A new task and data set for NLP

Ellie Pavlick[1] **Heng Ji**[2] **Xiaoman Pan**[2] **Chris Callison-Burch**[1]
[1]Computer and Information Science Department, University of Pennsylvania
[2]Computer Science Department, Rensselaer Polytechnic Institute

Abstract

We argue that NLP researchers are especially well-positioned to contribute to the national discussion about gun violence. Reasoning about the causes and outcomes of gun violence is typically dominated by politics and emotion, and data-driven research on the topic is stymied by a shortage of data and a lack of federal funding. However, data abounds in the form of unstructured text from news articles across the country. This is an ideal application of NLP technologies, such as relation extraction, coreference resolution, and event detection. We introduce a new and growing dataset, the Gun Violence Database, in order to facilitate the adaptation of current NLP technologies to the domain of gun violence, thus enabling better social science research on this important and under-resourced problem.

1 Introduction

The field of natural language processing often touts its mission as harnessing the information contained in human language: taking unstructured data in the form of speech and text, and transforming it into information that can be searched, categorized, and reasoned about. This is an ambitious goal, and the current state-of-the-art of language technology has made impressive strides towards understanding "who did what to whom, when, where, how, and why" (Kao and Poteet, 2007). Advances in NLP have enabled us to read news in real time (Petrović et al., 2010), identify the key players (Ruppenhofer et al., 2009), recognize the relationships between them (Riedel et al., 2013), summarize the new information (Wang et al., 2016), update central databases (Singhal, 2012), and use those databases to answer questions about the world (Berant et al., 2013).

Although these technological achievements are profound, often times we as researchers apply them to somewhat trivial settings like learning about the latest Hollywood divorces (Wijaya et al., 2015) or learning silly facts about the world, like that ⟨*white suites*, *will never go out of*, *style*⟩ (Fader et al., 2011). In this paper, we call the attention of the NLP community to one particularly good use case of our current technology, which could have profound policy implications: gun violence research.

Gun violence is an undeniable problem in the United States, but its causes are poorly understood, and attempts to reason about solutions are often marred by emotions and political bias. Research into the factors that cause and prevent gun violence is limited by the fact that data collection is expensive, and political agendas have all but eliminated funding on the topic. However, in the form of unstructured natural language published daily by newspapers across the country, data abounds. We argue that this is the exact type of information that NLP is designed to organize, and the positive social impact of doing so would be substantial. We introduce the Gun Violence Database (GVDB), a new dataset of gun violence articles paired with NLP annotations. Our hope is that the GVDB will facilitate the adaptation of core NLP technologies to the domain of gun violence. In turn, we believe these NLP technologies can help overcome the data vacuum that is currently preventing productive discussion about gun violence and its possible solutions.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1018–1024,
Austin, Texas, November 1-5, 2016.

What we have:	Daily reports of gun violence, published as free text by local newspapers and TV stations.
What we need:	Structured, queryable database with one record per incident.

Information Retrieval: Find articles about gun violence.
Event Detection: Identify precise incident being reported.
Temporal Annotation: Pinpoint precise time of the event.
NER: Extract key locations and participants from the event.
Semantic Role Labeling: Relate participants to their role in the incident (e.g. shooter, victim).
With-document Coref: Resolve mentions to consistently model each participant throughout the event.
Semantic Parsing: Extract precise, detailed information about participants, e.g. race, age, and gender.
Cross-document Coref: Recognize mentions of the same shooter or victim appearing in different articles.
Event Coref: Identify articles reporting the same event, and resolve to a single database entry.

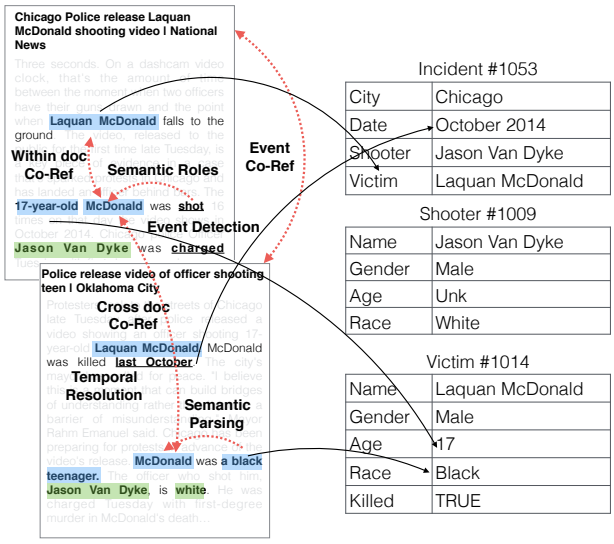

Figure 1: Turning daily news reports into usable data for public health and social science researchers is a textbook application of NLP technologies, and one that can have meaningful social impact.

2 Gun Violence's Data Problem

It is not difficult to motivate why gun violence is an important problem for research. Gun violence causes approximately 34,000 deaths in the US every year and more than twice as many injuries (FICAP, 2006), with violence especially high among young people and racial minorities (CDC, 2013).

The magnitude of the gun violence problem, the inherent gravity of the topic, and that fact that it inevitably leads to discussion of race, personal safety, and constitutional rights, makes the topic highly emotional and politically charged. Research into such hot-blooded topics stands to benefit immensely from data. In the past decade, machine learning researchers have championed data-driven decision making in place of oft-fallible human intuition. This approach has revolutionized the way we design and evaluate the effectiveness of business practices (Brynjolfsson et al., 2011; Kohavi et al., 2009), advertisements (Breese et al., 1998), and political campaigns (Issenberg, 2013). Gun violence policy should be no different. The problem is that researchers lack the data they need to answer the questions they want to ask. There is no single database[1] of gun violence incidents in the US, and the data that is available is mostly aggregated at the state level. Without locally-aggregated data, it is impossible to conduct meaningful studies of how firearm injury varies by community, a key step toward designing good policies for prevention (FICAP, 2006). However, for the past 25 years, research in this area has been, in the best case, massively underfunded (Roth et al., 1993) and in the worst case, actively blocked by federal legislation (Kassirer, 1995; Frankel, 2015; Bertrand, 2015). As a result, federal resources for gun violence research are orders of magnitude lower than is warranted (Branas et al., 2005), and there is no near-term likelihood of a federally-funded effort to collect detailed datasets to facilitate gun violence research.

Why NLP? Local newspapers and television stations report daily on gun injuries and fatalities. Many of these stories never make national news, but they represent precisely the kind of high-resolution data that epidemiologists need. The details of these reports could transform gun violence research if they were in a structured database, rather than spread

[1]There are 13 national data systems in the U.S., managed by separate federal agencies. The National Violent Death Registry System, arguably the most organized effort, receives data from only 16 states. Most large-scale epidemiological studies sample information from only 100 Emergency Departments.

across the text of thousands of web pages.

Replacing expensive, manual data entry with automated processing is exactly the type of problem that NLP is made to solve. In fact, the recent application of NLP tools to social science problems has generated a flurry of exciting and encouraging results. NLP has made novel contributions to the way scientists measure everything from income (Preoctiuc-Pietro et al., 2015b) to mental health (Preoctiuc-Pietro et al., 2015a; Schwartz et al., 2016; Choudhury et al., 2016), disease (Santillana et al., 2015; Ireland et al., 2015; Eichstaedt et al., 2015), and the quality of patient care (Nakhasi et al., 2016; Ranard et al., 2016).

Text mining has promise for the study of gun violence, too (Bushman et al., 2016). However, most questions about gun violence are not easily answered using shallow analyses like topic models or word clusters. Epidemiologists want to know, for example, does gun ownership lead to increases in gun violence? Or, is there evidence of contagion in suicides, and if so, does the style of reporting on suicides affect the likelihood that others will commit suicide after the initial event? Answering these questions requires extracting precise information from text: identifying entities, their actions, and their attributes specifically and reliably.

We believe this level of depth is well within the reach of current NLP technology. The state-of-the-art tools that NLP researchers have been building and fine-tuning for decades are an ideal fit for the problem described. Nearly every step of this process, from retrieving articles about gun violence to correctly determining whether the phrase *14 year old girl* describes the victim or the shooter, has been studied as a core NLP problem in its own right (Figure 1). These NLP tools have the potential to make a marked difference for gun violence researchers.

3 The Gun Violence Database

In order to facilitate the adaptation of NLP tools for use in gun violence research, we introduce the Gun Violence Database[2] (GVDB), a dataset for training and evaluating the performance of NLP systems in the domain of gun violence. The GVDB is the result of a large crowdsourced annotation effort. This annotation is ongoing, and the GVDB will be regularly updated with new data and new layers of annotation, making it an interesting and challenging data set on which to evaluate state-of-the-art NLP tools.

Crowdsourced Annotation The GVDB is built and updated through a continuously running crowdsourced annotation pipeline. The pipeline consists of daily crawls of local newspapers and television websites from across the US. The crawled articles are automatically classified using a high-recall text classifier, and then manually vetted by humans to filter out false positives. So far, the GVDB contains 60K articles (∼49M words) describing incidents of gun violence, and is (sadly) growing at a rate of nearly 1,000 per day.

Crowdsourced annotators then mark up the text of the articles with the key information we expect automated NLP systems to extract. In addition to classifying articles according to multiple binary dimensions (e.g. whether or not the shooting was intentional), annotators mark specific spans of the text which populate the database schema. For example, workers highlight the shooters, the victims, and the location.[3] These precise spans are stored in the database so that automated systems can be trained to reproduce the extracted information. Our annotation interface is shown in Figure 2.

At the time of writing, the GVDB contains 7,366 fully annotated articles (Table 1) coming from 1,512 US cities, and the database is continuing to grow. The latest version of the database will be maintained and available for download at `http://gun-violence.org/`.

60,443	Articles reporting incidents of gun violence
7,366	Articles fully-annotated for IE
6,804	*w/ location information*
5,394	*w/ shooter/victim information*
4,143	*w/ temporal information*
1,666	*w/ weapon information*

Table 1: Current contents of the GVDB. Size and level of annotation is continually growing. See Forthcoming Extensions.

Current Baselines To establish a baseline level of performance, we run an off-the-shelf information

[2] `http://gun-violence.org/`

[3] See supplementary material for all extracted information and screenshots.

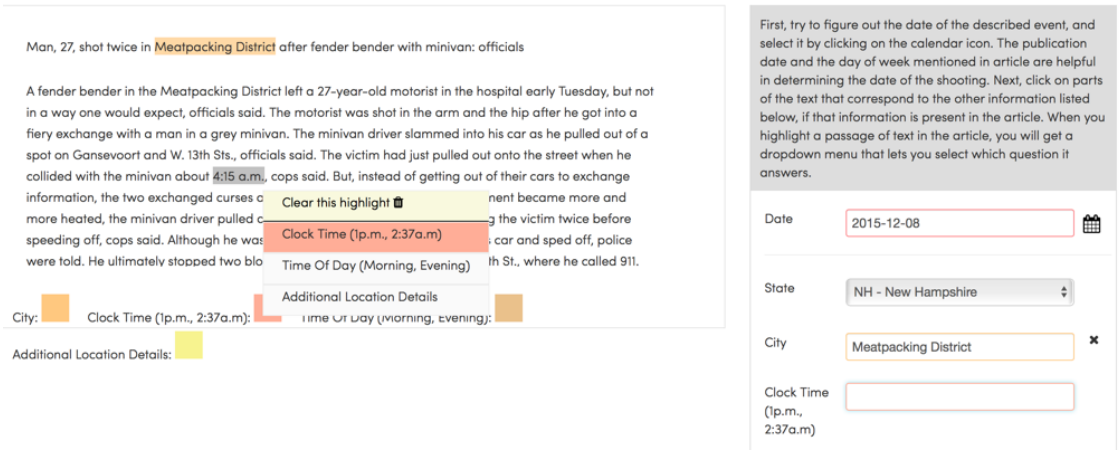

Figure 2: Annotation interface associates structured information (e.g. the time of day when the shooting occurred) with a specific span of text in the article.

extraction system on the 7,366 articles and measure precision and recall for identifying key information about the incidents. We use the Li et al. (2013) systems, which identifies a range of entities and events. We focus on the those events identified by the system which are relevant to the main fields in the GVDB schema.[4] We map the arguments of these events onto the corresponding database fields, e.g. the *agent* of the event corresponds to the GVDB's *shooter name*. Since the system identifies multiple such events per article, we count it as correct as long as one argument correctly matches the corresponding value in the GVDB (e.g. the system is correct as long as one extracted event has an *agent* which matches the GVDB's *shooter name* for that article). In addition, we run the Stanford CoreNLP TimeEx system (Chang and Manning, 2012) over the articles in order to identify the time of the reported incident.

We report the system's performance using both exact match against the gold annotation ("strict") as well as an approximate match, in which the system is correct if it is either a substring or a superstring of the gold annotation. E.g. if the victim name is *Sean Bolton*, the approximate metric will count both *Bolton* and *Officer Sean Bolton* as correct.

While performance is high for certain structured types of information, like dates and times, fields like victim and shooter name are much less reliably identified. Furthermore, many key pieces of information in the GVDB, such as age and race, are not supported by the off-the-shelf system. These baselines are evidence that NLP systems have potential, but require some effort to make their output usable for downstream research. Our hope is that the GVDB will serve as the impetus for undertaking this effort.

	Strict		Approx.	
	Prec.	Rec.	Prec.	Rec.
Date/Time	69.3%	66.9%	70.5%	68.1%
Location	19.9%	8.8%	30.8%	13.6%
Victim	10.2%	8.5%	59.5%	49.6%
Shooter	5.8%	3.9%	30.2%	20.1%
Weapon	2.1%	0.7%	36.8%	11.8%

Table 2: Performance of an off-the-shelf IE system on identifying key information about gun violence incidents from news articles. For "strict" vs. "approximate", see text.

Forthcoming Extensions The building of the GVDB is an ongoing effort, with new articles and deeper annotation being continuously added. We are currently adding approximately 300 new fully-annotated articles per day, while simultaneously enriching the annotation pipeline. The GVDB is soon to include annotation for event coreference, which will link articles describing the same incident, and cross-document coreference, which will link mentions of the same shooter/victim appearing in separate documents. In the future, the database will also include full within-document coreference annotation, with all mentions of a shooter/victim being flagged as such, and will incorporate visual data, so that within-article images are tagged with relevant

[4] Specifically, we focus on *Attack*, *Injure*, and *Die* events

information which may not be communicated by the text alone (e.g. race/approximate age).

4 Related Efforts

Several projects collect data about gun violence via newspaper teams (Boyle, 2013; Swaine et al., 2015) or volunteer crowds (Burghart, 2014; Wagner, 2014; Kirk and Kois, 2013). Perhaps the largest such effort is the Gun Violence Archive[5]. However, none are aimed at the eventual automation of the process. We believe that automating this data collection is key to keeping it scalable, consistent, and unbiased. Our focus is therefore on collecting data that is well-suited for training and evaluating NLP systems.

5 Conclusion

We believe that NLP researchers have the potential to significantly advance gun violence research. The shortage of data and funding for studying gun violence in America has severely limited the ability of scientists to have productive conversations about practical solutions. Applying core NLP technologies to local news reports of gun violence could transform raw text into structured, queryable data that public health researchers can use. We have introduced the Gun Violence Database, a new dataset of gun violence articles with rich NLP annotations which will support efforts on this new NLP task.

Acknowledgments

We would like to thank Douglas Wiebe for his advice and insight on building a useful resource for public health researchers. We also thank the students of the University of Pennsylvania's crowdsourcing class (NETS 213) for their involvement in building and testing a useful crowdsourcing pipeline for information extraction. Finally, we thank the developers at 10clouds for the excellent engineering and design of `http://gun-violence.org/`.

Fluency detection on communication networks

Abstract

When considering a social media corpus, we often have access to structural information about how messages are flowing between people or organizations. This information is particularly useful when the linguistic evidence is sparse, incomplete, or of dubious quality. In this paper we construct a simple model to leverage the structure of Twitter data to help determine the set of languages each user is fluent in. Our results demonstrate that imposing several intuitive constraints leads to improvements in performance and stability. We release the first annotated data set for exploring this task, and discuss how our approach may be extended to other applications.

1 Introduction

Language identification (LID) is an important first step in many NLP pipelines since most downstream tasks need to employ language-specific resources. In many situations, LID is a trivial task that can be addressed e.g. by a simple Naive Bayes classifier trained on word and character n-gram data (Lui and Baldwin, 2012): a document of significant length will be quickly disambiguated based on its vocabulary (King et al., 2014). However, social media platforms like Twitter produce data sets in which individual documents are extremely short, and language use is idiosyncratic: LID performance on such data is dramatically lower than on traditional corpora (Bergsma et al., 2012; Carter et al., 2013). The widespread adoption of social media throughout the world amplifies the problem as less-studied languages lack the annotated resources needed to train the most effective NLP models (e.g. treebanks for statistical parsing, tagged corpora for part-of-speech tagging, etc). All of this motivates the research community's continued interest in LID (Zampieri et al., 2014).

Tweet #1	Коз эверисинг ю ду ис мэджик
Tweet #2	omg favourite day of the week!

Table 1: Multilingual social media users often communicate in different languages depending on their intended audience, such as with these Russian and English tweets posted by the same Twitter account

In this paper, we consider the closely-related task of determining an actor's *fluencies*, the set of languages they are capable of speaking and understanding. The observed language data will be the same as for LID, but is now considered to indicate a latent property of the actor. This information has a number of downstream uses, such as providing a strong prior on the language of the actor's future communications, constructing monolingual data sets, and recommending appropriate content for display or further processing.

This paper also focuses on the situation where a very small amount of content has been observed from the particular user. While this may seem strange considering the volume of data generated by social media, this is dominated by particularly active users: for example, 30% of Twitter users post only once per month (Leetaru et al., 2013). This content-starved situation is exacerbated by certain use-cases, such as responding to emergency events where sudden focus is directed at a particular location, or focusing on new users with shallow histories.

2 Previous Work

Twitter and other social media platforms are a major area of ongoing NLP research, including dedicated workshops(NAA, 2015; ACL, 2014). Previous work has considered macroscopic properties of the entire Twitter network (Gabielkov et al., 2014), and pondered whether it is an "information" or "social" network (Myers et al., 2014). Studies have focused on determining user attributes such as gender (Li et al., 2015), political allegiance (Volkova et al., 2014), brand affinity (Pennacchiotti and Popescu, 2011a), sentiment analysis (West et al., 2014), and more abstract roles (Beller et al., 2014). Such demographic information is known to help downstream tasks (Hovy, 2015). Research involving social media communication networks has typically focused on *homophily*, the tendency of users to connect to others with similar properties (Barberá, 2014). A number of papers have employed features drawn from both the content and structure of network entities in pursuit of latent user attributes (Pennacchiotti and Popescu, 2011b; Campbell et al., 2014; Suwan et al., 2015).

3 Definitions

We refer to the entities that produce and consume communications as *Actors*, and the communications (packets of language data) as *Messages*. Each message occurs in a particular *Language*, and each actor has a set of *Fluencies*, representing the ability to produce and consume a message in a given language. We refer to a connected graph of such entities as a *Communication Network*. For Twitter data, messages are simply associated with a single actor, who is in turn associated with other actors via the "following" relationship, the actor's "friends" in Twitter's terminology.[1] We assume each message (tweet) is written in a single language, and actors are either fluent or not in each possible language.

[1]Note that, confusingly, Twitter's "friend" relationship is not symmetric: Mary's friends are users she has decided to follow, and not necessarily vise-versa.

4 Twitter Data Set

To build a suitable data set[2] for fluency detection, we first identified 1000 Twitter users who, according to the Twitter LID system, have tweeted in Russian and at least one additional language. For each of these "seed" users, we gather a local context (a "snowflake") as follows: we choose 20 of their friends at random. For each of these friends, we choose 15 of *their* friends (again, at random). Finally, we randomly pull 200 tweets for each identified user. The data set consists of 989 seed users, 165,042 friends, and 55,019,811 tweets. We preserve all Twitter meta-data for the users and tweets, such as location, follower count, hashtags, etc, though for the purposes of this paper we are only interested in the friendship structure and message text. We then had an annotator determine the set of languages each of the 1000 seed users is fluent in. For each seed user, the annotator was presented with their 200 tweets, grouped by Twitter language ID, and was asked to 1) flag users that appear to be bots and 2) list the languages they believe the user is fluent in. These steps are reflected in Figure 4. Over 50% (507) of the users were flagged as possible bots and not used in this study. The remaining 482 were observed employing 7 different languages: Russian, Ukrainian, German, Polish, Bulgarian, Latvian, and English. At most, a single user was found to be fluent in three languages.

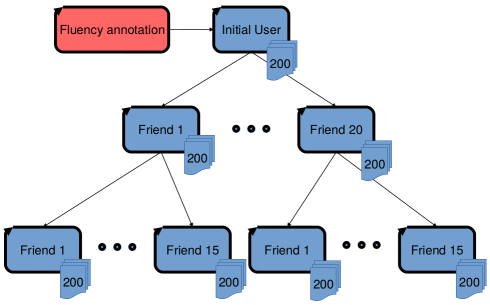

Figure 1: Structure of one snowflake in the Twitter Fluency data set.

5 Structure-Aware Fluency Model

Our goal was to explicitly model each actor's fluency in different languages, using a model with sim-

[2]The full data set is available at `www.university.edu/link`

ple, interpretable parameters that can be used to encode well-motivated assumptions about the data. In particular, we want to bias the model towards the belief that actors typically speak a small number of languages, and encode the belief that all actors participating in a message are highly likely to be fluent in its language. Our basic hypothesis is that, in addition to scores from traditional LID modules, such a model will benefit from considering the behavior of an actor's interlocutors. To test this, we designed a model that employs scores from an existing LID system, and compare performance with and without awareness of the communication network structure. To demonstrate the effectiveness of the model in situations with sparse or unreliable linguistic content, we perform experiments where the number of messages associated with each actor has been randomly down-sampled.

Linear Programming Linear Programming (LP) is a method for specifying constraints and cost functions in terms of linear relationships between variables, and then finding the optimal solution that respects the constraints. The restriction to linear equations ensures that the objective function is itself linear, and can be efficiently solved. If some or all variables are restricted to take discrete values, referred to as (Mixed) Integer Linear Programming (ILP), finding a solution becomes NP-hard, though common special cases remain efficiently solvable. We specify our model as an ILP with the hope that it provides sufficient expressiveness for the task, while remaining intuitive and tractable. Inference is performed using the Gurobi modeling toolkit (Gurobi Optimization, 2015).

Model definition Given a communication network with no LID information, ideally we would like to determine the language of each message, and the set of languages each actor is fluent in. Initially, we assume access to a probablistic LID system that maps unicode text to a distribution over possible languages. We use the following notation: $A_{1:T}$ and $M_{1:U}$ are the actors and messages, respectively. $F(a_i)$ is a binary vector indicating which languages we believe actor a_i is fluent in. $L(m_i)$ is a one-on binary vector indicating which language we believe message m_i is written in. $P(m_i)$ is the set of actors participating in message m_i: for Twitter data, where messages are (usually) not directed at specific users, we treat a user and the users' friends as participants. $LID(m_i)$ is a real vector representing the probability of message m_i being in each language, according to the LID system.

To build our ILP model, we iterate over actors and messages, defining constraints and the objective function as we go. There are two types of structural constraints: first, we restrict each message to have a single language assignment:

$$\sum L(m_i) = 1 \tag{1}$$

Second, we ensure that all actors participating in a given message are fluent in its language:

$$\forall a \in P(m_i), L(m_i) \times F(a) = 1 \tag{2}$$

The objective function also has two components: first, the *language fit* encourages the model to assign each message a language that has high probability according the the LID system:

$$\text{LF} = \sum_{m \in M} L(m) \times LID(m) \tag{3}$$

Second, the *structure fit* minimizes the cardinality of the actors' fluency sets (subject to the structural constraints), and thus avoids the trivial solution where each actor is fluent in all languages:

$$\text{SF} = -\sum_{a \in A} \sum F(a) \tag{4}$$

Finally, the two components of the objective function are combined with an empirically-determined *language weight* to get the complete objective function:

$$\text{LW} \times \text{LF} + (1.0 - \text{LW}) \times \text{SF} \tag{5}$$

Note that these are not all linear relationships: in particular, the multiplication operator cannot be used in ILP when the operands are both variables, as in equation 2. There are however techniques that can represent these situations in a linear program by introducing helper variables and constraints (Bisschop, 2015).

Language Identification Scores and Fluency Baseline To get LID scores, we ran the VaLID system (Bergsma et al., 2012) on each message, and normalize the output into distributions over 261 possible languages. VaLID is trained on Wikipedia data (i.e. out-of-domain relative to Twitter), although it does employ hand-specified rules for sanitizing tweet text, such as normalizing whitespace and removing URLs and user tags. VaLID uses a data-compression approach that is competitive with Twitter's in-house LID, despite no consideration of geographic or user priors. These language scores are used in the structure-aware model to compute the language fit.

Because VaLID makes no use of the communication network structure, we also use its scores to create a baseline structure-unaware fluency model. To get structure-unaware baseline scores for the fluency identification task, we average the LID distributions for each actor's messages and consider them fluent in a language if its probability is above an empirically-determined threshold.

Tuning parameters We empirically determine the thresholds for the baseline model and the language weights for the structure-aware model via a simple grid search, repeated 100 times. We randomly split the data into 20%/80% tune/test sets, and evaluate filter thresholds and language weights from 0 to 1 in .01 increments, with messages per actor ranging between 1 and 10. We expected the baseline model to have a consistent optimal threshold (though with higher performance variance with fewer messages), and this was borne out with optimal performance at a threshold of 0.06, independent of the number of messages per actor. For the structure-aware model, the optimal language weight was 0.9, although the entire range from 0.1–0.9 showed similar performance. This result was surprising, as we expect the structure-aware model to rely heavily on the structural fit when the number of messages is small, and on the language fit when the number is large. This trend doesn't emerge because the structural fit actually relies on the language fit to make assignments for the seed actor's friends and their messages.

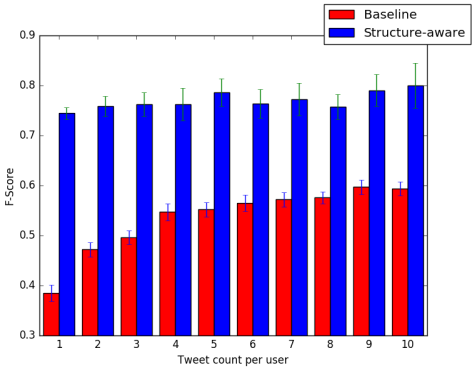

Figure 2: Performance of baseline and structure-aware models as a function of the number of messages per actor used as evidence. Each bar represents the average over 100 random tuning/testing splits, with whiskers showing the standard deviation.

6 Results and discussion

Figure 2 compares the performance[3] of the structure-aware ILP model with the baseline model as a function of the number of messages per actor, using the empirically-determined threshold and language weight. At the left extreme, the models only have a single, randomly-selected message from each actor. As this number increases, the baseline model improves as it becomes more likely to have seen enough messages to reflect the actor's full spectrum of language use. The structure-aware model is able to make immediate use of the actor's friends, immediately reaching high performance even when the language data is very sparse. Its most frequent type of error is over-hypothesizing fluency in both Ukrainian and Russian, when the user is in fact monolingual, followed by incorrectly hypothesizing fluency in English. This is understandable given the similarity of the languages in the former case, and the popularity of English expressions, titles, and the like in the latter.

7 Conclusion

We have presented promising results from leveraging structural information from a communication network to improve performance on fluency detection in situations where direct linguistic data is sparse. In addition to defining the task itself,

[3]F-score calculated based on correct and hypothesized fluency-assignments for each actor.

we release an annotated data set for training and evaluating future models. Planned future work includes a more flexible decoupling of the language and structure fits (in light of Section 5), and moving from pre-existing LID systems to joint models where LID scores are directly informed by structural information.

Characterizing the Language of Online Communities and its Relation to Community Reception

Trang Tran and **Mari Ostendorf**
Electrical Engineering, University of Washington, Seattle, WA
{ttmt001,ostendor}@uw.edu

Abstract

This work investigates style and topic aspects of language in online communities: looking at both utility as an identifier of the community and correlation with community reception of content. Style is characterized using a hybrid word and part-of-speech tag n-gram language model, while topic is represented using Latent Dirichlet Allocation. Experiments with several Reddit forums show that style is a better indicator of community identity than topic, even for communities organized around specific topics. Further, there is a positive correlation between the community reception to a contribution and the style similarity to that community, but not so for topic similarity.

1 Introduction

Online discussion forums provide a rich source of data for studying people's language usage patterns. Discussion platforms take on various forms: articles on many news sites have a comment section, many websites are dedicated to question answering (www.quora.com), and other platforms let users share personal stories, news, and random discoveries (www.reddit.com). Like their offline counterparts, online communities are often comprised of people with similar interests and opinions. Online communication, however, differs from in-person communication in an interesting aspect: explicit and quantifiable feedback. Many discussion forums give their users the ability to upvote and/or downvote content posted by another user. These explicit reward/penalty labels provide valuable information on the reaction of users in a community. In this work, we take advantage of the available user response to explore the relationship between community reception and the degree of stylistic/topical coherence to such communities. Using hybrid n-grams and Latent Dirichlet Allocation (LDA) topic models to represent style and topic for a series of classification tasks, we confirm that there exists a *community language style*, which is not simply characterized by the *topics* that online communities are organized around. Moreover, we show that language style is better at discriminating communities, especially between different communities that happen to discuss similar issues. In addition, we found a positive, statistically significant, correlation between the community feedback to comments and their style, but interestingly not with their topic. Finally, we analyze community language on the user level and show that more successful users (in terms of positive community reception) tend to be more *specialized*; in other words, analogous to offline communities, it is rare for a person to be an expert in multiple areas.

2 Related Work

It is well known that conversation partners become more linguistically similar to each other as their dialogue evolves, via many aspects such as lexical, syntactic, as well as acoustic characteristics (Niederhoffer and Pennebaker, 2002; Levitan et al., 2011). This pattern is observed even when the conversation is fictional (Danescu-Niculescu-Mizil and Lee, 2011), or happening on social media (Danescu-Niculescu-Mizil et al., 2011). Regarding the language of online discussions in particular, it has been shown that individual users' linguistic patterns evolve to match

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1030–1035,
Austin, Texas, November 1-5, 2016.

those of the community they participate in, reaching "linguistic maturity" over time (Nguyen and Rosé, 2011; Danescu-Niculescu-Mizil et al., 2013). In a multi-community setting, Tan and Lee (2015) found that users tend to explore more in different communities as they mature, adopting the language of these new communities. These works have mainly focused on the temporal evolution of users' language. Our work differs in that we use different language models to explore the role of topic and style, while also considering users in multiple communities. In addition, we look at community language in terms of its correlation with reception of posted content.

Other researchers have looked at the role of language in combination with other factors in Reddit community reception. Lakkaraju et al. (2013) proposed a community model to predict the popularity of a resubmitted content, revealing that its title plays a substantial role. Jaech et al. (2015) considered timing and a variety of language features in ranking comments for popularity, finding significant differences across different communities. In our work, we focus on community language, but explore different models to account for it.

3 Data

Reddit is a popular forum with thousands of subcommunities known as *subreddits*, each of which has a specific theme. We will refer to *subreddits* and *communities* interchangeably. Redditors can submit content to initiate a discussion thread whose root text we will refer to as a *post*. Under each *post*, users can discuss the post by contributing a *comment*. Both posts and comments can be upvoted and downvoted, and the net feedback is referred to as *karma* points.

We use eight subreddits that reflect Reddit's diverse topics, while limiting the amount of data to a reasonable size. In addition, we create an artificial distractor merged_others that serves as an open class in our classification tasks and for normalizing scores in correlation analysis. Statistics are listed in Table 1. The merged_others set includes 9 other subreddits that are similar in size and content diversity to the previous ones: books, chicago, nyc, seattle, explainlikeimfive, science, running, nfl, and todayilearned. Among these extra subreddits, the smallest in size is nyc (1.5M tokens, 76K comments), and the largest is todayilearned (88M tokens, 5M comments). All data is from the period between January 1, 2014 and January 31, 2015. In each subreddit, 20% of the threads are held out for testing.

subreddit	# posts	# cmts	% $k \leq 0$
askmen	4.5K	1.1M	10.6
askscience	0.9K	0.3M	9.1
askwomen	3.6K	0.8M	7.5
atheism	3.1K	1.0M	15.2
changemyview	2.3K	0.5M	16.7
fitness	2.4K	0.9M	8.6
politics	4.9K	2.2M	20.8
worldnews	9.9K	6.0M	23.6
merged_others	28.0K	14.2M	13.2

Table 1: Reddit dataset statistics

We use discussion threads with at least 100 comments, hypothesizing that smaller threads will not elicit enough community personality for our study. (Virtually all threads kept had only upvotes.) For training our models, we also exclude individual comments with non-positive karma ($k \leq 0$) in order to learn only from content that is less likely to be downvoted by the Reddit communities; percentages are noted in Table 1.

4 Models

We wish to characterize community language via *style* and *topic*. For modeling style, a popular approach has been combining the selected words with part-of-speech (POS) tags to construct models for genre detection (Stamatatos et al., 2000; Feldman et al., 2009; Bergsma et al., 2012) and data selection (Iyer and Ostendorf, 1999; Axelrod, 2014). For topic, a common approach is Latent Dirichlet Allocation (LDA) (Blei et al., 2003). We follow such approaches in our work, acknowledging the challenge of completely separating style/genre and topic factors raised previously (Iyer and Ostendorf, 1999; Sarawgi et al., 2011; Petrenz and Webber, 2011; Axelrod, 2014), which also comes out in our analysis. Generative language models are used for characterizing both style and topic, since they are well suited to handling texts of widely varying lengths.

4.1 Representing Style

Replacing words with POS tags reduces the possibility that the style model is learning topic, but re-

placing too many words loses useful community jargon. To explore this tradeoff, we compared four trigram language models representing different uses of words vs. POS tags in the vocabulary:

- `word_only`: a regular token-based language model (vocabulary: 156K words)
- `hyb-15k`: a hybrid word-POS language model over a vocabulary of 15K most frequent words across all communities in our data; all other words are converted to POS tags (vocabulary: 15K words + 38 tags)
- `hyb-500.30`: a hybrid word-POS language model over a vocabulary of 500 most frequent words in a subset of data balanced across communities, combined with the union of the 30 next most common words from each of the 17 subreddits; all other words are converted to POS tags (vocabulary: 854 words + 38 tags)
- `tag_only`: a language model using only POS tags as its vocabulary (vocabulary: 38 tags)

The hybrid models represent two intermediate sample points between the extremes of word-only and tag-only n-grams. For the `hyb-500.30` model, the mix of general and community-specific words was designed to capture distinctive community jargon. The general words include punctuation, function words, and words that are common in many subreddits (e.g., *sex, culture, see, dumb, simply*). The subreddit-specific words seem to reflect both broad topical themes and jargon or style words, as in (themes vs. style/jargon):

askmen: *wife, single* vs. *whatever, interested*
askwomen: *mom, husband* vs. *especially, totally*
askscience: *particle, planet* vs. *basically, x*
fitness: *exercises, muscles* vs. *cardio, reps, rack*

Tokenization and tagging are done using Stanford coreNLP (Manning et al., 2014). Punctuation is separated from the words and treated as a word. All language models are trigrams trained using the SRILM toolkit (Stolcke, 2002); modified Kneser-Ney smoothing is applied to the `word_only` language model, while Witten-Bell smoothing is applied to the `tag_only` and both hybrid models.

4.2 Representing Topic

We train 100- and 200-dimensional LDA topic models (Blei et al., 2003) using `gensim` (Řehůřek and Sojka, 2010). We remove all stopwords (250 words) and use tf-idf normalized word counts in each comment (as documents). The vocabulary consists of 156K words, similar to the vocabulary of the `word_only` language model. The topic models were trained on a subset of the training data, using all collected subreddits but randomly excluding roughly 15% of the training data of larger subreddits worldnews, todayilearned, and nfl.

ID	Frequent words
19	-lsb-, -rsb-, -rrb-, -lrb-, **, reddit, comment, confirmed, spanish, fair
29	sex, pilots, child, women, abortion, mail, birth, want, episodes, children
32	tax, government, taxes, iraq, pay, cia, land, money, income, people
34	africa, war, nation, global, germans, rebels, corruption, nations, fuel, world

Table 2: Examples of broadly used topics.

The topics learned exhibit a combination of ones that reflect general characteristics of online discussions or topics that arise in many forums, some that have more specific topics, and others that do not seem particularly coherent. Topics (from LDA-100) that consistently have high probability in all subreddits are shown in Table 2 with their top 10 words by frequency (normalized by the topic average). Topic 19 is likely capturing Reddit's writing conventions and formatting rules. Broadly used topics reflect women's issues (29) and news events (32, 34).

Online communities are typically organized around a common theme, but multiple topics might fall under that theme, particularly since some of the "topics" actually reflect style. A subreddit as a whole is characterized by a distribution of topics as learned via LDA, but any particular discussion thread would not necessarily reflect the full distribution. Therefore, we characterize each subreddit with multiple topic vectors. Specifically, we compute LDA topic vectors for each discussion thread in a subreddit, and learn 50 representative topic vectors for each subreddit via k-means clustering.

5 Community Classification

One method for exploring the relative importance of topic vs. style in online communication is through community classification experiments: given a discussion thread (or a user's comments), can we iden-

tify the community that it comes from more easily using style characteristics or topic characteristics? We formulate this task as a multi-class classification problem (8 communities and "other"), where samples are either at the discussion thread level or the user level. At the thread level, all comments (from multiple people) and the post in a discussion thread are aggregated and treated as a document to be classified. At the user level, we aggregate all comments made by a user in a certain subreddit and treat the collection (which may reflect multiple topics) as a document to be classified.

We classify document d_i to a subreddit according to $\hat{j} = \arg\max_j s_{i,j}$, where $s_{i,j}$ is a score of the similarity of d_i to community j. For the style models, $s_{i,j}$ is the log-probability under the respective trigram language model of community j. For the topic model, $s_{i,j}$ is computed using d_i's topic vector v_i as follows. For a subreddit j, we compute the cosine similarities $sim_{j,k}$ between v_i and the subreddit's topic vectors $w_{j,k}$ for $k = 1, \ldots, 50$. The final topic similarity score $s_{i,j}$ is the mean of the top 3 highest similarities: $s_{i,j} = (sim_{j,[1]} + sim_{j,[2]} + sim_{j,[3]})/3$, where $[\cdot]$ denotes the sorted cosine similarities' indices. The top-3 average captures the most prominent subreddit topics (as in a nearest-neighbor classifier). Averaging over all 50 $sim_{j,k}$ is ill suited to subreddits with broad topic coverage, and leads to poor classification results.

Table 3 summarizes the community classification results (as average accuracy across all subreddits) for each model described in Section 4. While all models beat the random baseline of 11%, the poor performance of the `tag_only` model confirms that POS tags alone are insufficient to characterize the community. Both for classifying threads and authors, `hyb-500.30` yields the best average classification accuracy, due to its ability to generalize POS structure while covering sufficient lexical content to capture the community's jargon and key topical themes. Neither topic model beats `hyb-500.30`, indicating that topic alone is not discriminative enough for community identification, even though specific communities coalesce around certain common topics. The `word_only` and `hyb-15k` models have performance on the threads that is similar to the topic models, since word features are sensitive to topic, as shown in (Petrenz and Webber, 2011).

Model	by thread	by author
random	11.1%	11.1%
word_only	68.9%	46.8%
tags_only	27.6%	18.8%
hyb-15k	69.4%	46.6%
hyb-500.30	**86.5%**	**51.0%**
topic-100	**71.1%**	27.5%
topic-200	69.6%	**27.7%**

Table 3: Average accuracy for classifying by posts and authors

Classifying authors is harder than classifying threads. Two factors are likely to contribute. First, treating a whole discussion thread as a document yields more data to base the decision on than a collection of author comments, since there are many authors who only post a few comments. Second, authors that have multi-community involvement may be less adapted to a specific community. The fact that word-based style models outperform topic models may be because the comments are from different threads so not matching typical topic distributions.

Subreddit confusion statistics indicate that certain communities are easier to identify than others. Both style and topic models do well in recognizing askscience: classification accuracy for threads is as much as 97%. Communities that were most confusable are intuitively similar: politics and worldnews, askmen and askwomen.

6 Community Feedback Correlation

In this section, we investigate whether the style and/or topic scores of a discussion or user are correlated with community response. For thread-level feedback, we use karma points of the discussion thread itself; for the user-level feedback, we compute each user's subreddit-dependent k-index (Jaech et al., 2015), defined similarly to the well-known h-index (Hirsch, 2005). Specifically, a user's k-index k_j in subreddit j is the maximum integer k such that the user has at least k comments with karma greater than k in that subreddit. User k-index scores have Zipfian distribution, as illustrated in Figure 1 for the worldnews subreddit.

We compute a *normalized* community similarity score $\tilde{s}_{i,j} = s_{i,j} - s_{i,m}$, where $s_{i,m}$ is the corresponding score from the subreddit merged_others. The correlation between $\tilde{s}_{i,j}$ and community feedback is reported for three models in Table 4 for the

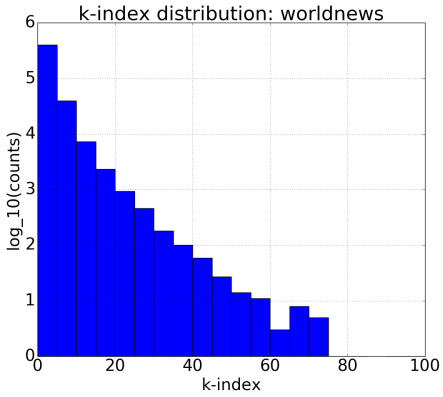

Figure 1: Distribution (log base 10 counts) of user k-index scores for the worldnews subreddit.

subreddit	hyb-500.30	word_only	topic-100
askmen	0.392*	0.222*	0.055
askscience	0.321*	-0.110	-0.166*
askwomen	0.501*	0.388*	0.005
atheism	0.137*	-0.229*	-0.251
chgmyvw	0.167*	-0.121*	-0.306*
fitness	0.130*	0.017	-0.313*
politics	0.533*	0.341*	0.011
worldnews	0.374*	0.148*	-0.277*

Table 4: Spearman rank correlation of thread $\tilde{s}_{i,j}$ with karma scores. (*) indicates statistical significance ($p < 0.05$).

thread level, and in Table 5 for the user level. On the thread level, the `hyb-500.30` style model consistently finds positive, statistically significant, correlation between the post's stylistic similarity score and its karma. This result suggests that language style adaptation does contribute to being well-received by the community. None of the other models explored in the previous section had this property, and for the topic models the correlation is mostly negative. On the user level, *all* correlations between a user's k-index and their style/topic match are statistically significant, though the `hyb-500.30` style model shows more positive correlation than other models. In both cases, the `word_only` model gives results between the style and topic models. The `hyb-15k` model has results that are similar to the `word_only` model, and the `tag_only` model has mostly negative correlation.

Examining users' multi-community involvement, we also find that users with high k-indices tend to participate in fewer subreddits. Among relatively

subreddit	hyb-500.30	word_only	topic-100
askmen	0.402	0.215	0.167
askscience	0.343	0.106	0.042
askwomen	0.451	0.260	0.165
atheism	0.296	0.024	0.107
chgmyvw	0.446	0.020	0.091
fitness	0.309	0.286	0.127
politics	0.453	0.317	0.177
worldnews	0.421	0.330	0.166

Table 5: Spearman rank correlation of authors' $\tilde{s}_{i,j}$ with their k-indices. All values are statistically significant ($p < 0.05$).

active users (having at least 100 comments), those with a max k-index of at least 100 participated in a median of 3 communities, while those with a max k-index of at most 5 participated in a median of 6 subreddits. Of the 42 users with max k-index of at least 100, only 4 achieve a k-index of at least 50 in one other community, and only 6 achieve a k-index of at least 20 in one other community.

7 Conclusion

In this work, we use hybrid n-grams and topic models to characterize style and topic of language in online communities. Since communities center on a common theme, topic characteristics are reflected in language style, but we find that the best model for determining community identity uses very few words and mostly relies on POS patterns. Using Reddit's community response system (karma), we also show that discussions and users with higher community endorsement are more likely to match the language style of the community, where the language model that best classifies the community is also most correlated with community response. In addition, online users tend to have more positive community response when they specialize in fewer subreddits. These results have implications for detecting newcomers in a community and the popularity of posts, as well as for language generation.

Abstract

Joint dependency parsing with disfluency detection is an important task in speech language processing. Recent methods show high performance for this task, although most authors make the unrealistic assumption that input texts are transcribed by human annotators. In real-world applications, the input text is typically the output of an automatic speech recognition (ASR) system, which implies that the text contains not only disfluency noises but also recognition errors from the ASR system. In this work, we propose a parsing method that handles both disfluency and ASR errors using an incremental shift-reduce algorithm with several novel features suited to ASR output texts. Because the gold dependency information is usually annotated only on transcribed texts, we also introduce an alignment-based method for transferring the gold dependency annotation to the ASR output texts to construct training data for our parser. We conducted an experiment on the Switchboard corpus and show that our method outperforms conventional methods in terms of dependency parsing and disfluency detection.

1 Introduction

Spontaneous speech is different from written text in many ways, one of which is that it contains disfluencies, that is, parts of the utterance that are corrected by the speaker during the utterance. NLP system performance is reported to deteriorate when there are disfluencies, for example, with SMT (Cho et al., 2014). Therefore, it is desirable to preprocess the speech before passing it to other NLP tasks.

There are a number of studies that address the problem of detecting disfluencies. Some of these studies include dependency parsing (Honnibal and Johnson, 2014; Wu et al., 2015; Rasooli and Tetreault, 2014), whereas others are dedicated systems (Qian and Liu, 2013; Ferguson et al., 2015; Hough and Purver, 2014; Hough and Schlangen, 2015; Liu et al., 2003). Among these studies, Honnibal (2014) and Wu (2015) address this problem by adding a new action to transition-based dependency parsing that removes the disfluent parts of the input sentence from the stack. Using this approach, they achieved high performance in terms of both dependency parsing and disfluency detection on the Switchboard corpus.

However, the authors assume that the input texts to parse are transcribed by human annotators, which, in practice, is unrealistic. In real-world applications, in addition to disfluencies, the input texts contain ASR errors; these issues might degrade the parsing performance. For example, proper nouns that are not contained in the ASR system vocabulary may break up into smaller pieces, yielding a difficult problem for the parsing unit (Cheng et al., 2015):

REF: what can we get at **Litanfeeth**
HYP: what can we get *it leaks on feet*

In this work, we propose a method for joint dependency parsing and disfluency detection that can robustly parse ASR output texts. Our parser handles both disfluencies and ASR errors using an incremental shift-reduce algorithm, with novel features that consider recognition errors of the ASR system.

Furthermore, to evaluate dependency parsing per-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1036–1041,
Austin, Texas, November 1-5, 2016.

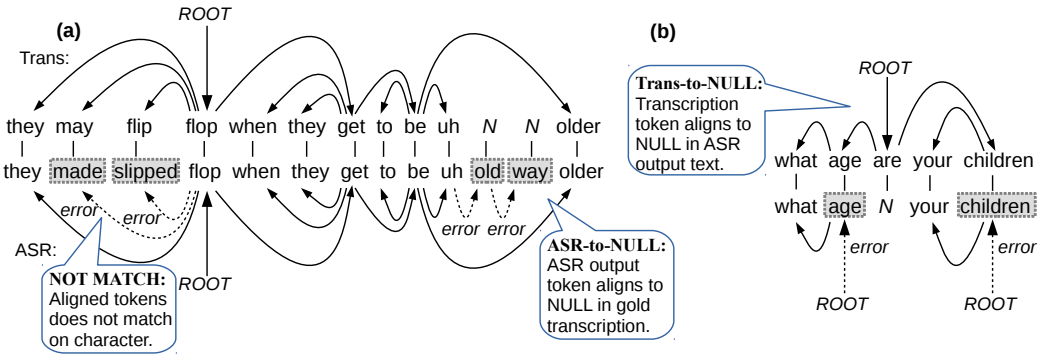

Figure 1: Examples of three problematic cases. Above shows the gold transcription and its tree, below shows the aligned ASR output and its newly transferred tree, where the dotted edges are ASR error edges.

formance on real human utterances, we create a tree-annotated corpus that contains ASR errors. [1]

2 Data Creation

To evaluate dependency parsing performance on real speech texts, we must create a tree-annotated corpus of ASR output texts.

Given a corpus that consists of speech data, transcription text and its syntactic annotation (e.g., the Switchboard corpus), we first apply the ASR system to the speech data. Next, we perform alignment between the ASR output texts and the transcription. Then, we transfer the gold syntactic annotation to the ASR output texts based on this alignment (Figure 1). The alignment is performed by minimizing the edit distance between the two sentences. We include "NULL" tokens in this alignment to allow for some tokens not having an aligned conterpart ("*N*" tokens in the Figure 1).

In the constructed trees, there are three problematic cases based on how an ASR output text and its transcription are aligned with each other: (1) a word in the ASR output text aligns with a NULL token in the transcription (**ASR-to-NULL**), (2) a word in the gold transcription aligns with a NULL in the ASR output (**Trans-to-NULL**), and (3) two words align, but do not match exactly in terms of characters (**NOT MATCH**). To create a consistent dependency tree that spans the entire sentence, we must address each of these cases.

[1]There are also studies that tackle the problem of disfluency detection in the context of speech recognition such as (Liu et al., 2003). Our work is novel in that our aim is to extend the joint method of disfluency detection with dependency parsing so that it can be applicable to the output of ASR system.

2.1 ASR-to-NULL

In the case of ASR-to-NULL, a token from the ASR system has no corresponding token in the gold transcription. In this case, we automatically annotate a dependency relation with an "error" label such that the token's head becomes the previous word token.

Figure 1(a) shows an example of this case. In the figure, the words "old" and "way" have no corresponding words in the gold transcription. Thus, we automatically annotate the dependency relations between ("old", "uh") and ("way", "old"), respectively, with the "error" label.

2.2 Trans-to-NULL

Although NULL tokens are introduced to facilitate alignment, as these tokens in the ASR output are not actual words, we must remove them in the final tree. Without any treatment, the gold transcription tokens aligned to these tokens are also deleted along with them. This causes the child tokens in the sentence not to have heads; consequently, these child tokens are not included in the syntactic tree. To avoid this problem, we instead attach them to the head of the deleted token.

For example, in Figure 1(b), the word "are" is missing in the ASR hypothesis. Then, this token's children lose their head in the transfer process. Thus, we rescue these children by attaching them to the head of "are", which, in this case, is ROOT token.

If the head of the removed token is also of the Trans-to-NULL type, then we look for an alternative head by climbing the tree in a recursive manner, until reaching ROOT. We also label the newly created edges in this process as "error".

2.3 NOT MATCH

In cases in which two aligned tokens do not match exactly on the character level, the mismatch is regarded as an instance of a substitution type of ASR error. Therefore, we encode this fact in the label of the arc from the token to its head.

In Figure 1(a), the words "made" and "slipped" in the ASR hypothesis do not match the gold transcription tokens, "may" and "flip", respectively. Therefore, we automatically re-label the arc from each token to its head as "error".

3 Transition-based Dependency Parsing

To parse texts that contain disfluencies and ASR errors, we extend the ArcEager shift-reduce dependency parser of (Zhang and Nivre, 2011). Our proposed parser adopts the same *Shift*, *Reduce*, *LeftArc*, and *RightArc* actions as ArcEager. To this parser we add three new actions, i.e., *Edit*, *LeftArcError*, and *RightArcError*, to handle disfluencies and ASR errors.

Edit action removes a disfluent token when it is the first element of the stack. This is different from Honnibal (2014)'s *Edit* action: theirs accumulates consecutive disfluent tokens on the top of the stack and removes them all at once, whereas our method removes this kind of token one-by-one. Use of this *Edit* action guarantees that the length of the action sequence is always $2n-1$. This property is advantageous because the parser can use the standard beam search and does not require normalization, such as those adopted in (Honnibal and Johnson, 2014) and (Zhu et al., 2013).

LeftArcError and *RightArcError* act in the same way as *LeftArc* and *RightArc*, except that these act only on ASR error tokens, whereas the original *LeftArc* and *RightArc* are reserved for non ASR error tokens. Using two different kinds of *Arc* actions for the two types of tokens (ASR error or not) allows for the weights not to be shared between them, and is expected to yield improved performance.

In the experiment below, we train all of the models using structured perceptron with max violation (Huang et al., 2012). The feature set is mainly based on (Honnibal and Johnson, 2014), such as the disfluency capturing features to inquire whether the token sequence inside the two specific spans match on word forms or POS tags. We adjusted these features to inspect the content of the buffer more carefully, because our parser decides if the word token is disfluent or not every time new token is shifted and hints for the decision lies much more in the buffer.

3.1 Backoff Action Feature

With the newly proposed *LeftArcError* and *RightArcError* actions, we fear that the relatively low frequency of "error" tokens may cause the weights for these actions to be updated too infrequently to be accurately generalized. We resort to using the "backoff action feature" to avoid this situation. This means that, for each action $a \in \{LeftArc, LeftArcError\}$, the score of performing it in a state s is calculated as follow:

$$SCORE(a, s) = \mathbf{w} \cdot \mathbf{f}(a, s) + \mathbf{w} \cdot \mathbf{f}(a', s) \quad (1)$$

where a' = *LeftArcBackoff*, $\mathbf{w}$ is the weight vector and $\mathbf{f}(\cdot, \cdot)$ is the feature representation, respectively. *LeftArcBackoff* is not actual action performed by our parser, rather it is used to provide the common feature representation which both *LeftArc* and *LeftArcError* can "back off" to. *RightArc* and *RightArcError* actions also calculate their scores as in Eq.(1), with a' = *RightArcBackoff*. The scores for all the other actions are calculated in the normal way: $SCORE(a, s) = \mathbf{w} \cdot \mathbf{f}(a, s)$.

3.2 WCN Feature

To better capture which parts of the texts are likely to be ASR errors, we use additional features extracted from a word confusion network (WCN) generated by ASR models. Marin (2015) reports his observation that WCN slots with more arcs tend to correspond to erroneous region. Following (Marin, 2015), we use mean and standard deviation of arc posteriors and the highest arc posterior in each WCN slot corresponding to each word token. We include in the feature vector these real-valued features for tokens on top of the stack and the first three elements of the buffer.

4 Experiment

We conducted experiments using both the proposed parsing method and the tree-annotated corpus based on the ASR output texts. Our experiments were performed using the Switchboard corpus (Godfrey et

al., 1992). This corpus consists of speech data and its transcription texts, and subset of which is annotated with POS tags, syntactic trees and disfluency information (repair, discourse marker and interjection) based on (Shriberg, 1994). [2]

4.1 ASR Settings

To obtain the ASR output texts of the corpus, we used the off-the-shelf NeuralNet recipe (Zhang et al., 2014) presented by Kaldi.[3] We used the jackknife method to obtain the ASR output texts throughout the syntactically annotated part of the corpus. [4]

From these ASR output texts, we created the tree-annotated corpus by applying the data creation method introduced in §2. Out of all 857,493 word tokens, there are 32,606 ASR-to-NULL, 34,952 Trans-to-NULL, and 93,138 NOT MATCH cases, meaning 15.6% of all word tokens had "error" labeled arcs.

4.2 Parsing Settings

We assigned POS tags to the created corpus using the Stanford POS tagger (Toutanova et al., 2003) trained on a part of the gold Switchboard corpus. [5]

We adopt the same train/dev/test split as in (Honnibal and Johnson, 2014), although the data size reduces slightly during the process of data creation. We report the unlabeled attachment score (UAS), which indicates how many heads of fluent tokens are correctly predicted. As for disfluency detection, we report precision/recall/F1-score values following the previous work in the literature.

As a baseline (To which we refer as *Base* in the following), we use an ArcEager parser with our proposed *Edit* action and the disfluency capturing features, trained on the train part of the gold Switchboard corpus. Using this parser on ASR output test data can be seen as reproducing the typical situation, in which a parser is trained on ASR-error-free texts, but nevertheless needs to parse the ASR output texts.

[2]We converted the phrase structure trees to dependency ones using the Stanford converter (de Marneffe et al., 2006).

[3]http://kaldi-asr.org/

[4]The average Word Error Rate of resulting models were 13.9 % on the Switchboard part of HUB5 evaluation dataset: https://catalog.ldc.upenn.edu/LDC2002S09

[5]We used a part of the corpus that is annotated with POS information but not syntactic one. The performance of the tagger is evaluated on the syntactically annotated part of the corpus; the tagger has an accuracy score of 95.0%.

ASR	ASR	*Ours*	**76.2**	**67.9**	57.9	**62.5**

Table 2: Parsing result on different train-test settings. $Trans$ refers to original Switchboard transcription text, ASR the text created through the data creation in §4.1. *Ours* is our proposed parser: *Base* + *ErrorAct* + *Backoff* + *WCN*.

4.3 Results and Analysis

In Table 1, based on the baseline *Base* parser, we report scores with the additional (and additive) use of *Left/RightArcError* actions (*ErrorAct*), the WCN feature (*WCN*), and the backoff action feature (*Backoff*), on our created corpus. Using *ErrorAct* resulted in 3.6% and 1.2% improvement in UAS and disfluency detection F1, respectively. *Backoff* contributes to further improved UAS, whereas *WCN* cause an increase in disfluency detection accuracy.

Table 2 reports performance on various train and test data settings. In Table 2, the Train and Test columns represent which data to use in training and testing; $Trans$ refers to the gold transcription text of the Switchboard corpus, and ASR the text created through the data creation in §4.1. When evaluated on the ASR texts, the parser trained on the ASR texts showed degraded performance compared to the parser trained on the gold transcription ($(\text{Train}, \text{Test}) = (ASR, ASR)$). Although both the train and test data are ASR texts and share characteristics, we did not observe domain adaptation effect. We hypothesized that the drop in the performance is due to the noisy nature of our corpus, which is created from the texts with ASR errors. Having ASR-

error-specific actions, *Left/RightArcError* mitigates this problem by separately treating the ASR error tokens and non ASR error tokens. Finally, with the newly proposed features, the parser trained on ASR texts outperforms the parser trained on the transcription texts with the improvement of 1.5% and 0.7% for UAS and disfluency detection, respectively.

However, when compared with the case of $(\text{Train}, \text{Test}) = (Trans, Trans)$, we observe significant decreases in performance in both of the tasks conducted on ASR texts. This result clearly poses a new challenge for the disfluency detection community.

5 Conclusion

In this work, we have proposed a novel joint transition-based dependency parsing method with disfluency detection. Using new actions, and new feature set, the proposed parser can parse ASR output texts robustly. We have also introduced a data construction method to evaluate dependency parsing and disfluency detection performance for real speech data. As the experimental results for ASR texts is significantly lower than that achieved for the gold transcription texts, we have clarified the need to develop a method that is robust to recognition errors in the ASR system.

Abstract

In this paper, we describe our approach of enabling an interactive dialogue system to recognize user emotion and sentiment in real-time. These modules allow otherwise conventional dialogue systems to have "empathy" and answer to the user while being aware of their emotion and intent. Emotion recognition from speech previously consists of feature engineering and machine learning where the first stage causes delay in decoding time. We describe a CNN model to extract emotion from raw speech input without feature engineering. This approach even achieves an impressive average of 65.7% accuracy on six emotion categories, a 4.5% improvement when compared to the conventional feature based SVM classification. A separate, CNN-based sentiment analysis module recognizes sentiments from speech recognition results, with 82.5 F-measure on human-machine dialogues when trained with out-of-domain data.

1 Introduction

Interactive dialogue systems and chatbots have been around for a while. Some, though not all, systems have statistical and machine learning modules to enable them to improve overtime. With the pervasiveness of such systems on mobile devices, expectations of user experience have also increased. We expect human-machine dialogues to get closer to human-human dialogues. One important factor is that we expect machines to understand our emotions and intent and respond with empathy.

We propose a module of emotion and sentiment recognition for an interactive dialogue system. This module enables the system to assess the user's current emotional state and sentiment, and thereby decide the appropriate response at every dialogue state. The dialogue management system handles the mixed-initiative dialogues while taking into account user emotion and sentiment, in addition to query content. Emotion and sentiment recognition enables our system to handle user queries previously unseen in training data. Positive user queries containing positive emotion and sentiment label would have a positive response, and similarly a negatively labeled statement would have a negative response. Examples are shown below:

User: *I lost my job.*
Response: *Sorry to hear that. Success is in never giving up.*
User: *I just graduated from college!*
Response: *Congratulations! I am happy for you.*
User: *I went on a vacation last month and it was pretty bad, I lost all my luggage*
Response: *That doesn't sound so good. Hope your next vacation will be a good one.*
User: *My last vacation was amazing, I loved it!*
Response: *That sounds great. I would like to travel with you.*

Meanwhile, dialogue systems like this need to have real-time recognition of user emotion and sentiment. Previous approaches of emotion recognition from speech involve feature engineering (Schuller et al., 2009; Schuller et al., 2010) as a first step which invariably causes delay in decoding. So we are interested in investigating a method to avoid feature engineering and instead use a Convolutional Neural

Network to extract emotion from raw audio input directly.

2 Speech Recognition

Our acoustic data is obtained from various public domain corpora and LDC corpora, comprised of 1385hrs of speech. We use Kaldi speech recognition toolkit (Povey et al., 2011) to train our acoustic models. We train deep neural network hidden Markov models (DNN-HMMs) using the raw audio together with encode-decode parallel audio. We apply layer-wise training of restricted Boltzmann machines (RBM) (Hinton, 2010), frame cross-entropy training with mini-batch stochastic gradient descent (SGD) and sequence discriminative training using state Minimum Bayes Risk (sMBR) criterion.

The text data, of approximately 90 million sentences, includes acoustic training transcriptions, filtered sentences of Google 1 billion word LM benchmark (Chelba et al., 2013), and other multiple domains (web news, music, weather). Our decoder allows streaming of raw audio or CELP encoded data through TCP/IP or HTTP protocol, and performs decoding in real time. The ASR system achieves 7.6% word error rate on our clean speech test data[1].

3 Real-Time Emotion Recognition from Time-Domain Raw Audio Input

In recent years, we have seen successful systems that gave high classification accuracies on benchmark datasets of emotional speech (Mairesse et al., 2007) or music genres and moods (Schermerhorn and Scheutz, 2011).

Most of such work consists of two main steps, namely feature extraction and classifier learning, which is tedious and time-consuming. Extracting high and low level features (Schuller et al., 2009), and computing over windows of audio signals typically takes a few dozen seconds to do for each utterance, making the response time less than real-time instantaneous, which users have come to expect from interactive systems. It also requires a lot of hand tuning. In order to bypass feature engineering, the current direction is to explore methods that can recognize emotion or mood directly from time-domain audio signals. One approach that has shown great potential is using Convolutional Neural Networks. In the following sections, we compare an approach of using CNN without feature engineering to a method that uses audio features with a SVM classifier.

3.1 Dataset

For our experiments on emotion recognition with raw audio, we built a dataset from the TED-LIUM corpus release 2 (Rousseau et al., 2014). It includes 207 hours of speech extracted from 1495 TED talks. We annotated the data with an existing commercial API followed by manual correction. We use these 6 categories: criticism, anxiety, anger, loneliness, happiness, and sadness. We obtained a total of 2389 segments for the criticism category, 3855 for anxiety, 12708 for anger, 3618 for loneliness, 8070 for happy and 1824 for sadness. The segments have an average length slightly above 13 seconds.

3.2 Convolutional Neural Network model

The Convolutional Neural Network (CNN) model using raw audio as input is shown in Figure 1. The raw audio samples are first down-sampled at 8 kHz, in order to optimize between the sampling rate and representation memory efficiency in case of longer segments. The CNN is designed with a single filter for real-time processing. We set a convolution window of size 200, which corresponds to 25 ms, and an overlapping step size of 50, equal to around 6 ms. The convolution layer performs the feature extraction, and models the variations among neighboring, overlapping frames. The subsequent max-pooling combines the contributions of all the frames, and gives as output a segment-based vector. This is then fed into a fully connected layer before the final softmax layer. These last layers perform a similar function as those of a fully connected Deep Neural Network (DNN), mapping the max-pooling output into a probabilistic distribution over the desired emotional output categories.

During decoding the processing time increases linearly with the length of the audio input segment. Thus the largest time contribution is due to the computations inside the network (He and Sun, 2015), which with a single convolution layer can be performed in negligible time for single utterances.

4 Sentiment Inference from Speech and Text

Convolutional Neural Networks (CNNs) have recently achieved remarkably strong performance also on the practically important task of sentence classification (Johnson and Zhang, 2014; Kalchbrenner et al., 2014; Kim, 2014). In our approach, we use a CNN-based classifier with Word2Vec to analyze the sentiment of recognized speech.

We train a CNN with one layer of convolution and max pooling (Collobert et al., 2011) on top of word embedding vectors trained on the Google News corpus (Mikolov et al., 2013) of size 300. We apply on top of the word vectors a convolutional sliding window of size 3, 4 and 5 to represent multiple features. We then apply a max-pooling operation over the output vectors of the convolutional layer, that allows the model to pick up the most valuable information wherever it happens in the input sentence, and give as output a fixed-length sentence encoding vector.

Emotion class	SVM	CNN
Criticism/Cynicism	55.0	61.2
Defensiveness/Anxiety	56.3	62.0
Hostility/Anger	72.8	72.9
Loneliness/Unfulfillment	61.1	66.6
Love/Happiness	50.9	60.1
Sadness/Sorrow	71.1	71.4
Average	61.2	**65.7**

Table 1: Accuracy obtained, percentage, in the Convolutional Neural Network model for emotion classification from raw audio samples.

We employ two distinct CNN channels: the first uses word embedding vectors directly as input, while the second fine-tunes them via back propagation (Kim, 2014). All the hidden layer dimensions are set to 100. The final softmax layer takes as input the concatenated sentence encoding vectors of the two channels, and gives as output is the probability distribution over a binary classification for sentiment analysis of text transcribed from speech by our speech recognizer.

To improve the performance of sentiment classification in real time conversation, we compare the performance on the Movie Review dataset used in Kim (2014) with the Twitter sentiment 140[2] dataset. This twitter dataset contains a total of 1.6M sentences with positive and negative sentiment labels. Before training the CNN model we apply some preprocessing as mentioned in Go et al. (2009).

5 Experiments

5.1 Experimental setup

For the speech emotion detection module we setup our experiments as binary classification tasks, in which each segment is classified as either part of a particular emotion category or not. For each category the negative samples were chosen randomly from the clips that did not belong to the positive category. We took 80% of the data as training set, and 10% each as development and test set. The development set was used to tune the hyperparameters and determine the early stopping condition. We implemented our CNN with the THEANO framework

[2] www.sentiment140.com

Corpus	Average Length	Size	Vocabulary Size	Words in Word2vec
Movie Review	20	10662	18765	16448
Twitter	12.97	1600000	273761	79663

Table 2: Corpus statistics for text sentiment experiments with CNN.

Model	Accuracy	Precision	Recall	F-score
CNN model (trained on Movie Review dataset)	67.8%	91.2%	63.5%	74.8
LIWC (keyword based)	**73.5%**	**80.3%**	77.3%	77.7
CNN model (trained on Twitter dataset)	72.17%	78.64%	**86.69%**	**82.5**

Table 3: Sentiment analysis result on human-machine dialogue when trained from Twitter and Movie Review dataset

(Bergstra et al., 2010). We chose rectified linear as the non-linear function for the hidden layers, as it generally provided better performance over other functions. We used standard backpropagation training, with momentum set to 0.9 and initial learning rate to 10^{-5}. As a baseline we used a linear-kernel SVM model from the LibSVM (Chang and Lin, 2011) library with the INTERSPEECH 2009 emotion feature set (Schuller et al., 2009), extracted with openSMILE (Eyben et al., 2010). These features are computed from a series of input frames and output a single static summary vector, e.g, the smooth methods, maximum and minimum value, mean value of the features from the frames (Liscombe et al., 2003).

A similar one-layer CNN setup was used also for the sentiment module, again with rectified linear as the activation function. As our dataset contains many neutral samples, we trained two distinct CNNs: one for positive sentiment and one for negative, and showed the average results among the two categories. For each of the two training corpora we took 10% as development set. We used as baseline a method that uses positive and emotion keywords from the Linguistic Inquiry and Word Count (LIWC 2015) dictionary (Pennebaker et al., 2015).

5.2 Results and discussion

5.2.1 Speech emotion recognition

Results obtained by this module are shown in Table 1. In all the emotion classes considered our CNN model outperformed the SVM baseline, sometimes marginally (in the angry and sad classes), sometimes more significantly (happy and criticism classes). It is particularly important to point out that our CNN does not use any kind of preprocessed features. The lower results for some categories, even on the SVM baseline, may be a sign of inaccuracy in manual labeling. We plan to work to improve both the dataset, with hand-labeled samples, and periodically retrain the model as ongoing work.

Processing time is another key factor of our system. We ran an evaluation of the time needed to perform all the operations required by our system (down-sampling, audio samples extraction and classification) on a commercial laptop. The system we used is a Lenovo x250 laptop with a Intel i5 CPU, 8 Gb RAM, an SSD hard disk and running Linux Ubuntu 16.04. Our classifier took an average of 162 ms over 10 segments randomly chosen from our corpus of length greater than 13 s, which corresponds to 13 ms per second of speech, hence achieving real-time performance on typical utterances. The key of the low processing time is the lightweight structure of the CNN, which uses only one filter. We replicated the evaluations with the same 10 segments on a two-filter CNN, where the second filter spans over 250 ms windows. Although we obtained higher performance with this structure in our preliminary experiments, the processing time raised to 6.067 s, which corresponds to around 500 ms per second of speech. This is over one order of magnitude higher than the one filter configuration, making it less suitable for time constrained applications such as dialogue systems.

5.2.2 Sentiment inference from ASR

Results obtained by this module are shown in Table 3. Our CNN model got a 6.1% relative improvement on F-score over the baseline when trained with the larger Twitter dataset. The keyword based method got a slightly better accuracy and precision and a much lower recall on our relatively small human-machine dialogue dataset (821 short utter-

ances). However, we noticed that the keyword based method accuracy fell sharply when tested on the larger Twitter dataset we used to train the CNN, yielding only 45% accuracy. We also expect to improve our CNN model in the future training it with more domain specific data, something not possible with a thesaurus based method.

6 Conclusion

In this paper, we have introduced the emotion and sentiment recognition module for an interactive dialog system. We described in detail the two parts involved, namely speech emotion and sentiment recognition, and discussed the results achieved. We have shown how deep learning can be used for such modules in this architecture, ranging from speech recognition, emotion recognition to sentiment recognition from dialogue. More importantly, we have shown that by using a CNN with a single filter, it is possible to obtain real-time performance on speech emotion recognition at 65.7% accuracy, directly from time-domain audio input, bypassing feature engineering. Sentiment analysis with CNN also leads to a 82.5 F-measure when trained from out-of-domain data. This approach of creating emotionally intelligent systems will help future robots to acquire empathy, and therefore rather than committing harm, they can act as friends and caregivers to humans.

A Neural Network Architecture for Multilingual Punctuation Generation

Miguel Ballesteros[1] **Leo Wanner**[1,2]
[1]NLP Group, Universitat Pompeu Fabra, Barcelona, Spain
[2] Catalan Institute for Research and Advanced Studies (ICREA)
miguel.ballesteros@upf.edu leo.wanner@upf.edu

Abstract

Even syntactically correct sentences are perceived as awkward if they do not contain correct punctuation. Still, the problem of automatic generation of punctuation marks has been largely neglected for a long time. We present a novel model that introduces punctuation marks into raw text material with transition-based algorithm using LSTMs. Unlike the state-of-the-art approaches, our model is language-independent and also neutral with respect to the intended use of the punctuation. Multilingual experiments show that it achieves high accuracy on the full range of punctuation marks across languages.

1 Introduction

Although omnipresent in (language learner) grammar books, punctuation received much less attention in linguistics and natural language processing (Krahn, 2014). In linguistics, punctuation is generally acknowledged to possess different functions. Its traditionally most studied function is that to encode prosody of oral speech, i.e., the prosodic *rhetorical* function; see, e.g., (Kirchhoff and Primus, 2014) and the references therein. In particular the comma is assumed to possess a strong rhetorical function (Nunberg et al., 2002). Its other functions are the grammatical function, which leads it to form a separate (along with semantics, syntax, and phonology) grammatical submodule (Nunberg, 1990), and the syntactic function (Quirk et al., 1972), which makes it reflect the syntactic structure of a sentence.

The different functions of punctuation are also reflected in different tasks in natural language processing (NLP): introduction of punctuation marks into a generated sentence that is to be read aloud, restoration of punctuation in speech transcripts, parsing under consideration of punctuation, or generation of punctuation in written discourse. Our work is centered in the last task. We present a novel punctuation generation algorithm that is based on the transition-based algorithm with long short-term memories (LSTMs) by Dyer et al. (2015) and character-based continuous-space vector embeddings of words using bidirectional LSTMs (Ling et al., 2015b; Ballesteros et al., 2015). The algorithm takes as input raw material without punctuation and effectively introduces the full range of punctuation symbols. Although intended, first of all, for use in sentence generation, the algorithm is function- and language-neutral, which makes it different, compared to most of the state-of-the-art approaches, which use function- and/or language-specific features.

2 Related Work

The most prominent punctuation-related NLP task has been so far introduction (or restoration) of punctuation in speech transcripts. Most often, classifier models are used that are trained on n-gram models (Gravano et al., 2009), on n-gram models enriched by syntactic and lexical features (Ueffing et al., 2013) and/or by acoustic features (Baron et al., 2002; Kolář and Lamel, 2012). Tilk and Alumäe (2015) use a lexical and acoustic (pause duration) feature-based LSTM model for the restoration of periods and commas in Estonian speech transcripts. The grammatical and syntactic functions of punctuation have been addressed in the context of written

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1048–1053,
Austin, Texas, November 1-5, 2016.

language. Some of the proposals focus on the grammatical function (Doran, 1998; White and Rajkumar, 2008), while others bring the grammatical and syntactic functions together and design rule-based grammatical resources for parsing (Briscoe, 1994) and surface realization (White, 1995; Guo et al., 2010). Guo et al. (2010) is one of the few works that is based on a statistical model for the generation of punctuation in the context of Chinese sentence generation, trained on a variety of syntactic features from LFG f-structures, preceding punctuation bigrams and cue words.

Our proposal is most similar to Tilk and Alumäe (2015), but our task is more complex since we generate the full range of punctuation marks. Furthermore, we do not use any acoustic features. Compared to Guo et al. (2010), we do not use any syntactic features either since our input is just raw text material.

3 Model

Our model is inspired by a number of recent works on neural architectures for structure prediction: Dyer et al. (2015)'s transition-based parsing model, Dyer et al. (2016)'s generative language model and phrase-structure parser, Ballesteros et al. (2015)'s character-based word representation for parsing, and Ling et al. (2015b)'s part-of-speech tagging .

3.1 Algorithm

We define a transition-based algorithm that introduces punctuation marks into sentences that do not contain any punctuation. In the context of NLG, the input sentence would be the result of the surface realization task (Belz et al., 2011). As in transition-based parsing (Nivre, 2004), we use two data structures: Nivre's *queue* is in our case the *input buffer* and his *stack* is in our case the *output buffer*. The algorithm starts with an input buffer full of words and an empty output buffer. The two basic actions of the algorithm are SHIFT, which moves the first word from the input buffer to the output buffer, and GENERATE, which introduces a punctuation mark after the first word in the output buffer. Figure 1 shows an example of the application of the two actions.

At each stage t of the application of the algorithm, the state, which is defined by the contents of the output and input buffers, is encoded in terms of a vector $\mathbf{s}_t$; see Section 3.3 for different alternatives of state representation. As Dyer et al. (2015), we use $\mathbf{s}_t$ to compute the probability of the action at time t as:

Transition	Output	Input
	[ ]	[No it was not]
SHIFT	[No]	[it was not]
GENERATE(",")	[No ,]	[it was not]
SHIFT	[No , it]	[was not]
SHIFT	[No , it was]	[not]
SHIFT	[No , it was not]	[ ]
GENERATE(".")	[No, it was not .]	[ ]

Figure 1: Transition sequence for the input sequence *No it was not* – with the output *No, it was not.*

$$p(z_t \mid \mathbf{s}_t) = \frac{\exp\left(\mathbf{g}_{z_t}^\top \mathbf{s}_t + q_{z_t}\right)}{\sum_{z' \in \mathcal{A}} \exp\left(\mathbf{g}_{z'}^\top \mathbf{s}_t + q_{z'}\right)} \quad (1)$$

where $\mathbf{g}_z$ is a vector representing the embedding of the action z, and q_z is a bias term for action z. The set $\mathcal{A}$ represents the actions (either SHIFT or GENERATE(p)).[1] $\mathbf{s}_t$ encodes information about previous actions (since it may include the history with the actions taken and the generated punctuation symbols are introduced in the output buffer, see Section 3.3), thus the probability of a sequence of actions $\boldsymbol{z}$ given the input sequence is:

$$p(\boldsymbol{z} \mid \boldsymbol{w}) = \prod_{t=1}^{|\boldsymbol{z}|} p(z_t \mid \mathbf{s}_t). \quad (2)$$

As in (Dyer et al., 2015), the model greedily chooses the best action to take given the state with no backtracking.[2]

3.2 Word Embeddings

Following the tagging model of Ling et al. (2015b) and the parsing model of Ballesteros et al. (2015), we compute character-based continuous-space vector embeddings of words using bidirectional LSTMs (Graves and Schmidhuber, 2005) to learn similar representation for words that are similar from an orthographic/morphological point of view.

[1] Note that GENERATE(p) includes all possible punctuations that the language in question has, and thus the number of classes the classifier predicts in each time step is #punctuations + 1.

[2] For further optimization, the model could be extended, for instance, by beam-search.

The character-based representations may be also concatenated with a fixed vector representation from a neural language model. The resulting vector is passed through a component-wise rectifier linear unit (ReLU). We experiment with and without pretrained word embeddings. To pretrain the fixed vector representations, we use the skip n-gram model introduced by Ling et al. (2015a).

3.3 Representing the State

We work with two possible representations of the input and output buffers (i.e, the state $\mathbf{s}_t$): (i) a look-ahead model that takes into account the immediate context (two embeddings for the input and two embeddings for the output), which we use as a baseline, and (ii) the LSTM model, which encodes the entire input sequence and the output sentence with LSTMs.

3.3.1 Baseline: Look-ahead Model

The look-ahead model can be interpreted as a 4-gram model in which two words belong to the input and two belong to the output. The representation takes the average of the two first embeddings of the output and the two first embeddings at the front of the input. The word embeddings contain all the richness provided by the character-based LSTMs and the pretrained skip n-gram model embeddings (if used). The resulting vector is passed through a component-wise ReLU and a softmax transformation to obtain the probability distribution over the possible actions given the state $\mathbf{s}_t$; see Section 3.1.

3.3.2 LSTM Model

The baseline look-ahead model considers only the immediate context for the input and output sequences. In the proposed model, we apply recurrent neural networks (RNNs) that encode the entire input and output sequences in the form of LSTMs. LSTMs are a variant of RNNs designed to deal with the vanishing gradient problem inherent in RNNs (Hochreiter and Schmidhuber, 1997; Graves, 2013). RNNs read a vector $\mathbf{x}_t$ at each time step and compute a new (hidden) state $\mathbf{h}_t$ by applying a linear map to the concatenation of the previous time step's state $\mathbf{h}_{t-1}$ and the input, passing then the outcome through a logistic sigmoid non-linearity.

We use a simplified version of the stack LSTM model of Dyer et al. (2015). The input buffer is encoded as a stack LSTM, into which we PUSH the entire sequence at the beginning and POP words from it at each time step. The output buffer is a sequence, encoded by an LSTM, into which we PUSH the final output sequence. As in (Dyer et al., 2015), we include a third sequence with the history of actions taken, which is encoded by another LSTM. As already mentioned above, the three resulting vectors are passed through a component-wise ReLU and a softmax transformation to obtain the probability distribution over the possible actions that can be taken (either to shift or to generate a punctuation mark), given the current state $\mathbf{s}_t$; see Section 3.1.

4 Experiments

To test our models, we carried experiments on five languages: Czech, English, French, German, and Spanish. English, French and Spanish are generally assumed to be characterized by prosodic punctuation, while for German the syntactic punctuation is more dominant (Kirchhoff and Primus, 2014). Czech punctuation also leans towards syntactic punctuation (Kolář et al., 2004), but due to its rather free word order we expect it to reflect prosodic punctuation as well.

The punctuation marks that the models attempt to predict (and that also occur in the training sets) for each language are listed in Table 1.[3] Commas represent around 55% and periods around 30% of the total number of marks in the datasets.

Czech	‘.’, ‘,’, ‘–’, ‘(’, ‘)’, ‘:’, ‘/’, ‘?’, ‘%’, ‘*’, ‘=’, ‘|’, ‘”’, ‘+’, ‘;’, ‘!’, ‘o’, ‘“’, ‘&’, ‘[’, ‘]’, ‘§’
English	‘–’, ‘(’, ‘)’, ‘,’, ‘ ” ’, ‘.’, ‘…’, ‘:’, ‘;’, ‘?’, ‘ “ ’, ‘}’, ‘{’
French	‘ ” ’, ‘,’, ‘–’, ‘:’, ‘?’, ‘(’, ‘)’, ‘.’, ‘!’, ‘…’
German	‘ ” ’, ‘(’, ‘)’, ‘,’, ‘.’, ‘/’, ‘:’, ‘–’, ‘…’, ‘?’, ‘ “ ’
Spanish	‘ ” ’, ‘(’, ‘)’, ‘,’, ‘–’, ‘.’, ‘:’, ‘?’, ‘¿’, ‘!’, ‘¡’

Table 1: Punctuation marks covered in our experiments.

4.1 Setup

The stack LSTM model uses two layers, each of dimension 100 for each input sequence. For both the

[3]The consideration of some of the symbols listed in Table 1 as punctuation marks may be questioned (see, e.g., ‘+’ or ‘§’ for Czech). However, all of them are labeled as punctuation marks in the corresponding tag sets, such that we include them.

Table 2: Results of the LSTM model and the Baseline (Look-ahead model) for precision, recall and F score for commas, periods and micro average for all punctuation symbols (including commas and periods) listed in Table 1. +Pre refers to models that include pretrained word embeddings.

look-ahead and the stack LSTM models, character-based embeddings, punctuation embeddings and pretrained embeddings (if used) also have 100 dimensions. Both models are trained to maximize the conditional log-likelihood (Eq. 2) of output sentences, given the input sequences.

For Czech, English, German, and Spanish, we use the wordforms from the treebanks of the CoNLL 2009 Shared Task (Hajič et al., 2009); the French dataset is by Candito et al. (2010). Development sets are used to optimize the model parameters; the results are reported for the held-out test sets.

4.2 Results and Discussion

Table 2 displays the outcome of the experiments for periods and commas in all five languages and summarizes the overall performance of our algorithm in terms of the micro-average figures. In order to test whether pretrained word embeddings provide further improvements, we incorporate them for English, Spanish and German.[4]

The figures show that the LSTMs that encode the entire context of a punctuation mark are better than a strong baseline that takes into account a 4-gram sliding window of tokens. They also show that character-based representations are already useful for the punctuation generation task on their own, but when concatenated with pretrained vectors, they are even more useful.

The model is capable of providing good results for all languages, being more consistent for English, Czech and German. Average sentence length may indicate why the model seems to be worse for Spanish and French, since sentences are longer in the Spanish (29.8) and French (27.0) datasets, compared to German (18.0), Czech (16.8) or English (24.0). The training set is also smaller in Spanish and French compared to the other languages. It is worth noting that the results across languages are not directly comparable since the datasets are different, and as shown in Table 1, the sets of punctuation marks that are to be predicted diverge significantly.

The figures in Table 2 cannot be directly compared with the figures reported by Tilk and Alumäe (2015) for their LSTM-model on period and comma restoration in speech transcripts: the tasks and datasets are different.

Our results prove that the state representation (through LSTMs, which have already been shown to be effective for syntax (Dyer et al., 2015; Dyer et al., 2016)) and character-based representations (which allow similar embeddings for words that are mor-

[4]Word embeddings for English, Spanish and German are trained using the AFP portion of the English Gigaword corpus (version 5), the German monolingual training data from the 2010 Machine Translation Workshop, and the Spanish Gigaword version 3 respectively.

phologically similar (Ling et al., 2015b; Ballesteros et al., 2015)) are capturing strong linguistic clues to predict punctuation.

5 Conclusions

We presented an LSTM-based architectured that is capable of adding punctuation marks to sequences of tokens as produced in the context of surface realization without punctuation with high quality and linear time.[5] Compared to other proposals in the field, the architecture has the advantage to operate on sequences of word forms, without any additional syntactic or acoustic features. This tool could be used for ASR (Tilk and Alumäe, 2015) and grammatical error correction (Ng et al., 2014). In the future, we plan to create cross-lingual models by applying multilingual word embeddings (Ammar et al., 2016).

Abstract

Neural network-based encoder-decoder models are among recent attractive methodologies for tackling natural language generation tasks. This paper investigates the usefulness of structural syntactic and semantic information additionally incorporated in a baseline neural attention-based model. We encode results obtained from an abstract meaning representation (AMR) parser using a modified version of Tree-LSTM. Our proposed attention-based AMR encoder-decoder model improves headline generation benchmarks compared with the baseline neural attention-based model.

1 Introduction

Neural network-based encoder-decoder models are cutting-edge methodologies for tackling natural language generation (NLG) tasks, *i.e.*, machine translation (Cho et al., 2014), image captioning (Vinyals et al., 2015), video description (Venugopalan et al., 2015), and headline generation (Rush et al., 2015).

This paper also shares a similar goal and motivation to previous work: improving the encoder-decoder models for natural language generation. There are several directions for enhancement. This paper respects the fact that NLP researchers have expended an enormous amount of effort to develop fundamental NLP techniques such as POS tagging, dependency parsing, named entity recognition, and semantic role labeling. Intuitively, this structural, syntactic, and semantic information underlying input text has the potential for improving the quality of NLG tasks. However, to the best of our knowledge, there is no clear evidence that syntactic and semantic information can enhance the recently developed encoder-decoder models in NLG tasks.

To answer this research question, this paper proposes and evaluates a headline generation method based on an encoder-decoder architecture on *Abstract Meaning Representation (AMR)*. The method is essentially an extension of *attention-based summarization (ABS)* (Rush et al., 2015). Our proposed method encodes results obtained from an AMR parser by using a modified version of Tree-LSTM encoder (Tai et al., 2015) as additional information of the baseline ABS model. Conceptually, the reason for using AMR for headline generation is that information presented in AMR, such as predicate-argument structures and named entities, can be effective clues when producing shorter summaries (headlines) from original longer sentences. We expect that the quality of headlines will improve with this reasonable combination (ABS and AMR).

2 Attention-based summarization (ABS)

ABS proposed in Rush et al. (2015) has achieved state-of-the-art performance on the benchmark data of headline generation including the DUC-2004 dataset (Over et al., 2007). Figure 1 illustrates the model structure of ABS. The model predicts a word sequence (summary) based on the combination of the neural network language model and an input sentence encoder.

Let V be a vocabulary. $\boldsymbol{x}_i$ is the i-th indicator vector corresponding to the i-th word in the input sentence. Suppose we have M words of an input sentence. $\boldsymbol{X}$ represents an input sentence, which

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1054–1059,
Austin, Texas, November 1-5, 2016.

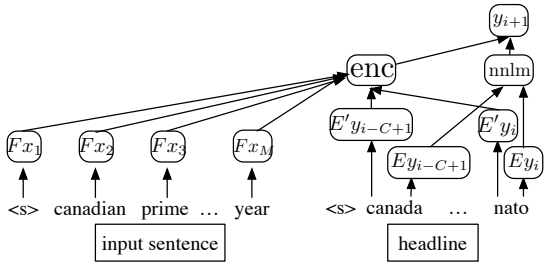

Figure 1: Model structure of 'attention-based summarization (ABS)'.

is represented as a sequence of indicator vectors, whose length is M. That is, $\boldsymbol{x}_i \in \{0,1\}^{|V|}$, and $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_M)$. Similarly, let $\boldsymbol{Y}$ represent a sequence of indicator vectors $\boldsymbol{Y} = (\boldsymbol{y}_1, \ldots, \boldsymbol{y}_L)$, whose length is L. Here, we assume $L < M$. $\boldsymbol{Y}_{C,i}$ is a short notation of the list of vectors, which consists of the sub-sequence in $\boldsymbol{Y}$ from $\boldsymbol{y}_{i-C+1}$ to $\boldsymbol{y}_i$. We assume a one-hot vector for a special start symbol, such as "$\langle$S$\rangle$", when $i < 1$. Then, ABS outputs a summary $\hat{\boldsymbol{Y}}$ given an input sentence $\boldsymbol{X}$ as follows:

$$\hat{\boldsymbol{Y}} = \arg\max_{\boldsymbol{Y}} \Big\{ \log p(\boldsymbol{Y}|\boldsymbol{X}) \Big\}, \quad (1)$$

$$\log p(\boldsymbol{Y}|\boldsymbol{X}) \approx \sum_{i=0}^{L-1} \log p(\boldsymbol{y}_{i+1}|\boldsymbol{X}, \boldsymbol{Y}_{C,i}), \quad (2)$$

$$p(\boldsymbol{y}_{i+1}|\boldsymbol{X}, \boldsymbol{Y}_{C,i}) \propto \exp\big(\mathrm{nnlm}(\boldsymbol{Y}_{C,i}) + \mathrm{enc}(\boldsymbol{X}, \boldsymbol{Y}_{C,i})\big), \quad (3)$$

where $\mathrm{nnlm}(\boldsymbol{Y}_{C,i})$ is a feed-forward neural network language model proposed in (Bengio et al., 2003), and $\mathrm{enc}(\boldsymbol{X}, \boldsymbol{Y}_{C,i})$ is an input sentence encoder with attention mechanism.

This paper uses D and H as denoting sizes (dimensions) of vectors for word embedding and hidden layer, respectively. Let $\boldsymbol{E} \in \mathbb{R}^{D\times|V|}$ be an embedding matrix of output words. Moreover, let $\boldsymbol{U} \in \mathbb{R}^{H\times(CD)}$ and $\boldsymbol{O} \in \mathbb{R}^{|V|\times H}$ be weight matrices of hidden and output layers, respectively[1]. Using the above notations, $\mathrm{nnlm}(\boldsymbol{Y}_{C,i})$ in Equation 3 can be written as follows:

$$\mathrm{nnlm}(\boldsymbol{Y}_{C,i}) = \boldsymbol{O}\boldsymbol{h}, \quad \boldsymbol{h} = \tanh(\boldsymbol{U}\tilde{\boldsymbol{y}}_c), \quad (4)$$

[1]Following Rush et al. (2015), we omit bias terms throughout the paper for readability, though each weight matrix also has a bias term.

where $\tilde{\boldsymbol{y}}_c$ is a concatenation of output embedding vectors from $i - C + 1$ to i, that is, $\tilde{\boldsymbol{y}}_c = (\boldsymbol{E}\boldsymbol{y}_{i-C+1} \cdots \boldsymbol{E}\boldsymbol{y}_i)$. Therefore, $\tilde{\boldsymbol{y}}_c$ is a (CD) dimensional vector.

Next, $\boldsymbol{F} \in \mathbb{R}^{D\times|V|}$ and $\boldsymbol{E}' \in \mathbb{R}^{D\times|V|}$ denote embedding matrices of input and output words, respectively. $\boldsymbol{O}' \in \mathbb{R}^{|V|\times D}$ is a weight matrix for the output layer. $\boldsymbol{P} \in \mathbb{R}^{D\times(CD)}$ is a weight matrix for mapping embedding of C output words onto embedding of input words. $\tilde{\boldsymbol{X}}$ is a matrix form of a list of input embeddings, namely, $\tilde{\boldsymbol{X}} = \big[\tilde{\boldsymbol{x}}_1, \ldots, \tilde{\boldsymbol{x}}_M\big]$, where $\tilde{\boldsymbol{x}}_i = \boldsymbol{F}\boldsymbol{x}_i$. Then, $\mathrm{enc}(\boldsymbol{X}, \boldsymbol{Y}_{C,i})$ is defined as the following equations:

$$\mathrm{enc}(\boldsymbol{X}, \boldsymbol{Y}_{C,i}) = \boldsymbol{O}'\bar{\boldsymbol{X}}\boldsymbol{p}, \quad (5)$$

$$\boldsymbol{p} \propto \exp(\tilde{\boldsymbol{X}}^{\mathrm{T}}\boldsymbol{P}\tilde{\boldsymbol{y}}'_c), \quad (6)$$

where $\tilde{\boldsymbol{y}}'_c$ is a concatenation of output embedding vectors from $i - C + 1$ to i similar to $\tilde{\boldsymbol{y}}_c$, that is, $\tilde{\boldsymbol{y}}'_c = (\boldsymbol{E}'\boldsymbol{y}_{i-C+1} \cdots \boldsymbol{E}'\boldsymbol{y}_i)$. Moreover, $\bar{\boldsymbol{X}}$ is a matrix form of a list of averaged input word embeddings within window size Q, namely, $\bar{\boldsymbol{X}} = [\bar{\boldsymbol{x}}_1, \ldots, \bar{\boldsymbol{x}}_M]$, where $\bar{\boldsymbol{x}}_i = \sum_{q=i-Q}^{i+Q} \frac{1}{Q}\tilde{\boldsymbol{x}}_q$.

Equation 6 is generally referred to as the attention model, which is introduced to encode a relationship between input words and the previous C output words. For example, if the previous C output words are assumed to align to $\boldsymbol{x}_i$, then the surrounding Q words $(\boldsymbol{x}_{i-Q}, \ldots, \boldsymbol{x}_{i+Q})$ are highly weighted by Equation 5.

3 Proposed Method

Our assumption here is that syntactic and semantic features of an input sentence can greatly help for generating a headline. For example, the meanings of subjects, predicates, and objects in a generated headline should correspond to the ones appearing in an input sentence. Thus, we incorporate syntactic and semantic features into the framework of headline generation. This paper uses an AMR as a case study of the additional features.

3.1 AMR

An AMR is a rooted, directed, acyclic graph that encodes the meaning of a sentence. Nodes in an AMR graph represent 'concepts', and directed edges represent a relationship between nodes. Concepts

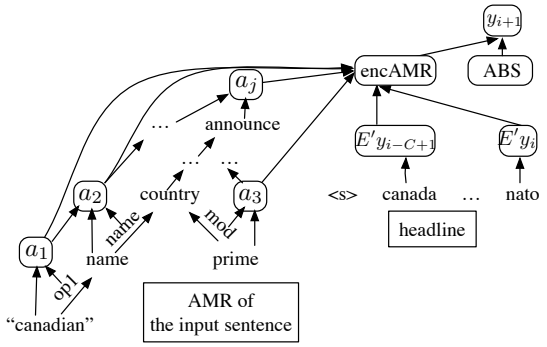

Figure 2: Model structure of our proposed attention-based AMR encoder; it outputs a headline using ABS and encoded AMR with attention.

consist of English words, PropBank event predicates, and special labels such as "person". For edges, AMR has approximately 100 relations (Banarescu et al., 2013) including semantic roles based on the PropBank annotations in OntoNotes (Hovy et al., 2006). To acquire AMRs for input sentences, we use the state-of-the-art transition-based AMR parser (Wang et al., 2015).

3.2 Attention-Based AMR Encoder

Figure 2 shows a brief sketch of the model structure of our attention-based AMR encoder model. We utilize a variant of child-sum Tree-LSTM originally proposed in (Tai et al., 2015) to encode syntactic and semantic information obtained from output of the AMR parser into certain fixed-length embedding vectors. To simplify the computation, we transform a DAG structure of AMR parser output to a tree structure, which we refer to as "*tree-converted AMR structure*". This transformation can be performed by separating multiple head nodes, which often appear for representing coreferential concepts, to a corresponding number of out-edges to head nodes. Then, we straightforwardly modify Tree-LSTM to also encode edge labels since AMR provides both node and edge labels, and original Tree-LSTM only encodes node labels.

Let $\boldsymbol{n}_j$ and $\boldsymbol{e}_j$ be N and E dimensional embeddings for labels assigned to the j-th node, and the out-edge directed to its parent node[2]. $\boldsymbol{W}_{in}$, $\boldsymbol{W}_{fn}$, $\boldsymbol{W}_{on}$, $\boldsymbol{W}_{un} \in \mathbb{R}^{D\times N}$ are weight matrices for node embeddings $\boldsymbol{n}_j$[3]. Similarly, $\boldsymbol{W}_{ie}$, $\boldsymbol{W}_{fe}$, $\boldsymbol{W}_{oe}$, $\boldsymbol{W}_{ue} \in \mathbb{R}^{D\times E}$ are weight matrices for edge embeddings $\boldsymbol{e}_j$. $\boldsymbol{W}_{ih}$, $\boldsymbol{W}_{fh}$, $\boldsymbol{W}_{oh}$, $\boldsymbol{W}_{uh} \in \mathbb{R}^{D\times D}$ are weight matrices for output vectors connected from child nodes. $B(j)$ represents a set of nodes, which have a direct edge to the j-th node in our tree-converted AMR structure. Then, we define embedding $\boldsymbol{a}_j$ obtained at node j in tree-converted AMR structure via Tree-LSTM as follows:

$$\tilde{\boldsymbol{h}}_j = \sum_{k\in B(j)} \boldsymbol{a}_k, \tag{7}$$

$$\boldsymbol{i}_j = \sigma\Big(\boldsymbol{W}_{in}\boldsymbol{n}_j + \boldsymbol{W}_{ie}\boldsymbol{e}_j + \boldsymbol{W}_{ih}\tilde{\boldsymbol{h}}_j\Big), \tag{8}$$

$$\boldsymbol{f}_{jk} = \sigma\Big(\boldsymbol{W}_{fn}\boldsymbol{n}_j + \boldsymbol{W}_{fe}\boldsymbol{e}_j + \boldsymbol{W}_{fh}\boldsymbol{a}_k\Big), \tag{9}$$

$$\boldsymbol{o}_j = \sigma\Big(\boldsymbol{W}_{on}\boldsymbol{n}_j + \boldsymbol{W}_{oe}\boldsymbol{e}_j + \boldsymbol{W}_{oh}\tilde{\boldsymbol{h}}_j\Big), \tag{10}$$

$$\boldsymbol{u}_j = \tanh\Big(\boldsymbol{W}_{un}\boldsymbol{n}_j + \boldsymbol{W}_{ue}\boldsymbol{e}_j + \boldsymbol{W}_{uh}\tilde{\boldsymbol{h}}_j\Big), \tag{11}$$

$$\boldsymbol{c}_j = \boldsymbol{i}_j \odot \boldsymbol{u}_j \sum_{k\in B(j)} \boldsymbol{f}_{jk} \odot \boldsymbol{c}_k, \tag{12}$$

$$\boldsymbol{a}_j = \boldsymbol{o}_j \odot \tanh(\boldsymbol{c}_j). \tag{13}$$

Let J represent the number of nodes in tree-converted AMR structure obtained from a given input sentence. We introduce $\boldsymbol{A} \in \mathbb{R}^{D\times J}$ as a matrix form of a list of hidden states $\boldsymbol{a}_j$ for all j, namely, $\boldsymbol{A} = [\boldsymbol{a}_1, \ldots, \boldsymbol{a}_J]$. Let $\boldsymbol{O}'' \in \mathbb{R}^{|V|\times D}$ be a weight matrix for the output layer. Let $S \in \mathbb{R}^{D\times(CD)}$ be a weight matrix for mapping the context embedding of C output words onto embeddings obtained from nodes. Then, we define the attention-based AMR encoder '$\mathrm{encAMR}(\boldsymbol{A}, \boldsymbol{Y}_{C,i})$' as follows:

$$\mathrm{encAMR}(\boldsymbol{A}, \boldsymbol{Y}_{C,i}) = \boldsymbol{O}''\boldsymbol{A}\boldsymbol{s}, \tag{14}$$

$$\boldsymbol{s} \propto \exp(\boldsymbol{A}^{\mathrm{T}}\boldsymbol{S}\tilde{\boldsymbol{y}}'_c). \tag{15}$$

Finally, we combine our attention-based AMR encoder shown in Equation 14 as an additional term of Equation 3 to build our headline generation system.

4 Experiments

To demonstrate the effectiveness of our proposed method, we conducted experiments on benchmark data of the abstractive headline generation task described in Rush et al. (2015).

[2]We prepare a special edge embedding for a root node.

[3]As with Equation 4, all the bias terms are omitted, though each weight matrix has one.

Table 1: Results of methods on each dataset. We marked $*$ on the ABS+AMR results if we observed statistical difference ($p < 0.05$) between ABS (re-run) and ABS+AMR on the t-test. (R-1: ROUGE-1, R-2: ROUGE-2, R-L: ROUGE-L)

For a fair comparison, we followed their evaluation setting. The training data was obtained from the first sentence and the headline of a document in the annotated Gigaword corpus (Napoles et al., 2012)[4]. The development data is DUC-2003 data, and test data are both DUC-2004 (Over et al., 2007) and sentence-headline pairs obtained from the annotated Gigaword corpus as well as training data[5]. All of the generated headlines were evaluated by ROUGE (Lin, 2004)[6]. For evaluation on DUC-2004, we removed strings after 75-characters for each generated headline as described in the DUC-2004 evaluation. For evaluation on Gigaword, we forced the system outputs to be at most 8 words as in Rush et al. (2015) since the average length of headline in Gigaword is 8.3 words. For the preprocessing for all data, all letters were converted to lower case, all digits were replaced with '#', and words appearing less than five times with 'UNK'. Note that, for further evaluation, we prepared 2,000 sentence-headline pairs randomly sampled from the test data section of the Gigaword corpus as our additional test data.

In our experiments, we refer to the baseline neural attention-based abstractive summarization method described in Rush et al. (2015) as "**ABS**", and our proposed method of incorporating AMR structural information by a neural encoder to the baseline method described in Section 3 as "**ABS+AMR**". Additionally, we also evaluated the performance of the AMR encoder *without* the attention mechanism, which we refer to as "**ABS+AMR(w/o attn)**", to investigate the contribution of the attention mechanism on the AMR encoder. For the parameter estimation (training), we used stochastic gradient descent to learn parameters. We tried several values for the initial learning rate, and selected the value that achieved the best performance for each method. We decayed the learning rate by half if the log-likelihood on the validation set did not improve for an epoch. Hyper-parameters we selected were $D = 200$, $H = 400$, $N = 200$, $E = 50$, $C = 5$, and $Q = 2$. We re-normalized the embedding after each epoch (Hinton et al., 2012).

For ABS+AMR, we used the two-step training scheme to accelerate the training speed. The first phase learns the parameters of the ABS. The second phase trains the parameters of the AMR encoder by using 1 million training pairs while the parameters of the baseline ABS were fixed and unchanged to prevent overfitting.

Table 1 shows the recall of ROUGE (Lin, 2004) on each dataset. ABS (re-run) represents the performance of ABS re-trained by the distributed scripts[7]. We can see that the proposed method, ABS+AMR, outperforms the baseline ABS on all datasets. In particular, ABS+AMR achieved statistically significant gain from ABS (re-run) for ROUGE-1 and ROUGE-2 on DUC-2004. However in contrast, we observed that the improvements on Gigaword (the same test data as Rush et al. (2015)) seem to be limited compared with the DUC-2004 dataset. We assume that this limited gain is caused largely by the quality of AMR parsing results. This means that the

[4]Training data can be obtained by using the script distributed by the authors of Rush et al. (2015).

[5]Gigaword test data can be obtained from `https://github.com/harvardnlp/sent-summary`

[6]We used the ROUGE-1.5.5 script with option "`-n2 -m -b75 -d`", and computed the average of each ROUGE score.

Figure 3: Examples of generated headlines on Gigaword. **I**: input, **G**: true headline, **A**: ABS (re-run), and **P**: ABS+AMR.

Gigaword test data provided by Rush et al. (2015) is already pre-processed. Therefore, the quality of the AMR parsing results seems relatively worse on this pre-processed data since, for example, many low-occurrence words in the data were already replaced with "UNK". To provide evidence of this assumption, we also evaluated the performance on our randomly selected 2,000 sentence-headline test data also taken from the test data section of the annotated Gigaword corpus. "Gigaword (randomly sampled)" in Table 1 shows the results of this setting. We found the statistical difference between ABS(re-run) and ABS+AMR on ROUGE-1 and ROUGE-2.

We can also observe that ABS+AMR achieved the best ROUGE-1 scores on all of the test data. According to this fact, ABS+AMR tends to successfully yield semantically important words. In other words, embeddings encoded through the AMR encoder are useful for capturing important concepts in input sentences. Figure 3 supports this observation. For example, ABS+AMR successfully added the correct modifier 'saudi' to "crown prince" in the first example. Moreover, ABS+AMR generated a consistent subject in the third example.

The comparison between ABS+AMR(w/o attn) and ABS+AMR (with attention) suggests that the attention mechanism is necessary for AMR encoding. In other words, the encoder without the attention mechanism tends to be overfitting.

5 Related Work

Recently, the Recurrent Neural Network (RNN) and its variant have been applied successfully to various NLP tasks. For headline generation tasks, Chopra et al. (2016) exploited the RNN decoder (and its variant) with the attention mechanism instead of the method of Rush et al. (2015): the combination of the feed-forward neural network language model and attention-based sentence encoder. Nallapati et al. (2016) also adapted the RNN encoder-decoder with attention for headline generation tasks. Moreover, they made some efforts such as hierarchical attention to improve the performance. In addition to using a variant of RNN, Gulcehre et al. (2016) proposed a method to handle infrequent words in natural language generation. Note that these recent developments do not conflict with our method using the AMR encoder. This is because the AMR encoder can be straightforwardly incorporated into their methods as we have done in this paper, incorporating the AMR encoder into the baseline. We believe that our AMR encoder can possibly further improve the performance of their methods. We will test that hypothesis in future study.

6 Conclusion

This paper mainly discussed the usefulness of incorporating structural syntactic and semantic information into novel attention-based encoder-decoder models on headline generation tasks. We selected abstract meaning representation (AMR) as syntactic and semantic information, and proposed an attention-based AMR encoder-decoder model. The experimental results of headline generation benchmark data showed that our attention-based AMR encoder-decoder model successfully improved standard automatic evaluation measures of headline generation tasks, ROUGE-1, ROUGE-2, and ROUGE-L. We believe that our results provide empirical evidence that syntactic and semantic information obtained from an automatic parser can help to improve the neural encoder-decoder approach in NLG tasks.

Abstract

Word embedding models learn vectorial word representations that can be used in a variety of NLP applications. When training data is scarce, these models risk losing their generalization abilities due to the complexity of the models and the overfitting to finite data. We propose a regularized embedding formulation, called *Robust Gram* (RG), which penalizes overfitting by suppressing the disparity between target and context embeddings. Our experimental analysis shows that the RG model trained on small datasets generalizes better compared to alternatives, is more robust to variations in the training set, and correlates well to human similarities in a set of word similarity tasks.

1 Introduction

Word embeddings represent each word as a unique vector in a linear vector space, encoding particular semantic and syntactic structure of the natural language (Arora et al., 2016). In various lingual tasks, these sequence prediction models shown superior results over the traditional count-based models (Baroni et al., 2014). Tasks such as sentiment analysis (Maas et al., 2011) and sarcasm detection (Ghosh et al., 2015) enjoys the merits of these features.

These word embeddings optimize features and predictors simultaneously, which can be interpreted as a factorization of the word cooccurence matrix C. In most realistic scenarios these models have to be learned from a small training set. Furthermore, word distributions are often skewed, and optimizing the reconstruction of $\hat{C}$ puts too much emphasis on the high frequency pairs (Levy and Goldberg, 2014). On the other hand, by having an unlucky and scarce data sample, the estimated $\hat{C}$ rapidly deviates from the underlying true cooccurence, in particular for low-frequency pairs (Lemaire and Denhire, 2008). Finally, noise (caused by stemming, removal of high frequency pairs, typographical errors, etc.) can increase the estimation error heavily (Arora et al., 2015).

It is challenging to derive a computationally tractable algorithm that solves all these problems. Spectral factorization approaches usually employ Laplace smoothing or a type of SVD weighting to alleviate the effect of the noise (Turney and Pantel, 2010). Alternatively, iteratively optimized embeddings such as Skip Gram (SG) model (Mikolov et al., 2013b) developed various mechanisms such as undersampling of highly frequent hub words apriori, and throwing rare words out of the training.

Here we propose a fast, effective and generalizable embedding approach, called Robust Gram, that penalizes complexity arising from the factorized embedding spaces. This design alleviates the need from tuning the aforementioned pseudo-priors and the preprocessing procedures. Experimental results show that our regularized model 1) generalizes better given a small set of samples while other methods yield insufficient generalization 2) is more robust to arbitrary perturbations in the sample set and alternations in the preprocessing specifications 3) achieves much better performance on word similarity task, especially when similarity pairs contains unique and hardly observed words in the vocabulary.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1060–1065,
Austin, Texas, November 1-5, 2016.

2 Robust Gram Embeddings

Let $|y| = V$ the vocabulary size and N be the total number of training samples. Denote x, y to be $V \times 1$ discrete word indicators for the context and target: corresponding to the context and word indicators c, w in word embedding literature. Define $\Psi_{d\times V}$ and $\Phi_{d\times V}$ as word and context embedding matrices. The projection on the matrix column space, Φx, gives us the embedding $\vec{x} \in R^d$. We use Φx and Φ_x interchangeably. Using a very general formulation for the regularized optimization of a (embedding) model, the following objective is minimized:

$$J = \sum_{i}^{N} \mathcal{L}(\Psi, \Phi, x_i, y_i) + g(\Psi, \Phi) \qquad (1)$$

where $\mathcal{L}(\Psi, \Phi, x_i, y_i)$ is the loss incurred by embedding example target y_i using context x_i and embedding parameters Ψ, Φ, and where $g(\Psi, \Phi)$ is a regularization of the embedding parameters. Different embedding methods differ in the form of specified loss function and regularization. For instance, the Skip Gram likelihood aims to maximize the following conditional:

$$\begin{aligned} \mathcal{L}(\Psi, \Phi, x, y) &= -\log p(y|x, \Phi, \Psi) \\ &= -\log \frac{\exp(\Psi_y^T \Phi_x)}{\sum_{y'} \exp(\Psi_{y'}^T \Phi_x)} \end{aligned} \qquad (2)$$

This can be interpreted as a generalization of Multinomial Logistic Regression (MLR). Rewriting $(\Psi y)^T(\Phi x) = (y^T \Psi^T \Phi x) = y^T W x = W_y x$ shows that the combination of Φ and Ψ become the weights in the MLR. In the regression the input x is transformed to directly predict y. The Skip Gram model, however, transforms both the context x and the target y, and can therefore be seen as a generalization of the MLR.

It is also possible to penalize the quadratic loss between embeddings (Globerson et al., 2007):

$$\mathcal{L}(.) = -\log \frac{\exp(-||\Psi_y - \Phi_x||^2)}{\sum_{y'} \exp(-||\Psi_{y'} - \Phi_x||^2)} \qquad (3)$$

Since these formulations predefine a particular embedding dimensionality d, they impose a low rank constraint on the factorization $W = \Psi^T \Phi$. This means that $g(\Psi, \Phi)$ contains $\lambda rank(\Phi^T \Psi)$ with a sufficiently large λ. The optimization with an explicit rank constraint is NP hard. Instead, approximate rank constraints are utilized with a Trace Norm (Fazel et al., 2001) or Max Norm (Srebro and Shraibman, 2005). However, adding such constraints usually requires semidefinite programs which quickly becomes computationally prohibitive even with a moderate vocabulary size.

Do these formulations penalize the complexity? Embeddings under quadratic loss are already regularized and avoids trivial solutions thanks to the second term. They also incorporate a bit weighted data-dependent ℓ_2 norm. Nevertheless, choosing a log-sigmoid loss for Equation 1 brings us to the Skip Gram model and in that case, ℓ_p regularization is not stated. Without such regularization, unbounded optimization of $2Vd$ parameters has potential to converge to solutions that does not generalize well.

To avoid this overfitting, in our formulation we choose g_1 as follows:

$$g_1 = \sum_{v}^{V} \lambda_1 \left(||\Psi_v||_2^2 + ||\Phi_v||_2^2 \right) \qquad (4)$$

where Ψ_v is the row vector of words.

Moreover, an appropriate regularization can also penalize the deviance between low rank matrices Ψ and Φ. Although there are words in the language that may have different context and target representations, such as *the* [1], it is natural to expect that a large proportion of the words have a shared representation in their context and target mappings. To this end, we introduce the following regularization:

$$g_2 = \lambda_2 ||\Psi - \Phi||_F^2 \qquad (5)$$

where F is the Frobenius matrix norm. This assumption reduces learning complexity significantly while a good representation is still retained, optimization under this constraint for large vocabularies is going to be much easier because we limit the degrees of freedom.

The Robust Gram objective therefore becomes:

$$LL + \lambda_1 \sum_{v}^{V} \left(||\Psi_v||_2^2 + ||\Phi_v||_2^2 \right) + \lambda_2 ||\Psi - \Phi||_F^2 \qquad (6)$$

[1] Consider prediction of *Suleiman* from *the*, and *the* from *oasis*. We expect *the* to have different vectorial representations.

where $LL = \sum_i^N \mathcal{L}(p(y_i|x_i, \Psi, \Phi))$ is the data log-likelihood, $p(y_i|x_i, \Psi, \Phi)$ is the loglinear prediction model, and $\mathcal{L}$ the cross entropy loss. Since we are in the pursuit of preserving/restoring low masses in $\hat{C}$, norms such as ℓ_2 allow each element to still possess a small probability mass and encourage smoothness in the factorized $\Psi^T\Phi$ matrix. As $\mathcal{L}$ is picked as the cross entropy, Robust Gram can be interpreted as a more principled and robust counterpart of Skip Gram objective.

One may ask what particular factorization Equation 6 induces. The objective searches for Ψ, Φ matrices that have similar eigenvectors in the vector space. A spectral PCA embedding obtains an asymmetric decomposition $W = U\Sigma V^T$ with $\Psi = U$ and $\Phi = \Sigma V$, albeit a convincing reason for embedding matrices to be orthonormal lacks. In the Skip Gram model, this decomposition is more symmetric since neither Ψ nor Φ are orthonormal and diagonal weights are distributed across the factorized embeddings. A symmetric factorization would be: $\Psi = U\Sigma^{0.5}$,$\Phi = \Sigma^{0.5}V^T$ as in (Levy and Goldberg, 2014). The objective in Eq. 6 converges to a more symmetric decomposition since $||\Psi - \Phi||$ is penalized. Still some eigenvectors across context and target maps are allowed to differ if they pay the cost. In this sense our work is related to power SVD approaches (Caron, 2000) in which one searches an a to minimize $||W - U\Sigma^a\Sigma^{1-a}V^T||$. In our formulation, if we enforce a solution by applying a strong constraint on $||\Psi - \Phi||_F^2$, then our objective will gradually converge to a symmetric powered decomposition such that $U \approx V$.

3 Experiments

The experiments are performed on a subset of the Wikipedia corpus containing approximately 15M words. For a systematic comparison, we use the same symmetric window size adopted in (Pennington et al., 2014), 10. Stochastic gradient learning rate is set to 0.05. Embedding dimensionality is set to 100 for model selection and sensitivity analysis. Unless otherwise is stated, we discard the most frequent 20 hub words to yield a final vocabulary of 26k words. To understand the relative merit of our approach [2] , Skip Gram model is picked as the baseline. To retain the learning speed, and avoid inctractability of maximum likelihood learning, we learn our embeddings with Noise Contrastive Estimation using a negative sample (Gutmann and Hyvärinen, 2012).

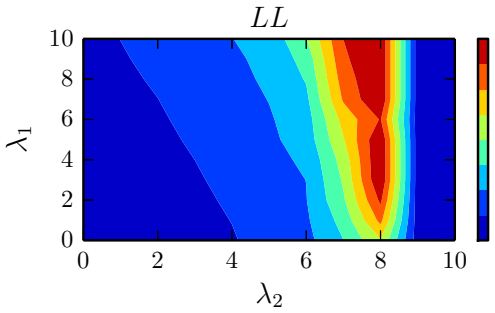

Figure 1: The LL objective for varying λ_1, λ_2.

3.1 Model Selection

For model selection, we are going to illustrate the log likelihood of different model instances. However, exact computation of the LL is computationally difficult since a full pass over the validation likelihood is time-consuming with millions of samples. Hence, we compute a stochastic likelihood with a few approximation steps. We first subsample a million samples rather than a full evaluation set, and then sample few words to predict in the window context similar to the approach followed in (Levy and Goldberg, 2014). Lastly, we approximate the normalization factor with one negative sample for each prediction score (Mnih and Kavukcuoglu, 2013)(Gutmann and Hyvärinen, 2012). Such an approximation works fine and gives smooth error curves. The reported likelihoods are computed by averaging over 5-fold cross validation sets.

Results. Figure 1 shows the likelihood LL obtained by varying $\{\lambda_1, \lambda_2\}$. The plot shows that there exits a unique minimum and both constraints contribute to achieve a better likelihood compared to their unregularized counterparts (for which $\lambda_1 = \lambda_2 = 0$). In particular, the regularization imposed by the differential of context and target embeddings g_2 contributes more than the regularization on the em-

[2] Our implementation can be downloaded from `github.com/taygunk/robust_gram_embeddings`

beddings Ψ and Φ separately. This is to be expected as g_2 also incorporates an amount of norm bound on the vectors. The region where both constraints are employed gives the best results. Observe that we can simply enhance the effect of g_2 by adding a small amount of bounded norm g_1 constraint in a stable manner. Doing this with pure g_2 is risky because it is much more sensitive to the selection of λ_2. These results suggest that the convex combination of stable nature of g_1 with potent regularizer of g_2, finally yields comparably better regularization.

3.2 Sensitivity Analysis

In order to test the sensitivity of our model and baseline Skip Gram to variations in the training set, we perform two sensitivity analyses. First, we simulate a missing data effect by randomly dropping out $\gamma \in [0, 20]$ percent of the training set. Under such a setting, robust models are expected to be effected less from the inherent variation. As an addition, we inspect the effect of varying the minimum cut-off parameter to measure the sensitivity. In this experiment, from a classification problem perspective, each instance is a sub-task with different number of classes (words) to predict. Instances with small cut-off introduces classification tasks with very few training samples. This cut-off choice varies in different studies (Pennington et al., 2014; Mikolov et al., 2013b), and it is usually chosen based on heuristic and storage considerations.

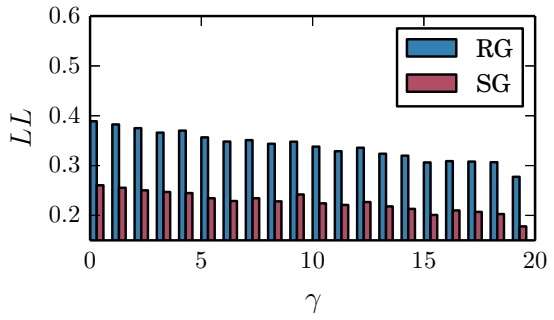

Figure 2: Training dropouts effect on LL.

Results. Figure 2 illustrates the likelihood of the Robust and Skip Gram model by varying the dropout ratio on the training set. As the training set shrinks, both models get lower LL. Nevertheless, likelihood decay of Skip Gram is relatively faster. When 20% drop is applied, the LL drops to 74% in the SG model. On the other hand the RG model not only starts with a much higher LL, the drop is also to 75.5%, suggesting that RG objective is more resistant to random variations in the training data.

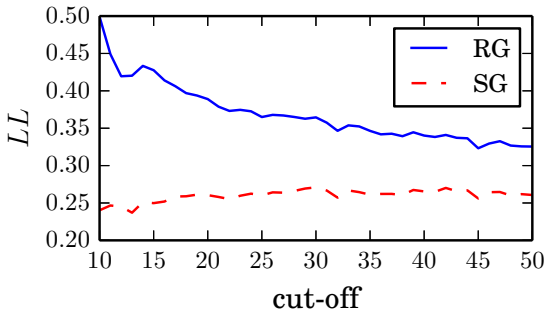

Figure 3: LL w.r.t the cut-off parameter.

Figure 3 shows the results of varying the rare-words cut-off threshold. We observe that the likelihood obtained by the Skip Gram is consistently lower than that of the Robust Gram. The graph shows that throwing out these rare words helps the objective of SG slightly. But for the Robust Gram removing the rare words actually means a significant decrease in useful information, and the performance starts to degrade towards the SG performance. RG avoids the overfitting occurring in SG, but still extracts useful information to improve the generalization.

3.3 Word Similarity Performance

The work of (Schnabel et al., 2015) demonstrates that intrinsic tasks are a better proxy for measuring the generic quality than extrinsic evaluations. Motivated by this observation, we follow the experimental setup of (Schnabel et al., 2015; Agirre et al., 2009), and compare word correlation estimates of each model to human estimated similarities with Spearman's correlation coefficient. The evaluation is performed on several publicly available word similarity datasets having different sizes. For datasets having multiple subjects annotating the word similarity, we compute the average similarity score from all subjects.

We compare our approach to set of techniques on the horizon of spectral to window based approaches. A fully spectral approach, HPCA, (Lebret and Le-

bret, 2013) extracts word embeddings by running a Hellinger PCA on the cooccurrence matrix. For this method, context vocabulary upper and lower bound parameters are set to $\{1, 10^{-5}\}$, as promoted by its author. GLoVe (Pennington et al., 2014) approach formulates a weighted least squares problem to combine global statistics of cooccurence and efficiency of window-based approaches. Its objective can be interpreted as an alternative to the cross-entropy loss of Robust Gram. The x_{max}, α values of the GLoVe objective is by default set to $100, 3/4$. Finally, we also compare to shallow representation learning networks such as Skip Gram and Continuous Bag of Words (CBoW) (Mikolov et al., 2013a), competitive state of the art window based baselines.

We set equal window size for all these models, and iterate three epochs over the training set. To yield more generality, all results obtained with 300 dimensional embeddings and subsampling parameters are set to 0. For Robust Gram approach, we have set $\lambda_1, \lambda_2 = \{0.3, 0.3\}$. To obtain the similarity results, we use the final Φ context embeddings.

Results. Table 1 depicts the results. The first observation is that in this setting, obtaining word similarity using HPCA and GLoVe methods are suboptimal. Frankly, we can conjecture that this scarce data regime is not in the favor of the spectral methods such as HPCA. Its poor performance can be attributed to its pure geometric reconstruction formulation, which runs into difficulties by the amount of inherent noise. Compared to these, CBoW's performance is moderate except in the RW dataset where it performs the worst. Secondly, the performance of the SG is relatively better compared to these approaches. Surprisingly, under this small data setting, RG outperforms all of its competitors in all datasets except for RG65, a tiny dataset of 63 words containing very common words. It is admissible that RG sacrifices a bit in order to generalize to a large variety of words. Note that it especially wins by a margin in MEN and Rare Words (RW) datasets, having the largest number of similarity query samples. As the number of query samples increases, RG embeddings' similarity modeling accuracy becomes clearly perceptible. The promising result Robust Gram achieves in RW dataset also sheds light on why CBoW performed worst on RW: CBOW overfits rapidly confirming the recent studies on the stability of CBoW (Luo et al., 2014). Finally, these word similarity results suggest that RG embeddings can yield much more generality under data scarcity.

	RG65	WS	WSS	WSR	MEN	RW
Size	63	353	203	252	3000	2034
CBoW	48.5	59.7	71.8	61.3	56.5	26.4
GloVe	48.9	56.2	61.5	59.1	53.0	30.0
SG	**59.2**	**71.7**	74.6	66.5	64.7	33.5
HPCA	32.1	48.6	52.9	51.5	49.9	30.7
RG	59.0	**71.7**	**74.8**	**66.7**	**65.8**	**34.0**

Table 1: Spearman's ρ coefficient. Higher is better.

4 Conclusion

This paper presents a regularized word embedding approach, called Robust Gram. In this approach, the model complexity is penalized by suppressing deviations between the embedding spaces of the target and context words. Various experimental results show that RG maintains a robust behaviour under small sample size situations, sample perturbations and it reaches a higher word similarity performance compared to its competitors. The gain from Robust Gram increases notably as diverse test sets are used to measure the word similarity performance.

In future work, by taking advantage of the promising results of Robust Gram, we intend to explore the model's behaviour in various settings. In particular, we plan to model various corpora, i.e. predictive modeling of sequentially arriving network packages. Another future direction might be encoding available domain knowledge by additional regularization terms, for instance, knowledge on synonyms can be used to reduce the degrees of freedom of the optimization. We also plan to enhance the underlying optimization by designing Elastic constraints (Zou and Hastie, 2005) specialized for word embeddings.

Abstract

Lexical simplification of scientific terms represents a unique challenge due to the lack of a standard parallel corpora and fast rate at which vocabulary shift along with research. We introduce SimpleScience, a lexical simplification approach for scientific terminology. We use word embeddings to extract simplification rules from a parallel corpora containing scientific publications and Wikipedia. To evaluate our system we construct SimpleSciGold, a novel gold standard set for science-related simplifications. We find that our approach outperforms prior context-aware approaches at generating simplifications for scientific terms.

1 Introduction

Lexical simplification, the process of reducing the complexity of words by replacing them with simpler substitutes (e.g., *sodium* in place of *Na*; *insects* in place of *lepidopterans*) can make scientific texts more accessible to general audiences. Human-in-the-loop interfaces present multiple possible simplifications to a reader (on demand) in place of jargon and give the reader familiar access points to understanding jargon (Kim et al., 2015). Unfortunately, simplification techniques are not yet of high enough quality for fully automated scenarios.

Currently lexical simplification pipelines for scientific texts are rare. The vast majority of prior methods assume a domain independent context, and rely on Wikipedia and Simple English Wikipedia, a subset of Wikipedia using simplified grammar and terminology, to learn simplifications (Biran et al., 2011; Paetzold and Specia, 2015), with translation-based approaches using an aligned version (Coster and Kauchak, 2011; Horn et al., 2014; Yatskar et al., 2010). However, learning simplifications from Wikipedia is not well suited to lexical simplification of scientific terms. Though generic or established terms may appear in Wikipedia, novel terms associated with new advances may not be reflected. Wikipedia's editing rules also favor generality over specificity and eliminate redundancy, both of which are problematic in providing a rich training set that matches simple and complex terms. Further, some approaches work by detecting all pairs of words in a corpus and filtering to isolate synonym or hypernym-relationship pairs using WordNet (Biran et al., 2011). Like Wikipedia, WordNet is a general purpose semantic database (Miller, 1995), and does not cover all branches of science nor integrate new terminology quickly.

Word embeddings do not require the use of prebuilt ontologies to identify associated terms like simplifications. Recent work indicates that they may improve results for simplification *selection*: determining which simplifications for a given complex word can be used without altering the meaning of the text (Paetzold and Specia, 2015). Embeddings have also been explored to extract hypernym relations from general corpora (Rei and Briscoe, 2014). However, word embeddings have not been used for *generating* lexical simplifications. We provide a novel demonstration of how using embeddings on a scientific corpus is better suited to learning scientific term simplifications than prior approaches that use WordNet as a filter and Wikipedia as a corpus.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1066–1071,
Austin, Texas, November 1-5, 2016.

INPUT: Finally we show that the transient immune activation that renders mosquitoes resistant to the human malaria parasite has little to no effect on mosquito fitness as a measure of survival or fecundity under laboratory conditions. **CANDIDATE RULES**: {fecundity→fertility} {fecundity→productivity} **OUTPUT**: Finally we show that the transient immune activation that renders mosquitoes resistant to the human malaria parasite has little to no effect on mosquito fitness as a measure of survival or (**fertility**; **productivity**) under laboratory conditions.

Table 1: Input sentence, candidate rules and output sentence. (Further examples provided as supplementary material.)

We introduce SimpleScience, a novel lexical simplification pipeline for scientific terms, which we apply to a scientific corpus of nearly 500k publications in Public Library of Science (PLOS) and PubMed Central (PMC) paired with a general corpus from Wikipedia. We validate our approach using SimpleSciGold, a gold standard set that we create using crowdsourcing that contains 293 sentences containing scientific terms with an average of 21 simplifications per term. We show how the SimpleScience pipeline achieves better performance (F-measure: 0.285) than the prior approach to simplification generation applied to our corpus (F-measure: 0.136). We further find that the simplification selection techniques used in prior work to determine which simplifications are a good fit for a sentence do not improve performance when our generation pipeline is used. [1]

2 Parallel corpora: Scientific and General

We assembled a *scientific corpus* of papers from the entire catalog of PLOS articles and the National Library of Medicine's Pubmed Central (PMC) archive (359,324 fulltext articles). The PLOS corpus of 125,378 articles includes articles from PLOS One and each speciality PLOS journal (e.g., Pathogens, Computational Biology). Our *general corpus* includes all 4,776,093 articles from the Feb. 2015 English Wikipedia snapshot. We chose Wikipedia as it covers many scientific concepts and usually contains descriptions of those concepts using simpler language than the research literature. We obtained all datasets from DeepDive (Ré and Zhang, 2015).

3 SimpleScience Design

3.1 Generating Simplifications

Our goal is to learn simplification rules in the form *complex word→simple word*. One approach identifies all pairwise permutations of 'content' terms and then applies semantic (i.e., WordNet) and simplicity filters to eliminate pairs that are not simplifications(Biran et al., 2011). We adopt a similar pipeline but leverage distance metrics on word embeddings and a simpler frequency filter in place of WordNet. Embeddings identify words that share context in an unsupervised, scalable way and are more efficient than constructing co-occurrence matrices (Biran et al., 2011). As our experiments demonstrate, our approach improves performance on a scientific test set over prior work.

3.1.1 Step 1: Generating Word Embeddings

We used the Word2Vec system (Mikolov et al., 2013) to learn word vectors for each content word in the union of vocabulary of the scientific and general corpus. While other approaches exist (Pennington et al., 2014; Levy and Goldberg, 2014), Word2Vec has been shown to produce both fast and accurate results (Mikolov et al., 2013). We set the embedding *dimension* to 300, the *context-window* to 10, and use the skip-gram architecture with negative-sampling,which is known to produce quality results for rare entities (Mikolov et al., 2013).

3.1.2 Step 2: Filtering Pairs

Given the set of all pairwise permutations of words, we retain a simplification rule of two words w_1, w_2 if the cosine similarity $cos(w_1, w_2)$ between the word vectors is greater than a threshold a. We use grid search, described below, to parameterize a.

We then apply additional filtering rules. To avoid rules comprised of words with the same stem (e.g., *permutable*, *permutation*) we stem all words (using the Porter stemmer in the Python NLTK library (Bird et al., 2009)). The POS of each word is determined by Morphadorner (Burns, 2013) and pairs that differ in POS are omitted (e.g., *permutation* (noun), *change(d)* (verb)); Finally, we omit rules where one word is a prefix of the other and the suffix is one of *s, es, ed, ly, er*, or *ing*.

To retain only rules of the form *complex word* →

simple word we calculate the *corpus complexity*, C (Biran et al., 2011) of each word w as the ratio between the frequency (f) in the scientific versus general corpus: $C_w = f_{w,scientific}/f_{w,general}$. The *lexical complexity*, L, of a word is calculated as the word's character length, and the final complexity of the word as $C_w \times L_w$. We require that the final complexity score of the first word in the rule be greater than the second.

While this simplicity filter has been shown to work well in general corpora (Biran et al., 2011), it is sensitive to very small differences in the frequencies with which both words appear in the corpora. This is problematic given the distribution of terms in our corpora, where many rarer scientific terms may appear in small numbers in both corpora.

We introduce an additional constraint that requires that the second (simple) word in the rule occur in the general corpus at least k times. This helps ensure that we do not label words that are at a similar complexity level as simplifications. We note that this filter aligns with prior work that suggests that features of the hypernym in hypernym-hyponym relations influence performance more than features of the hyponym (Rei and Briscoe, 2014).

Parameterization: We use a grid search analysis to identify which measures of the set including $cos(w_1, w_2)$, $f_{w1,scientific}$, $f_{w2,scientific}$, $f_{w1,general}$, and $f_{w2,general}$ most impact the F-measure when we evaluate our generation approach against our scientific gold standard set (Sec. 4), and to set the specific parameter values. Using this method we identify a=0.4 for cosine similarity and k=3,000 for the frequency of the simple term in the general corpus. Full results are available in supplementary material.

3.2 Applying Simplifications

In prior context-aware simplification systems, the decision of whether to apply a simplification rule in an input sentence is complex, involving several similarity operations on word co-occurrence matrices (Biran et al., 2011) or using embeddings to incorporate co-occurrence context for pairs generated using other means (Paetzold and Specia, 2015). However, the SimpleScience pipline already considers the context of appearance for each word in deriving simplifications via word embeddings learned from a large corpus. We see no additional improvements in F-measure when we apply two variants of context similarity thresholds to decide whether to apply a rule to an input sentence. The first is the cosine similarity between the distributed representation of the simple word and the sum of the distributed representations of all words within a window l surrounding the complex word in the input sentence (Paetzold and Specia, 2015). The second is the cosine similarity of a minimum shared frequency co-occurrence matrix for the words in the pair and the co-occurrence matrix for the input sentence (Biran et al., 2011).

In fully automated applications, the top rule from the ranked candidate rules is used. We find that ranking by the cosine similarity between the word embeddings for the complex and simple word in the rule leads to the best performance at the top slot (full results in supplementary material).

4 Evaluation

4.1 SimpleSciGold Test Set

To evaluate our pipeline, we develop SimpleSciGold, a scientific gold standard set of sentences containing complex scientific terms which is modeled after the general purpose gold standard set created by Horn et al. (2014).

To create SimpleSciGold, we start with scientific terms from two sources: we utilized all 304 complex terms from unigram rules by (Vydiswaran et al., 2014), and added another 34,987 child terms from rules found by mining direct parent-child relations for unigrams in the Medical Subject Headings (MeSH) ontology (United States National Library of Medicine, 2015). We chose complex terms with pre-existing simplifications as it provided a means by which we could informally check the crowd generated simplifications for consistency.

To obtain words in context, we extracted 293 sentences containing unique words in this set from PLOS abstracts from PLOS Biology, Pathology, Genetics, and several other journals. We present 10 MTurk crowdworkers with a task ("HIT") showing one of these sentences with the complex word bolded. Workers are told to read the sentence, consult online materials (we provide direct links to a Wikipedia search, a standard Google search, and

SimpleScience ($cos \geq .4, f_{w,simple} \geq 0$)	PLOS/PMC, Wikip.	10,910,536	0.720	0.032	0.061

Table 2: Simplification Generation Results. SimpleScience achieves the highest F-measure with a cosine threshold of 0.4 and a frequency of the simple word in the general corpus of 3000.

a Google "define" search on the target term), and add their simplification suggestions. Crowdworkers first passed a multiple choice practice qualification in which they were presented with sentences containing three complex words in need of simplification along with screenshots of Wikipedia and dictionary pages for the terms. The workers were asked to identify which of 5 possible simplifications listed for each complex word would preserve the meaning while simplifying. 108 workers took part in the gold standard set creation task, completing an average of 27 HITs each. The resulting SimpleSciGold standard set consists of an average of 20.7 simplifications for each of the 293 complex words in corresponding sentences.

4.2 Simplification Generation

We compare our word embedding generation process (applied to our corpora) to Biran et al.'s (2011) approach (applied to the Wikipedia and Simple English Wikipedia corpus as well as our scientific corpora). Following the evaluation method used in Paetzold and Specia (2015), we calculate *potential* as the proportion of instances for which at least one of the substitutions generated is present in the gold standard set, *precision* as the proportion of generated instances which are present in the gold standard set, and *F-measure* as their harmonic mean.

Our SimpleScience approach outperforms the original approach by Biran et al. (2011) applied to the Wikipedia and SEW corpus as well as to the scientific corpus (Table 1).

4.3 Applying Simplifications

We find that neither prior selection approaches yield performance improvements over our generation process. We evaluate the performance of ranking candidate rules by cosine similarity (to find the top rule for a fully automated application), and achieve precision of 0.389 at the top slot. In our supplementary materials, we provide additional results for potential, precision and F-measure at varying numbers of slots (up to 5), where we test ranking by cosine similarity of embeddings as well as by the second filter used in our pair generation step: the frequency of the simple word in the simple corpus.

4.4 Antonym Prevalence Analysis

A risk of using Word2Vec in place of WordNet is that the simpler terms generated by our approach may represent terms with opposite meanings (antonyms). While a detailed analysis is beyond the scope of this paper, we compared the likelihood of seeing antonyms in our results using a gold standard set of antonyms for biology, chemistry, and physics terms from WordNik (Wordnik, 2009). Specifically, we created an antonym set consisting of the 304 terms from the biology, chemistry, and physics categories in Wictionary for which at least one antonym is listed in WordNik. We compared antonym pairs with rules that produced by the SimpleScience pipeline (Fig. 1). We observed that 14.5% of the time (44 out of 304 instances), an antonym appeared at the top slot among results. 51.3% of the time (156 out of 304 instances), no antonyms in the list appeared within the top 100 ranked results. These results suggest that further filters are necessary to ensure high enough quality results for fully automated applications of scientific term simplification.

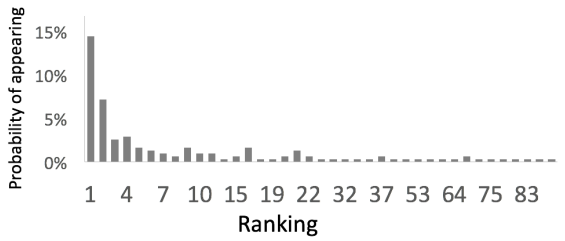

Figure 1: Probability of an antonym in our test set occurring as a suggested simpler term in the top 100 slots in the SimpleScience pipeline.

5 Limitations and Future Work

A risk of using Word2Vec to find related terms, rather than querying a lexical database like WordNet, is that generated rules may include antonyms. Adding techniques to filter antonym rules, such as using co-reference chains (Adel and Schütze, 2014), is important in future work.

We achieve a precision of 0.389 at the top slot on our SimpleSciGold standard set when we apply our generation method and rank candidates by cosine similarity. This level of precision is higher than that achieved by various prior ranking methods used in Lexenstein (Paetzold and Specia, 2015), with the exception of using machine learning techniques like SVM (Paetzold and Specia, 2015). Future work should explore how much the precision of our SimpleScience pipeline can be improved by adopting more sophisticated ranking methods. However, we suspect that even the highest precision obtained on general corpora and gold standard sets in prior work is not sufficient for fully automated simplification. An exciting area for future work is in applying the SimpleScience pipeline in interactive simplification suggestion interfaces for those reading or writing about science (Kim et al., 2015).

6 Conclusion

In this work, we introduce SimpleScience, a lexical simplification approach to address the unique challenges of simplifying scientific terminology, including a lack of parallel corpora, shifting vocabulary, and mismatch with using general purpose databases for filtering. We use word embeddings to extract simplification rules from a novel parallel corpora that contains scientific publications and Wikipedia. Using SimpleSciGold, a gold standard set that we created using crowdsourcing, we show that using embeddings and simple frequency filters on a scientific corpus outperforms prior approaches to simplification generation, and renders the best prior approach to simplification selection unnecessary.

Automatic Features for Essay Scoring – An Empirical Study

Fei Dong and **Yue Zhang**
Singapore University of Technology and Design
fei_dong@mymail.sutd.edu.sg and yue_zhang@sutd.edu.sg

Abstract

Essay scoring is a complicated processing requiring analyzing, summarizing and judging expertise. Traditional work on essay scoring focused on automatic handcrafted features, which are expensive yet sparse. Neural models offer a way to learn syntactic and semantic features automatically, which can potentially improve upon discrete features. In this paper, we employ convolutional neural network (CNN) for the effect of automatically learning features, and compare the result with the state-of-art discrete baselines. For in-domain and domain-adaptation essay scoring tasks, our neural model empirically outperforms discrete models.

1 Introduction

Automatic essay scoring (AES) is the task of building a computer-based grading system, with the aim of reducing the involvement of human raters as far as possible. AES is challenging since it relies not only on grammars, but also on semantics, discourse and pragmatics. Traditional approaches treat AES as a classification (Larkey, 1998; Rudner and Liang, 2002), regression (Attali and Burstein, 2004; Phandi et al., 2015), or ranking classification problem (Yannakoudakis et al., 2011; Chen and He, 2013), addressing AES by supervised learning. Features are typically bag-of-words, spelling errors and lengths, such word length, sentence length and essay length, etc. Some grammatical features are considered to assess the quality of essays (Yannakoudakis et al., 2011). A drawback is feature engineering, which can be time-consuming, since features need to be carefully handcrafted and selected to fit the approriate model. A further drawback of manual feature templates is that they are sparse, instantiated by discrete pattern-matching. As a result, parsers and semantic analyzers are necessary as a preprocessing step to offer syntactic and semantic patterns for feature extraction. Given variable qualities of student essays, such analyzers can be highly unreliable.

Neural network approaches have been shown to be capable of inducing dense syntactic and semantic features automatcially, giving competitive results to manually designed features for several tasks (Kalchbrenner et al., 2014; Johnson and Zhang, 2014; dos Santos and Gatti, 2014). In this paper, we empirically investigate a neural network method to learn features automatically for AES, without the need of external pre-processing. In particular, we build a hierarchical CNN model, with one lower layer representing sentence structures and one upper layer representing essay structure based on sentence representations. We compare automatically-induced features by the model with state-of-art baseline handcrafted features. Empirical results show that neural features learned by CNN are very effective in essay scoring task, covering more high-level and abstract information compared to manual feature templates.

2 Related Work

Following the first AES system Project Essay Grade (PEG) been developed in 1966 (Page, 1994), a number of commercial systems have come out, such as IntelliMetric 2, Intelligent Essay Assessor (IEA) (Foltz et al., 1999) and e-rater system (Attali and Burstein, 2004). The e-rater system now plays a

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1072–1077,
Austin, Texas, November 1-5, 2016.

second human rater's role in the Test of English as a Foreign Language (TOEFL) and Graduate Record Examination (GRE). The e-rater extracts a number of complex features, such as grammatical error and lexical complexity, and uses stepwise linear regression. IEA uses Latent Semantic Analysis (LSA) (Landauer et al., 1998) to create semantic vectors for essays and measure the semantic similarity between the vectors.

In the research literature, Larkey (1998) and Rudner and Liang (2002) treat AES as classification using bag-of-words features. Other recent work formulates the task as a preference ranking problem (Yannakoudakis et al., 2011; Chen and He, 2013). Yannakoudakis et al. (2011) formulated AES as a pairwise ranking problem by ranking the order of pair essays based on their quality. Features consist of word, POS n-grams features, complex grammatical features and so on. Chen and He (2013) formulated AES into a listwise ranking problem by considering the order relation among the whole essays and features contain syntactical features, grammar and fluency features as well as content and prompt-specific features. Phandi et al. (2015) use correlated Bayesian Linear Ridge Regression (cBLRR) focusing on domain-adaptation tasks. All these previous methods use discrete handcrafted features.

Recently, Alikaniotis et al. (2016) also employ a neural model to learn features for essay scoring automatically, which leverages a score-specific word embedding (SSWE) for word representations and a two-layer bidirectional long-short term memory network (LSTM) to learn essay representations. Alikaniotis et al. (2016) show that by combining SSWE, LSTM outperforms traditional SVM model. On the other hand, using LSTM alone does not give significantly more accuracies compared to SVM. This conforms to our preliminary experiments with the LSTM structure. Here, we use CNN without any specific embeddings and show that our neural models could outperform baseline discrete models on both in-domain and cross-domain senarios.

CNN has been used in many NLP applications, such as sequence labeling (Collobert et al., 2011) , sentences modeling (Kalchbrenner et al., 2014), sentences classification (Kim, 2014), text categorization (Johnson and Zhang, 2014; Zhang et al., 2015) and sentimental analysis (dos Santos and Gatti, 2014), etc. In this paper, we explore CNN representation ability for AES tasks on both in-domain and domain-adaptation settings.

Feature Type	Feature Description
Length	Number of characters, words, sentences, etc.
POS	Relative and absolute number of bad POS n-grams
Prompt	Relative and absolute number of words and their synonyms in the essay appearing in the prompt
Bag-of-words	Count of useful unigrams and bigrams (unstemmed, stemmed and spell corrected)

Table 1: Feature description used by EASE.

3 Baseline

Bayesian Linear Ridge Regression (BLRR) and Support Vector Regression (SVR) (Smola and Vapnik, 1997) are chosen as state-of-art baselines. Feature templates follow (Phandi et al., 2015), extracted by EASE[1], which are briefly listed in Table 1. "Useful n-grams" are determined using the Fisher test to separate the good scoring essays and bad scoring essays. Good essays are essays with a score greater than or equal to the average score, and the remainder are considered as bad scoring essays. The top 201 n-grams with the highest Fisher values are chosen as the bag of features and these top 201 n-grams constitute useful n-grams. Correct POS tags are generated using grammatically correct texts, which is done by EASE. The POS tags that are not included in the correct POS tags are treated as bad POS tags, and these bad POS tags make up the "bad POS n-grams" features.

The features tend to be highly useful for the in-domain task since the discrete features of same prompt data share the similar statistics. However, for different prompts, features statistics vary significantly. This raises challenges for discrete feature patterns.

ML-ρ (Phandi et al., 2015) was proposed to address this issue. It is based on feature augmentation, incorporating explicit correlation into augmented feature spaces. In particular, it expands baseline feature vector $\mathbf{x}$ to be $\Phi^s(\mathbf{x}) = (\rho\mathbf{x}, (1-\rho^2)^{1/2}\mathbf{x})$ and $\Phi^t(\mathbf{x}) = (\mathbf{x}, \mathbf{0_p})$ for source and target domain data

[1] https://github.com/edx/ease

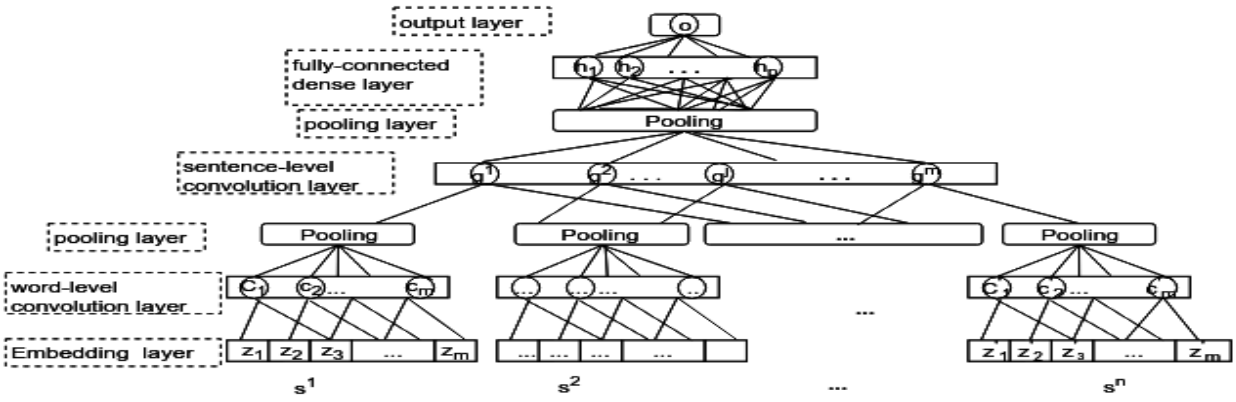

Figure 1: Hierarchical CNN structure

in R^{2p} respectively, with ρ being the correlation between source and target domain data. Then BLRR and maximum likelihood estimation are used to the optimize correlation. All the baseline models require POS-tagging as a pre-processing step, extracting syntactic features based on POS-tags.

4 Model

Word Representations We use word embedding with an embedding matrix $E_w \in R^{d_w \times V_w}$ where d_w is the embedding dimension, and V_w represents words vocabulary size. A word vector z_i is represented by $z_i = E_w w_i$ where w_i is the i-th word in a sentence. In contrast to the baseline models, our CNN model does not rely on POS-tagging or other pre-processing.

CNN Model We take essay scoring as a regression task and employ a two-layer CNN model, in which one convolutional layer is used to extract sentences representations, and the other is stacked on sentence vectors to learn essays representations. The architecture is depicted in Figure 1. Given an input sentence z_1, z_2, ..., z_n, a convolution layer with a *filter* $\mathbf{w} \in R^{h \times k}$ is applied to a window of h words to produce n-grams features. For instance, a feature c_i is generated from a window of words $z_{i:i+h-1}$ by $c_i = f(\mathbf{w} \cdot z_{i:i+h-1} + b)$, $b \in R$ is the bias term and f is the non-linear activation function rectified linear unit (ReLU).

The filter is applied to the all possible windows in a sentence to produce a feature map $\mathbf{c} = [c_1, c_2, ..., c_{m-h+1}]$. For $\mathbf{c}^j$ of the j-th sentence in an essay, max-pooling and average pooling function are used to produce the sentence vector $s^j = max\{\mathbf{c}^j\} \oplus avg\{\mathbf{c}^j\}$. The second convolutional layer takes s^1, s^2,..., s^n as inputs, followed by pooling layer (max-pooling and average-pooling) and a fully-connected hidden layer. The hidden layer directly connects to output layer which generates a score.

5 Experiments

5.1 Setup

Data We use the Automated Student Assessment Prize (ASAP)[2] dataset as evaluation data for our task, which contains 8 prompts of different genres as listed in Table 2. The essay scores are scaled into the range from 0 to 1. The settings of data preparation follow (Phandi et al., 2015). We use quadratic weighted kappa (QWK) as the metric. For domain-adaptation (cross-domain) experiments, we follow (Phandi et al., 2015), picking four pairs of essay prompts, namely, 1→2, 3→4, 5→6 and 7→8, where 1→2 denotes prompt 1 as source domain and prompt

2 as target domain. All source domain essays are used as training data. Target domain data are randomly divided into 5 folds, where one fold is used as test data, and other 4 folds are collected together to sub-sample target domain train data. The sub-sampled sizes are 10, 25, 50, 100, with the larger sampled sets containing the smaller ones. And we repeated sub-sampling 5 times for each target training number to alleviate bias.

Hyper-parameters We use Adagrad for optimization. Word embeddings are randomly initialized and the hyper-parameter settings are listed in Table 3.

5.2 Results

In-domain The in-domain results are shown in Figure 2. The average values of all 8 prompt sets are listed in Table 4. For the in-domain task, CNN outperforms the baseline model SVR on all prompts of essay sets, and is competitive to BLRR. For the statistical significance, neural model is significantly better than baseline models with the p-value less than 10^{-5} at the confidence level of 95%. The average kappa value over 8 prompts is close to that of human raters.

Cross-domain The domain-adaptation results are shown in Table 5. It can be seen that our CNN

	CNN	**0.570**	**0.590**	**0.568**	**0.587**

Table 5: Cross-domain results.

model outperforms ML-ρ on almost all pairs of adaptation experiments. ML-ρ domain-adaptation method's performance improves as the size of target domain training data increases. However, compared to ML-ρ, target training data size has less impact on our neural model. Even if the target training size is small, the neural model still gives strong performance. This results from the fact that neural model could learn more high-level and abstract features compared to traditional models with handcrafted discrete features. We plot the confusion matrix between truth and model prediction on test data in Figure 4, which shows that prediction scores of neural model tend to be closer to true values, which is very important in our task.

5.3 Feature Analysis

To visualize the features learned by our model, we use t-distributed stochastic neighbor embedding (t-SNE) (Van der Maaten and Hinton, 2008), projecting 50-dimensional features into 2-dimensional space. We take two domain pairs 3→4 and 5→6 as examples on the cross-domain task, extracting fully-connected hidden-layer features for target domain data using model trained on source domain data. The results are showed in Figure 3. The baseline discrete features are more concentrated, which shows that patterns on source prompt are weak in differentiating target prompt essays. By using ML-ρ and leveraging 100 target prompt training examples, the discrete features patterns are more scattered, increasing the differentiating power. In contrast, CNN

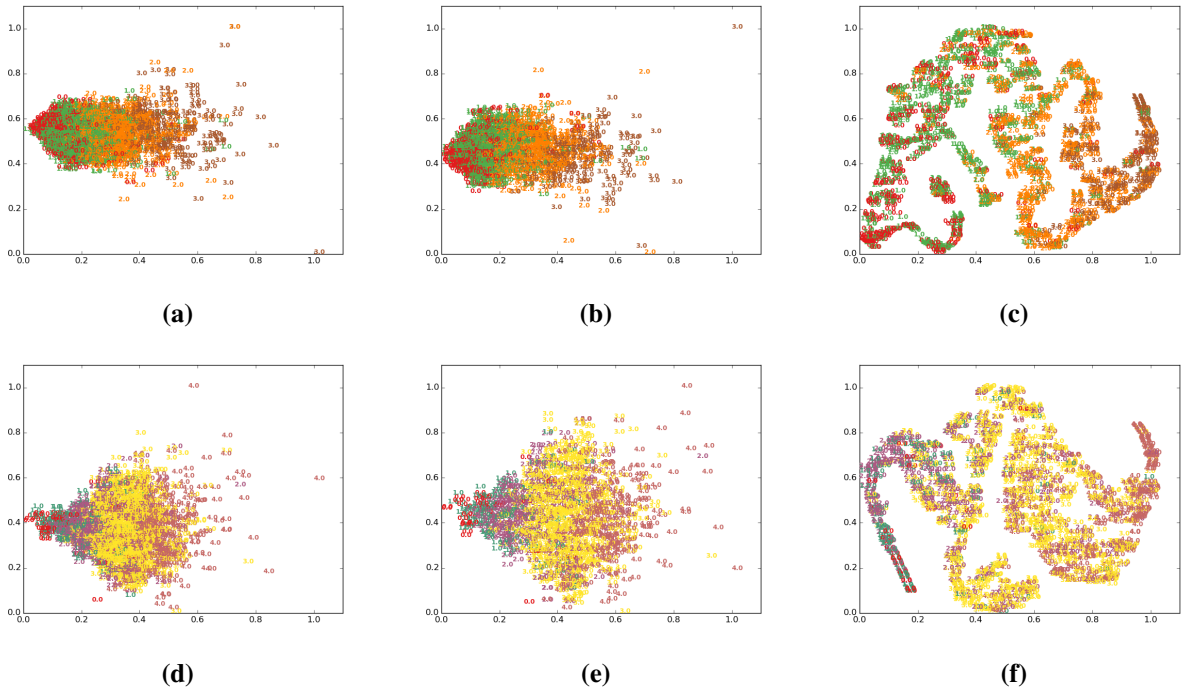

Figure 3: Visualization of discrete and neural features using t-SNE (each value represents an essay of the corresponding score). Top: Set 4 (3→4), Bottom: Set 6 (5→6). (a) discrete features; (b) ML-ρ features, $n_t = 100$; (c) neural features; (d) discrete features; (e) ML-ρ features, $n_t = 100$; (f) neural features.

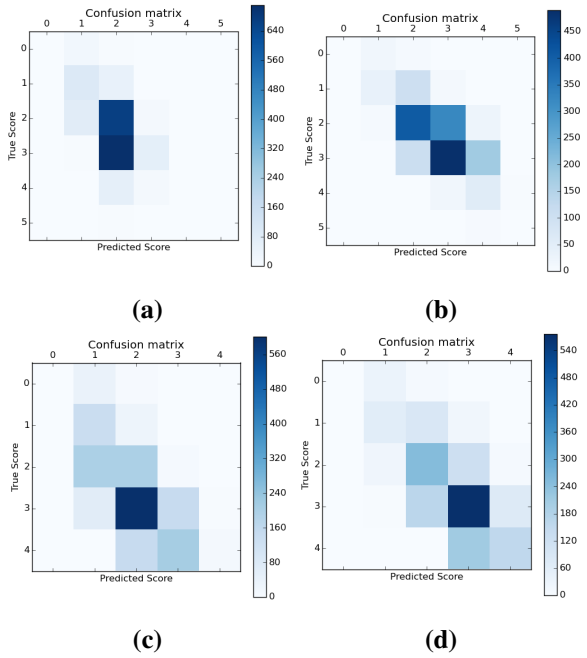

Figure 4: Confusion matrix of true and prediction scores by two different models on test data when target training size $n_t = 10$. (a) ML-ρ on 1→2; (b) CNN model on 1→2; (c) ML-ρ on 5→6; (d) CNN model on 5→6.

features trained on source prompt are sparse when used directly on the target prompt. This shows that neural features learned by the CNN model can better differentiate essays of different qualities. Without manual templates, such features automatically capture subtle and complex information that is relevant to the task.

6 Conclusion

We empirically investigated a hierarchical CNN model for automatic essay scoring, showing automatically learned features competitive to discrete handcrafted features for both in-domain and domain-adaptation tasks. The results demonstrate large potential for deep learning in AES.

Abstract

We present a novel semi-supervised approach for sequence transduction and apply it to semantic parsing. The unsupervised component is based on a generative model in which latent sentences generate the unpaired logical forms. We apply this method to a number of semantic parsing tasks focusing on domains with limited access to labelled training data and extend those datasets with synthetically generated logical forms.

1 Introduction

Neural approaches, in particular attention-based sequence-to-sequence models, have shown great promise and obtained state-of-the-art performance for sequence transduction tasks including machine translation (Bahdanau et al., 2015), syntactic constituency parsing (Vinyals et al., 2015), and semantic role labelling (Zhou and Xu, 2015). A key requirement for effectively training such models is an abundance of supervised data.

In this paper we focus on learning mappings from input sequences x to output sequences y in domains where the latter are easily obtained, but annotation in the form of (x, y) pairs is sparse or expensive to produce, and propose a novel architecture that accommodates semi-supervised training on sequence transduction tasks. To this end, we augment the transduction objective ($x \mapsto y$) with an autoencoding objective where the input sequence is treated as a latent variable ($y \mapsto x \mapsto y$), enabling training from both labelled pairs and unpaired output sequences. This is common in situations where we encode natural language into a logical form governed by some grammar or database.

While such an autoencoder could in principle be constructed by stacking two sequence transducers, modelling the latent variable as a series of discrete symbols drawn from multinomial distributions creates serious computational challenges, as it requires marginalising over the space of latent sequences Σ_x^*. To avoid this intractable marginalisation, we introduce a novel differentiable alternative for draws from a softmax which can be used with the reparametrisation trick of Kingma and Welling (2014). Rather than drawing a discrete symbol in Σ_x from a softmax, we draw a distribution over symbols from a logistic-normal distribution at each time step. These serve as continuous relaxations of discrete samples, providing a differentiable estimator of the expected reconstruction log likelihood.

We demonstrate the effectiveness of our proposed model on three semantic parsing tasks: the GEOQUERY benchmark (Zelle and Mooney, 1996; Wong and Mooney, 2006), the SAIL maze navigation task (MacMahon et al., 2006) and the Natural Language Querying corpus (Haas and Riezler, 2016) on OpenStreetMap. As part of our evaluation, we introduce simple mechanisms for generating large amounts of unsupervised training data for two of these tasks.

In most settings, the semi-supervised model outperforms the supervised model, both when trained on additional generated data as well as on subsets of the existing data.

Dataset	Example
GEO	what are the high points of states surrounding mississippi answer(high_point_1(state(next_to_2(stateid('mississippi'))))))
NLMAPS	Where are kindergartens in Hamburg? query(area(keyval('name','Hamburg')),nwr(keyval('amenity','kindergarten')),qtype(latlong))
SAIL	turn right at the bench into the yellow tiled hall $(1, 6, 90)$ FORWARD - FORWARD - RIGHT - STOP $(3, 6, 180)$

Table 1: Examples of natural language x and logical form y from the three corpora and tasks used in this paper. Note that the SAIL corpus requires additional information in order to map from the instruction to the action sequence.

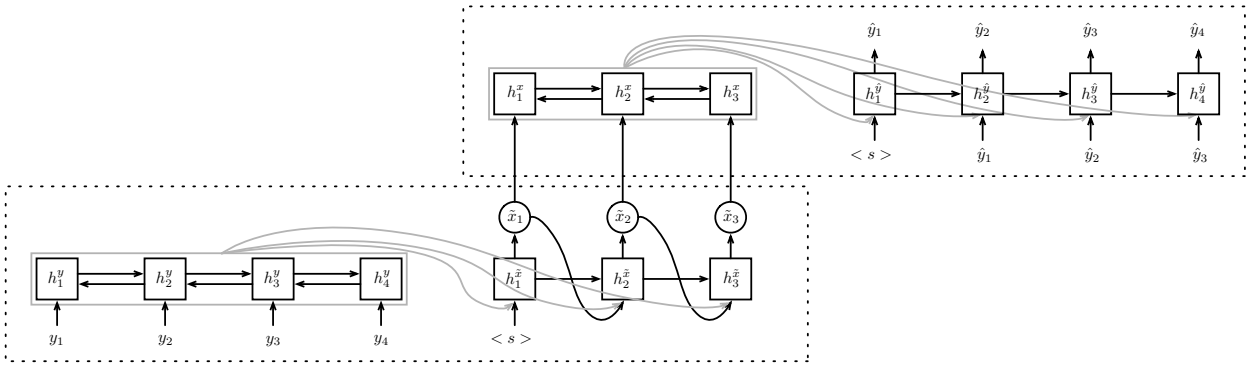

Figure 1: SEQ4 model with attention-sequence-to-sequence encoder and decoder. Circle nodes represent random variables.

2 Model

Our sequential autoencoder is shown in Figure 1. At a high level, it can be seen as two sequence-to-sequence models with attention (Bahdanau et al., 2015) chained together. More precisely, the model consists of four LSTMs (Hochreiter and Schmidhuber, 1997), hence the name SEQ4. The first, a bidirectional LSTM, encodes the sequence y; next, an LSTM with stochastic output, described below, draws a sequence of distributions $\tilde{x}$ over words in vocabulary Σ_x. The third LSTM encodes these distributions for the last one to attend over and reconstruct y as $\hat{y}$. We now give the details of these parts.

2.1 Encoding y

The first LSTM of the encoder half of the model reads the sequence y, represented as a sequence of one-hot vectors over the vocabulary Σ_y, using a bidirectional RNN into a sequence of vectors $h^y_{1:L_y}$ where L_y is the sequence length of y,

$$h^y_t = \left(f^{\rightarrow}_y(y_t, h^{y,\rightarrow}_{t-1}); f^{\leftarrow}_y(y_t, h^{y,\leftarrow}_{t+1})\right), \qquad (1)$$

where $f^{\rightarrow}_y, f^{\leftarrow}_y$ are non-linear functions applied at each time step to the current token y_t and their recurrent states $h^{y,\rightarrow}_{t-1}$, $h^{y,\leftarrow}_{t+1}$, respectively.

Both the forward and backward functions project the one-hot vector into a dense vector via an embedding matrix, which serves as input to an LSTM.

2.2 Predicting a Latent Sequence $\tilde{x}$

Subsequently, we wish to predict x. Predicting a discrete sequence of symbols through draws from multinomial distributions over a vocabulary is not an option, as we would not be able to backpropagate through this discrete choice. Marginalising over the possible latent strings or estimating the gradient through naïve Monte Carlo methods would be a prohibitively high variance process because the number of strings is exponential in the maximum length (which we would have to manually specify) with the vocabulary size as base. To allow backpropagation, we instead predict a sequence of distributions $\tilde{x}$ over the symbols of Σ_x with an RNN attending over

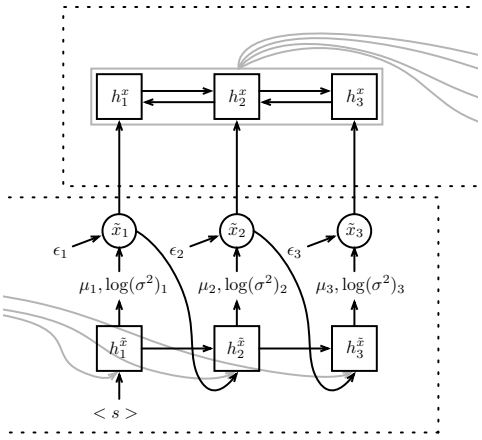

Figure 2: Unsupervised case of the SEQ4 model.

$h^y = h^y_{1:L_y}$, which will later serve to reconstruct y:

$$\tilde{x} = q(x|y) = \prod_{t=1}^{L_x} q(\tilde{x}_t|\{\tilde{x}_1, \cdots, \tilde{x}_{t-1}\}, h^y) \quad (2)$$

where $q(x|y)$ models the mapping $y \mapsto x$. We define $q(\tilde{x}_t|\{\tilde{x}_1, \cdots, \tilde{x}_{t-1}\}, h^y)$ in the following way:

Let the vector $\tilde{x}_t$ be a distribution over the vocabulary Σ_x drawn from a logistic-normal distribution[1], the parameters of which, $\mu_t, \log(\sigma^2)_t \in \mathbb{R}^{|\Sigma_x|}$, are predicted by attending by an LSTM attending over the outputs of the encoder (Equation 2), where $|\Sigma_x|$ is the size of the vocabulary Σ_x. The use of a logistic normal distribution serves to regularise the model in the semi-supervised learning regime, which is described at the end of this section. Formally, this process, depicted in Figure 2, is as follows:

$$h_t^{\tilde{x}} = f_{\tilde{x}}(\tilde{x}_{t-1}, h_{t-1}^{\tilde{x}}, h^y) \quad (3)$$

$$\mu_t, \log(\sigma_t^2) = l(h_t^{\tilde{x}}) \quad (4)$$

$$\epsilon \sim \mathcal{N}(0, I) \quad (5)$$

$$\gamma_t = \mu_t + \sigma_t \epsilon \quad (6)$$

$$\tilde{x}_t = \mathrm{softmax}(\gamma_t) \quad (7)$$

where the $f_{\tilde{x}}$ function is an LSTM and l a linear transformation to $\mathbb{R}^{2|\Sigma_x|}$. We use the reparametrisation trick from Kingma and Welling (2014) to draw from the logistic normal, allowing us to backpropagate through the sampling process.

[1]The logistic-normal distribution is the exponentiated and normalised (i.e. taking softmax) normal distribution.

2.3 Encoding x

Moving on to the decoder part of our model, in the third LSTM, we embed[2] and encode $\tilde{x}$:

$$h_t^x = \left(f_x^{\rightarrow}(\tilde{x}_t, h_{t-1}^{x,\rightarrow}); f_x^{\leftarrow}(\tilde{x}_t, h_{t+1}^{x,\leftarrow})\right) \quad (8)$$

When x is observed, during supervised training and also when making predictions, instead of the distribution $\tilde{x}$ we feed the one-hot encoded x to this part of the model.

2.4 Reconstructing y

In the final LSTM, we decode into y:

$$p(\hat{y}|\tilde{x}) = \prod_{t=1}^{L_y} p(\hat{y}_t|\{\hat{y}_1, \cdots, \hat{y}_{t-1}\}, h^{\tilde{x}}) \quad (9)$$

Equation 9 is implemented as an LSTM attending over $h^{\tilde{x}}$ producing a sequence of symbols $\hat{y}$ based on recurrent states $h^{\hat{y}}$, aiming to reproduce input y:

$$h_t^{\hat{y}} = f_{\hat{y}}(\hat{y}_{t-1}, h_{t-1}^{\hat{y}}, h^{\tilde{x}}) \quad (10)$$

$$\hat{y}_t \sim \mathrm{softmax}(l'(h_t^{\hat{y}})) \quad (11)$$

where $f_{\hat{y}}$ is the non-linear function, and the actual probabilities are given by a softmax function after a linear transformation l' of $h^{\hat{y}}$. At training time, rather than $\hat{y}_{t-1}$ we feed the ground truth y_{t-1}.

2.5 Loss function

The complete model described in this section gives a reconstruction function $y \mapsto \hat{y}$. We define a loss on this reconstruction which accommodates the unsupervised case, where x is not observed in the training data, and the supervised case, where (x, y) pairs are available. Together, these allow us to train the SEQ4 model in a semi-supervised setting, which experiments will show provides some benefits over a purely supervised training regime.

Unsupervised case When x isn't observed, the loss we minimise during training is the reconstruction loss on y, expressed as the negative log-likelihood $NLL(\hat{y}, y)$ of the true labels y relative to the predictions $\hat{y}$. To this, we add as a regularising

[2]Multiplying the distribution over words and an embedding matrix averages the word embedding of the entire vocabulary weighted by their probabilities.

term the KL divergence $KL[q(\gamma|y)\|p(\gamma)]$ which effectively penalises the mean and variance of $q(\gamma|y)$ from diverging from those of a prior $p(\gamma)$, which we model as a diagonal Gaussian $\mathcal{N}(0, I)$. This has the effect of smoothing the logistic normal distribution from which we draw the distributions over symbols of x, guarding against overfitting of the latent distributions over x to symbols seen in the supervised case discussed below. The unsupervised loss is therefore formalised as

$$\mathcal{L}_{unsup} = NLL(\hat{y}, y) + \alpha KL[q(\gamma|y)\|p(\gamma)] \quad (12)$$

with regularising factor α is tuned on validation, and

$$KL[q(\gamma|y)\|p(\gamma)] = \sum_{i=1}^{L_x} KL[q(\gamma_i|y)\|p(\gamma)] \quad (13)$$

We use a closed form of these individual KL divergences, described by Kingma and Welling (2014).

Supervised case When x is observed, we additionally minimise the prediction loss on x, expressed as the negative log-likelihood $NLL(\tilde{x}, x)$ of the true labels x relative to the predictions $\tilde{x}$, and do not impose the KL loss. The supervised loss is thus

$$\mathcal{L}_{sup} = NLL(\tilde{x}, x) + NLL(\hat{y}, y) \quad (14)$$

In both the supervised and unsupervised case, because of the continuous relaxation on generating $\tilde{x}$ and the reparameterisation trick, the gradient of the losses with regard to the model parameters is well defined throughout SEQ4.

Semi-supervised training and inference We train with a weighted combination of the supervised and unsupervised losses described above. Once trained, we simply use the $x \mapsto y$ decoder segment of the model to predict y from sequences of symbols x represented as one-hot vectors. When the decoder is trained without the encoder in a fully supervised manner, it serves as our supervised sequence-to-sequence baseline model under the name S2S.

3 Tasks and Data Generation

We apply our model to three tasks outlined in this section. Moreover, we explain how we generated additional unsupervised training data for two of these tasks. Examples from all datasets are in Table 1.

3.1 GeoQuery

The first task we consider is the prediction of a query on the GEO corpus which is a frequently used benchmark for semantic parsing. The corpus contains 880 questions about US geography together with executable queries representing those questions. We follow the approach established by Zettlemoyer and Collins (2005) and split the corpus into 600 training and 280 test cases. Following common practice, we augment the dataset by referring to the database during training and test time. In particular, we use the database to identify and anonymise variables (cities, states, countries and rivers) following the method described in Dong and Lapata (2016).

Most prior work on the GEO corpus relies on standard semantic parsing methods together with custom heuristics or pipelines for this corpus. The recent paper by Dong and Lapata (2016) is of note, as it uses a sequence-to-sequence model for training which is the unidirectional equivalent to S2S, and also to the decoder part of our SEQ4 network.

3.2 Open Street Maps

The second task we tackle with our model is the NLMAPS dataset by Haas and Riezler (2016). The dataset contains 1,500 training and 880 testing instances of natural language questions with corresponding machine readable queries over the geographical OpenStreetMap database. The dataset contains natural language question in both English and German but we focus only on single language semantic parsing, similar to the first task in Haas and Riezler (2016). We use the data as it is, with the only pre-processing step being the tokenization of both natural language and query form[3].

3.3 Navigational Instructions to Actions

The SAIL corpus and task were developed to train agents to follow free-form navigational route instructions in a maze environment (MacMahon et al., 2006; Chen and Mooney, 2011). It consists of a small number of mazes containing features such as objects, wall and floor types. These mazes come together with a large number of human instructions paired with the required actions[4] to reach the goal

[3] We removed quotes, added spaces around `()`, and separated the question mark from the last word in each question.

[4] There are four actions: `LEFT`, `RIGHT`, `GO`, `STOP`.

state described in those instructions.

We use the sentence-aligned version of the SAIL route instruction dataset containing 3,236 sentences (Chen and Mooney, 2011). Following previous work, we accept an action sequence as correct if and only if the final position and orientation exactly match those of the gold data. We do not perform any pre-processing on this dataset.

3.4 Data Generation

As argued earlier, we are focusing on tasks where aligned data is sparse and expensive to obtain, while it should be cheap to get unsupervised, monomodal data. Albeit that is a reasonable assumption for real world data, the datasets considered have no such component, thus the approach taken here is to generate random database queries or maze paths, i.e. the machine readable side of the data, and train a semi-supervised model. The alternative not explored here would be to generate natural language questions or instructions instead, but that is more difficult to achieve without human intervention. For this reason, we generate the machine readable side of the data for GEOQUERY and SAIL tasks[5].

For GEOQUERY, we fit a 3-gram Kneser-Ney (Chen and Goodman, 1999) model to the queries in the training set and sample about 7 million queries from it. We ensure that the sampled queries are different from the training queries, but do not enforce validity. This intentionally simplistic approach is to demonstrate the applicability of our model.

The SAIL dataset has only three mazes. We added a fourth one and over 150k random paths, including duplicates. The new maze is larger (21×21 grid) than the existing ones, and seeks to approximately replicate the key statistics of the other three mazes (maximum corridor length, distribution of objects, etc). Paths within that maze are created by randomly sampling start and end positions.

4 Experiments

We evaluate our model on the three tasks in multiple settings. First, we establish a supervised baseline to compare the S2S model with prior work. Next, we train our SEQ4 model in a semi-supervised setting on the entire dataset with the additional monomodal training data described in the previous section.

Finally, we perform an "ablation" study where we discard some of the training data and compare S2S to SEQ4. S2S is trained solely on the reduced data in a supervised manner, while SEQ4 is once again trained semi-supervised on the same reduced data plus the machine readable part of the discarded data (SEQ4-) or on the extra generated data (SEQ4+).

Model	Accuracy
Zettlemoyer and Collins (2005)	79.3
Zettlemoyer and Collins (2007)	86.1
Liang et al. (2013)	87.9
Kwiatkowski et al. (2011)	88.6
Zhao and Huang (2014)	88.9
Kwiatkowski et al. (2013)	89.0
Dong and Lapata (2016)	84.6
Jia and Liang (2016)[6]	89.3
S2S	86.5
SEQ4	87.3

Table 2: Non-neural and neural model results on GEOQUERY using the train/test split from (Zettlemoyer and Collins, 2005).

Training We train the model using standard gradient descent methods. As none of the datasets used here contain development sets, we tune hyperparameters by cross-validating on the training data. In the case of the SAIL corpus we train on three folds (two mazes for training and validation, one for test each) and report weighted results across the folds following prior work (Mei et al., 2016).

4.1 GeoQuery

The evaluation metric for GEOQUERY is the accuracy of exactly predicting the machine readable query. As results in Table 2 show, our supervised S2S baseline model performs slightly better than the comparable model by Dong and Lapata (2016). The semi-supervised SEQ4 model with the additional generated queries improves on it further.

The ablation study in Table 3 demonstrates a widening gap between supervised and semi-

[5]Our randomly generated unsupervised datasets can be downloaded from `http://deepmind.com/publications`

[6]Jia and Liang (2016) used hand crafted grammars to generate additional supervised training data.

Sup. data	S2S	SEQ4-	SEQ4+
5%	21.9	30.1	26.2
10%	39.7	42.1	42.1
25%	62.4	70.4	67.1
50%	80.3	81.2	80.4
75%	85.3	84.1	85.1
100%	86.5	86.5	87.3

Table 3: Results of the GEOQUERY ablation study.

Model	Accuracy
Haas and Riezler (2016)	68.30
S2S	78.03

Table 4: Results on the NLMAPS corpus.

supervised as the amount of labelled training data gets smaller. This suggests that our model can leverage unlabelled data even when only small amount of labelled data is available.

4.2 Open Street Maps

We report results for the NLMAPS corpus in Table 4, comparing the supervised S2S model to the results posted by Haas and Riezler (2016). While their model used a semantic parsing pipeline including alignment, stemming, language modelling and CFG inference, the strong performance of the S2S model demonstrates the strength of fairly vanilla attention-based sequence-to-sequence models. It should be pointed out that the previous work reports the number of correct answers when queries were executed against the dataset, while we evaluate on the strict accuracy of the generated queries. While we expect these numbers to be nearly equivalent, our evaluation is strictly harder as it does not allow for reordering of query arguments and similar relaxations.

We investigate the SEQ4 model only via the ablation study in Table 5 and find little gain through the semi-supervised objective. Our attempt at cheaply generating unsupervised data for this task was not successful, likely due to the complexity of the underlying database.

4.3 Navigational Instructions to Actions

Model extension The experiments for the SAIL task differ slightly from the other two tasks in that the language input does not suffice for choosing an action. While a simple instruction such as *'turn left'* can easily be translated into the action sequence `LEFT-STOP`, more complex instructions such as *'Walk forward until you see a lamp'* require knowledge of the agent's position in the maze.

Sup. data	S2S	SEQ4-
5%	3.22	3.74
10%	17.61	17.12
25%	33.74	33.50
50%	49.52	53.72
75%	66.93	66.45
100%	78.03	78.03

Table 5: Results of the NLMAPS ablation study.

To accomplish this we modify the model as follows. First, when encoding action sequences, we concatenate each action with a representation of the maze at the given position, representing the maze-state akin to Mei et al. (2016) with a bag-of-features vector. Second, when decoding action sequences, the RNN outputs an action which is used to update the agent's position and the representation of that new position is fed into the RNN as its next input.

Training regime We cross-validate over the three mazes in the dataset and report overall results weighted by test size (cf. Mei et al. (2016)). Both our supervised and semi-supervised model perform worse than the state-of-the-art (see Table 6), but the latter enjoys a comfortable margin over the former. As the S2S model broadly reimplements the work of Mei et al. (2016), we put the discrepancy in performance down to the particular design choices that we did not follow in order to keep the model here as general as possible and comparable across tasks.

The ablation studies (Table 7) show little gain for the semi-supervised approach when only using data from the original training set, but substantial improvement with the additional unsupervised data.

5 Discussion

Supervised training The prediction accuracies of our supervised baseline S2S model are mixed with respect to prior results on their respective tasks. For GEOQUERY, S2S performs significantly better than the most similar model from the literature (Dong and Lapata, 2016), mostly due to the fact that y and x are

Input from unsupervised data (y)	Generated latent representation (x)
answer smallest city loc_2 state stateid _STATE_	what is the smallest city in the state of _STATE_ </S>
answer city loc_2 state next_to_2 stateid _STATE_	what are the cities in states which border _STATE_ </S>
answer mountain loc_2 countryid _COUNTRY_	what is the lakes in _COUNTRY_ </S>
answer state next_to_2 state all	which states longer states show peak states to </S>

Table 8: Positive and negative examples of latent language together with the randomly generated logical form from the unsupervised part of the GEOQUERY training. Note that the natural language (x) does not occur anywhere in the training data in this form.

Model	Accuracy
Chen and Mooney (2011)	54.40

encoded with bidirectional LSTMs. With a unidirectional LSTM we get similar results to theirs.

On the SAIL corpus, S2S performs worse than the state of the art. As the models are broadly equivalent we attribute this difference to a number of task-specific choices and optimisations[7] made in Mei et al. (2016) which we did not reimplement for the sake of using a common model across all three tasks.

For NLMAPS, S2S performs much better than the state-of-the-art, exceeding the previous best result by 11% despite a very simple tokenization method and a lack of any form of entity anonymisation.

Semi-supervised training In both the case of GEOQUERY and the SAIL task we found the semi-supervised model to convincingly outperform the fully supervised model. The effect was particularly notable in the case of the SAIL corpus, where performance increased from 58.60% accuracy to 63.25% (see Table 6). It is worth remembering that the supervised training regime consists of three folds of tuning on two maps with subsequent testing on the third map, which carries a risk of overfitting to the training maps. The introduction of the fourth unsupervised map clearly mitigates this effect. Table 8 shows some examples of unsupervised logical forms being transformed into natural language, which demonstrate how the model can learn to sensibly ground unsupervised data.

Ablation performance The experiments with additional unsupervised data prove the feasibility of our approach and clearly demonstrate the usefulness of the SEQ4 model for the general class of sequence-to-sequence tasks where supervised data is hard to come by. To analyse the model further, we also look at the performance of both S2S and SEQ4 when reducing the amount of supervised training data available to the model. We compare three settings: the supervised S2S model with reduced training data, SEQ4- which uses the removed training data in an unsupervised fashion (throwing away the natural language) and SEQ4+ which uses the randomly generated unsupervised data described in Section 3. The S2S model behaves as expected on all three tasks, its performance dropping with the size of the training data. The performance of SEQ4- and SEQ4+ requires more analysis.

In the case of GEOQUERY, having unlabelled data from the true distribution (SEQ4-) is a good thing

[7] In particular we don't use beam search and ensembling.

when there is enough of it, as clearly seen when only 5% of the original dataset is used for supervised training and the remaining 95% is used for unsupervised training. The gap shrinks as the amount of supervised data is increased, which is as expected. On the other hand, using a large amount of extra, generated data from an approximating distribution (SEQ4+) does not help as much initially when compared with the unsupervised data from the true distribution. However, as the size of the unsupervised dataset in SEQ4- becomes the bottleneck this gap closes and eventually the model trained on the extra data achieves higher accuracy.

For the SAIL task the semi-supervised models do better than the supervised results throughout, with the model trained on randomly generated additional data consistently outperforming the model trained only on the original data. This gives further credence to the risk of overfitting to the training mazes already mentioned above.

Finally, in the case of the NLMAPS corpus, the semi-supervised approach does not appear to help much at any point during the ablation. These indistinguishable results are likely due to the task's complexity, causing the ablation experiments to either have to little supervised data to sufficiently ground the latent space to make use of the unsupervised data, or in the higher percentages then too little unsupervised data to meaningfully improve the model.

6 Related Work

Semantic parsing The tasks in this paper all broadly belong to the domain of semantic parsing, which describes the process of mapping natural language to a formal representation of its meaning. This is extended in the SAIL navigation task, where the formal representation is a function of both the language instruction and a given environment.

Semantic parsing is a well-studied problem with numerous approaches including inductive logic programming (Zelle and Mooney, 1996), string-to-tree (Galley et al., 2004) and string-to-graph (Jones et al., 2012) transducers, grammar induction (Kwiatkowski et al., 2011; Artzi and Zettlemoyer, 2013; Reddy et al., 2014) or machine translation (Wong and Mooney, 2006; Andreas et al., 2013).

While a large number of relevant literature focuses on defining the grammar of the logical forms (Zettlemoyer and Collins, 2005), other models learn purely from aligned pairs of text and logical form (Berant and Liang, 2014), or from more weakly supervised signals such as question-answer pairs together with a database (Liang et al., 2011). Recent work of Jia and Liang (2016) induces a synchronous context-free grammar and generates additional training examples (x, y), which is one way to address data scarcity issues. The semi-supervised setup proposed here offers an alternative solution to this issue.

Discrete autoencoders Very recently there has been some related work on discrete autoencoders for natural language processing (Suster et al., 2016; Marcheggiani and Titov, 2016, *i.a.*) This work presents a first approach to using effectively discretised sequential information as the latent representation without resorting to draconian assumptions (Ammar et al., 2014) to make marginalisation tractable. While our model is not exactly marginalisable either, the continuous relaxation makes training far more tractable. A related idea was recently presented in Gülçehre et al. (2015), who use monolingual data to improve machine translation by fusing a sequence-to-sequence model and a language model.

7 Conclusion

We described a method for augmenting a supervised sequence transduction objective with an autoencoding objective, thereby enabling semi-supervised training where previously a scarcity of aligned data might have held back model performance. Across multiple semantic parsing tasks we demonstrated the effectiveness of this approach, improving model performance by training on randomly generated unsupervised data in addition to the original data.

Going forward it would be interesting to further analyse the effects of sampling from a logistic-normal distribution as opposed to a softmax in order to better understand how this impacts the distribution in the latent space. While we focused on tasks with little supervised data and additional unsupervised data in y, it would be straightforward to reverse the model to train it with additional labelled data in x, i.e. on the natural language side. A natural extension would also be a formulation where semi-supervised training was performed in both x and y.

For instance, machine translation lends itself to such a formulation where for many language pairs parallel data may be scarce while there is an abundance of monolingual data.

EQUATION PARSING : Mapping Sentences to Grounded Equations

Subhro Roy **Shyam Upadhyay** **Dan Roth**
University of Illinois, Urbana Champaign

Abstract

Identifying mathematical relations expressed in text is essential to understanding a broad range of natural language text from election reports, to financial news, to sport commentaries to mathematical word problems. This paper focuses on identifying and understanding mathematical relations described within a single sentence. We introduce the problem of Equation Parsing – given a sentence, identify noun phrases which represent variables, and generate the mathematical equation expressing the relation described in the sentence. We introduce the notion of projective equation parsing and provide an efficient algorithm to parse text to projective equations. Our system makes use of a high precision lexicon of mathematical expressions and a pipeline of structured predictors, and generates correct equations in 70% of the cases. In 60% of the time, it also identifies the correct noun phrase $\rightarrow$ variables mapping, significantly outperforming baselines. We also release a new annotated dataset for task evaluation.

1 Introduction

Understanding text often involves reasoning with respect to quantities mentioned in it. Understanding the news article statement in Example 1 requires identifying relevant entities and the mathematical relations expressed among them in text, and determining how to compose them. Similarly, solving a math word problem with a sentence like Example 2, requires realizing that it deals with a *single* number, knowing the meaning of *"difference"* and composing the right equation – *"25"* needs to be subtracted from a number only after it is multiplied by 3.

Example 1 *Emanuel's campaign contributions total three times those of his opponents put together.*
Example 2 *Twice a number equals 25 less than triple the same number.*
Example 3 *Flying with the wind , a bird was able to make 150 kilometers per hour.*
Example 4 *The sum of two numbers is 80.*
Example 5 *There are 54 5-dollar and 10-dollar notes.*

As a first step towards understanding such relations, we introduce the Equation Parsing task - given a sentence expressing a mathematical relation, the goal is to generate an equation representing the relation, and to map the variables in the equation to their corresponding noun phrases. To keep the problem tractable, in this paper we restrict the final output equation form to have at most two (possibly coreferent) variables, and assume that each quantity mentioned in the sentence can be used at most once in the final equation.[1] In example 1, the gold output of an equation parse should be $V_1 = 3 \times V_2$, with $V_1 =$ "Emanuel's campaign contributions" and $V_2 =$ "those of his opponents put together".

The task can be seen as a form of semantic parsing (Goldwasser and Roth, 2011; Kwiatkowski et al., 2013) where instead of mapping a sentence to a logical form, we want to map it to an equation. However,

[1] We empirically found that around 97% of sentences describing a relation have this property.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1088–1097,
Austin, Texas, November 1-5, 2016.

there are some key differences that make this problem very challenging in ways that differ from the "standard" semantic parsing. In Equation Parsing, not all the components of the sentence are mapped to the final equation. There is a need to identify noun phrases that correspond to variables in the relations and determine that some are irrelevant and can be dropped. Moreover, in difference from semantic parsing into logical forms, in Equation Parsing multiple phrases in the text could correspond to the same variable, and identical phrases in the text could correspond to multiple variables.

We call the problem of mapping noun phrases to variables the problem of *grounding variables*. Grounding is challenging for various reasons, key among them are that: (i) The text often does not mention *"variables"* explicitly, e.g., the sentence in example 3 describes a mathematical relation between the speed of bird and the speed of wind, without mentioning "speed" explicitly. (ii) Sometimes, multiple noun phrases could refer to the same variable. For instance, in example 2, both *"a number"* and *"the same number"* refer to the same variable. On the other hand, the same noun phrase might refer to multiple variables, as in example 4, where the noun phrase "two numbers" refer to two variables.

In addition, the task involves deciding which of the quantities identified in the sentence are relevant to the final equation generation. In example 5, both "5" and "10" are not relevant for the final equation "$V_1 + V_2 = 54$". Finally, the equation needs to be constructed from a list of relevant quantities and grounded variables. Overall, the output space becomes exponential in the number of quantities mentioned in the sentence.

Determining the final equation that corresponds to the text is an inference step over a very large space. To address this, we define the concept of "projectivity" - a condition where the final equation can be generated by combining adjacent numbers or variables, and show that most sentences expressing mathematical relations exhibit the projectivity property. Finally, we restrict our inference procedure to only search over equations which have this property.

Our approach builds on a pipeline of structured predictors that identify irrelevant quantities, recognize coreferent variables, and, finally, generate equations. We also leverage a high precision lexicon of mathematical expressions and develop a greedy lexicon matching strategy to guide inference. We discuss and exemplify the advantages of this approach and, in particular, explain where the "standard" NLP pipeline fails to support equation parsing, and necessitates the new approach proposed here. Another contribution of this work is the development of a new annotated data set for the task of equation parsing. We evaluate our method on this dataset and show that our method predicts the correct equation in 70% of the cases and that in 60% of the time we also ground all variables correctly.

The next section presents a discussion of related work. Next we formally describe the task of equation parsing. The following sections describe our equation representation and the concept of projectivity, followed by the description of our algorithm to generate the equations and variable groundings from text. We conclude with experimental results.

2 Related Work

The work most related to this paper is (Madaan et al., 2016), which focuses on extracting relation triples where one of the arguments is a number. In contrast, our work deals with multiple variables and complex equations involving them. There has been a lot of recent work in automatic math word problem solving (Kushman et al., 2014; Roy et al., 2015; Hosseini et al., 2014; Roy and Roth, 2015). These solvers cannot handle sentences individually. They require the input to be a complete math word problem, and even then, they only focus on retrieving a set of answer values without mentioning what each answer value corresponds to. Our work is also conceptually related to work on semantic parsing – mapping natural language text to a formal meaning representation (Wong and Mooney, 2007; Clarke et al., 2010; Cai and Yates, 2013; Kwiatkowski et al., 2013; Goldwasser and Roth, 2011). However, as mentioned earlier, there are some significant differences in the task definition that necessitate the development of a new approach.

3 The Equation Parsing Task

Equation parsing takes as input a sentence x describing a single mathematical equation, comprising one or two variables and other quantities mentioned in x.

Let N be the set of noun phrases in the sentence x. The output of the task is the mathematical equation described in x, along with a mapping of each variable in the equation to its corresponding noun phrase in N. We refer to this mapping as the "grounding" of the variable; the noun phrase represents what the variable stands for in the equation. Table 1 gives an example of an input and output for the equation parsing of the text in example 2. Since an equation can be written in various forms, we use the form which most agrees with text, as our target output. So, for example 1, we will choose $V_1 = 3 \times V_2$ and not $V_2 = V_1 \div 3$. In cases where several equation forms seem to be equally likely to be the target equation, we randomly choose one of them, and keep this choice consistent across the dataset.

The Equation Parsing Task	
Input	*Twice a number equals 25 less than triple the same number.*
Output	$2 \times V_1 = (3 \times V_1) - 25$ *(Equation)* V_1 = "a number" *(Grounding)*

Table 1: Input and output for Equation Parsing

3.1 Equation Parse Representation

In this section, we introduce an equation parse for a sentence. An equation parse of a sentence x is a pair (T, E), where T represents a set of *triggers* extracted from x, and E represents an *equation tree* formed with the set T as leaves. We now describe these terms in detail.

Trigger Given a sentence x mentioning a mathematical relation, a trigger can either be a *quantity trigger* expressed in x, or *variable trigger* which is a noun phrase in x corresponding to a variable. A *quantity trigger* is a tuple (q, s), where q is the numeric value of the quantity mentioned in text, and s is the span of text from the sentence x which refers to the quantity. A *variable trigger* is a tuple (l, s), where l represents the label of the variable, and s represents the noun phrase representing the variable. For example, for the sentence in Fig 1, the spans "Twice", "25", and "triple" generate quantity triggers, whereas "a number" and "the same number" generate variable triggers, with label V_1.

Trigger List The trigger list T for a sentence x contains one trigger for each variable mention and each numeric value used in the final equation expressed by the sentence x. The trigger list might consist of multiple triggers having the same label, or extracted from the same span of text. In the example sentence in Fig 1, the trigger list comprises two triggers having the same label V_1. The final trigger list for the example in Fig 1 is {(2, "2"), (V_1, "a number"), (25, "25"), (3, "triple"), (V_1, "the same number")}. Note that there can be multiple valid trigger lists. In our example, we could have chosen both variable triggers to point to the same mention "a number". Quantity triggers in the trigger list form the ***quantity trigger list***, and the variable triggers in trigger list form the ***variable trigger list***.

Notation	Definition
Quantity Trigger	Mention of a quantity in text
Variable Trigger	Noun phrase coupled with variable label
Trigger	Quantity or variable trigger
Quantity Trigger List	List of quantity triggers, one for each number mention in equation
Variable Trigger List	List of variable triggers, one for each variable mention in equation
Trigger List	Union of quantity and variable trigger list
Equation Tree	Binary tree representation of equation
$lc(n)$, $rc(n)$	Left and right child of node n
$\textsc{Expr}(n)$	Expression represented by node n
$\odot(n)$	Operation at node n
$\textsc{Order}(n)$	Order of operation at node n
$\text{Location}(n)$	Character offset of trigger representing leaf node n
$\text{Span-Start}(n)$, $\text{Span-End}(n)$	Start and end character offsets of span covered by node n

Table 2: Summary of notations used in the paper

Equation Tree An equation tree of a sentence x is a binary tree whose leaves constitute the trigger list of x, and internal nodes (except the root) are labeled with one of the following operations – *addition, subtraction, multiplication, division*. In addition, for nodes which are labeled with subtraction or division, we maintain a separate variable to determine order of its children. The root of the tree is always labeled with the operation *equal*.

An equation tree is a natural representation for an equation. Each node n in an equation tree represents an expression $\textsc{Expr}(n)$, and the label of the parent node determines how the expressions of its children are to be composed to construct its own expression. Let us denote the label for a non-leaf node

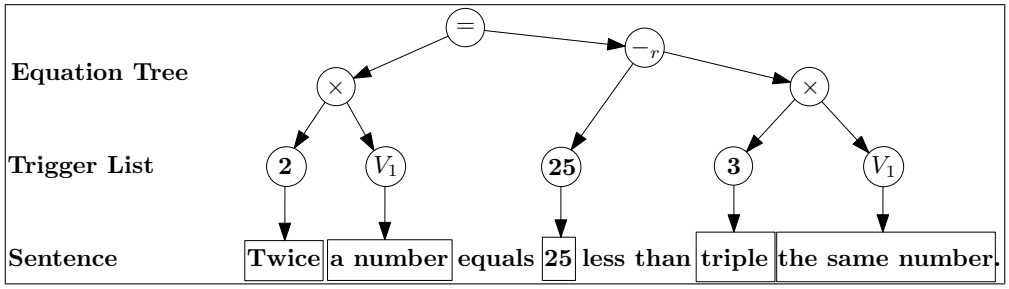

Figure 1: A sentence with its trigger list and equation tree. $-_r$ indicates subtraction with order rl.

n to be $\odot(n)$, where $\odot(n) \in \{+, -, \times, \div, =\}$ and the order of a node n's children by $\textsc{Order}(n)$ (defined only for subtraction and division nodes), which takes values lr (Left-Right) or rl (Right-Left). For a leaf node n, the expression $\textsc{Expr}(n)$ represents the variable label, if n is a variable trigger, and the numeric value of the quantity, if it is a quantity trigger. Finally, we use $lc(n)$ and $rc(n)$ to represent the left and right child of node n, respectively. The equation represented by the tree can be generated as follows. For all non-leaf nodes n, we have

$$\textsc{Expr}(n) = \begin{cases} \textsc{Expr}(lc(n)) \odot(n) \textsc{Expr}(rc(n)) \\ \quad \text{if } \odot(n) \in \{+, \times, =\} \\ \textsc{Expr}(lc(n)) \odot(n) \textsc{Expr}(rc(n)) \\ \quad \text{if } \odot(n) \in \{-, \div\} \wedge \textsc{Order}(n) = lr \\ \textsc{Expr}(rc(n)) \odot(n) \textsc{Expr}(lc(n)) \\ \quad \text{if } \odot(n) \in \{-, \div\} \wedge \textsc{Order}(n) = rl \end{cases} \quad (1)$$

Given an equation tree $\mathcal{T}$ of a sentence, the equation represented by it is the expression generated by the root of $\mathcal{T}$ (following Equation 1). Referring to the equation tree in Fig 1, the node marked "$-_r$" represents $(3 \times V_1) - 25$, and the root represents the full equation $2 \times V_1 = (3 \times V_1) - 25$.

4 Projectivity

For each leaf n of an equation tree T, we define a function $\text{Location}(\cdot)$, to indicate the position of the corresponding trigger in text. We also define for each node n of equation tree T, functions $\text{Span-Start}(n)$ and $\text{Span-End}(n)$ to denote the minimum span of text containing the leaves of the subtree rooted at n. We define them as follows:

$$\text{Span-Start}(n) = \begin{cases} \text{Location}(n) & \text{if } n \text{ is a leaf} \\ \min(\text{Span-Start}(lc(n)), \text{Span-Start}(rc(n))) & \\ \quad \text{otherwise} & \end{cases}$$

$$\text{Span-End}(n) = \begin{cases} \text{Location}(n) & \text{if } n \text{ is a leaf} \\ \max(\text{Span-End}(lc(n)), \text{Span-End}(rc(n))) & \\ \quad \text{otherwise} & \end{cases}$$

An equation tree T is called *projective* iff for every node n of T, either $\text{Span-End}(lc(n)) \leq \text{Span-Start}(rc(n))$ or $\text{Span-End}(rc(n)) \leq \text{Span-Start}(lc(n))$. In other words, the span of the left child and the right child cannot intersect in a projective equation tree[2].

The key observation, as our corpus analysis indicates, is that for most sentences, *there exists* a trigger list, such that the equation tree representing the relation in the sentence is projective. However this might involve mapping two mentions of the same variable to different noun phrases. Figure 1 shows an example of a projective equation tree, which requires different mentions of V_1 to be mapped to different noun phrases. If we had mapped both mentions of V_1 to same noun phrase "a number", the resulting equation tree would not have been projective. We collected 385 sentences which represent an equation with one or two mentions of variables, and each number in the sentence used at most once in the equation. We found that only one sentence among these could not generate a projective equation tree. (See Section 6.1 for details on dataset

[2]This is more general than the definition of projective trees used in dependency parsing (McDonald et al., 2005).

creation). Therefore, we develop an algorithmic approach for predicting projective equation trees, and show empirically that it compares favourably with ones which do not make the projective assumption.

5 Predicting Equation Parse

Equation parsing of a sentence involves predicting three components – Quantity Trigger List, Variable Trigger List and Equation Tree. We develop three structured prediction modules to predict each of the above components.

All our prediction modules take a similar form: given input x and output y, we learn a scoring function $f_w(x, y)$, which scores how likely is the output y given input x. The scoring function $f_w(x, y)$ is linear, $f_w(y) = w^T \phi(x, y)$, where $\phi(x, y)$ is a feature vector extracted from x and y. The inference problem, that is, the prediction y^* for an input x is then: $y^* = \arg\max_{y \in \mathcal{Y}} f_w(y)$, where $\mathcal{Y}$ is the set of all allowed values of y.

5.1 Predicting Quantity Trigger List

Given input text and the quantities mentioned in it, the role of this step is to identify , for each quantity in the text, whether it should be part of the final equation. For instance, in example 5 in Section 1, both "5" and "10" are not relevant for the final equation "$V_1 + V_2 = 54$". Similarly, in example 4, the number "two" is irrelevant for the equation "$V_1 + V_2 = 80$".

We define for each quantity q in the sentence, a boolean value $\mathrm{Relevance}(q)$, which is set to $true$ if q is relevant for the final equation, and to $false$ otherwise. For the structured classification, the input x is the sentence along with a set of recognized quantities mentioned in it, and the output y is the relevance values for all quantities in the sentence. We empirically found that predicting all relevance values jointly performs better than having a binary classifier predict each one separately. The feature function $\phi(x, y)$ used for the classification generates neighborhood features (from neighborhood of q) and quantity features (properties of the quantity mention). Details added to the appendix.

5.2 Predicting Variable Trigger List

The goal of this step is to predict the variable trigger list for the equation. Our structured classifier takes as input the sentence x, and the output y is either one or two noun-phrases, representing variables in the final equation. As we pointed out earlier, multiple groundings might be valid for any given variable, hence there can be multiple valid variable trigger lists. For every sentence x, we construct a set Y of valid outputs. Each element in Y corresponds to a valid variable trigger list. Finally, we aim to output only one of the elements of Y.

We modified the standard structured prediction algorithm to consider "superset supervision" and take into account multiple gold structures for an input x. We assume access to N training examples of the form : $(x_1, Y_1), (x_2, Y_2), \ldots, (x_N, Y_N)$, where each Y_i is a set of valid outputs for the sentence x_i. Since we want to output only one variable trigger list, we want to score at least one y from Y_i higher than all other possible outputs, for each x_i. We use a modified latent structured SVM to learn the weight vector w. The algorithm treats the best choice among all of Y_i as a latent variable. At each iteration, for all x_i, the algorithm chooses the best choice y_i^* from the set Y_i, according to the weight vector w. Then, w is updated by learning on all (x_i, y_i^*) by a standard structured SVM algorithm. The details of the algorithm are in Algorithm 1. The distinction from standard latent structural SVM is in line 5 of Algorithm 1. In order to get the best choice y_i^* for input x_i, we search only inside Y_i, instead of all of $\mathcal{Y}$. A similar formulation can be found in Björkelund and Kuhn

Algorithm 1 Structural SVM with Superset Supervision

Input: Training data $T = \{(x_1, Y_1), (x_2, Y_2), \ldots, (x_N, Y_N)\}$
Output: Trained weight vector w

1: $w \leftarrow w_0$
2: **repeat**
3: $\quad T' \leftarrow \emptyset$
4: $\quad$ **for all** $(x_i, Y_i) \in T$ **do**
5: $\quad\quad y_i^* \leftarrow \arg\max_{y \in Y_i} w^T \phi(x_i, y)$
6: $\quad\quad T' \leftarrow T' \cup \{(x_i, y_i^*)\}$
7: $\quad$ **end for**
8: $\quad$ Update w by running standard Structural SVM algorithm on T'
9: **until** convergence
10: **return** w

(2014). The features $\phi(x, y)$ used for variable trigger prediction include variable features (properties of noun phrase indicating variable) and neighborhood features (lexical features from neighborhood of variable mention). Details added to the appendix.

If the output of the classifier is a pair of noun phrases, we use a rule based variable coreference detector, to determine whether both noun phrases should have the same variable label or not. The rules for variable coreference are as follows :

1. If both noun phrases are the same, and they do not have the token "two" or "2", they have the same label.

2. If the noun phrases are different, and the noun phrase appearing later in the sentence contains tokens "itself", "the same number", they have the same label.

3. In all other cases, they have different labels.

Finally, each noun phrase contributes one variable trigger to the variable trigger list.

5.3 Predicting Equation Tree

It is natural to assume that the syntactic parse of the sentence could be very useful in addressing all the predictions we are making in the equation parsing tasks. However, it turns out that this is not the case – large portions of the syntactic parse will not be part of the equation parse, hence we need the aforementioned modules to address this. Nevertheless, in the next task of predicting the equation tree, we attempted to constraint the output space using guidance from the syntactic tree; we found, though, that even enforcing this weak level of output expectation is not productive. This was due to the poor performance of current syntactic parsers on the equation data (eg., in 32% of sentences, the Stanford parser made a mistake which does not allow recovering the correct equation).

The tree prediction module receives the trigger list predicted by the previous two modules, and the goal is to create an equation tree using the trigger list as the leaves of that tree. The input x is the sentence and the trigger list, and the output y is the equation tree representing the relation described in the sentence. We assume that the output will be a projective equation tree. For features $\phi(x, y)$, we extract for each non-leaf node n of the equation tree y, neighborhood features (from neighborhood of node spans of n's children), connecting text features (from text between the spans of n's children) and number features (properties of number in case of leaf nodes). Details are included in the appendix.

The projectivity assumption implies that the final equation tree can be generated by combining only adjacent nodes, once the set of leaves is sorted based on $\text{Span-Start}(\cdot)$ values. This allows us to use CKY algorithm for inference. A natural approach to further reduce the output space is to conform to the projective structure of the syntactic parse of the sentence. However, we found this to adversely affect performance, due to the poor performance of syntactic parser on equation data.

Lexicon To bootstrap the equation parsing process, we developed a high precision lexicon to translate mathematical expressions to operations and orders, like "sum of A and B" translates to "A+B", "A minus B" translates to "A-B", etc. (where A and B denote placeholder numbers or expressions). At each step of CKY, while constructing a node n of the equation tree, we check for a lexicon text expression corresponding to node n. If found, we allow only the corresponding operation (and order) for node n, and do not explore other operations or orders. We show empirically that reducing the space using this greedy lexicon matching help improve performance. We found that using the lexicon rules as features instead of hard constraints do not help as much. Note that our lexicon comprises only generic math concepts, and around 50% of the sentences in our dataset do not contain any pattern from the lexicon.

Finally, given input sentence, we first predict the quantity trigger and the variable trigger lists. Given the complete trigger list, we predict the equation tree relating the components of the trigger list.

5.4 Alternatives

A natural approach could be to jointly learn to predict all three components, to capture the dependencies among them. To investigate this, we developed a structured SVM which predicts all components jointly, using the union of the features of each component. We use approximate inference, first enumerating possible trigger lists, and then equation trees,

and find the best scoring structure. However, this method did not outperform the pipeline method. The worse performance of joint learning is due to: (1) search space being too large for the joint model to do well given our dataset size of 385, and (2) our independent classifiers being good enough, thus supporting better joint inference. This tradeoff is strongly supported in the literature (Punyakanok et al., 2005; Sutton and McCallum, 2007).

Another option is to enforce constraints between trigger list predictions, such as, variable triggers should not overlap with the quantity triggers. However, we noticed that often noun phrases returned by the Stanford parser were noisy, and would include neighboring numbers within the extracted noun phrases. This prevented us from enforcing such constraints.

6 Experimental Results

We now describe the data set, and the annotation procedure used. We then evaluate the system's performance on predicting trigger list, equation tree, and the complete equation parse.

6.1 Dataset

We created a new dataset consisting of 385 sentences extracted from algebra word problems and financial news headlines. For algebra word problems, we used the MIT dataset (Kushman et al., 2014), and two high school mathematics textbooks, Elementary Algebra (College of Redwoods) and Beginning and Intermediate Algebra (Tyler Wallace). Financial news headlines were extracted from The Latest News feed of MarketWatch, over the month of February, 2015. *All* sentences with information describing a mathematical relation among at most two (possibly coreferent) variables, were chosen. Next, we pruned sentences which require multiple uses of a number to create the equation. This only removed a few time related sentences like *"In 10 years, John will be twice as old as his son."*. We empirically found that around 97% of sentences describing a relation fall under the scope of our dataset.

The annotators were shown each sentence paired with the normalized equation representing the relation in the sentence. For each variable in the equation, the annotators were asked to mark spans of text which best describe what the variable represents. The annotation guidelines are provided in the appendix. We wanted to consider only noun phrase constituents for variable grounding. Therefore, for each annotated span, we extracted the noun phrase with maximum overlap with the span, and used it to represent the variables. Finally, a tuple with each variable being mapped to one of the noun phrases representing it, forms a valid output grounding (variable trigger list). We computed inter-annotator agreement on the final annotations where only noun phrases represent variables. The agreement (kappa) was 0.668, indicating good agreement. The average number of mention annotations per sentence was 1.74.

6.2 Equation Parsing Modules

In this section, we evaluate the performance of the individual modules of the equation parsing process. We report Accuracy - the fraction of correct predictions. Table 3 shows the 5-fold cross validation accuracy of the various modules. In each case, we also report accuracy by removing each feature group, one at a time. In addition, for equation tree prediction, we also show the effect of lexicon, projectivity, conforming to syntactic parse constraints, and using lexicon as features instead of hard constraints. For all our experiments, we use the Stanford Parser (Socher et al., 2013), the Illinois POS tagger (Roth and Zelenko, 1998) and the Illinois-SL structured prediction package (Chang et al., 2015).

6.3 Equation Parsing Results

In this section, we evaluate the performance of our system on the overall equation parsing task. We report Equation Accuracy - the fraction of sentences for which the system got the equation correct, and Equation+Grounding Accuracy - the fraction of sentences for which the system got both the equation and the grounding of variables correct. Table 4 shows the overall performance of our system, on a 5-fold cross validation. We compare against Joint Learning - a system which jointly learns to predict all relevant components of an equation parse (Section 5.4). We also compare with SPF (Artzi and Zettlemoyer, 2013), a publicly available semantic parser, which can learn from sentence-logical form pairs. We train SPF with sentence-equation pairs

Quantity Trigger List Prediction	Accuracy
All features	**95.3**
No Neighborhood features	42.5
No Quantity features	93.2

Variable Trigger List Prediction	Accuracy
All features	**75.5**
No Variable features	58.6
No Neighborhood features	70.3

Equation Tree Prediction	Accuracy
All features	**78.9**
No Neighborhood features	64.3
No Connecting Text features	70.2
No Number features	77.6
No Lexicon	72.7
No Projectivity	72.8
Conform with Syntactic Parse	70.2
Lexicon as Features	74.5

Table 3: Performance of system components

Source	Equation Accuracy	Equation + Grounding Accuracy
Our System	**71.3**	**61.2**
Joint Learning	60.9	50.0
SPF	3.1	N/A

Table 4: Performance on equation parsing

and a seed lexicon for mathematical terms (similar to ours), and report equation accuracy. Our structured predictors pipeline approach is shown to be superior to both Joint Learning and SPF.

SPF gets only a few sentences correct. We attribute this to the inability of SPF to handle overlapping mentions (like in Example 4), as well as its approach of parsing the whole sentence to the final output form. The developers of SPF also confirmed [3] that it is not suitable for equation parsing and that these results are expected. Since equation parsing is a more involved process, a slight adaptation of SPF does not seem possible, necessitating a more involved process , of the type we propose. Our approach, in contrast to SPF, can handle overlapping mentions, selects triggers from text, and parses the trigger list to form equations.

[3]Private communication

6.4 Error Analysis

For variable trigger list prediction, around 25% of the errors were due to the predictor choosing a span which is contained within the correct span, e.g., when the target noun phrase is "The cost of a child's ticket", our predictor chose only "child's ticket". Although this choice might be sufficient for downstream tasks, we consider it to be incorrect in our current evaluation. Another 25% of the errors were due to selection of entities which do not participate in the relation. For example, in "A rancher raises 5 times as many cows as horses.", our predictor chose "A rancher" and "cows" as variables, whereas the relation exists between "cows" and "horses". For the prediction of the equation tree, we found that 35% of the errors were due to rare math concepts expressed in text. For example, "7 dollars short of the price" represents 7 dollars should be subtracted from the price. These errors can be handled by carefully augmenting the lexicon. Another 15% of the errors were due to lack of world knowledge, requiring understanding of time, speed, and distance.

7 Conclusion

This paper investigates methods that identify and understand mathematical relations expressed in text. We introduce the equation parsing task, which involves generating an equation from a sentence and identifying what the variables represent. We define the notion of projectivity, and construct a high precision lexicon, and use these to reduce the equation search space. Our experimental results are quite satisfying and raise a few interesting issues. In particular, it suggests that predicting equation parses using a pipeline of structured predictors performs better than jointly trained alternatives. As discussed, it also points out the limitation of the current NLP tools in supporting these tasks. Our current formulation has one key limitation; we only deal with expressions that are described within a sentence. Our future work will focus on lifting this restriction, in order to allow relations expressed across multiple sentences and multiple relations expressed in the same sentence. Code and dataset are available at `http://cogcomp.cs.illinois.edu/page/publication_view/800`.

A Features

A.1 Quantity Trigger List Prediction

The feature function $\phi(x, y)$ used for the classification generates the following features :

1. **Neighborhood features** : For each quantity q in the input sentence, we add unigrams and bigrams generated from a window around q, part of speech tags of neighborhood tokens of q. We conjoin these features with $\text{Relevance}(q)$.

2. **Quantity Features** : For each quantity q, we add unigrams and bigrams of the phrase representing the quantity. Also, we add a feature indicating whether the number is associated with number one or two, and whether it is the only number present in the sentence. These features are also conjoined with $\text{Relevance}(q)$.

A.2 Variable Trigger List Prediction

The features $\phi(x, y)$ used for variable trigger prediction are as follows:

1. **Variable features** : Unigrams and bigrams generated from the noun phrase representing variables, part of speech tags of tokens in noun phrase representing variables.

2. **Neighborhood Features** : Unigrams and POS tags from neighborhood of variables.

All the above features are conjoined with two labels, one denoting whether y has two variables or one, and the second denoting whether y has two variables represented by the same noun phrase.

A.3 Equation Tree Prediction

For features $\phi(x, y)$, we extract for each non-leaf node n of the equation tree y, the following:

1. **Neighborhood Features** : Unigrams, bigrams and POS tags from neighborhood of $\text{Span-Start}(lc(n))$, $\text{Span-Start}(rc(n))$, $\text{Span-End}(lc(n))$ and $\text{Span-End}(rc(n))$, conjoined with $\odot(n)$ and $\text{ORDER}(n)$.

2. **Connecting Text Features** : Unigrams, bigrams and part of speech tags between $\min(\text{Span-End}(lc(n)), \text{Span-End}(rc(n)))$ and $\max(\text{Span-Start}(lc(n)), \text{Span-Start}(rc(n)))$, conjoined with $\odot(n)$ and $\text{ORDER}(n)$.

3. **Number Features** : In case we are combining two leaf nodes representing quantity triggers, we add a feature signifying whether one number is larger than the other.

B Annotation Guidelines

The annotators were shown each sentence paired with the normalized equation representing the relation in the sentence. For each variable in the equation, the annotators were asked to mark spans of text which best describe what the variable represents. They were asked to annotate associated entities if exact variable description was not present. For instance, in example 3 (Section 1), the relation holds between the speed of bird and the speed of wind. However, *"speed"* is not explicitly mentioned in the sentence. In such cases, the annotators were asked to annotate the associated entities *"the wind"* and *"a bird"* as representing variables.

The guidelines also directed annotators to choose the longest possible mention, in case they feel the mention boundary is ambiguous. As a result, in the sentence, *"City Rentals rent an intermediate-size car for 18.95 dollars plus 0.21 per mile."*, the phrase *"City Rentals rent an intermediate-size car"* was annotated as representing variable. We allow multiple mentions to be annotated for the same variable. In example 2 (Section 1), both *"a number"* and *"the same number"* were annotated as representing the same variable.

Abstract

This paper presents an approach to extract implicit interpretations from modal constructions. Importantly, our approach uses a deterministic procedure to normalize eventualities and generate potential interpretations. An annotation effort demonstrates that these interpretations are intuitive to humans and most modal constructions convey at least one interpretation. Experimental results show that the task is challenging but can be automated.

1 Introduction

People use language to communicate not only facts, but also intentions, uncertain information and points of view. Modality can be broadly defined as a grammatical phenomenon used to express the speaker's opinion or attitude towards a proposition (Lyons, 1977). Modality has also been defined as "the category of meaning used to talk about possibilities and necessities, essentially, states of affairs beyond the actual." (Hacquard, 2011). Within computational linguistics, processing modality has proven useful for, among others, recognizing textual entailment (Snow et al., 2006; MacCartney et al., 2006), machine translation (Murata et al., 2005; Baker et al., 2012), and sentiment analysis (Wiebe et al., 2005).

In the absence of modality markers, it is understood that the author of a proposition agrees with it (Hengeveld and Mackenzie, 2008). Adding a modality marker—also referred to as cue—casts doubt on the truth of the proposition, e.g., *Mary got a new job last week* vs. *Mary likely got a new job last week*. Modality is surprisingly common (Morante and Sporleder, 2012), and notoriously difficult to annotate and process automatically (Rubinstein et al., 2013; Vincze et al., 2011). In MEDLINE, 11% of sentences contain speculative language (Light et al., 2004) and in biomedical abstracts, 18% (Vincze et al., 2008). Rubin (2006) reports that 59% of statements in 80 New York Times articles include epistemic modality. Despite modality being ubiquitous, there is not an agreed upon annotation schema.

In this paper, we extract implicit interpretations intuitively understood by humans when reading modal constructions. We do not follow any specific theory of modality. Instead, we manipulate modal constructions to automatically generate potential interpretations, and then assign factuality scores to them. Consider statement (1) below:

1. John likely contracted the disease when a mouse bit him in the Adirondacks.

Even though *likely* syntactically attaches to *contracted*, a natural reading suggests that *John contracted the disease* is factual; the only bit of uncertain information is how (or when) he contracted the disease. In other words, assuming that the author of statement (1) is truthful, event *contracted* occurred with AGENT *John* and THEME *the disease*, but the MANNER (or TIME) may not have been *when a mouse bit him in the Adirondacks*.

A key feature of the work presented in this paper is that the interpretations extracted from modal constructions are not tied to any syntactic or semantic representation. Given modal constructions in plain text, we extract implicit interpretations in plain text, and these interpretations can be processed with any existing NLP pipeline. The main contributions of

this paper are: (1) procedure to automatically generate potential interpretations from modal constructions; (2) annotations assessing the factuality of potential interpretations generated from OntoNotes;[1] and (3) experimental results using several features.

2 Previous Work

Theoretical works in philosophy and linguistics have studied modality for decades (Palmer, 2001; Jespersen, 1992). Morante and Sporleder (2012) summarize some of these works and related phenomena, e.g., evidentiality, certainty, factuality, subjectivity. There are several expressions that have modal meanings (Fintel, 2006), including auxiliaries (must, should, etc.), adverbs (perhaps, possibly, etc.) nouns (possibility, chance, etc.) adjectives (necessary, possible, etc.) and conditionals (e.g., If the light is on, Sandy is home). Most previous works in computational linguistics target modal adverbs (Rubinstein et al., 2013; Carretero and Zamorano-Mansilla, 2013; de Waard and Maat, 2012), and some also target other modal triggers such as reporting verbs (e.g., The evidence *suggests* that he caused the fire), references, or all verbs (Diab et al., 2009). Following these previous works, we focus on modal adverbs.

Beyond theoretical works, there are many proposals to annotate modality. Doing so has proven challenging: following different annotations schemas on the same source text yields little overlap (Vincze et al., 2011), and Carretero and Zamorano-Mansilla (2013) present an analysis of disagreements when targeting modal adverbs. Annotation schemas typically include 3 tasks: identifying modality triggers, their scopes, and sources (Quaresma et al., 2014; Sánchez and Vogel, 2015). Many also classify the modality into several types (epistemic, circumstantial, ability, deontic, etc.) or a fine-grained taxonomy (Rubinstein et al., 2013; Nissim et al., 2013). In this paper, we are not concerned with modeling modality per se, or classifying instances of modality into predefined classes or hierarchies. Instead, we extract implicit interpretations from modal constructions in order to mirror intuitive readings.

FactBank is probably the best-known corpus for event factuality (Saurí and Pustejovsky, 2009). It was created following carefully crafted annotation guidelines and examples comprising 34 pages.[2] The guidelines detail a manual normalization step to "identify the full event that needs to be assessed in terms of its factuality" (p. 12), and the annotation process includes identifying the sources that are assessing factuality (p. 15). de Marneffe et al. (2012) reannotate a subset of FactBank with factuality values from the reader's perspective—they call it veridicality—using crowdsourcing. Both FactBank and de Marneffe et al. (2012), rely on manual normalization to identify the eventuality whose factuality is being annotated. Instead, we present an automated approach: we manipulate semantic roles and syntactic dependencies deterministically to generate several potential interpretations per modal construction, and then assess their factuality.

Many other efforts expand on FactBank using crowdsourced annotations, different annotation schemas (usually simpler) or other domains. Prabhakaran et al. (2012) use crowdsourcing to classify propositions into 5 modalities: ability, effort, intention, success and want. Soni et al. (2014) target the factuality of quotes (direct and indirect) in Twitter. Lee et al. (2015) detect events and assess factuality using easy-to-understand short instructions to crowdsource annotations. Unlike us, they annotate factuality at the individual token level, where annotated tokens are deemed events by annotators. Prabhakaran et al. (2015) define and annotate propositional heads with four categories: (1) non-belief propositions, or (2) committed, non-committed or reported belief. Instead of assessing factuality only for propositional heads (usually verbs, one assessment per proposition), we do so for potential interpretations automatically generated by manipulating verbs and their arguments deterministically.

All works cited in the previous two paragraphs either manually normalize text prior to assessing factuality—making automation from plain text impossible—or assess factuality for tokens deemed events (ordered, delay, agreed, etc.) or full propositions (a verb and all its arguments). Unlike them, we automatically generate potential interpretations from a single modal construction—or, equivalently, automatically generate several normalizations—and then assess their factuality.

3 Terminology and Background

We use the term *modal construction* to refer to verb-argument structures modified by a modal adverb (possibly, probably, etc.). We use the term *implicit interpretation*, or *interpretation* to save space, to refer to meaning intuitively understood by humans when reading a modal construction. *Potential interpretations* are interpretations automatically generated whose factuality has yet to be determined. The *factuality* of an interpretation is a score indicating its likelihood—whether it is true, false or unknown given the modal construction.

We work on top of OntoNotes (Hovy et al., 2006) because it includes text from several genres (news, broadcast and telephone conversations, weblogs, etc.) and includes part-of-speech tags, parse trees, PropBank-style semantic roles and other linguistic information.[3] Very briefly, PropBank (Palmer et al., 2005) has two kinds of semantic roles: numbered roles (ARG$_0$, ARG$_1$, etc.), which are defined in verb-specific framesets, and argument modifiers (ARGM-TMP, ARGM-LOC, etc.), we refer the reader to the aforementioned reference, and the guidelines and framesets[4] for more details. We transformed the parse trees in OntoNotes into syntactic dependencies using Stanford CoreNLP (Manning et al., 2014).

4 Corpus Creation

We define a two-step procedure to create a corpus of modal constructions and the implicit interpretations intuitively understood by humans when reading them. First, we automatically generate potential interpretations from modal constructions by manipulating syntactic dependencies and semantic roles. Second, we manually score potential interpretations according to their likelihood. These interpretations and scores are later used to learn how to score potential interpretations automatically (Section 6).

4.1 Generating Potential Interpretations

Selecting Modal Constructions. OntoNotes is a large corpus containing 63,918 sentences. Creating a corpus of interpretations for all modal constructions is outside the scope of this paper. In order to alleviate the annotation effort, we focus on selected modal constructions. Specifically, we select verb-argument structures that have one ARGM-ADV or ARGM-MNR role, and that role is one of the following modal adverbs: certainly, clearly, definitely, likely, obviously, possibly, probably, surely, or unlikely. These adverbs are the most frequent that satisfy the above filter. Additionally, we discard verb-argument structures with *to be* as the main verb. These rules retrieve 324 modal constructions.

Automatic Normalization. Modal constructions often occur in long multi-clause sentences. In order to identify the eventuality from which potential interpretations should be generated, we automatically normalize the original sentence. Normalizing consists of a battery of deterministic steps implemented using syntactic dependencies and semantic roles. In contrast with previous work (Section 2), our normalization is fully automated. Hereafter, we use *verb* to refer to the main verb in the modal construction, *adverb* to the modal adverb, and *sem_roles* to all semantic roles in the modal construction.

1. Remove *adverb*.
2. Convert negated verb-argument structures into their positive counterparts. We follow 3 steps inspired by the rules to form negation proposed by (Huddleston and Pullum, 2002):
   (a) Remove the negation mark by deleting the token whose syntactic dependency is *neg*.
   (b) Remove auxiliaries, expand contractions, and fix third-person singular and past tense. For example (before: after), *doesn't go*: *goes*, *didn't go*: *went*, *won't go*: *will go*. To implement this step, we loop through tokens whose head is the negated verb with dependency *aux*, and use a list of irregular verbs[5] and grammar rules to convert to third-person singular and past tense based on orthographic patterns.
   (c) Rewrite negatively-oriented polarity-sensitive items. For example (before: after), *anyone*: *someone*, *any longer*: *still*, *yet*: *already*. *at all*: *somewhat*. We use the correspondences between negatively-oriented and positively-

Sent. 1: The danger is [probably]$_{\text{ARGM-ADV}}$ [he]$_{\text{ARG}_0}$ [can]$_{\text{ARGM-MOD}}$ [not]$_{\text{ARGM-NEG}}$ [deliver]$_{verb}$ [the promises that he made during the campaign.]$_{\text{ARG}_1}$		
Normalization	Step	Output
	1	The danger is he cannot deliver the promises that he made during the campaign.
	2	The danger is he can deliver the promises that he made during the campaign.
	3	The danger is he will deliver the promises that he made during the campaign.
	4	He will deliver the promises that he made during the campaign.
	5	He will deliver the promises that he made during the campaign.
Sent. 2: [...] I wouldn't define victory as simply not raising taxes—although [I]$_{\text{ARG}_0,\, v_1,\, v_2}$ [definitely]$_{\text{ARGM-ADV},\, v_1}$ [would]$_{\text{ARGM-MOD},\, v_1}$ [like]$_{v_1}$ [to [defer]$_{v_2}$ [raising taxes]$_{\text{ARG}_1,\, v_2}$ [as long as prudently possible.]$_{\text{ARG}_2,\, v_2}$]$_{\text{ARG}_1,\, v_1}$		
Normalization	Step	Output
	1	I wouldn't define [...] although I would like to defer raising taxes as long as prudently possible.
	2, 3	I would define [...] although I will like to defer raising taxes as long as prudently possible.
	4	I will like to defer raising taxes as long as prudently possible.
	5	Normalization 1: I will like to defer raising taxes as long as prudently possible. Normalization 2: I will defer raising taxes as long as prudently possible.
Interpretations	From	Potential Interpretation
	norm. 1	$\{\text{ARG}_0\}$ will like to defer raising taxes as long as prudently possible.
		I will like $\{$to $\text{ARG}_1\}$.
	norm. 2	$\{\text{ARG}_0\}$ will defer raising taxes as long as prudently possible.
		I will defer $\{\text{ARG}_1\}$ as long as prudently possible.
		I will defer raising taxes $\{\text{ARG}_2\}$.
		I will defer $\{\text{ARG}_1\}$ $\{\text{ARG}_2\}$.

Table 1: Step-by-step execution of the procedure to automatically normalize modal constructions (Sentences 1 and 2) and generate potential interpretations (Sentence 2).

oriented polarity-sensitive items by (Huddleston and Pullum, 2002, pp. 831).

3. Fix modal verbs and tense. If a modal verb (can, could, may, would, should, must, etc.) has as syntactic head *verb*, we transform the modal construction into past or future depending on the modal and tense of *verb*. For example: *could go: went*, *can go: will go*, *should have gone: went*. We use the same grammar rules and list of irregular verbs as in Step (2b).
4. Select relevant tokens. We remove all tokens in the original sentence except *verb* and tokens belonging to the roles in *sem_roles*. Additionally, we fix phrasal verbs by adding tokens with the part-of-speech tag RP whose syntactic head is *verb* and dependency type *prt* (semantic roles in OntoNotes are annotated for verb tokens, missing the preposition when *verb* is a phrasal verb would inadvertently change meaning). We also add all tokens to the left of *verb* until we find the first token whose part-of-speech tag does not start with VB, MD, RB or EX (verbs, modals, adverbs and existential *there*).
5. Generate additional normalizations. If *verb* is followed by TO + $verb_2$ (e.g., want to go, like to play, intend to pass), we generate an additional normalization for $verb_2$ after merging the semantic roles of *verb* and $verb_2$.

Table 1 exemplifies the automatic normalization step by step with 2 modal constructions.

Generating Potential Interpretations in Plain Text. Inspired by the rules Blanco and Sarabi (2016) used to generate interpretations from negation, we generate potential interpretations from modal constructions by toggling off combinations of roles in *sem_roles*. We consider numbered roles (ARG_0–ARG_5), and argument modifiers (ARGM-) ending in LOC, TMP, MNR, PRP, CAU, EXT, PRD or DIR.

Table 1 lists some potential interpretations generated from a sample modal construction. The total number of potential interpretations for the 324 selected modal construction is 1,756 (average: 5.4).

We recognize that our procedure to generate implicit interpretations is unable to generate some useful interpretations. For example, from *This is [a person who]*$_{\text{ARG}_1}$ *[likely]*$_{\text{ARGM-ADV}}$ *[died]*$_{verb}$ *[on impact versus perhaps freezing to death]*$_{\text{ARGM-MNR}}$, we

generate *This is a person who died* {ARGM-MNR}, which is factual: the only uncertain information is the manner in which the person died. Since we toggle off semantic roles of *verb*, our procedure is unable to generate *A person died on impact* and *A person died freezing to death*; the former interpretation would receive a higher factuality score than the latter. We argue that automation is preferable, and reserve for future work generating interpretations that require splitting semantic roles.

4.2 Scoring Potential Interpretations

After automatically generating potential interpretations, we collected manual annotations to determine their factuality. The annotation interface showed the original sentence containing the modal construction, the previous and next sentences as context, and no additional information. Following previous work (Saurí and Pustejovsky, 2009; de Marneffe et al., 2012), we found it useful not to restrict answers to *yes* or *no*, but to allow for degrees of certainty. Specifically, we asked "Given the 3 sentences above, do you believe that the statement [potential interpretation] below is true?". Answers are a score ranging from -5 to 5, where -5 indicates *Certainly no*, 5 indicates *Certainly yes*, and the scores in between indicate a continuum of certainty (0 indicates *unknown*).

After pilot annotations, we examined disagreements and defined the following simple guidelines:

1. Context (previous sentence, target sentence, and next sentence) is taken into account.
2. World knowledge available at the time the original sentence was authored—not new knowledge available after—is taken into account.
3. Semantic roles toggled off are replaced with a semantically related substitute (Turney and Pantel, 2010) for the original role, e.g., give: take, customer: sales associate.

5 Corpus Analysis

The total number of modal constructions selected is 324 and the number of potential interpretations automatically generated in 1,756 (average: 5.4 interpretation per modal construction). 39.4% of interpretations are scored with a high degree of certainty. We define *high certainty* as a score below -3 (interpretation is false) or larger than 3 (interpretation is true). Importantly, on overage, modal constructions have 2.13 interpretations scored with high certainty, and 1.23 scored 3 or higher. In other words, on average, our procedure generates over 2 interpretation that are either true or false, and over 1 interpretation that is true per modal construction.

# roles toggled off	#	%≠ 0	Mean score	
			> 0	< 0
0	345	87.25	3.96	-3.94
1	800	48.50	3.67	-3.90
2	479	20.46	3.55	-4.03
3	120	5.83	3.50	-3.00

Table 2: Number of interpretations generated by toggling off 0, 1, 2 or 3 roles (#), percentage of interpretations not scored zero (% $\neq$ 0), and mean scores of interpretations with positive and negative scores.

Role	#	% ≠ 0	Mean score	
			> 0	< 0
None	345	87.25	3.96	-3.94
ARG_1	671	30.40	3.60	-3.92
ARG_0	604	25.50	3.72	-3.94
ARG_2	140	28.57	3.85	-3.84
ARGM-MNR	271	32.84	3.40	-3.85
ARGM-TMP	231	28.57	3.71	-3.84
ARGM-LOC	82	23.17	3.43	-4.60
Other	290	20.00	3.38	-3.87

Table 3: Number of interpretations generated by toggling off each semantic role (#), percentage of interpretations not scored zero (% $\neq$ 0), and mean score of interpretations with positive and negative scores.

Tables 2 and 3 present basic corpus statistics. The percentage of interpretations annotated with a score different than 0 depends greatly on the number of roles toggled off (Table 2): 0: 87.25%, 1: 48.50%, 2: 20.46%, 3: 5.83%. Note that the number of roles toggled off does not significantly affect the mean score of interpretations not scored 0 (Table 2, last 2 columns). Most interpretations have either ARG_0 or ARG_1 toggled off (Table 3), and the percentages of interpretations not scored zero range from 20% to 32.84% depending on the semantic role. Note that the average score of interpretations scored positively and negatively, however, does not depend on whether a semantic role is toggled off.

	Original sentence and sample of automatically generated potential interpretations	Score
1	Context, previous sentence: *The last thing we want to do is react to every wild statement that they make.* Original sentence: *[But]*$_{\text{ARGM-DIS}}$ *[they]*$_{\text{ARG}_0}$ *[certainly]*$_{\text{ARGM-ADV}}$ *[chose]*$_{\textit{verb}}$ *[that]*$_{\text{ARG}_1}$ *[to get our attention and that of the international community.]*$_{\text{ARGM-PRP}}$ Context, next sentence: *Uh but what they've got to realize is there is no magic bullet here.*	
	- Interpretation 1.1: But they chose that to get our attention and that of the international community.	5
	- Interpretation 1.2: But they chose $\{\text{ARG}_1\}$ to get our attention and that of the international community.	-5
2	Context, previous sentence: *Saddam Hussein (interrupting): Before you offer me your rotten goods, I ask you did you find weapons of mass destruction in Iraq or not?* Original sentence: *Rumsfeld (disconcerted): We haven't found them yet, but [we]*$_{\text{ARG}_0}$ *[will]*$_{\text{ARGM-MOD}}$ *[surely]*$_{\text{ARGM-ADV}}$ *[find]*$_{\textit{verb}}$ *[them]*$_{\text{ARG}_1}$ *[one day]*$_{\text{ARGM-TMP}}$. Context, next sentence: *Do you deny that you had intentions to manufacture a nuclear bomb?*	
	- Interpretation 2.1: We will find them one day.	4
	- Interpretation 2.2: We will find them $\{\text{ARGM-TMP}\}$.	-3
3	*"This is a rare case of [a company with a big majority holder which]*$_{\text{ARG}_0}$ *[will]*$_{\text{ARGM-MOD}}$ *[probably]*$_{\text{ARGM-ADV}}$ *[act]*$_{\textit{verb}}$ *[in the interests of the minority holders]*$_{\text{ARG}_1}$*", one investor says.*	
	- Interpretation 3.1: $\{\text{ARG}_0\}$ will act in the interests of the minority holders.	4
	- Interpretation 3.2: A company with a big majority holder will act $\{\text{ARG}_1\}$.	4
4	*I wouldn't define victory as simply not raising taxes—although [I]*$_{\text{ARG}_0,\, v_1,\, v_2}$ *[definitely]*$_{\text{ARGM-ADV},\, v_1}$ *[would]*$_{\text{ARGM-MOD},\, v_1}$ *[like]*$_{v_1}$ *[to [defer]*$_{v_2}$ *[raising taxes]*$_{\text{ARG}_1,\, v_2}$ *[as long as prudently possible.]*$_{\text{ARG}_2,\, v_2}$*]*$_{\text{ARG}_1,\, v_1}$	
	- Interpretation 4.1: I will like to defer raising taxes as long as prudently possible.	5
	- Interpretation 4.2: I will defer raising taxes as long as prudently possible.	1

Table 4: Annotation Examples. For each example, we show the original sentence containing the modal construction, context if helpful to determine scores, and 2 selected interpretations and their scores. Square brackets indicate semantic roles.

5.1 Annotation Quality

The annotation guidelines (Section 4.2) to score potential interpretations were defined after examining disagreements in pilot annotations. After defining the guidelines, inter-annotator agreement was 0.92 on 18% of randomly selected interpretations.[6] Agreement measures designed for categorical labels are unsuitable, as not all disagreements are equal, e.g., 4 vs. 5, -2 vs. 5. Because of the high agreement and following previous work (Agirre et al., 2012), the rest of interpretations were annotated once.

5.2 Annotation Examples

Table 4 presents annotation examples. For each example, we include the original sentence containing a selected modal construction, its context (previous and next sentence) if helpful for scoring, and 2 automatically generated potential interpretations with their annotated scores.

Example (1) shows that context helps in determining the factuality of potential interpretations (item (1) in the guidelines). After reading the three sentences, it is clear that *they* are making *wild statements*, and are hoping to get *attention* for it. Interpretation 1.1 removes adverb *certainly* and receives the highest score, 5. Interpretation 1.2 is obtained after toggling off ARG_1, and receives the lowest score, -5. This low score is justified by item (3) in our annotation guidelines: replacing *wild statements* with a semantically (different but) related substitute, e.g., *But they chose reasonable statements / good manners to get our attention and that of the international community*, yields an unlikely interpretation.

The interpretations in Example (2) show again the importance of context, and also exemplify item (2) in the annotation guidelines. Interpretation 2.1, *We will find them one day* receives a high score $(4/5)$, as given the context (and assuming that Rumsfeld is truthful), it is very likely that they will find the weapons of mass destruction, but it is not guaranteed. Note that annotators are not allowed to use the fact that the weapons were never found (item (2) in the guidelines). In Interpretation 2.2, *one day* could be replaced with *never / at no time* or similar constructions, and doing so yields the opposite of the intended meaning (score: -3). A possible descrip-

[6] We set an internal deadline of 3 days after agreeing on the guidelines, and we could annotate 18% of instances in that time.

Type	Feature	Description
baseline	adverb	Word form of adverb
	adverb_pos	Part-of-speech of adverb
	verb	Word form of verb
	verb_pos	Part-of-speech of verb
	distance	Number of tokens between adverb and verb
	direction	Whether adverb occurs before or after verb
adverb and verb	adverb_rel_pos	Part-of-speech tags of the parent, and left and right siblings of adverb
	adverb_subcat	Concatenation of part-of-speech tags of all siblings of adverb
	verb_rel_pos	Part-of-speech tags of the parent, and left and right siblings of verb
	adverb_subcat	Concatenation of part-of-speech tags of all siblings of verb
	path, path_l	Syntactic path between adverb and verb, and length of the path
	ancestor	POS tag of the lowest common ancestor between verb and adverb
	has_sem_role	Flags indicating whether a semantic role is in the modal construction
interpretation	num_roles_int	Number of roles toggled off in the potential interpretation
	sem_roles_int	Flags indicating which roles are toggled off in the interpretation
	roles_distance	Number of tokens between each semantic role and verb
	roles_direction	Whether each semantic role occurs before or after verb
	roles_path	Syntactic path between each role and verb
	roles_path_l	Length of syntactic path between each role and verb

Table 5: Features used to predict factuality scores to automatically generated potential interpretations. Features extracted from semantic role are extracted for ARG_0–ARG_5 and modifiers (ARGM-) ending in LOC, TMP, MNR, PRP, CAU, EXT and PRD.

tion of these scores could be "almost certainly true" (4 out of 5), and "most probably false" (-3 out of -5). We see scores as a continuum of certainty, but textual description may help understand the examples.

Example (3) demonstrates the usefulness of the normalization process—specifically, Step 4, selecting relevant tokens—and the importance of replacing roles with semantically related substitutes (item (3) in the guidelines). In interpretation 3.1, $\{\text{ARG}_0\}$ *will act in the interests of the minority holders*, ARG_0 can be replaced with *a company with several minority holders*, yielding a valid interpretation scored 4 (out of 5). Similarly, in interpretation 3.2, *A company with a big majority holder will act* $\{\text{ARG}_1\}$, ARG_1 can be replaced with *in the interests of the big majority holder*, yielding another valid interpretation also scored 4 (out of 5).

Finally, Example (4) shows Step 5 in the automatic normalization procedure (Section 4). By creating an additional verb-argument structure, we are able to differentiate between liking to do something (Interpretation 4.1, score 5/5) and actually doing that something (Interpretation 4.2, score 1/5).

6 Learning to Score Potential Interpretations

In order to automatically score potential interpretations, we follow a standard supervised machine learning approach. Each potential interpretation becomes an instance, and we split modal constructions (and their potential interpretations) into training (80%) and test (20%). When splitting, we make sure that the amount of modal constructions for each adverb in each split is proportional, i.e., 80% of modal constructions with each adverb are in the train split and the rest in the test split. Splitting instances randomly would assign interpretations generated from the same modal construction to the train and test splits, and bias the results.

We trained a Support Vector Machine (SVM) for regression with RBF kernel using scikit-learn (Pedregosa et al., 2011), which uses LIBSVM (Chang and Lin, 2011). The SVM parameters (C and γ) were tuned using 10-fold cross-validation with the training set, and we report results using the test split.

Features	Pearson
baseline	-0.029
adverb and verb	0.025
interpretation	0.494
baseline + adverb and verb	-0.013
baseline + interpretation	0.463
adverb and verb + interpretation	0.465
baseline + adverb and verb + interpretation	0.468

Table 6: Pearson correlations obtained with test instances and several feature combinations.

6.1 Feature Selection

The full set of features is detailed in Table 5. *Baseline* features are simple features characterizing *adverb* and *verb* and we do not elaborate on them. *Adverb and verb* features are extracted from the modal construction (constituent tree and semantic roles) and provide additional information about the modal construction. *Interpretation* features characterize the potential interpretation whose factuality is being scored, and are also derived from the constituent tree and semantic roles.

Most *adverb and verb* features are standard in semantic role labeling (Gildea and Jurafsky, 2002). We include the part-of-speech tags of the parent, and left and right siblings of *adverb* and *verb*, as well as their subcategorization, i.e., the concatenation of the sibling's part-of-speech tags. We also include syntactic path between *adverb* and *verb*, and its length. Additionally, we include the common ancestor, i.e., the syntactic node of the lowest common node that is an ancestor of both *adverb* and *verb*, and use binary features to indicate whether each semantic role is present in the modal construction.

Finally, *interpretation* features characterize the semantic roles toggled off to generate the potential interpretation. We include the number of roles toggled off to generate the potential interpretation, and binary flags indicating which roles. Additionally, for each role toggled off, we include the distance from the verb (number of tokens), whether it occurs before or after the verb, the syntactic path to the verb and the length of the path.

7 Experimental Results

Table 6 details results obtained with test instances using several feature combinations derived from gold linguistic information (POS tags, parse trees, semantic roles, etc.). *Baseline* and *adverb and verb* features, which characterize the modal construction from which potential interpretation are extracted, are virtually useless. They yield Pearson correlations of -0.029 and 0.025 individually, and -0.013 combined. These results suggest that the verb and adverb in the modal construction (word forms, syntactic paths, etc.) are insufficient to rank potential interpretations generated from the modal construction.

Interpretation features, which capture differences between potential interpretations being scored (number of roles toggled off, roles toggled off, etc.), obtain a modest Pearson correlation of 0.494. Combining *interpretation* features with other features proved detrimental, Pearson correlations are between 0.463 and 0.468.

8 Conclusions

Modality is a pervasive phenomenon used to talk about what is not factual. In this paper, we have presented a methodology to extract implicit interpretations from modal constructions. First, we automatically generate potential interpretations using syntactic dependencies and semantic roles, and then assign to them a factuality score.

The most important conclusion of the work presented here is that several interpretations automatically generated from a single modal construction often receive scores indicating high certainty. Indeed, on average, modal constructions have 2.13 interpretations scored lower or equal than -3, or higher or equal than 3. This contrast with previous work, which only assess factuality of one normalization per proposition.

Experimental results using supervised machine learning and relatively simple features show that the task is challenging but can be automated. We believe better results could be obtained by incorporating features capturing knowledge in the context of the modal construction, including other clauses in the same sentence, and the previous and next sentences. Another extension of the current work is to investigate a similar approach for other modality markers such as nouns (e.g., possibility, chance), adjectives (e.g.necessary, probable,) and certain verbs (e.g., claim, suggests).

Abstract

This paper presents a two-step procedure to extract positive meaning from verbal negation. We first generate potential positive interpretations manipulating syntactic dependencies. Then, we score them according to their likelihood. Manual annotations show that positive interpretations are ubiquitous and intuitive to humans. Experimental results show that dependencies are better suited than semantic roles for this task, and automation is possible.

1 Introduction

Negation is a complex phenomenon present in all human languages, allowing for the uniquely human capacities of denial, contradiction, misrepresentation, lying, and irony (Horn and Wansing, 2015). Despite negation always being marked—in the absence of a negation cue, statements are positive—acquiring and understanding sentences that contain negation is more challenging than those that do not. Children acquire negation after learning to communicate (Nordmeyer and Frank, 2013), and adults take longer to process negated statements than positive ones (Clark and Chase, 1972).

In any given language, humans communicate in positive terms most of the time, and use negation to express something unusual or an exception (Horn, 1989). Albeit most sentences are affirmative, negation is ubiquitous (Morante and Sporleder, 2012): In scientific papers, 13.76% of statements contain a negation (Szarvas et al., 2008); in product reviews, 19% (Councill et al., 2010); and in Conan Doyle stories, 22.23% (Morante and Daelemans, 2012). In OntoNotes (Hovy et al., 2006), 10.15% of statements contain a verb negated with *not*, *n't* or *never*.

From a theoretical point of view, it is accepted that negation conveys positive meaning (Rooth, 1992; Huddleston and Pullum, 2002). For example, when reading (1) *John didn't order the right parts*, humans intuitively understand that (1a) *John ordered something*, or more specifically, (1b) *John ordered the wrong parts*. Interpretation (1a) can be obtained after determining that *n't* does not negate verb *order*, but its THEME, i.e., *the right parts*. Interpretation (1b) can be obtained after determining that *n't* is actually negating *right*, an adjective modifying *parts*.

Determining which words are intended to be negated—identifying the foci of negation, thereby revealing positive interpretations—is challenging. First, as exemplified in (1a, 1b), there is a granularity continuum yielding interpretations that entail each other, e.g., (1b) entails (1a). Second, a single negation often yields several positive interpretations, e.g., from (2) *John doesn't eat meat*, we can extract that (2a) *John eats something other than meat* and (2b) *Some people eat meat, but not John*.

This paper presents a methodology to extract positive interpretations from verbal negation. The main contributions are: (1) deterministic procedure to generate potential interpretations by manipulating syntactic dependencies; (2) analysis showing that dependencies yield finer-grained interpretations and better results than previous work using semantic roles; (3) a corpus of negations and their positive interpretations;[1] and (4) experimental results with gold-standard and predicted linguistic information.

2 Terminology, Scope and Focus

Negation is well-understood in grammars, which detail the valid ways to form a negation (Quirk et al., 2000; van der Wouden, 1997). Negation can be expressed by verbs (e.g., *avoid* running), nouns (e.g., the *absence* of evidence), adjectives (e.g., it is *pointless*), adverbs (e.g., I *never* tried Persian food before), prepositions (e.g., you can exchange it *without* a problem), determiners (e.g., the new law has *no* direct implications), pronouns (e.g., *nobody* will keep election promises), and others. In this paper, we focus on verbal negation, i.e., when the negation mark—usually an adverb such as *never* and *not*—is grammatically associated with a verb.

Positive Interpretations. In philosophy and linguistics, it is generally accepted that negation conveys positive meaning (Horn, 1989). This positive meaning ranges from implicatures, i.e., what is suggested in an utterance even though neither expressed nor strictly implied (Blackburn, 2008), to entailments. Other terms used in the literature include implied meanings (Mitkov, 2005), implied alternatives (Rooth, 1985) and semantically similars (Agirre et al., 2013). We do not strictly fit into any of this terminology, we reveal positive interpretations as intuitively done by humans when reading text.

2.1 Scope and Focus

From a theoretical perspective, it is accepted that negation has scope and focus, and that the focus—not just the scope—yields positive interpretations (Horn, 1989; Rooth, 1992; Taglicht, 1984). Scope is "the part of the meaning that is negated" and focus "the part of the scope that is most prominently or explicitly negated" (Huddleston and Pullum, 2002).

Consider the following statement in the context of the recent refugee crisis: (2) *Mr. Haile was* not *looking for heaven in Europe*. By definition, scope refers to "all elements whose individual falsity would make the negated statement strictly true", and focus is "the element of the scope that is intended to be interpreted as false to make the overall negative true" (Huddleston and Pullum, 2002). The falsity of any of the truth conditions below makes statement (2) true, thus the scope of the negation is (2a–2d):

2a. Somebody was looking for something somewhere. [verb *looking*]

2b. Mr. Haile was looking for something somewhere. [AGENT of looking, *Mr. Haile*]

2c. Somebody was looking for heaven somewhere. [THEME of looking, *heaven*]

2d. Somebody was looking for something in Europe. [LOCATION of looking, *in Europe*]

Determining the focus is almost always more challenging than the scope. The challenge relies on determining which of the truth conditions (2a–2d) is intended to be interpreted as false to make the negated statement true: all of them qualify, but some are more likely. A natural reading of statement (2) suggests that *Mr. Haile was looking for something (a regular life, a job, etc.) in Europe, but not heaven*. Determining that the focus is *heaven*, i.e., that everything in statement (2) is positive except the THEME of *looking*, is the key to reveal the intended positive interpretation. Note that scope on its own does not identify positive interpretations, and other foci yield unlikely positive interpretations, e.g., *Mr. Haile was looking for heaven somewhere, but not in Europe*.

It is worth noting that while scope is defined from a logical standpoint, in most negations there are several possible foci and corresponding positive interpretations. For example, given (3) *Most jobs now don't last for decades*, the following are valid positive interpretations: (3a) *Few jobs now last for decades*, (3b) *Most jobs in the past lasted for decades*, and (3c) *Most jobs now last for a few years*.

Granularity of Focus. The definition of focus does not provide guidelines about identifying the element of the scope that is the focus. The larger the focus, the more generic the corresponding positive interpretation; and the smaller the focus, the more specific the corresponding positive interpretation. Let us consider statement (3) again. A possible focus is *Most jobs*, yielding the positive interpretation *Something now lasts for decades, but not most jobs*. Another possible focus is *Most*, yielding the interpretation *Few (not most) jobs now last for decades*. We argue that the latter is preferable, as it yields a more specific interpretation and it entails the former: if some jobs last for decades, then something lasts for decades, but not the other way around.

We use the term *coarse-grained focus* to refer to foci that include *all* tokens belonging to an argument of a verb (e.g., *Most Jobs* above), and *fine-grained focus* to refer to foci that do not (e.g., *Most* above).

3 Previous Work

Within computational linguistics, approaches to process negation are shallow, or target scope and focus detection. Popular semantic representations such as semantic roles (Palmer et al., 2005; Baker et al., 1998) or AMR (Banarescu et al., 2013) do not reveal the positive interpretations we target in this paper. Shallow approaches are usually application-specific. In sentiment and opinion analysis, negation has been reduced to marking as negated all words between a negation cue and the first punctuation mark (Pang et al., 2002), or within a five-word window of a negation cue (Hu and Liu, 2004). The examples throughout this paper show that these techniques are insufficient to reveal implicit positive interpretations.

3.1 Scope Annotations and Detection

Scope of negation detection has received a lot of attention, mostly using two corpora: BioScope in the medical domain (Szarvas et al., 2008) and CD-SCO (Morante and Daelemans, 2012). BioScope annotates negation cues and linguistic scopes exclusively in biomedical texts. CD-SCO annotates negation cues, scopes, and negated events or properties in selected Conan Doyle stories.

There have been several supervised proposals to detect the scope of negation using BioScope and CD-SCO (Özgür and Radev, 2009; Øvrelid et al., 2010). Automatic approaches are mature (Abu-Jbara and Radev, 2012): F-scores are 0.96 for negation cue detection, and 0.89 for negation cue and scope detection (Velldal et al., 2012; Li et al., 2010). Fancellu et al. (2016) present the best results to date using CD-SCO, and analyze the main sources of errors. Outside BioScope and CD-SCO, Reitan et al. (2015) present a negation scope detector for tweets, and show that it improves sentiment analysis. As shown in Section 2, scope detection is insufficient to reveal positive interpretations from negation.

3.2 Focus Annotation and Detection

While focus of negation has been studied for decades in philosophy and linguistics (Section 2), corpora and automated tools are scarce. Blanco and Moldovan (2011) annotate focus of negation in the 3,993 negations marked with ARGM-NEG semantic role in PropBank (Palmer et al., 2005). Their annotations, PB-FOC, were used in the *SEM-2012 Shared Task (Morante and Blanco, 2012). Their guidelines require annotators to choose as focus the semantic role that "is most prominently negated" or the verb. If several roles may be the focus, they prioritize "the one that yields the most meaningful implicit [positive] information", but do not specify what *most meaningful* means. Their approach has 2 limitations. First, because they select one focus per negation, they only extract one positive interpretation per negation. Second, because they select as focus a semantic role, they only consider coarse-grained foci. Consider again statement (3) from Section 2.1. By design, their approach is limited to extract a single interpretation even though interpretations (3a–3c) are valid. Similarly, their approach is limited to select as focus *Most jobs*—all tokens belonging to a semantic role—although *Most* yields a "more meaningful" interpretation: *Something now lasts for decades* (generic, worse) vs. *Few jobs now last for decades* (specific, better).

Blanco and Sarabi (2016) present a complimentary approach to extract and score several positive interpretations from a single verbal negation. Their methodology is grounded on semantic roles and does not consider fine-grained foci. In this paper, we improve upon their work: we extract both coarse- and fine-grained interpretations, and also extract several interpretations from one negation.

Anand and Martell (2012) reannotate PB-FOC and argue that positive interpretations arising from scalar implicatures and neg-raising predicates should be separated from those arising from focus detection. They argue that 27.4% of negations with a focus annotated in PB-FOC do not have one. In this paper, we are not concerned about annotating foci per se, but about extracting positive interpretations from negation, as intuitively done by humans.

Automatic systems to detect the focus of negation yield modest results. Blanco and Moldovan (2011) obtain an accuracy of 65.5 using supervised learning and features derived from gold-standard linguistic information. With predicted linguistic information, Rosenberg and Bergler (2012) report an F-measure of 58.4 using 4 linguistically sound heuristics, and Zou et al. (2014) an F-measure of 65.62 using contextual discourse information. Blanco and Sarabi (2016) obtain Pearson correlation of 0.642

ranking coarse-grained interpretations. Unlike the work presented here, none of these systems extract fine-grained interpretations from a single negation.

4 Corpus Creation

Our goal is to create a corpus of negations and their positive interpretations. We put a strong emphasis on automation and simplicity. First, we deterministically generate potential positive interpretations from verbal negations by manipulating syntactic dependencies (Section 4.1). Second, we ask annotators to score potential positive interpretations (Section 4.2). Positive interpretations and their scores are later used to learn models to rank potential interpretations automatically (Section 6). Generating potential interpretations deterministically prior to scoring them proved very beneficial. After pilot experiments, it became clear that asking annotators to propose positive interpretations complicates the annotation effort (lower agreements) as well as learning.

We decided to work on top of OntoNotes (Hovy et al., 2006)[2] instead of plain text or other corpora for several reasons. First, OntoNotes includes gold linguistic annotations such as part-of-speech tags, parse trees and semantic roles. Second, unlike BioScope, CD-SCO and PB-FOC (Section 3.2), OntoNotes includes sentences from several genres, e.g., newswire, broadcast news and conversations, magazines, the web. We transformed the parse trees in OntoNotes into syntactic dependencies using Stanford CoreNLP (Manning et al., 2014).

4.1 Manipulating Syntactic Dependencies to Generate Potential Positive Interpretations

OntoNotes contains 63,918 sentences. Annotating all positive interpretations from all negations is outside the scope of this paper. Instead, we target selected representative negations.

Selecting Negations. We first select all verbal negations by retrieving all tokens whose syntactic head is a verb and dependency type *neg*.[3] Then, we discard negations from sentences that contain two negations, conditionals, commas or questions. Finally, we discard negations if the negated verb is *to be* or it does not have a subject (dependency *nsubj* or *nsubjpass*).

Converting Negated Statements into their positive counterparts. We apply 3 steps inspired after the grammatical rules to form negation detailed by Huddleston and Pullum (2002, Ch. 9):

1. Remove the negation mark by deleting the token with syntactic dependency *neg*.
2. Remove auxiliaries, expand contractions, and fix third-person singular and past tense. For example (before: after), *doesn't go*: *goes*, *didn't go*: *went*, *won't go*: *will go*. We loop through the tokens whose head is the negated verb with dependency *aux*, and use a list of irregular verbs and grammar rules to convert to third-person singular and past tense.
3. Rewrite negatively-oriented polarity-sensitive items. For example (before: after), *anyone*: *someone*, *any longer*: *still*, *yet*: *already*. *at all*: *somewhat*. We use the correspondences between negatively-oriented and positively-oriented polarity-sensitive items by (Huddleston and Pullum, 2002, pp. 831).

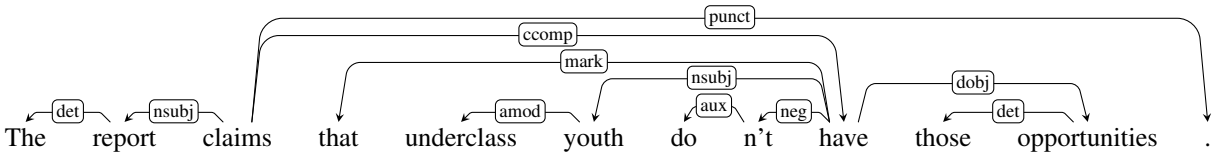
Selecting Relevant tokens. Verbal negation often occurs in multi-clause sentences. In order to identify the relevant (syntactically negated) eventuality, we simplify the original statement by including only the negated verb and all tokens that are dependents of the verb, i.e., tokens reachable from the negated verb traversing dependencies. For example, from *Individuals familiar with the Justice Department's policy said that Justice officials hadn't any knowledge of the IRS's actions in the last week*, after getting the positive counterpart and selecting relevant tokens, we obtain *Justice officials had some knowledge of the IRS's actions in the last week*.

Generating Interpretations. Given the simplified positive counterpart, generating all combinations of tokens as potential foci would result in 2^t potential positive interpretations for t tokens. To avoid a brute-force approach that generates many nonsensical potential interpretations, we define a procedure grounded on syntactic dependencies.

The main idea is to run a modified breadth-first traversal of the dependency tree to select subtrees that are potential foci. We start the traversal from the negated verb and stop it at depth 3, selecting as potential foci the subtrees rooted at all tokens except

[2] We use the CoNLL-2011 Shared Task distribution (Pradhan et al., 2011), `http://conll.cemantix.org/2011/`

[3] The Stanford manual describes and exemplifies all syntactic dependencies (de Marneffe and Manning, 2008).



Negated statement: The report claims that underclass youth don't have those opportunities.			
Positive counterpart	Step 1		The report claims that underclass youth do have those opportunities.
	Step 2		The report claims that underclass youth have those opportunities.
	Step 3		The report claims that underclass youth have those opportunities. (idem)
Relevant tokens	Underclass youth have those opportunities.		
Potential positive interpretations	*none*	coarse	Underclass youth [some verb] those opportunities, *but not have*.
	nsubj	coarse	[Some people] have those opportunities, but not *Underclass youth*.
	amod	fine	[Some adjective] youth have those opportunities, but not *Underclass youth*.
	nsubj	fine	Underclass [some people] have those opportunities, but not *Underclass youth*.
	dobj	coarse	Underclass youth have [something], but not *those opportunities*.
	det	fine	Underclass youth have [some] opportunities, but not *those opportunities*.
	dobj	fine	Underclass youth have those [something], but not *those opportunities*.

Table 1: Negated statement and syntactic dependencies (top), and automatically generated positive counterpart and potential positive interpretations (bottom). For potential interpretations, we include the dependency from the focus to the rest of the interpretation.

those whose syntactic dependency is *aux*, *auxpass* or *punct* (auxiliary, passive auxiliary and punctuation). Additionally, we discard potential foci that consist only of (1) the determiners *the*, *a* and an, or (2) a single token with part-of-speech tag TO, CC, UH, POS, XX, IN, WP or dependency relation *prt*. These rules were defined after manually observing several examples and concluding that the corresponding positive interpretation was useless. For example, from the negated statement *And our credit standards haven't changed one iota*, we avoid generating the useless potential interpretation *Our credit standards X changed one iota, but not have changed.* (focus would be *have*, with dependency *aux*). Similarly, from *It is not supported by the text or history of the Constitution*, we avoid generating potential interpretation *It is supported by X text or history of the Constitution, but not by the text or history of the Constitution* (focus would be *the*); and from *You don't want to get yourself too upset about these things*, potential interpretation *You want X get yourself too upset about these things, but not to get* (focus would be *to*, with part-of-speech tag TO).

Once potential foci are selected, we generate positive interpretations by rewriting each focus with "someone/some people/something/etc." and appending "but not text_of_focus" at the end. Additionally, if the first token of the focus is a preposition, we include it to improve readability, e.g., *didn't leave [by noon]*: *left by sometime, but not by noon*.

Note that potential interpretations obtained from foci that are direct syntactic dependents of the negated verb are coarse-grained interpretations, and the rest are fine-grained interpretations. Table 1 exemplifies the procedure step by step.

4.2 Scoring Potential Positive Interpretations

After generating potential positive interpretations automatically, we asked annotators to score them. Annotators had access to the original negated sentence, the previous and next sentence as context, and one potential positive interpretation at a time. The interface asked *Given the three sentences [previous sentence, negated sentence and next sentence] above, do you think the statement [positive interpretation] below is true?* Annotators were forced to answer with a score from 0 to 5, where 0 means *absolutely disagree* and 5 means *absolutely agree*. We did not provide descriptions for intermediate scores or use categorical labels. This simple guidelines were sufficient to reliably score plausible positive interpretations automatically generated (Section 5).

5 Corpus Analysis

The procedure described in Section 4.1 generates 9729 potential positive interpretations (5865 coarse-grained and 3864 fine-grained) from 1671 verbal negations. Out of all these potential positive interpretations, we annotate 1700 (1008 coarse- and 692

	Negated statement, context if relevant to determining scores, and all positive interpretations	Score
1	Context, previous statement:You're not giving me enough benefits. Negated Statement: You're not paying me for my overtime work. Context, next statement: Well I think the Walton family does take it personally.	
	- Int. 1.1 [coarse, root]: You're [some verb] me for my overtime work, but not *paying*.	4
	- Int. 1.2 [coarse, nsubj]: [Some people]'re paying me for my overtime work, but not *you*.	0
	- Int. 1.3 [coarse, dobj]: You're paying [somebody] for my overtime work, but not *me*.	1
	- Int. 1.4 [coarse, prep]: You're paying me for [something], but not *for my overtime work*.	5
	- Int. 1.5 [fine, poss]: You're paying me for [somebody's] overtime work, but not *for my overtime work*.	0
	- Int. 1.6 [fine, nn]: You're paying me for my [some adjective] work, but not *for my overtime work*.	5
	- Int. 1.7 [fine, pobj]: You're paying me for my overtime [something] but not *for my overtime work*.	0
2	Negated Statement: Those concerns aren't expressed in public.	
	- Int. 2.1 [coarse, root]: Those concerns are [some verb] in public, but not *expressed*.	5
	- Int. 2.2 [coarse, nsubjpass]: [Some things] are expressed in public, but not *Those concerns*.	5
	- Int. 2.3 [fine, nsubjpass]: Those [some noun] are expressed in public, but not *Those concerns*.	2
	- Int. 2.4 [fine, det]: [Some] concerns are expressed in public but, not *Those concerns*.	4
	- Int. 2.5 [coarse, prep]: Those concerns are expressed in [somewhere], but not *in public*.	5

Table 3: Negated statements, all potential positive interpretations automatically generated and their manually assigned scores.

Dependency	#	%	Mean	SD
nsubj	358	21.13%	3.36	1.47
dobj	237	14.05%	3.73	1.57
pobj	178	10.51%	3.48	1.59
ccomp	125	7.29%	3.29	1.77
advmod	108	6.39%	3.33	1.59
xcomp	90	5.28%	3.92	1.50
amod	67	3.96%	4.08	1.29
conj	40	2.38%	2.80	1.60
advcl	40	2.32%	2.84	1.80
nsubjpass	35	2.17%	3.63	1.51
other	209	13.34%	2.9	1.7
verb	213	12.5%	2.01	1.46
All	1,700	100.00%	3.20	1.66

Table 2: Basic corpus analysis. For each dependency, we show the number of potential interpretations generated (#) and percentage (%), mean score and standard deviation.

fine-grained). Overall, the mean score is 3.20, and the standard deviation is 1.66. Table 2 shows basic statistics for potential foci, where *dependency* indicates the dependency from the potential focus to a token outside the potential focus. Most foci are *nsubj*, *dobj* and *pobj*, and the mean scores and standard deviation are similar for most dependencies.

Annotation Quality. In order to ensure annotation quality, we calculated Pearson correlation. Kappa and other measures designed for categorical labels are ill-suited for our annotations, since not all disagreements between numeric scores are the same, e.g., 4 vs. 5 should be counted as higher agreement, than 1 vs. 5. Overall Pearson correlation was 0.75.

5.1 Annotation Examples

Table 3 presents 2 statements that contain verbal negation, the list of positive interpretations automatically generated and the annotated scores.

Example (1) is a simple negated clause, yet we generate 7 potential positive interpretations and 3 of them receive high scores (4 or 5). Given *You're not paying me for my overtime work* and the previous statement, it is reasonable to believe that the author is in an employee-employer relationship, and the employer is not fair to the employee. Interpretations 1.1, 1.4 and 1.6 are implicit positive interpretations intuitively understood by humans when reading the original negated statement. Namely, Interpretation 1.1: *You (the employer) are nickel-and-diming me for my overtime work* (focus is *paying*), Interpretation 1.4: *You (the employer) are paying me for something* (focus is *my overtime work*), and Interpretation 1.6: *You (the employer) are paying me for my regular work* (focus is *overtime*). These interpretations show the benefits of fine-grained interpretations: Interpretation 1.6 is a refinement of Interpretation 1.4, and the former is more desirable than the latter as it reveals more specific positive knowledge. The remaining interpretations are legible, but do not make sense given the negated statement, e.g., interpretation 1.2: *Somebody (but not the employer) pays me for my overtime* (focus is *You*).

Example (2) is also a simple negated clause, and 4 out of 5 interpretations receive high scores, capturing valid positive meaning. Specifically, Interpreta-

Type	Name	Description
Basic	neg_mark	word form of negation mark
	verb	word form and part-of-speech tag of verb
	coarse_or_fine	flag indicating whether interpretation is coarse- or fine-grained
Path	syn_path_dep	syntactic path from focus to verb (concatenation of dependencies)
	syn_path_pos	syntactic path from focus to verb (concatenation of part-of-speech tags)
	syn_path_last_dep	last syntactic dependency in syn_path_dep (direct dependent of verb)
	syn_path_last_pos	last part-of-speech tag in syn_path_pos (direct dependent of verb)
Focus	focus_length	number of words in subgraph chosen as focus
	focus_first_word	word form and part-of-speech tag of first word in focus
	focus_last_word	word form and part-of-speech tag of last word in focus
	focus_direction	flag indicating whether focus occurs before or after verb
	focus_head_word	word form of head of focus
	focus_head_pos	part-of-speech tag of head of focus
	focus_head_rel	syntactic dependency of head of focus

Table 4: Features used to score potential positive interpretations automatically generated.

tion 2.1: *Those concerns are avoided in public* (focus is *expressed*), Interpretation 2.2: *Something is expressed in public* (focus is *Those concerns*), Interpretation 2.4: *Some concerns (but not problematic or secret concerns) are expressed in public* (focus is *Those*), and Interpretation 2.5: *Those concerns are expressed in private* (focus is *in public*).

5.2 Syntactic Dependencies vs. Semantic Roles

The procedure presented in Section 4.1 is not the first to generate potential positive interpretations from negation (Section 3.2). Our approach has 2 advantages with respect to those grounded on semantic roles (Blanco and Sarabi, 2016): (1) it generates both coarse- and fine-grained interpretations, and (2) learning to score interpretations is easier because state-of-the-art tools extract dependencies more reliably than semantic roles.

To support claim (1), we compare the interpretations generated with our procedure and previous work using semantic roles. 96.12% of interpretations generated using roles are also generated using syntactic dependencies. Also, using dependencies allow us to generate 67.9% of additional (fine-grained) interpretations not obtainable with roles.

To support claim (2), we compare interpretations generated with gold and predicted linguistic information (roles or dependencies). The overlap with semantic roles is 70.1%, and with syntactic dependencies, 92.8%. Syntactic dependencies are thus better in a realistic scenario because they allow us to automatically generate (and score) most interpretations.

6 Supervised Learning to Score Potential Positive Interpretations

We follow a standard supervised machine learning approach. The 1,700 potential positive interpretations along with their scores become instances, and we divide them into training (80%) and test splits (20%) making sure that all interpretations generated from a sentence are assigned to either the training or test splits. Note that splitting instances randomly would not be sound: training with some interpretations generated from a negation, and testing with the rest of interpretations generated from the same negation would be an unfair evaluation.

We train a Support Vector Machine for regression with RBF kernel using scikit-learn (Pedregosa et al., 2011), which in turn uses LIBSVM (Chang and Lin, 2011). SVM parameters (C and γ) were tuned using 10-fold cross-validation with the training set, and results are calculated using the test set.

6.1 Feature Selection

Table 4 presents the full feature set. Features are relatively simple and characterize the verbal negation from which a potential interpretation was generated, as well as the interpretation per se, i.e., the dependency subgraph chosen as potential focus.

Basic features account for the negation mark, the negation verb (word form and part-of-speech tag) and a binary flag indicating whether we are scoring a coarse- or fine-grained interpretation.

Path features are derived from the syntactic path

Features	Gold	Predicted
neg_mark	-0.109	-0.077
basic	0.033	0.026
basic + path	0.474	0.482
basic + path + focus	0.530	0.560

Table 5: Pearson correlations obtained with the test split. Results are provided using gold-standard and predicted linguistic information (part-of-speech tags and syntactic dependencies).

between the subgraph selected as focus and the verb. We include the actual path (concatenation of dependencies and up/down symbols), and the modified path using part-of-speech tags. Additionally, we also include the last dependency and part-of-speech tag, i.e., the ones closest to the verb in the path.

Focus features characterize the dependency subgraph chosen as focus to generate the potential interpretation. Specifically, we include the number of tokens, word form and part-of-speech tags of the first and last tokens, and whether the focus occurs before or after the verb. We also include features derived form the head of the focus, which we define as the token whose syntactic head is outside the focus. We include the word form and part-of-speech of the focus head, as well as its the dependency.

7 Experiments and Results

We report results obtained with several combinations of features in Table 5. We detail results obtained with features extracted from gold-standard and predicted linguistic annotations (part-of-speech tags and syntactic dependencies) as annotated in the *gold* and *auto* files from the CoNLL-2011 Shared Task release of OntoNotes (Pradhan et al., 2011). All models are trained with gold-standard linguistic annotations, and tested with either gold-standard or predicted linguistic annotations.

Testing with gold-standard POS tags and syntactic dependencies. Training with the word form of the negation mark is virtually useless, it yields a Pearson correlation of -0.109. *Basic* features (negation mark, verb and flag indicating coarse- or fine-grained interpretation) are also ineffective to score potential interpretations (Pearson: 0.033). Including features derived from the syntactic *path* yields higher correlation, 0.474, even though these features only capture the syntactic relationship between the focus from which the interpretation was generated and the verb. Finally, adding *focus* features yields the best results (Pearson: 0.53, $+11.8\%$).

Testing with predicted POS tags and syntactic dependencies. We selected 20% of positive interpretations in our corpus as test instances, totalling 379 interpretations (Section 6). When executing the procedure to generate potential interpretations (Section 4.1) with predicted linguistic information, however, we are unable to generate all of them due to incorrect and missing syntactic dependencies. Specifically, 352 of the 379 interpretations are generated (92.8%). While we do not generate 7.2% of instances, this percentage is substantially lower than previous work grounded on semantic roles (Section 5.2).

Pearson correlations with predicted linguistic information are calculated using the 352 instances that were also generated with gold dependencies (and thus assigned a score during the manual annotations). Correlations are slightly higher and follow a similar trend than the correlations obtained with gold-standard linguistic information. These results should be taken with a grain of salt: the test instances are not exactly the same, and the 352 test instances in this scenario are presumably easier to score than the remainder 27, as dependencies were predicted correctly.

8 Conclusions

Humans intuitively extract positive meaning from negation when reading text. This paper presents an automated procedure to generate potential positive interpretations from verbal negation, and score them according to their likelihood. Our procedure is grounded on syntactic dependencies, allowing us to extract fine-grained interpretations beyond semantic roles (67.9% additional interpretations). Additionally, because dependencies are extracted automatically more reliably than semantic roles, we generate 92.8% of all potential interpretations when using predicted linguistic information, as opposed to 70.1% with semantic roles.

On average, we generate 6.4 potential interpretations per verbal negation (coarse-grained: 3.8, fine-grained: 2.6). Manual annotations show that potential interpretations are deemed likely. The mean

score is 3.20 (out of 5.0), thus we extract a substantial amount of positive meaning.

The work presented in this paper is not tied to any existing semantic representation. While we rely heavily on syntactic dependencies, positive interpretations are generated in plain text, and they could be processed, along with the original negated statement, with any NLP pipeline.

Demographic Dialectal Variation in Social Media: A Case Study of African-American English

Su Lin Blodgett[†] **Lisa Green**[*] **Brendan O'Connor**[†]

University of Massachusetts Amherst

Abstract

Though dialectal language is increasingly abundant on social media, few resources exist for developing NLP tools to handle such language. We conduct a case study of dialectal language in online conversational text by investigating African-American English (AAE) on Twitter. We propose a distantly supervised model to identify AAE-like language from demographics associated with geo-located messages, and we verify that this language follows well-known AAE linguistic phenomena. In addition, we analyze the quality of existing language identification and dependency parsing tools on AAE-like text, demonstrating that they perform poorly on such text compared to text associated with white speakers. We also provide an ensemble classifier for language identification which eliminates this disparity and release a new corpus of tweets containing AAE-like language.

Data and software resources are available at: http://slanglab.cs.umass.edu/TwitterAAE

1 Introduction

Owing to variation within a standard language, regional and social dialects exist within languages across the world. These varieties or dialects differ from the standard variety in syntax (sentence structure), phonology (sound structure), and the inventory of words and phrases (lexicon). Dialect communities often align with geographic and sociological factors, as language variation emerges within distinct social networks, or is affirmed as a marker of social identity.

As many of these dialects have traditionally existed primarily in oral contexts, they have historically been underrepresented in written sources. Consequently, NLP tools have been developed from text which aligns with mainstream languages. With the rise of social media, however, dialectal language is playing an increasingly prominent role in online conversational text, for which traditional NLP tools may be insufficient. This impacts many applications: for example, dialect speakers' opinions may be mischaracterized under social media sentiment analysis or omitted altogether (Hovy and Spruit, 2016). Since this data is now available, we seek to analyze current NLP challenges and extract dialectal language from online data.

Specifically, we investigate dialectal language in publicly available Twitter data, focusing on African-American English (AAE), a dialect of Standard American English (SAE) spoken by millions of people across the United States. AAE is a linguistic variety with defined syntactic-semantic, phonological, and lexical features, which have been the subject of a rich body of sociolinguistic literature. In addition to the linguistic characterization, reference to its speakers and their geographical location or speech communities is important, especially in light of the historical development of the dialect. Not all African-Americans speak AAE, and not all speakers of AAE are African-American; nevertheless, speakers of this variety have close ties with specific communities of African-Americans (Green, 2002). Due to its widespread use, established history in the sociolinguistic literature, and demographic associations, AAE provides an ideal starting point for the development of a statistical model that uncovers dialectal

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1119–1130,
Austin, Texas, November 1-5, 2016.

language. In fact, its presence in social media is attracting increasing interest for natural language processing (Jørgensen et al., 2016) and sociolinguistic (Stewart, 2014; Eisenstein, 2015; Jones, 2015) research.[1] In this work we:

- Develop a method to identify *demographically-aligned* text and language from geo-located messages (§2), based on distant supervision of geographic census demographics through a statistical model that assumes a soft correlation between demographics and language.
- Validate our approach by verifying that text aligned with African-American demographics follows well-known phonological and syntactic properties of AAE, and document the previously unattested ways in which such text diverges from SAE (§3).
- Demonstrate *racial disparity* in the efficacy of NLP tools for language identification and dependency parsing—they perform poorly on this text, compared to text associated with white speakers (§4, §5).
- Improve language identification for U.S. online conversational text with a simple ensemble classifier using our demographically-based distant supervision method, aiming to eliminate racial disparity in accuracy rates (§4.2).
- Provide a corpus of 830,000 tweets aligned with African-American demographics.

2 Identifying AAE from Demographics

The presence of AAE in social media and the generation of resources of AAE-like text for NLP tasks has attracted recent interest in sociolinguistic and natural language processing research; Jones (2015) shows that nonstandard AAE orthography on Twitter aligns with historical patterns of African-American migration in the U.S., while Jørgensen et al. (2015) investigate to what extent it supports well-known sociolinguistics hypotheses about AAE. Both, however, find AAE-like language on Twitter through keyword searches, which may not yield broad corpora reflective of general AAE use. More recently, Jørgensen et al. (2016) generated a large unlabeled corpus of text from hip-hop lyrics, subtitles from *The Wire* and *The Boondocks*, and tweets from a region of the southeast U.S. While this corpus does indeed capture a wide variety of language, we aim to discover AAE-like language by utilizing finer-grained, neighborhood-level demographics from across the country.

Our approach to identifying AAE-like text is to first harvest a set of messages from Twitter, cross-referenced against U.S. Census demographics (§2.1), then to analyze words against demographics with two alternative methods, a seedlist approach (§2.2) and a mixed-membership probabilistic model (§2.3).

2.1 Twitter and Census data

In order to create a corpus of demographically-associated dialectal language, we turn to Twitter, whose public messages contain large amounts of casual conversation and dialectal speech (Eisenstein, 2015). It is well-established that Twitter can be used to study both geographic dialectal varieties[2] and minority languages.[3]

Some methods exist to associate messages with authors' races; one possibility is to use birth record statistics to identify African-American-associated names, which has been used in (non-social media) social science studies (Sweeney, 2013; Bertrand and Mullainathan, 2003). However, metadata about authors is fairly limited on Twitter and most other social media services, and many supplied names are obviously not real.

Instead, we turn to geo-location and induce a distantly supervised mapping between authors and the demographics of the neighborhoods they live in (O'Connor et al., 2010; Eisenstein et al., 2011b; Stewart, 2014). We draw on a set of geo-located Twitter messages, most of which are sent on mobile phones, by authors in the U.S. in 2013. (These are selected from a general archive of the "Gardenhose/Decahose" sample stream of public Twit-

[1] Including a recent linguistics workshop: http://linguistlaura.blogspot.co.uk/2016/06/using-twitter-for-linguistic-research.html

[2] For example, of American English (Huang et al., 2015; Doyle, 2014).

[3] For example, Lynn et al. (2015) develop POS corpora and taggers for Irish tweets; see also related work in §4.1.

ter messages (Morstatter et al., 2013)). Geolocated users are a particular sample of the userbase (Pavalanathan and Eisenstein, 2015), but we expect it is reasonable to compare users of different races within this group.

We look up the U.S. Census blockgroup geographic area that the message was sent in; blockgroups are one of the smallest geographic areas defined by the Census, typically containing a population of 600–3000 people. We use race and ethnicity information for each blockgroup from the Census' 2013 American Community Survey, defining four covariates: percentages of the population that are non-Hispanic whites, non-Hispanic blacks, Hispanics (of any race), and Asian.[4] Finally, for each user u, we average the demographic values of all their messages in our dataset into a length-four vector $\pi_u^{(census)}$. Under strong assumptions, this could be interpreted as the probability of which race the user is; we prefer to think of it as a rough proxy for likely demographics of the author and the neighborhood they live in.

Messages were filtered in order to focus on casual conversational text; we exclude tweets whose authors had 1000 or more followers, or that (a) contained 3 or more hashtags, (b) contained the strings "http", "follow", or "mention" (messages designed to generate followers), or (c) were retweeted (either containing the string "rt" or marked by Twitter's metadata as re-tweeted).

Our initial Gardenhose/Decahose stream archive had 16 billion messages in 2013; 90 million were geo-located with coordinates that matched a U.S. Census blockgroup. 59.2 million tweets from 2.8 million users remained after pre-processing; each user is associated with a set of messages and averaged demographics $\pi_u^{(census)}$.

2.2 Direct Word-Demographic Analysis

Given a set of messages and demographics associated with their authors, a number of methods could be used to infer statistical associations between language and demographics.

Direct word-demographic analysis methods use the $\pi_u^{(census)}$ quantities to calculate statistics at the word level in a single pass. An intuitive approach is to calculate the *average demographics per word*. For a token in the corpus indexed by t (across the whole corpus), let $u(t)$ be the author of the message containing that token, and w_t be the word token. The average demographics of word type w is:[5]

$$\pi_w^{(softcount)} \equiv \frac{\sum_t 1\{w_t = w\}\pi_{u(t)}^{(census)}}{\sum_t 1\{w_t = w\}}$$

We find that terms with the highest $\pi_{w,\text{AA}}$ values (denoting high average African-American demographics of their authors' locations) are very non-standard, while Stewart (2014) and Eisenstein (2013) find large $\pi_{w,\text{AA}}$ associated with certain AAE linguistic features.

One way to use the $\pi_{w,k}$ values to construct a corpus is through a seedlist approach. In early experiments, we constructed a corpus of 41,774 users (2.3 million messages) by first selecting the $n = 100$ highest-$\pi_{w,\text{AA}}$ terms occurring at least $m = 3000$ times across the data set, then collecting all tweets from frequent authors who have at least 10 tweets and frequently use these terms, defined as the case when at least $p = 20\%$ of their messages contain at least one of the seedlist terms. Unfortunately, the n, m, p thresholds are ad-hoc.

2.3 Mixed-Membership Demographic-Language Model

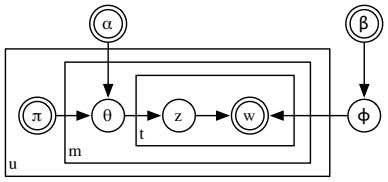
The direct word-demographics analysis gives useful validation that the demographic information may yield dialectal corpora, and the seedlist approach can assemble a set of users with heavy dialectal usage. However, the approach requires a number of ad-hoc thresholds, cannot capture authors who only occasionally use demographically-aligned language, and cannot differentiate language use at the message-level. To address these concerns, we develop a mixed-membership model for demographics and language use in social media.

The model directly associates each of the four demographic variables with a topic; i.e. a unigram language model over the vocabulary.[6] The model assumes an author's mixture over the topics tends to

[4] See appendix for additional details.

[5] $\pi_{w,k}$ has the flavor of "soft counts" in multinomial EM. By changing the denominator to $\sum_t \pi_{u(t)}^{(census)}$, it calculates a unigram language model that sums to one across the vocabulary. This hints at a more complete modeling approach (§2.3).

[6] To build the vocabulary, we select all words used by at least 20 different users, resulting in 191,873 unique words; other words are mapped to an out-of-vocabulary symbol.



$$\theta_m \sim Dir(\alpha\pi_u), \;\; \phi \sim Dir(\beta/V)$$
$$z_t \sim \theta_m, \;\; w_z \sim \phi_{z_t}$$

Figure 1: Mixed-membership model for users (u), messages (m) and tokens (t). Observed variables have a double lined border.

be similar to their Census-associated demographic weights, and that every message has its own topic distribution. This allows for a single author to use different types of language in different messages, accommodating multidialectal authors. The message-level topic probabilities θ_m are drawn from an asymmetric Dirichlet centered on $\pi_u^{(census)}$, whose scalar concentration parameter α controls whether authors' language is very similar to the demographic prior, or can have some deviation. A token t's latent topic z_t is drawn from θ_m, and the word itself is drawn from ϕ_{z_t}, the language model for the topic (Figure 1).

Thus the model learns *demographically-aligned* language models for each demographic category. The model is much more tightly constrained than a topic model—for example, if $\alpha \rightarrow \infty$, θ becomes fixed and the likelihood is concave as a function of ϕ—but it still has more joint learning than a direct calculation approach, since the inference of a messages' topic memberships θ_m is affected not just by the Census priors, but also by the language used. A tweet written by an author in a highly AA neighborhood may be inferred to be non-AAE-aligned if it uses non-AAE-associated terms; as inference proceeeds, this information is used to learn sharper language models.

We fit the model with collapsed Gibbs sampling (Griffiths and Steyvers, 2004) with repeated sample updates for each token t in the corpus,

$$p(z_t = k \mid w, z_{-t}) \propto \frac{N_{wk} + \beta/V}{N_k + \beta} \frac{N_{mk} + \alpha\pi_{uk}}{N_m + \alpha}$$

where N_{wk} is the number of tokens where word w occurs under topic $z = k$, N_{mk} is the number of tokens in the current message with topic k, etc.; all counts exclude the current t position. We observed convergence of the log-likelihood within 100 to 200 iterations, and ran for 300 total.[7] We average together count tables from the last 50 Gibbs samples for analysis of posterior topic memberships at the word, message, and user level; for example, the posterior probability a particular user u uses topic k, $P(z = k \mid u)$, can be calculated as the fraction of tokens with topic k within messages authored by u.

We considered α to be a fixed control parameter; setting it higher increases the correlations between $P(z = k \mid u)$ and $\pi_{u,k}^{(census)}$. We view the selection of α as an inherently difficult problem, since the correlation between race and AAE usage is already complicated and imperfect at the author-level, and census demographics allow only for rough associations. We set $\alpha = 10$ which yields posterior user-level correlations of $P(z = AA \mid u)$ against $\pi_{u,AA}$ to be approximately 0.8.

This model has broadly similar goals as non-latent, log-linear generative models of text that condition on document-level covariates (Monroe et al., 2008; Eisenstein et al., 2011a; Taddy, 2013). The formulation here has the advantage of fast inference with large vocabularies (since the partition function never has to be computed), and gives probabilistic admixture semantics at arbitrary levels of the data. This model is also related to topic models where the selection of θ conditions on covariates (Mimno and McCallum, 2008; Ramage et al., 2011; Roberts et al., 2013), though it is much simpler without full latent topic learning.

In early experiments, we used only two classes (AA and not AA), and found Spanish terms being included in the AA topic. Thus we turned to four race categories in order to better draw out non-AAE language. This removed Spanish terms from the AA topic; interestingly, they did not go to the Hispanic topic, but instead to Asian, along with other foreign languages. In fact, the correlation between users' Census-derived proportions of Asian populations, versus this posterior topic's proportions, is only 0.29, while the other three topics correlate to their respective Census priors in the range 0.83 to 0.87. This indicates the "Asian" topic actually functions as a background topic (at least in part). Better modeling of demographics and non-English

[7] Our straightforward single core implementation (in Julia) spends 80 seconds for each iteration over 586 million tokens.

language interactions is interesting potential future work.

By fitting the model to data, we can directly analyze unigram probabilities within the model parameters ϕ, but for other analyses, such as analyzing larger syntactic constructions and testing NLP tools, we require an explicit corpus of messages.

To generate a user-based AA-aligned corpus, we collected all tweets from users whose posterior probability of using AA-associated terms under the model was at least 80%, and generated a corresponding white-aligned corpus as well. In order to remove the effects of non-English languages, and given uncertainty about what the model learned in the Hispanic and Asian-aligned demographic topics, we focused only on AA- and white-aligned language by imposing the additional constraint that each user's combined posterior proportion of Hispanic or Asian language was less than 5%. Our two resulting user corpora contain 830,000 and 7.3 million tweets, for which we are making their message IDs available for further research (in conformance with the Twitter API's Terms of Service). In the rest of the work, we refer to these as the AA- and white-aligned corpora, respectively.

3 Linguistic Validation

Because validation by manual inspection of our AA-aligned text is impractical, we turn to the well-studied phonological and syntactic phenomena that traditionally distinguish AAE from SAE. We validate our model by reproducing these phenomena, and document a variety of other ways in which our AA-aligned text diverges from SAE.

3.1 Lexical-Level Variation

We begin by examining how much AA- and white-aligned lexical items diverge from a standard dictionary. We used SCOWL's largest wordlist with level 1 variants as our dictionary, totaling 627,685 words.[8]

We calculated, for each word w in the model's vocabulary, the ratio

$$r_k(w) = \frac{p(w|z = k)}{p(w|z \neq k)}$$

where the $p(.|.)$ probabilities are posterior inferences, derived from averaged Gibbs samples of the sufficient statistic count tables N_{wk}.

We selected heavily AA- and white-aligned words as those where $r_{AA}(w) \geq 2$ and $r_{white}(w) \geq 2$, respectively. We find that while 58.2% of heavily white-aligned words were not in our dictionary, fully 79.1% of heavily AA-aligned words were not. While a high number of out-of-dictionary lexical items is expected for Twitter data, this disparity suggests that the AA-aligned lexicon diverges from SAE more strongly than the white-aligned lexicon.

3.2 Internet-Specific Orthographic Variation

We performed an "open vocabulary" unigram analysis by ranking all words in the vocabulary by $r_{AA}(w)$ and browsed them and samples of their usage. Among the words with high r_{AA}, we observe a number of Internet-specific orthographic variations, which we separate into three types: abbreviations (e.g. *llh*, *kmsl*), shortenings (e.g. *dwn*, *dnt*), and spelling variations which do not correlate to the word's pronunciation (e.g. *axx*, *bxtch*). These variations do not reflect features attested in the literature; rather, they appear to be purely orthographic variations highly specific to AAE-speaking communities online. They may highlight previously unknown linguistic phenomena; for example, we observe that *thoe* (SAE *though*) frequently appears in the role of a discourse marker instead of its standard SAE usage (e.g. *Girl Madison outfit THOE*). This new use of *though* as a discourse marker, which is difficult to observe using the SAE spelling amidst many instances of the SAE usage, is readily identifiable in examples containing the *thoe* variant. Thus, non-standard spellings provide valuable windows into a variety of linguistic phenomena.

In the next section, we turn to variations which do appear to arise from known phonological processes.

3.3 Phonological Variation

Many phonological features are closely associated with AAE (Green, 2002). While there is not a perfect correlation between orthographic variations and people's pronunciations, Eisenstein (2013) shows that some genuine phonological phenomena, including a number of AAE features, are accurately reflected in orthographic variation on social media. We therefore validate our model by verifying that spellings reflecting known AAE phonological features align closely with the AA topic.

[8] http://wordlist.aspell.net/

AAE	Ratio	SAE
sholl	1802.49	sure
iont	930.98	I don't
wea	870.45	where
talmbout	809.79	talking about
sumn	520.96	something

Table 1: Of 31 phonological variant words, top five by ratio $r_{AA}(w)$. SAE translations are shown for reference.

We selected 31 variants of SAE words from previous studies of AAE phonology on Twitter (Jørgensen et al., 2015; Jones, 2015). These variations display a range of attested AAE phonological features, such as derhotacization (e.g. *brotha*), deletion of initial *g* and *d* (e.g. *iont*), and realization of voiced *th* as *d* (e.g. *dey*) (Rickford, 1999).

Table 1 shows the top five of these words by their $r_{AA}(w)$ ratio. For 30 of the 31 words, $r \geq 1$, and for 13 words, $r \geq 100$, suggesting that our model strongly identifies words displaying AAE phonological features with the AA topic. The sole exception is the word *brotha*, which appears to have been adopted into general usage as its own lexical item.

3.4 Syntactic Variation

We further validate our model by verifying that it reproduces well-known AAE syntactic constructions, investigating three well-attested AAE aspectual or preverbal markers: habitual *be*, future *gone*, and completive *done* (Green, 2002). Table 2 shows examples of each construction.

To search for the constructions, we tagged the corpora using the ARK Twitter POS tagger (Gimpel et al., 2011; Owoputi et al., 2013),[9] which Jørgensen et al. (2015) show has similar accuracy rates on both AAE and non-AAE tweets, unlike other POS taggers. We searched for each construction by searching for sequences of unigrams and POS tags characterizing the construction; e.g. for habitual *be* we searched for the sequences O-*be*-V and O-*b*-V. Nonstandard spellings for the unigrams in the patterns were identified from the ranked analysis of §3.2.

We examined how a message's likelihood of using each construction varies with the message's posterior probability of AA. We split all messages into deciles based on the messages' posterior probability of AA. From each decile, we sampled 200,000 messages and calculated the proportion of messages containing the three syntactic constructions.

[9] Version 0.3.2: http://www.cs.cmu.edu/~ark/TweetNLP/

Construction	Example	Ratio
O-*be/b*-V	*I be tripping bruh*	11.94
gone/gne/gon-V	*Then she gon be single Af*	14.26
done/dne-V	*I done laughed so hard that I'm weak*	8.68

Table 2: AAE syntactic constructions and the ratios of their occurrences in the AA- vs. white-aligned corpora (§2.3).

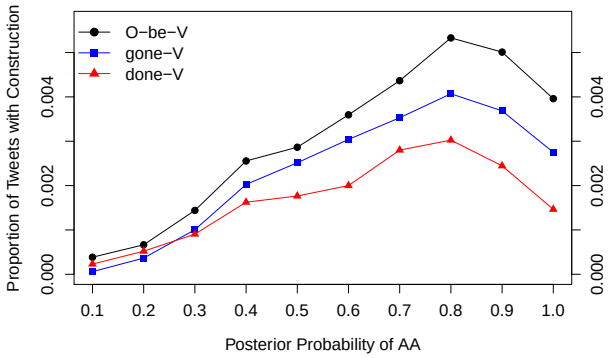


Figure 2: Proportion of tweets containing AAE syntactic constructions by messages' posterior probability of AA. On the x-axis, 0.1 refers to the decile [0, 0.1).

For all three constructions, we observed the clear pattern that as messages' posterior probabilities of AA increase, so does their likelihood of containing the construction. Interestingly, for all three constructions, frequency of usage peaks at approximately the [0.7, 0.8) decile. One possible reason for the decline in higher deciles might be tendency of high-AA messages to be shorter; while the mean number of tokens per message across all deciles in our samples is 9.4, the means for the last two deciles are 8.6 and 7.1, respectively.

Given the important linguistic differences between our demographically-aligned subcorpora, we hypothesize that current NLP tools may behave differently. We investigate this hypothesis in §4 and §5.

4 Lang ID Tools on AAE

4.1 Evaluation of Existing Classifiers

Language identification, the task of classifying the major world language in which a message is written, is a crucial first step in almost any web or social

	AAE	White-Aligned
langid.py	13.2%	7.6%
Twitter-1	8.4%	5.9%
Twitter-2	24.4%	17.6%

Table 3: Proportion of tweets in AA- and white-aligned corpora classified as non-English by different classifiers. (§4.1)

media text processing pipeline. For example, in order to analyze the opinions of U.S. Twitter users, one might throw away all non-English messages before running an English sentiment analyzer.

Hughes et al. (2006) review language identification methods; social media language identification is challenging since messages are short, and also use non-standard and multiple (often related) languages (Baldwin et al., 2013). Researchers have sought to model code-switching in social media language (Rosner and Farrugia, 2007; Solorio and Liu, 2008; Maharjan et al., 2015; Zampieri et al., 2013; King and Abney, 2013), and recent workshops have focused on code-switching (Solorio et al., 2014) and general language identification (Zubiaga et al., 2014). For Arabic dialect classification, work has developed corpora in both traditional and Romanized script (Cotterell et al., 2014; Malmasi et al., 2015) and tools that use n-gram and morphological analysis to identify code-switching between dialects and with English (Elfardy et al., 2014).

We take the perspective that since AAE is a dialect of American English, it ought to be classified as English for the task of major world language identification. Lui and Baldwin (2012) develop *langid.py*, one of the most popular open source language identification tools, training it on over 97 languages from texts including Wikipedia, and evaluating on both traditional corpora and Twitter messages. We hypothesize that if a language identification tool is trained on standard English data, it may exhibit disparate performance on AA- versus white-aligned tweets. Since language identifiers are typically based on character n-gram features, they may get confused by the types of lexical/orthographic divergences seen in §3. To evaluate this hypothesis, we compare the behavior of existing language identifiers on our subcorpora.

We test *langid.py* as well as the output of Twitter's in-house identifier, whose predictions are included in a tweet's metadata (from 2013, the time of data collection); the latter may give a language code or a missing value (*unk* or an empty/null value). We record the proportion of non-English predictions by these systems; *Twitter-1* does not consider missing values to be a non-English prediction, and *Twitter-2* does.

We noticed emojis had seemingly unintended consequences on *langid.py*'s classifications, so removed all emojis by characters from the relevant Unicode ranges. We also removed @-mentions.

User-level analysis We begin by comparing the classifiers' behavior on the AA- and white-aligned corpora. Of the AA-aligned tweets, 13.2% were classified by *langid.py* as non-English; in contrast, 7.6% of white-aligned tweets were classified as such. We observed similar disparities for *Twitter-1* and *Twitter-2*, illustrated in Table 3.

It turns out these "non-English" tweets are, for the most part, actually English. We sampled and annotated 50 tweets from the tweets classified as non-English by each run. Of these 300 tweets, only 3 could be unambiguously identified as written in a language other than English.

Message-level analysis We examine how a message's likelihood of being classified as non-English varies with its posterior probability of AA. As in §3.4, we split all messages into deciles based on the messages' posterior probability of AA, and predicted language identifications on 200,000 sampled messages from each decile.

For all three systems, the proportion of messages classified as non-English increases steadily as the messages' posterior probabilities of AA increase. As before, we sampled and annotated from the tweets classified as non-English, sampling 50 tweets from each decile for each of the three systems. Of the 1500 sampled tweets, only 13 ($\sim$0.87%) could be unambiguously identified as being in a language other than English.

4.2 Adapting Language Identification for AAE

Natural language processing tools can be improved to better support dialects; for example, Jørgensen et al. (2016) use domain adaptation methods to improve POS tagging on AAE corpora. In this section, we contribute a fix to language identification to correctly identify AAE and other social media messages as English.

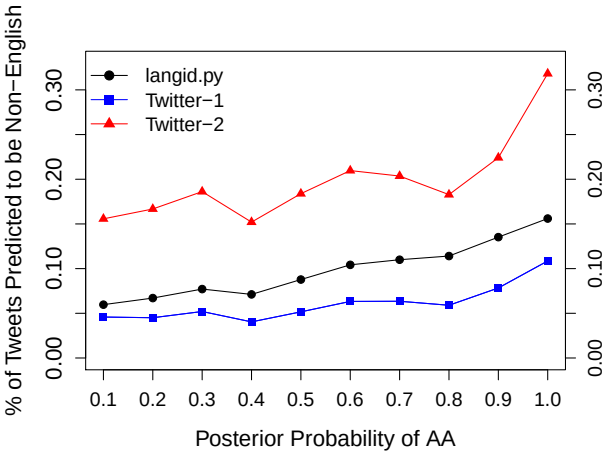

Figure 3: Proportion of tweets classified as non-English by messages' posterior probability of AA. On the x-axis, 0.1 refers to the decile [0, 0.1).

4.2.1 Ensemble Classifier

We observed that messages where our model infers a high probability of AAE, white-aligned, or "Hispanic"-aligned language almost always are written in English; therefore we construct a simple ensemble classifier by combining it with *langid.py*.

For a new message $\vec{w}$, we predict its demographic-language proportions $\hat{\theta}$ via posterior inference with our trained model, given a symmetric α prior over demographic-topic proportions (see appendix for details). The ensemble classifier, given a message, is as follows:

- Calculate langid.py's prediction $\hat{y}$.
- If $\hat{y}$ is English, accept it as English.
- If $\hat{y}$ is non-English, and at least one of the message's tokens are in demographic model's vocabulary: Infer $\hat{\theta}$ and return English only if the combined AA, Hispanic, and white posterior probabilities are at least 0.9. Otherwise return the non-English $\hat{y}$ decision.

Another way to view this method is that we are effectively training a system on an extended Twitter-specific English language corpus softly labeled by our system's posterior inference; in this respect, it is related to efforts to collect new language-specific Twitter corpora (Bergsma et al., 2012) or minority language data from the web (Ghani et al., 2001).

4.2.2 Evaluation

Our analysis from §4.1 indicates that this method would correct erroneous false negatives for AAE messages in the training set for the model. We further confirm this by testing the classifier on a sample of 2.2 million geolocated tweets sent in the U.S. in 2014, which are not in the training set.

Message set	*langid.py*	Ensemble
High AA	80.1%	99.5%
High White	96.8%	99.9%
General	*88.0%*	*93.4%*

Table 4: Imputed recall of English messages in 2014 messages. For the *General* set these are an approximation; see text.

In addition to performance on the entire sample, we examine our classifier's performance on messages whose posterior probability of using AA- or white-associated terms was greater than 0.8 within the sample, which in this section we will call high AA and high white messages, respectively. Our classifier's precision is high across the board, at 100% across manually annotated samples of 200 messages from each sample.[10] Since we are concerned about the system's overall recall, we impute recall (Table 4) by assuming that all high AA and high white messages are indeed English. Recall for *langid.py* alone is calculated by $\frac{n}{N}$, where n is the number of messages predicted to be English by *langid.py*, and N is the total number of messages in the set. (This is the complement of Table 3, except evaluated on the test set.) We estimate the ensemble's recall as $\frac{n+m}{N}$, where $m = (n_{flip})P(\text{English} \mid flip)$ is the expected number of correctly changed classifications (from non-English to English) by the ensemble and the second term is the precision (estimated as 1.0). We observe the baseline system has considerable difference in recall between the groups which is solved by the ensemble.

We also apply the same calculation to the general set of all 2.2 million messages; the baseline classifies 88% as English. This is a less accurate approximation of recall since we have observed a substantial presence of non-English messages. The ensemble classifies an additional 5.4% of the messages as English; since these are all (or nearly all) correct, this

[10] We annotated 600 messages as English, not English, or not applicable, from 200 sampled each from general, high AA, and high white messages. Ambiguous tweets which were too short (e.g. "Gm") or contained only named entities (e.g. "Tennessee") were excluded from the final calculations. The resulting samples have 197/197, 198/198, and 200/200 correct English classifications, respectively.

reflects at least a 5.4% gain to recall.

5 Dependency Parser Evaluation

Given the lexical and syntactic variation of AAE compared to SAE, we hypothesize that syntactic analysis tools also have differential accuracy. Jørgensen et al. (2015) demonstrate this for part-of-speech tagging, finding that SAE-trained taggers had disparate accuracy on AAE versus non-AAE tweets.

We assess a publicly available syntactic dependency parser on our AAE and white-aligned corpora. Syntactic parsing for tweets has received some research attention; Foster et al. (2011) create a corpus of constituent trees for English tweets, and Kong et al. (2014)'s *Tweeboparser* is trained on a Twitter corpus annotated with a customized unlabeled dependency formalism; since its data was uniformly sampled from tweets, we expect it may have low disparity between demographic groups.

We focus on widely used syntactic representations, testing the *SyntaxNet* neural network-based dependency parser (Andor et al., 2016),[11] which reports state-of-the-art results, including for web corpora. We evaluate it against a new manual annotation of 200 messages, 100 randomly sampled from each of the AA- and white-aligned corpora described in §2.3.

SyntaxNet outputs grammatical relations conforming to the Stanford Dependencies (SD) system (de Marneffe and Manning, 2008), which we used to annotate messages using *Brat*,[12] comparing to predicted parses for reference. Message order was randomized and demographic inferences were hidden from the annotator. To increase statistical power relative to annotation effort, we developed a partial annotation approach to only annotate edges for the root word of the first major sentence in a message. Generally, we found that that SD worked well as a descriptive formalism for tweets' syntax; we describe handling of AAE and Internet-specific non-standard issues in the appendix. We evaluate labeled recall of the annotated edges for each message set:

Parser	AA	Wh.	Difference
SyntaxNet	64.0 (2.5)	80.4 (2.2)	16.3 (3.4)
CoreNLP	50.0 (2.7)	71.0 (2.5)	21.0 (3.7)

Bootstrapped standard errors (from 10,000 message resamplings) are in parentheses; differences are statistically significant ($p < 10^{-6}$ in both cases).

The white-aligned accuracy rate of 80.4% is broadly in line with previous work (compare to the parser's unlabeled accuracy of 89% on English Web Treebank full annotations), but parse quality is much worse on AAE tweets at 64.0%. We test the Stanford CoreNLP neural network dependency parser (Chen and Manning, 2014) using the *english_SD* model that outputs this formalism;[13] its disparity is worse. Soni et al. (2014) used a similar parser[14] on Twitter text; our analysis suggests this approach may suffer from errors caused by the parser.

6 Discussion and Conclusion

We have presented a distantly supervised probabilistic model that employs demographic correlations of a dialect and its speaker communities to uncover dialectal language on Twitter. Our model can also close the gap between NLP tools' performance on dialectal and standard text.

This represents a case study in dialect *identification*, *characterization*, and ultimately language technology *adaptation* for the dialect. In the case of AAE, dialect identification is greatly assisted since AAE speakers are strongly associated with a demographic group for which highly accurate governmental records (the U.S. Census) exist, which we leverage to help identify speaker communities. The notion of non-standard dialectal language implies that the dialect is underrepresented or underrecognized in some way, and thus should be inherently difficult to collect data on; and of course, *many* other language communities and groups are not necessarily officially recognized. An interesting direction for future research would be to combine distant supervision with unsupervised linguistic models to automatically uncover such underrecognized dialectal language.

Abstract

Linguistic research on multilingual societies has indicated that there is usually a preferred language for expression of emotion and sentiment (Dewaele, 2010). Paucity of data has limited such studies to participant interviews and speech transcriptions from small groups of speakers. In this paper, we report a study on 430,000 unique tweets from Indian users, specifically Hindi-English bilinguals, to understand the language of preference, if any, for expressing opinion and sentiment. To this end, we develop classifiers for opinion detection in these languages, and further classifying opinionated tweets into positive, negative and neutral sentiments. Our study indicates that Hindi (i.e., the native language) is preferred over English for expression of negative opinion and swearing. As an aside, we explore some common pragmatic functions of code-switching through sentiment detection.

1 Introduction

The pattern of language use in a multilingual society is a complex interplay of socio-linguistic, discursive and pragmatic factors. Sometimes speakers have a preference for a particular language for certain conversational and discourse settings; on other occasions, there is fluid alteration between two or more languages in a single conversation, also known as *Code-switching* (CS) or *Code-mixing*[1]. Understanding and characterizing language preference in multilingual societies has been the subject matter of linguistic inquiry for over half a century (see Milroy and Muysken (1995) for an overview).

Conversational phenomena such as CS were observed only in speech and therefore, all previous studies are based on data collected from a small set of speakers or from interviews. With the growing popularity of social media, we now have an abundance of conversation-like data that exhibit CS and other speech phenomena, hitherto unseen in text (Bali et al., 2014). Leveraging such data from Twitter, we conduct a large-scale study on language preference, if any, for the expression of opinion and sentiment by Hindi-English (Hi-En) bilinguals.

We first build a corpus of 430,000 unique India-specific tweets across four domains (sports, entertainment, politics and current events) and automatically classify the tweets by their language: English, Hindi and Hi-En CS. We then develop an opinion detector for each language class to further categorize them into opinionated and non-opinionated tweets. Sentiment detectors further classify the opinionated tweets as positive, negative or neutral. Our study shows that there is a strong preference towards Hindi (i.e. the native language or L1) over English (L2) for expression of negative opinion. The effect is clearly visible in CS tweets, where a switch from English to Hindi is often correlated with a switch from a positive to negative sentiment. This is referred to as the *polarity–switch* function of CS (Sanchez, 1983). Using the same experimental technique, we also explore other pragmatic functions of CS, such as *reinforcement* and *narrative–evaluative*.

* This work was done when the author was a Research Fellow at Microsoft Research Lab India.

[1] Although some linguists differentiate between Code-switching and Code-mixing, this paper will use the two terms interchangeably.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1131–1141,
Austin, Texas, November 1-5, 2016.

Apart from being the first large-scale quantitative study of language preference in multilingual societies, this work also has several other contributions: (a) We develop one of the first opinion and sentiment classifiers for Romanized Hindi and CS Hi-En tweets with higher accuracy than the only known previous attempt (Sharma et al., 2015b). (b) We present a novel methodology for automatically detecting pragmatic functions of code-switching through opinion and sentiment detection.

The rest of the paper is organized as follows: Sec. 2 introduces language preference, functions of CS and Hindi-English bilingualism on the web. Sec. 3 formulates the problem and presents the fundamental questions that this paper seeks to answer. Sec. 4 and 5 discuss dataset creation and opinion and sentiment detection techniques respectively. Sec. 6 evaluates the hypotheses in light of the observations on the tweet corpus. We conclude in Sec. 7, and raise some interesting sociolinguistic questions for future studies.

2 Background and Related Work

In order to situate the questions addressed in our work in existing literature, we present a brief overview of the past research in pragmatic and discursive analysis of code-switching, and specifically, on language preference for emotional expression. A primer to Hi-En bilingualism and its presence in social media shall follow.

2.1 CS Functions and Language Preference

In multilingual communities, where there are more than one linguistic channels for information exchange, the choice of the channel depends on a variety of factors, and is usually unpredictable (Auer, 1995). Nevertheless, linguistic studies point out certain frequently-observed patterns. For instance, certain speech activities might be exclusively or more commonly related to a certain language choice (e.g. Fishman (1971) reports use of English for professional purposes and Spanish for informal chat for English-Spanish bilinguals from Puerto Rico). Apart from association between such conversational contexts and language preference, language alteration is often found to be used as a signaling device to imply certain pragmatic functions (Barredo, 1997; Sanchez, 1983; Nishimura, 1995; Maschler, 1991; Maschler, 1994) such as: (a) reported speech (b) narrative to evaluative switch (c) reiterations or emphasis (d) topic shift (e) puns and language play (f) topic/comment structuring etc. Attempts of predicting the preferred language, or even exhaustively listing such functions, have failed. However, linguists agree that language alteration in multilingual communities is not a random process.

Of specific interest to us are the studies on language preference for expression of emotions. Through large-scale interviews and two decades of research, Dewaele (2004; 2010) argued that for most multilinguals, L1 (the dominant language, which is often, but not always, the native or mother tongue) is the language preference for emotions, which include emotional inner speech, swearing and even emotional conversations. Dewaele argues that emotionally charged words in L1 elicit stronger emotions than those in other languages, and hence L1 is preferred for emotion expression.

2.2 Hindi-English Bilingualism

Around 125 million people in India speak English, half of whom have Hindi as their mother-tongue. The large proportion of the remaining half, especially those residing in the metropolitan cities, also know at least some Hindi. This makes Hi-En code-switching, commonly called *Hinglish*, extremely widespread in India. There is historical attestation, as well as recent studies on the growing use of Hinglish in general conversation, and in entertainment and media (see Parshad et al. (2016) and references therein). Several recent studies (Bali et al., 2014; Barman et al., 2014; Solorio et al., 2014; Sequiera et al., 2015) also provide evidence of Hinglish and other instances of CS on online social media such as Twitter and Facebook. In a Facebook dataset analyzed by Bali et al. (2014), almost all sufficiently long conversation threads were found to be multilingual, and as much as 17% of the comments had CS. This study also indicates that on online social media, Hindi is seldom written in the Devanagari script. Instead, loose Roman transliteration, or Romanized Hindi, is common, especially when users code-switch between Hindi and English.

While there has been some effort towards computational processing of CS text (Solorio and Liu, 2008; Solorio and Liu, 2010; Vyas et al., 2014; Peng

et al., 2014), to the best of our knowledge, there has been no study on automatic identification of functional aspects of CS or any large-scale, data-driven study of language preference. The current study adds to the growing repertoire of work on quantitative analysis of social media data for understanding socio-linguistic and pragmatic issues, such as detection of depression (De Choudhury et al., 2013), politeness (Danescu-Niculescu-Mizil et al., 2013), speech acts (Vosoughi and Roy, 2016), and social status (Tchokni et al., 2014).

3 Problem Formulation

Along the lines of (Dewaele, 2010), we ask the following question: *Is there a preferred language for expression of opinion and sentiment by the Hi-En bilinguals on Twitter?*

3.1 Definitions

More formally, let $\Lambda = \{h, e, m\}$ be the set of languages: Hindi (h), English (e) and Mixed (m), i.e., code-switched. Let $\Sigma = \{d, r\}$, be the set of scripts:[2] Devanagari (d) and Roman (r). Let us further introduce a set of sentiments, $\diamondsuit = \{+, -, 0, \otimes\}$, where $+$, $-$ and 0 respectively denote utterances with positive, negative and neutral opinions. $\otimes$ denote non-opinionated (like factual) texts.

Let $T = \{t_1, t_2, \ldots t_{|T|}\}$ be a set of tweets (or any text) generated by Hi-En bilinguals. We define:

- $\lambda(T)$, $\sigma(T)$ and $\diamond(T)$ as the subsets of T that respectively contain all tweets in language λ, script σ and sentiment $\diamond$.
- $\lambda\sigma\diamond(T) = \lambda(T) \cap \sigma(T) \cap \diamond(T)$. Likewise, we also define $\lambda\diamond(T) = \lambda(T) \cap \diamond(T)$, $\lambda\sigma(T) = \lambda(T) \cap \sigma(T)$ and $\sigma\diamond(T) = \sigma(T) \cap \diamond(T)$.

The preference towards a language-script pair $\lambda\sigma$ for expressing a type of sentiment $\diamond$ is given by the probability

$$pr(\lambda\sigma|\diamond; T) = \frac{pr(\diamond|\lambda\sigma; T)pr(\lambda\sigma|T)}{pr(\diamond|T)} \quad (1)$$

However, pr($\lambda\sigma$), which defines the prior probability of choosing $\lambda\sigma$ for a tweet is dependent on a large number of socio-linguistic parameters beyond sentiment. For instance, on social media, English is overwhelmingly more common than any Indic language (Bali et al., 2014). This is because (a) English tweets come from a large number of users apart from Hi-En bilinguals and (b) English is the preferred language for tweeting even for Hi-En bilinguals because it expands the target audience of the tweet by manifolds. The preference of $\lambda\sigma$ for expressing $\diamond$, therefore, can be quantified as:

$$pr(\diamond|\lambda\sigma; T) = \frac{|\lambda\sigma\diamond(T)|}{|\lambda\sigma(T)|} \quad (2)$$

We say $\lambda\sigma$ is the preferred language-script choice over $\lambda'\sigma'$ for expressing sentiment $\diamond$ if and only if

$$pr(\diamond|\lambda\sigma; T) > pr(\diamond|\lambda'\sigma'; T) \quad (3)$$

The strength of the preference is directly proportionate the ratio of the probabilities: $pr(\diamond|\lambda\sigma; T)/pr(\diamond|\lambda'\sigma'; T)$. An alternative but related way of characterizing the preference is through comparing the odds of choosing a sentiment type $\diamond$ to its polar opposite - $\diamond'$. We say, $\lambda\sigma$ is the preferred language-script pair for expressing $\diamond$, if

$$\frac{pr(\diamond|\lambda\sigma; T)}{pr(\diamond'|\lambda\sigma; T)} > \frac{pr(\diamond|\lambda'\sigma'; T)}{pr(\diamond'|\lambda'\sigma'; T)} \quad (4)$$

3.2 Hypotheses

Now we can formally define the two hypotheses, we intend to test here.

Hypothesis I: For Hi-En bilinguals, Hindi is the preferred language for expression of opinion on Twitter. Therefore, we expect

$$pr(\{+, -, 0\}|hd; T) > pr(\{+, -, 0\}|er; T) \quad (5)$$

$$\text{i.e.,} \quad pr(\otimes|hd; T) < pr(\otimes|er; T) \quad (6)$$

And similarly,

$$pr(\otimes|hr; T) < pr(\otimes|er; T) \quad (7)$$

Hypothesis II: For Hi-En bilinguals, Hindi is the preferred language for expression of negative sentiment. Therefore,

$$pr(-|hd; T) \approx pr(-|hr; T) > pr(-|er; T) \quad (8)$$

[2] Tweets in mixed script are rare and hence we do not include a symbol for it, though the framework does not preclude such possibilities.

In particular, we would like to hypothesize that the odds of choosing Hindi for negative over positive is really high compared to the odds for English. I.e.,

$$\frac{pr(-|hd;T)}{pr(+|hd;T)} \approx \frac{pr(-|hr;T)}{pr(+|hr;T)} > \frac{pr(-|er;T)}{pr(+|er;T)} \quad (9)$$

A special case of the above hypotheses arise in the context of code-mixing, i.e., for the set $mr(T)$. Since the mixed tweets certainly come from proficient bilinguals and have both Hi and En fragments, we can reformulate our hypotheses at a tweet level. Let $m^hr(T)$ and $m^er(T)$ respectively denote the set of Hi and En fragments in $mr(T)$.

Hypothesis Ia: Hindi is the preferred language for expression of opinion in Hi-En code-mixed tweets. Therefore, we expect

$$\text{i.e.,} \quad pr(\otimes|m^hr;T) < pr(\otimes|m^er;T) \quad (10)$$

Hypothesis IIa: Hindi is the preferred language for expression of negative sentiment in Hi-En code-switched tweets. Therefore,

$$pr(-|m^hr;T) > pr(-|m^er;T) \quad (11)$$

$$\frac{pr(-|m^hr;T)}{pr(+|m^hr;T)} > \frac{pr(-|m^er;T)}{pr(+|m^er;T)} \quad (12)$$

Likewise, the above hypotheses also apply for the Devanagari script, though for technical reasons, we do not test them here.

Besides comparing aggregate statistics on $mr(T)$, it is also interesting to look at the sentiment of $m^hr(t_i)$ and $m^er(t_i)$ for each tweet t_i. In particular, for every pair of $\diamond \neq \diamond'$, we want to study the fraction of tweets in $mr(T)$ where $m^hr(t_i)$ has sentiment $\diamond$ and $m^er(t_i)$ has $\diamond'$. Let this fraction be $pr(h\diamond \leftrightarrow e\diamond'; mr(T))$. Under "no-preference for language" (i.e., the null) hypothesis, we would expect $pr(h\diamond \leftrightarrow e\diamond'; mr(T)) \approx pr(h\diamond' \leftrightarrow e\diamond; mr(T))$. However, if $pr(h\diamond \leftrightarrow \diamond'; mr(T))$ is significantly higher than $pr(h\diamond' \leftrightarrow e\diamond; mr(T))$, it means that speakers prefer to switch from English to Hindi when they want to express a sentiment $\diamond$ and vice versa.

Pragmatic Functions of Code-Switching: When native speakers tend to switch from Hindi to English when they switch from an expression with sentiment $\diamond$ to one with $\diamond'$, or in other words $\diamond \leftrightarrow \diamond'$, we say this is an observed pragmatic function of code-switching between Hindi and English (note that the order of the languages is important), if and only if

$$\frac{pr(h\diamond \leftrightarrow e\diamond'; mr(T))}{pr(h\diamond' \leftrightarrow e\diamond; mr(T))} > 1 \quad (13)$$

Topic (# tweets): Hashtags
Sports (188K): #IndvsPak, #IndvsUae, #IndvsSa
Movies (82K): #MSG3successfulweeks, #MSGincinemas, #BlockbusterMSG, #Shamitabh, #PK
Politics (92K): #DelhiDecides, #RahulonlLeave, #AAPStorm, #AAPSweep
Current Events (68K): #RailBudget2015, #Beefban, #LandAcquisitionBill, #UnionBudget2015

Table 1: Hashtags used and number of tweets collected

3.3 A Note on Statistical Significance

All the statistics defined here are likelihoods; Equations 9, 12 and 13, in particular, state our hypothesis in the form of the *Likelihood Ratio Test*. However, the true classes λ and $\diamond$ are unknown; we predict the class labels using automatic language and sentiment detection techniques that have non-negligible errors. Under such a situation, the likelihoods cannot be considered as true *test statistics*, and consequently, hypothesis testing cannot be done per se. Nevertheless, we can use these as descriptive statistics and investigate the status of the aforementioned hypotheses.

4 Datasets

We collected tweets with certain India-specific hashtags (Table 1) using the Twitter Search API (Twi, 2015b) over three months (December 2014 – February 2015). In this paper, we use tweets in Devanagari script Hindi (hd), and Roman script English (er), Hindi (hr) and Hi-En Mixed (mr). English and mixed tweets written in Devanagari are extremely rare (Bali et al., 2014) and we do not study them here. We filter out tweets labeled by the Twitter API (Twi, 2015a) as German, Spanish, French, Portuguese, Turkish, and all non-Roman script languages (except Hindi).

We experiment on the following different corpora:

$\boldsymbol{T_{All}}$: All tweets after filtering. This corpus contains 430,000 unique tweets posted by 1,25,396 unique users.

$\boldsymbol{T_{BL}}$: Tweets from users who are certainly Hi-En bilinguals, which are approximately 55% (240,000) of the tweets in $\boldsymbol{T_{All}}$. We define a user to be a Hi-En bilingual if there is at least one mr tweet from the user, or if the user has tweeted at least once in Hindi (hd or hr) and once in English (er).

$\boldsymbol{T_{spo}, T_{mov}, T_{pol}, T_{eve}}$: Topic-wise corpora for sports, movies, politics and events (Table 1).

$\boldsymbol{T_{CS}}$: Tweets with inter-sentential CS. We define these as tweets containing at least one sequence of 5 contiguous Hindi words and one sequence of 5 contiguous English words. The corpus has 3,357 tweets.

SAC: 1000 monolingual tweets (er, hr, hd) and 260 mixed (mr) tweets manually annotated with sentiment and opinion labels. These were annotated by two linguists, both fluent Hi-En speakers. The annotators first checked whether the tweet is opinionated or $\otimes$ and then identified polarity of the opinionated tweets ($+$, $-$ or 0). Thus, the tweets are classified into the four classes in the set $\diamond$. If a tweet contains both opinion and $\otimes$, each fragment was individually annotated. The inter-annotator agreement is 77.5% ($\kappa = 0.59$) for opinion annotation and 68.4% ($\kappa = 0.64$) over all four classes. A third linguist independently corrected the disagreements.

$\mathbf{LLC_{Test}}$: 141 er, 137 hr, and 241 mr tweets annotated by a Hi-En bilingual form the test set for the Language Labeling system (Sec. 5.1).

SAC and $\mathbf{LLC_{Test}}$ can be downloaded and used for research purposes[3].

Note that apart from **SAC** and $\mathbf{LLC_{Test}}$, all corpora are subsets of $\boldsymbol{T_{All}}$. For generalizability of our observations, it is important to ensure that the tweets in $\boldsymbol{T_{All}}$ come from a large number of users and the datasets do not over-represent a small set of users. In Figure 1, we plot the minimum fraction of users required (x-axis) to cover a certain percentage of the tweets in $\boldsymbol{T_{All}}$ (y-axis). Tweets from at least 10%, i.e., 12.5K users are needed to cover 50% of the corpus. As expected, we do observe a power-law-like distribution, where a few users contribute a large number of tweets, and a large number of users contribute a few tweets each. We believe that 12.5K users is sufficient to ensure an unbiased study.

Further, we classify the users into three specific groups (i) news channels, (ii) general users (having $\leq$ 10,000 followers), (iii) popular users or celebrities (having $>$ 10,000 followers). Interestingly, for both $\mathbf{T_{All}}$, and $\mathbf{T_{BL}}$ corpora, we observe that around 98% of all users are general, and 96% of all tweets come from such users. Hence, most observations from these corpora are expected to be representative of the average online linguistic behavior of a Hi-En bilingual.

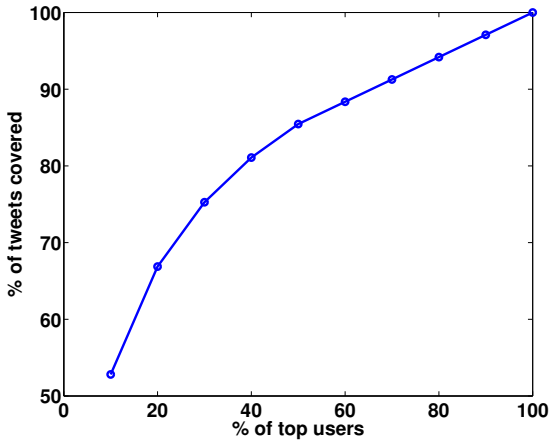

Figure 1: Distribution of cumulative % of tweets and # of users (sorted in descending order by number of tweets).

5 Method

Fig. 2 diagrammatically summarizes our experimental method. We identify the language used in each tweet before detecting opinion and sentiment.

5.1 Language Labeling

Tweets in Devanagari script are accurately detected by the Twitter API as Hindi tweets – we label these as hd, though a small fraction of them could also be md. To classify Roman script tweets as er, hr or mr, we use the system that performed best in the FIRE 2013 shared task for word-level language detection of Hi-En text (Gella et al., 2013). This system uses character n-gram features with a Maximum Entropy model for labeling each input word with a language label (either English or Hindi). We design minor modifications to the system to improve its performance on Twitter data, which are omitted here due to paucity of space.

5.2 Opinion and Sentiment Detection

Most of the existing research in opinion detection (Qadir, 2009; Brun, 2012; Rajkumar et al.,

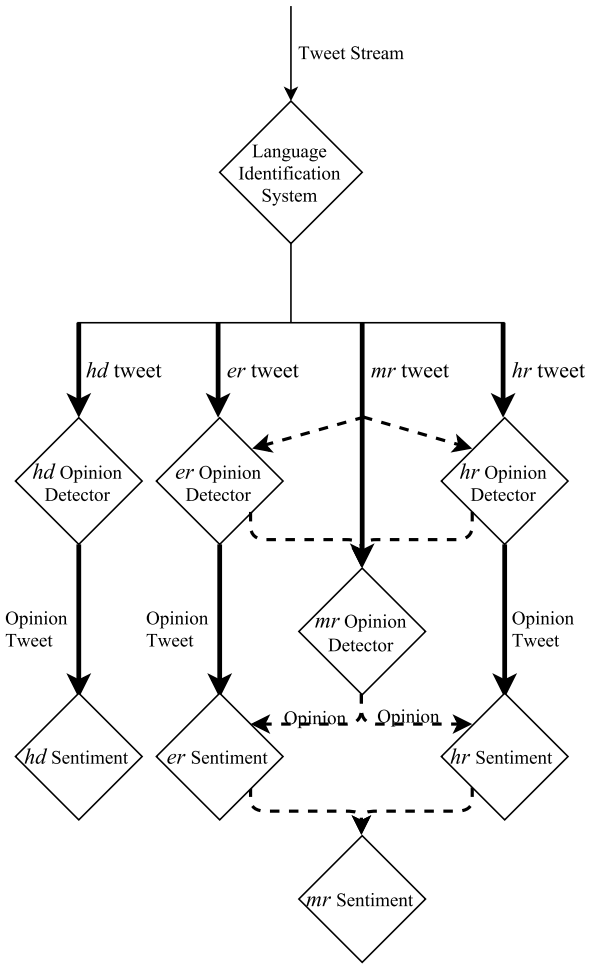

Figure 2: Overview of the experimental method.

2014) and sentiment analysis (Mohammad, 2012; Mohammad et al., 2013; Mittal et al., 2013; Rosenthal et al., 2015) focus on monolingual tweets and sentences. Recently, there has been a couple of studies on sentiment detection of code-switched tweets (Vilares et al., 2015; Sharma et al., 2015b). Sharma et al. (2015b) use Hindi SentiWordNet and normalization techniques to detect sentiment in Hi-En CS tweets.

We propose a two-step classification model. We first identify whether a tweet is opinionated or non-opinionated ($\otimes$). If the tweet is opinionated, we further classify it according to its sentiment ($+$, $-$ or 0). Fig. 2 shows the architecture of the proposed model. Two-step classification was empirically found to be better than a single four-class classifier.

We develop individual classifiers for each language class (er, hr, hd, mr) using an SVM with RBF kernel from Scikit-learn (Pedregosa et al., 2011). We use the **SAC** dataset (Sec. 4) as training data and features as described in Sec. 5.3.

5.3 Classifier Features

For opinion classification (opinion or $\otimes$), we propose a set of event-independent lexical features and Twitter-specific features. (i) **Subjective words:** Expected to be present in opinion tweets. We use lexicons from Volkova et al. (2013) for er and Bakliwal et al. (2012) for hd. We Romanize the hd lexicon for the hr classifiers (ii) **Elongated words:** Words with one character repeated more than two times, e.g. *sooo, naaahhhhi* (iii) **Exclamations:** Presence of contiguous exclamation marks (iv) **Emoticons**[4] (v) **Question marks:** Queries are generally non-opinionated. (vi) **Wh-words:** These are used to form questions (vii) **Modal verbs:** e.g. *should, could, would, cud, shud* (viii) **Excess hashtags:** Presence of more than two hashtags (ix) **Intensifiers:** Generally used to emphasize sentiment, e.g., *we shouldn't get* **too** *comfortable* (x) **Swear words**[5]**:** Prevalent in opinionated tweets, e.g. *that was a* f__ing *no ball!!!! #indvssa* (xi) **Hashtags:** Hashtags might convey user sentiment (Barbosa et al., 2012). We manually identify hashtags in our corpus that represent explicit opinion. (xii) **Domain lexicon:** For hr, & hd category tweets, we construct sentiment lexicons from 1000 manually annotated tweets. Each word or phrase in this lexicon represents $+$, or $-$, or 0 sentiment. (xiii) **Twitter user mentions** (xiv) **Pronouns:** Opinion is often in first person using pronouns like *I* and *we*.

For sentiment classification, we use emoticons, swear words, exclamation marks and elongated words as described above. We also use subjective words from various lexicons (Mohammad and Turney, 2013; Volkova et al., 2013; Bakliwal et al., 2012; Sharma et al., 2015a). Additionally, we use – (i) **Sentiment words:** From Hashtag Sentiment and Sentiment140 lexicons (Mohammad et al., 2013). We also manually annotate hashtags from our dataset that represent sentiment. (ii) **Negation:** A negated context is tweet segment that begins with a negation word and ends with a punctuation mark (Pang et al., 2002). The list of negation words are

[4]The list of emoticons was extracted from Wikipedia

[5]Swear word lexicons from *noswearing.com*, *youswear.com*

Classifier	er	hd	hr	mr
Opinion	72.6	72.0	79.9	73.5
Sentiment	64.4	61.5	62.7	63.4

Table 2: Accuracy of the opinion and sentiment classifiers. All values are in %.

taken from Christopher Potts' sentiment tutorial[6].

The mr opinion classifier uses the output from the er and hr classifiers as features (Fig. 2), along with an additional feature that represents whether the majority of the words in the tweet are Hindi or not. A similar strategy is used for mr sentiment detection.

5.4 Evaluation

We evaluated the language labeling system on the $\boldsymbol{LLC_{Test}}$ corpus, on which the precision (recall) values were $0.93(0.91)$, $0.90(0.85)$ and $0.88(0.92)$ for er, hr and mr classes respectively. The tweet-level classification accuracy was 89.8%.

The opinion and sentiment classifiers were evaluated using 10-fold cross validation on the **SAC** dataset. Table 2 details the class-wise accuracy. For comparison, we also reimplemented the dictionary and dependency-based method by Qadir (2009). The accuracy of the opinion classifier on the er tweets was found to be 65.7%, 7% lower than our system. We also compared our mr sentiment classifier with that of Sharma et al. (2015b). As their method performs two class sentiment detection ($+$ and $-$), we select such tweets from **SAC**. Their system achieves an accuracy of 68.2%, which is 4% lower than the accuracy of our system.

An analysis of the errors showed more false negatives (i.e., opinions labeled $\otimes$) than false positives in opinion classification. Sentiment misclassification is uniformly distributed.

Table 3 reports the accuracy of the opinion classifier for feature ablation experiments. For all three language-script pairs, lexicon and non-word (emoticons, elongated words, hashtags, exclamation) features are the most effective, though all features have some positive contribution towards the final accuracy of opinion detection. For hr and hd tweets, domain knowledge is significant, as shown by the 4% accuracy drop with removing the domain lexicon.

$\|hr(T)\|/\|T\|$	0.08	0.05	0.05	0.09
$\|mr(T)\|/\|T\|$	0.15	0.08	0.06	0.17

Table 4: Distribution across classes in Λ

6 Experiments and Observations

In this section, we report our experiments on 430,000 unique tweets (T_{All}), and its various subsets as defined in Sec 4. First, we run the language detection system on the corpora. Table 4 shows the language-wise distribution. We see that language preference varies by topic, which is not surprising. Due to paucity of space, the correlation between language usage and topic will not be discussed at length here, but we will highlight cases where the differences are striking.

We apply the language-specific opinion and sentiment classifiers to tweets detected as the corresponding language class. In the following subsections, we empirically investigate the hypotheses.

6.1 Status of Hypotheses I and II

Table 5 shows $pr(\otimes|\lambda\sigma;T)$, $pr(-|\lambda\sigma;T)$ and $pr(-|\lambda\sigma;T)/pr(+|\lambda\sigma;T)$ for T_{All}, T_{BL} and two randomly selected topics – Movie and Politics. The statistics are fairly consistent over the corpora, with slight differences but similar trends in T_{mov}.

Statistic	$\lambda\sigma$	T_{BL}	T_{All}	T_{pol}	T_{mov}
$pr(\otimes\|\lambda\sigma;T)$	er	0.34	0.35	0.37	0.29
	hd	0.45	0.47	0.48	0.49
	hr	0.38	0.39	0.37	0.49
$pr(-\|\lambda\sigma;T)$	er	0.16	0.17	0.22	0.07
	hd	0.18	0.17	0.19	0.16
	hr	0.24	0.25	0.27	0.13
$\frac{pr(-\|\lambda\sigma;T)}{pr(+\|\lambda\sigma;T)}$	er	0.35	0.38	0.59	0.11
	hd	3.00	3.27	5.67	1.90
	hr	1.46	1.60	1.96	0.55

Table 5: Sentiment across languages: Statistics concerning hypotheses I and II.

We need the first statistic in order to investigate **Hypothesis I** (Eqs. 6 and 7), and the two latter ones for verifying **Hypothesis II** (Eqs. 8 and 9).

Contrary to Eqs. 6 and 7, for all corpora except T_{mov}, we observe the following trend:

$$pr(\otimes|hd;T) > pr(\otimes|hr;T) \geq pr(\otimes|er;T)$$

In other words, hd is more commonly preferred for expressing non-opinions than hr and er. Hypothesis I is clearly untrue for these corpora, though due to the small differences between hr and er, we cannot claim that English is the preferred language for expressing opinions. A closer scrutiny of the corpora revealed that hd tweets mostly come from official sources (news channels, political parties, production houses) and celebrities, which are mostly factual. hr tweets are from general users and show similar trends as English. Thus, in general, there seems to be no preferred language for expressing opinion by the Hi-En bilinguals on Twitter.

In the context of **Hypothesis II**, we see the general pattern (with some topic specific variations):

$$pr(-|hr;T) > pr(-|hd;T) \geq pr(-|er;T)$$

The pattern emerges even more strongly, when we look at $pr(-|\lambda\sigma;T)/pr(+|\lambda\sigma;T)$. The odds of expressing a negative opinion over positive opinion in Hindi is between 1.5 and 6 (T_{mov} exhibits a slightly different pattern but similar preference, T_{pol} shows a stronger preference towards Hindi for negative sentiment), whereas the same for English is between 0.1 and 0.6. In other words, English is more preferred for expressing positive opinion, and Hindi for negative opinion. These observations provide very strong evidence in favor of Hypothesis II.

Statistic	m^hr	m^er
$pr(\otimes\|\lambda\sigma;T_{CS})$	0.39	0.45
$pr(-\|\lambda\sigma;T_{CS})$	0.22	0.14
$pr(-\|\lambda\sigma;T_{CS})/pr(+\|\lambda\sigma;T_{CS})$	2.2	0.34

Table 6: T_{CS} statistics for testing hypotheses Ia and IIa

6.2 Status of Hypotheses Ia and IIa

Recall that **Hypothesis Ia** and **Hypothesis IIa** are essentially same as Hypotheses I and II, but applied on m^hr and m^er fragments from the T_{CS} corpus.

Table 6 reports the three statistics necessary for testing these hypotheses. $pr(\otimes|m^er;T_{CS})$ is slightly greater than $pr(\otimes|m^hr;T_{CS})$, which is what we would expect if Hypothesis Ia was true. However, since the difference is small, we view it as a trend rather than a proof of Hypothesis Ia.

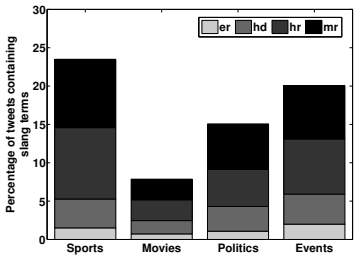
The statistics clearly show that Hypothesis IIa holds true for T_{CS}. The fraction of negative sentiment in m^hr is over 1.5 times higher than that of m^er. Further, the odds of expressing a negative sentiment in Hindi over positive sentiment in Hindi in a code-switched tweet is 6.5 times higher than the same odds for English.

6.3 Switching Functions

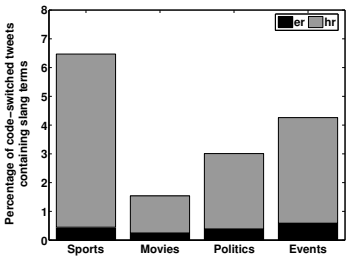
Recall that using Eq. 13 (Sec. 3), we can estimate the preference, if any, for switching to a particular language while changing the sentiment. In particular, research in socio-linguistics has shown that users often switch between languages when they switch from non-opinion ($\otimes$) to opinion ($\{+,-,0\}$). This is called the *Narrative-Evaluative* function of CS (Sanchez, 1983). This function appears in 46.1% of the tweets in $\boldsymbol{T_{CS}}$. We find that

$$\frac{pr(h\{+,-,0\} \leftrightarrow e\otimes;T_{CS})}{pr(h\otimes \leftrightarrow e\{+,-,0\};T_{CS})} = 0.86$$

which indicates that there is no preference for switching to Hindi (or English) while switching between opinion and non-opinion. This is also confirmed above in the context of hypotheses I and Ia. While switching between opinion and non-opinion in a tweet, users do switch language. However, we



(a) Abusive tweets



(b) Swearing pref. in T_{CS}

Figure 3: Distribution of swear words by language

observe no particular preference for the languages chosen for each part.

We also report two other pragmatic functions:

$$\frac{pr(h- \leftrightarrow e\{+,0,\otimes\}; T_{CS})}{pr(h\{+,0,\otimes\} \leftrightarrow e-; T_{CS})} = 1.98$$

$$\frac{pr(h- \leftrightarrow e+; T_{CS})}{pr(h+ \leftrightarrow e-; T_{CS})} = 10.27$$

The latter function is called *polarity switch*. The extremely high value for these ratios is an evidence for a strong preference towards switching language from English to Hindi while switching to negative sentiment (and switching to English when sentiment changes from negative to positive).

We also observe cases where there is a language switch, but no sentiment switch and hence, we cannot evaluate language preference using Eq. 13 (because $\diamond = \diamond'$). In $\boldsymbol{T_{CS}}$, 15.3% of the tweets show *Positive Reinforcement*, where both fragments are of positive sentiment. *Negative Reinforcement* is defined similarly and is seen in 8.7% of the tweets. Other tweets in $\boldsymbol{T_{CS}}$ likely have pragmatic functions that cannot be identified based on sentiment.

6.4 Language Preference for Swearing

Since there is evidence that the native language (Hindi, in this case) is preferred for swearing (Dewaele, 2004), we computed the fraction of tweets that contain swear words in each language class. Fig. 3a shows the distribution across topics. The languages hr and mr have a much higher fraction of abusive tweets than er and hd. Fig. 3b shows the distribution of abusive $m^h r$ and $m^e r$ fragments for tweets in T_{CS}. Interestingly, over 90% of the swear words occur in $m^h r$. Both distributions strongly suggest a preference for swearing in Hindi.

7 Conclusion

In this paper, through a large scale empirical study of nearly half a million tweets, we tried to answer a fundamental question regarding multilingualism, namely, is there a preferred language for expression of sentiment. We also looked at some of the pragmatic functions of code-switching. Our results indicate a strong preference for using Hindi, L1 for the users from whom these tweets come, for expressing negative sentiment, including swearing. However, we do not observe any particular preference towards Hindi for expressing opinions.

Previous linguistic studies (Dewaele, 2004; Dewaele, 2010) have already shown a preference for L1 for expressing emotion and swearing. However, we observe that for expressing positive emotion, English (which would be L2) is the language of preference. This raises some intriguing socio-linguistic questions. Is it the case that English being the language of aspiration in India, it is preferred for positive expression? Or is it because Hindi is specifically preferred for swearing and therefore, is the language of preference for negative emotion? How do such preferences vary across topics, users and other multilingual communities? How representative of the society is this kind of social media study? We plan to explore some of these questions in the future.

Our study also indicates that inferences drawn on multilingual societies by analyzing data in just one language (usually English), which has been the norm so far, are likely to be incorrect.

Abstract

Significant events are characterized by interactions between entities (such as countries, organizations, or individuals) that deviate from typical interaction patterns. Analysts, including historians, political scientists, and journalists, commonly read large quantities of text to construct an accurate picture of when and where an event happened, who was involved, and in what ways. In this paper, we present the *Capsule* model for analyzing documents to detect and characterize events of potential significance. Specifically, we develop a model based on topic modeling that distinguishes between topics that describe "business as usual" and topics that deviate from these patterns. To demonstrate this model, we analyze a corpus of over two million U.S. State Department cables from the 1970s. We provide an open-source implementation of an inference algorithm for the model and a pipeline for exploring its results.

1 Introduction

Foreign embassies of the United States government communicate with one another and with the U.S. State Department through diplomatic cables. The National Archive collects these cables in a corpus, which traces the (declassified) diplomatic history of the United States.[1] The corpus contains, for example, over two million cables sent between 1973 and 1978.

Most of these cables describe diplomatic "business as usual," such as arrangements for visiting officials, recovery of lost or stolen passports, or obtaining lists of names for meetings and conferences. For example, the embassies sent 8,635 cables during the week of April 21, 1975. Here is one, selected at random:

> Hoffman, UNESCO Secretariat, requested info from PermDel concerning an official invitation from the USG RE subject meeting scheduled 10–13 JUNE 1975, Madison, Wisconsin. Would appreciate info RE status of action to be taken in order to inform Secretariat. Hoffman communicating with Dr. John P. Klus RE list of persons to be invited.

But, hidden in the corpus are also cables about important diplomatic events—the cables and events that are most interesting to historians, political scientists, and journalists. For example, during that same week, the U.S. was in the last moments of the Vietnam War and, on April 30, 1975, lost its hold on Saigon. This marked the end of the war and induced a mass exodus of refugees. Here is one cable about this event:

> GOA program to move Vietnamese Refugees to Australia is making little progress and probably will not cover more than 100-200 persons. Press comment on smallness of program has recognized difficulty of getting Vietnamese out of Saigon, but "Canberra Times" Apr 25 sharply critical of government's performance. [...] Labor government clearly hopes whole matter will somehow disappear.

Our goal in this paper is to develop a tool to help historians, political scientists, and journalists wade

[1] The National Archives' corpus also includes messages sent by diplomatic pouch; however, for brevity, and at the risk of being imprecise, we also refer to these messages as "cables."

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1142–1152,
Austin, Texas, November 1-5, 2016.

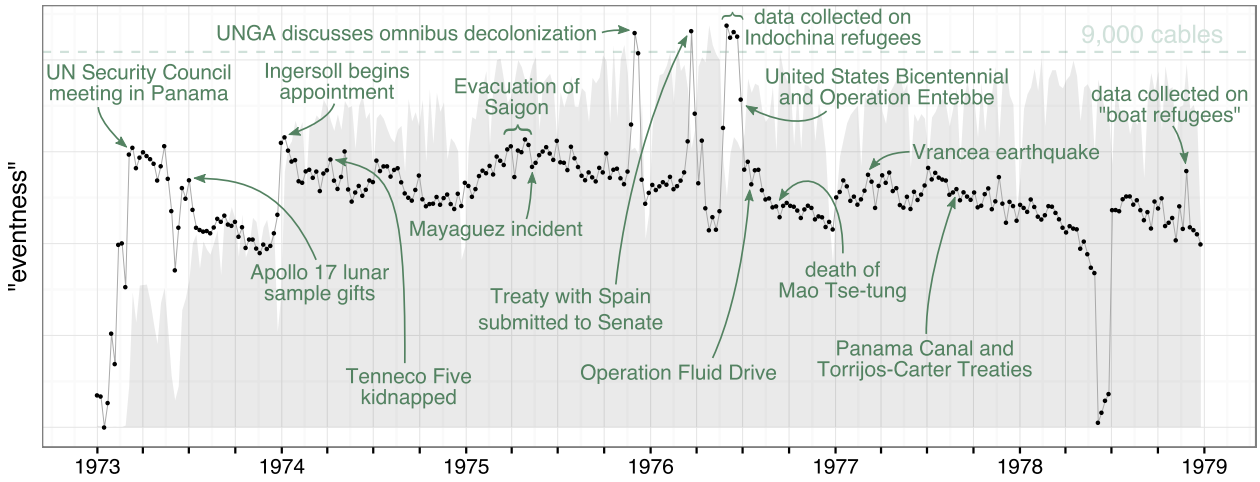

Figure 1: Capsule's analysis (described in detail in section 5) of two million cables from the National Archives' corpus. The y-axis represents a loose measure of "eventness" (equation (5)). The gray background depicts the number of cables sent over time.

through corpora of documents to find potentially significant events and the primary sources around them. We present *Capsule*, a probabilistic model for detecting and characterizing important events, such as the fall of Saigon, in large corpora of historical communication, such as diplomatic cables from the 1970s.

Figure 1 illustrates Capsule's analysis of two million cables from the National Archives' corpus. The y-axis represents "eventness," a loose measure of how strongly a week's cables deviate from typical diplomatic "business as usual" to discuss some matter that is common to many embassies. (We describe this measure of "eventness" in detail in section 3.)

This figure shows that Capsule detects many well-known events between 1973 and 1978, including the fall of Saigon (April 30, 1975) and the death of Mao Tse-tung (September 9, 1976). Capsule also uncovers obscure, but significant, events that have largely escaped the attention of scholars, such as when the U.S. defended its control of the Panama Canal before the United Nations Security Council (March 19, 1973). Capsule therefore provides a new way to detect and characterize historical moments that may be of interest to historians, political scientists, and journalists.

The intuition behind Capsule is this: Embassies write cables throughout the year, usually describing typical diplomatic business, such as visits from government officials. Sometimes, however, important events occur, such as the fall of Saigon, that pull embassies away from their typical activities and lead them to write cables that discuss these events and their consequences. Capsule therefore operationalizes an "event" as a moment in history when multiple embassies deviate from their usual topics of discussion and each embassy deviates in a similar way.

Capsule embeds this intuition into a Bayesian model that uses latent variables to encode what "business as usual" means for each embassy, to characterize the events of each week, and to identify the cables that discuss those events. Given a corpus of cables, the corresponding posterior distribution of the latent variables provides a filter for the cables that isolates important moments in diplomatic history. Figure 1 depicts the mean of this posterior distribution.

We present the Capsule model in section 3, providing both a formal model specification and guidance on how to use the model to detect and characterize real-world events. In section 4, we validate Capsule using simulated data, and in section 5, we use it to analyze over two million U.S. State Department cables. Although we describe Capsule in the context of diplomatic cables, it is suitable for exploring any corpus with the same underlying structure: text (or other discrete multivariate data) generated over time by known entities. This includes email, consumer behavior, social media posts, and opinion articles.

2 Related Work

We first review previous work on automatic event detection and other related concepts, to contextualize our approach in general and Capsule in particular.

In both univariate and multivariate settings, ana-

lysts often want to predict whether or not rare events will occur (Weiss and Hirsh, 1998; Das et al., 2008). In contrast, Capsule is intended to help analysts explore and understand their data; our goal is human interpretability rather than prediction or forecasting.

Events can be construed as either anomalies—temporary deviations from usual behavior—or "changepoints" that mark persistent shifts in usual behavior (Guralnik and Srivastava, 1999; Adams and MacKay, 2007). We focus on events as anomalies.

Event detection in the context of news articles (Zhao et al., 2012; Zhao et al., 2007; Zhang et al., 2002; Li et al., 2005; Wang et al., 2007; Allan et al., 1998) and social media posts (Atefeh and Khreich, 2015; VanDam, 2012; Lau et al., 2012; Jackoway et al., 2011; Sakaki et al., 2010; Reuter and Cimiano, 2012; Becker et al., 2010; Sayyadi et al., 2009) usually means identifying clusters of documents. For news, the goal is to create new clusters as novel stories appear; each article is assumed to be associated with one event, which does not allow for distinctions between typical content and rare events. For social media, the goal is to identify rare events, but the resultant methods are intended for short documents, and are not appropriate for longer documents that may contain information about a variety of subjects.

Many existing methods for detecting events from text focus on individual vocabulary terms, often weighted by tf-idf values (Fung et al., 2005; Kumaran and Allan, 2004; Brants et al., 2003; Das Sarma et al., 2011; Zhao et al., 2007; Zhao et al., 2012). We characterize events by bursts in groups of terms.

Although groups of terms can be summarized directly (Peng et al., 2007; Chakrabarti and Punera, 2011; Gao et al., 2012), topic models (Blei, 2012) provide a way to automatically identify groups of related terms and reduce the dimensionality of text data. Researchers have previously used topic models to detect events mentioned in social media posts (Lau et al., 2012; Dou et al., 2012) and to find posts relevant to particular, monitored events (VanDam, 2012). Capsule uses topics to characterize both typical diplomatic content and potentially significant events.

In addition to modeling text over time, researchers have also used spatial information (Neill et al., 2005; Mathioudakis et al., 2010; Liu et al., 2011) and information about authors (Zhao et al., 2007) and news outlets (Wang et al., 2007) to enhance event detection. We rely on author information to characterize diplomatic "business as usual" for each embassy.

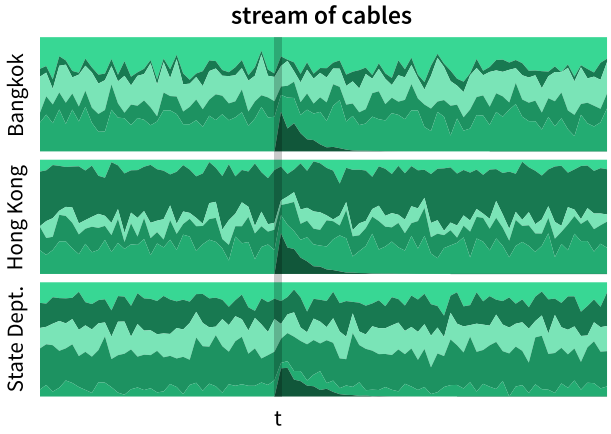

Figure 2: Cartoon intuition. The y-axis represents the stacked proportions of cables about various topics, while the x-axis represents time. The Bangkok embassy, Hong Kong embassy, and U.S. State Department all have typical diplomatic business, about which they usually send cables. When an event occurs during time interval t, the cables alter to cover the event before returning to "business as usual." Capsule discovers the entities' typical concerns, as well as the timing and content of events.

Event detection is closely related to detecting and characterizing relationships between entities (Schein et al., 2015; Linderman and Adams, 2014; Das Sarma et al., 2011). Capsule can trivially use sender–receiver pairs instead of authors, and the model specification can be tailored to reflect network structure.

Finally, there are connections between Capsule and recent work on Poisson processes. In particular, we can interpret Capsule as a collection of related discrete-time Poisson processes with random intensity measures. Further, marginalizing out the event strengths (described in section 3.1) reveals that the use of a vocabulary term by one embassy can "excite" the use of that term by another. This suggests a close relationship to Hawkes processes (Hawkes, 1971).

3 The Capsule Model

In this section, we present the Capsule model for detecting and characterizing significant diplomatic events. We first provide the intuition behind Capsule, and then formally specify the model. We also explain how to use Capsule to explore a corpus and how to learn the posterior distribution of the latent variables.

Consider an entity like the Bangkok embassy, as

illustrated in figure 2. We can imagine that this entity sends a stream of diplomatic cables over time—some to the U.S. State Department, others to other American embassies, such as the one in Hong Kong. Embassies usually write cables that describe typical diplomatic business. For example, the Bangkok embassy might write about topics regarding southeast Asia more generally. We can think of a topic as being a probability distribution over vocabulary terms.

Now imagine that an event, such as the capture of Saigon during the Vietnam War, occurs during a particular time interval t. We cannot directly observe the occurrence of this event, but we can observe the stream of cables and the event's impact on it. When the event occurs, multiple entities deviate from their usual topics of discussion simultaneously, before returning to their usual behavior, as depicted in figure 2. For example, the day after the capture of Saigon, the majority of the diplomatic cables written by the Bangkok embassy and several other entities were about Vietnam War refugees. If we think of the event as another probability distribution over vocabulary terms, then each entity's stream of cables reflects its typical concerns, as well as any significant events.

3.1 Model Specification

We now define the Capsule model. Our data come from *entities* (e.g., embassies) who send *messages* (e.g., diplomatic cables) over *time*; specifically, we observe the number of times n_{dv} that each vocabulary term v occurs in each message d. Each message is associated with an author entity a_d and a time interval t_d within which that message was sent.

We model each message with a bank of Poisson distributions[2]—one for each vocabulary term:

$$n_{dv} \sim \text{Poisson}\left(\lambda_{dv}\right). \tag{1}$$

The rate λ_{dv} blends the different influences on message content. Specifically, it blends three types of *topics*, intended to capture "business-as-usual" discussion and content related to significant events.

We operationalize each topic as a specialized probability distribution over vocabulary terms (the set of unique words in the corpus of messages), as is common in topic models (Blei et al., 2003; Canny, 2004; Gopalan et al., 2014)—i.e., each term is associated with each topic, but with a different probability.

Topic Type	Top Terms
General	visit, hotel, schedule, arrival
Entity	soviet, moscow, ussr, agreement
Event	saigon, evacuation, vietnam, help

Table 1: The highest-probability vocabulary terms for examples of the three types of topics (general, entity, and event). These examples come from the analysis that we describe section 5.

Each message blends 1) general topics $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_K$ about diplomacy (e.g., terms about diplomats, terms about communication), 2) an entity topic $\boldsymbol{\eta}_{a_d}$ specific to the author of that message (e.g., terms about Hong Kong),[3] and 3) event topics $\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_T$ that are specific to the events in recent time intervals (e.g., terms about a coup, terms about the death of a dignitary).

Examples of these three types of topics are in table 1. The general topic relates to planning travel, the entity topic captures words related to the U.S.S.R., and the event topic captures words related to the evacuation of Saigon toward the end of the Vietnam War.

The messages share the three types of topics in different ways: all messages share the general topics, messages written by a single entity share an entity topic, and messages in the same time interval use the event topics in similar ways. Each message blends its corresponding topics with a set of message-specific strengths. As a result, each message captures a different mix of general diplomacy discussion, entity-specific terms, and recent events. Specifically, the Poisson rate for vocabulary term v in message d is

$$\lambda_{dv} = \sum_{k=1}^{K} \theta_{dk}\beta_{kv} + \zeta_d \eta_{a_d v} + \sum_{t=1}^{T} f(t_d, t)\, \epsilon_{dt}\gamma_{tv}, \tag{2}$$

where θ_{dk} is message d's strength for general topic k, ζ_d is message d's strength for a_d's entity topic, and ϵ_{dt} is message d's strength for event topic t. The function $f(\cdot)$ ensures that the events influences decay over time. As we describe in appendix B, we

[2] Readers familiar with topic modeling may expect a multinomial model of term occurrences, but Poisson models of counts better capture messages with different lengths (Canny, 2004).

[3] The entity-specific topics play a similar role to the background topics introduced by Paul and Dredze (2012).

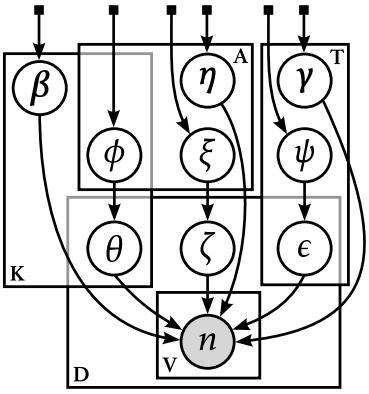

Figure 3: Graphical model for Capsule. Observed term counts depend on general topics $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_K$, entity topics $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_A$, and event topics $\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_T$, as well as message-specific strengths $\boldsymbol{\theta}_d$, ζ_d, and $\boldsymbol{\epsilon}_d$. Variables $\boldsymbol{\phi}_1, \ldots, \boldsymbol{\phi}_A$ and $\xi_1, \ldots, \xi_A$ represent entity-specific strengths, while $\psi_1, \ldots, \psi_T$ allow time intervals to be more or less "eventful." Black squares denote hyperparameters (unlabeled for visual simplicity).

compared several different decay functions (exponential, linear, and step) and found that the following exponential decay function works well in practice:

$$f(t_d, t) = \begin{cases} 0 & t \leq t_d < t + \tau \\ \exp\left(\frac{-(t_d - t)}{\tau / 5}\right) & \text{otherwise.} \end{cases} \quad (3)$$

Dividing τ by five means that we can interpret it as the number of time intervals after which an event will have little impact on the content of the messages.

We place hierarchical gamma priors over the message-specific strengths, introducing entity-specific strengths $\boldsymbol{\phi}_1, \ldots, \boldsymbol{\phi}_A$ and $\xi_1, \ldots, \xi_A$ that allow different entities to focus on different topics and event strengths $\psi_1, \ldots, \psi_T$ that allow different time intervals to be more or less "eventful." We place Dirichlet priors over the topics. The graphical model is in figure 3 and the generative process is in figure 4.

Given a corpus of messages, learning the posterior distribution of the latent variables uncovers the three types of topics, the message- and entity-specific strengths, and the event strengths. In section 3.3, we explain how an analyst can use the event strengths as a filter that isolates potentially significant messages.

3.2 Learning the Posterior Distribution

In order to use Capsule to to explore a corpus of messages, we must first learn the posterior distribution of the latent variables—the general topics, the entity topics, the event topics, the message- and entity-specific strengths, and the event strengths—conditioned on the observed term counts. As for many Bayesian models, this posterior distribution is not tractable to compute; approximating it is therefore our central statistical and computational problem. We introduce an approximate inference algorithm for Capsule, based on variational methods (Jordan et al., 1999),[4], which

- for $k = 1, \ldots, K$,
  - draw general topic $\boldsymbol{\beta}_k \sim \text{Dirichlet}_V(\alpha, \ldots, \alpha)$
  - for each entity $a = 1, \ldots, A$,
    - ► draw entity-specific strength $\phi_{ak} \sim \text{Gamma}(s, r)$
- for each entity $a = 1, \ldots, A$,
  - draw entity topic $\boldsymbol{\eta}_a \sim \text{Dirichlet}_V(\alpha, \ldots, \alpha)$
  - draw entity-specific strength $\xi_a \sim \text{Gamma}(s, r)$
- for each time interval $t = 1, \ldots, T$,
  - draw event topic $\boldsymbol{\gamma}_t \sim \text{Dirichlet}_V(\alpha, \ldots, \alpha)$
  - draw event strength $\psi_t \sim \text{Gamma}(s, r)$
- for each message $d = 1, \ldots, D$, sent during time interval t_d by author entity a_d,
  - for each general topic $k = 1, \ldots, K$,
    - ► draw message-specific strength $\theta_{dk} \sim \text{Gamma}(s, \phi_{a_d k})$
  - draw message-specific strength $\zeta_d \sim \text{Gamma}(s, \xi_{a_d})$
  - for each time interval $t = 1, \ldots, T$,
    - ► draw message-specific strength $\epsilon_{dt} \sim \text{Gamma}(s, \psi_t)$
  - for each vocabulary term $v = 1, \ldots, V$,
    - ► set $\lambda_{dv} = \sum_{k=1}^{K} \theta_{dk} \beta_{kv} + \zeta_d \eta_{a_d v} + \sum_{t=1}^{T} f(t_d, t)\, \epsilon_{dt} \gamma_{tv}$
    - ► draw term counts $n_{d,v} \sim \text{Poisson}(\lambda_{dv})$

Figure 4: Generative process for Capsule. We use s and r to denote top-level (i.e., fixed) shape and rate hyperparameters; they can be set to different values for different variables.

[4] Source code: `https://github.com/ajbc/capsule`.

we outline in appendix A.[5] This algorithm produces a fitted variational distribution which be can then be used as a proxy for the true posterior distribution.

3.3 Detecting and Characterizing Events

We can use the mean of the fitted variational distribution to explore the data. Specifically, we can explore "business-as-usual" content using the posterior expected values of the general topics $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_K$ and the entity topics $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_A$, and we can detect and characterize events using the posterior expected values of the event strengths and the event topics.

To detect events, we define an measure that quantifies the "eventness" of time interval t. Specifically, we first compute how relevant each message d is to that time interval: $m_{dt} = f(t_d, t)\,\mathbb{E}[\epsilon_{dt}]$. Using these relevancy values, we then compute the proportion of each message's term counts that are associated with the event topic specific to time interval t:

$$p_{dt} = \frac{m_{dt}}{\sum_k \mathbb{E}[\theta_{dk}] + \mathbb{E}[\zeta_d] + \sum_{t'} m_{dt'}}. \quad (4)$$

Finally, we aggregate these values over messages:

$$\frac{1}{\sum_d f(t_d, t)} \sum_{d=1}^{D} p_{dt}, \quad (5)$$

where the multiplicative fraction ensures that messages that were sent during time intervals that are further from t contribute less than than messages that were sent during time intervals that are closer to t.

We can characterize an event t by selecting the highest-probability vocabulary terms from $\mathbb{E}[\boldsymbol{\gamma}_t]$. By ordering the messages according to $m_{dt} = f(t_d, t)\,\mathbb{E}[\epsilon_{dt}]$, we can also identify the messages that are most strongly associated with event t.

In section 5, we explore the cables associated with significant events in the National Archives' corpus of diplomatic cables. To make Capsule more accessible for historians, political scientists, and journalists, we have released an open-source tool for visualizing its results.[6] This tool allows analysts to browse a corpus of messages and the mean of the corresponding posterior distribution, including general topics, entity topics, and event topics. Figure 5 contains several screenshots of the tool's browsing interface.

[5] Appendices are in the supplemental material.

Bottom: summary of the week of May 12, 1975, including top vocabulary terms, relevant cables, and text from Wikipedia.

4 Model Validation with Simulated Data

Before using Capsule to explore a corpus of real messages (described in section 5), we provide a quantitative validation of the model using simulated data.

We used the generative process in figure 4 to create ten data sets, each with 100 time intervals, ten general topics, ten entities, and roughly 20,000 messages. We then used these data sets to compare Capsule's event detection performance to that of four baseline methods. We also compared the methods' abilities to identify the most relevant messages for each event.

4.1 Detecting Events

For each data set, we ordered the time intervals from most to least eventful, using the "eventness" measure described in section 3.3 and the simulated values of the latent variables. We then treated these ranked lists of time intervals as "ground truth" and assessed how well each method was able to recover them.

For Capsule itself, we used our approximate inference algorithm to obtain a fitted variational distribution for each simulated data set. We then ordered the time intervals using our "eventness" measure and the posterior expected values of the latent variables.

For our first baseline, we constructed an "event-only" version of Capsule by dropping the first and

second terms in equation (2). We used this baseline to test whether modeling "business as usual" discussion makes it easier to detect significant events. We obtained a fitted variational distribution for this model using a variant of our approximate inference algorithm, and then ordered the time intervals using our "eventness" measure, modified appropriately, and the posterior expected values of the latent variables.

For our second baseline, we drew inspiration from previous work on event detection in the context of news articles, and focused on each time interval's deviation in term counts from the average. Specifically, we ordered the time intervals $1, \ldots, T$ for each simulated data set according to this measure:

$$\sum_{v=1}^{V} \sum_{\substack{d=1 \\ t_d = t}}^{D} \left| n_{dv} - \frac{1}{D} \sum_{d=1}^{D} n_{dv} \right|. \quad (6)$$

We added tf-idf term weights for our third baseline:

$$\sum_{v=1}^{V} \text{tf-idf}\,(v) \sum_{\substack{d=1 \\ t_d = t}}^{D} \left| n_{dv} - \frac{1}{D} \sum_{d=1}^{D} n_{dv} \right|. \quad (7)$$

Finally, we randomly ordered the time intervals for each data set to serve as a straw-man baseline.

We also experimented with baselines that involved term-count deviations on the entity level and topic-usage deviations on the message level (Dou et al., 2012), but found that they were not competitive.

For each data set, we compared each method's ranked list of time intervals to the corresponding "ground-truth" list of time intervals, by dividing the sum of the lists' actual set overlap at each rank by the sum of their maximum set overlap at each rank:

$$\frac{\sum_{r=1}^{T} |S_r^{\text{truth}} \cap S_r^{\text{method}}|}{\sum_{r=1}^{T} r}, \quad (8)$$

where S_r^{truth} is a set of the top r time intervals according to the "ground-truth" list and S_r^{method} is a set of the top r time intervals according to the method.

Figure 6 shows that Capsule outperforms all four baseline methods. These results serve as a sanity check for both the model and its implementation.

4.2 Identifying Relevant Messages

For each data set, we created a list of the most relevant messages for each time interval t by computing $f(t_d, t)\,\epsilon_{dt}$ for each message d (using the simulated values of ϵ_{dt}) and ordering the messages accordingly. We then treated these ranked lists of messages as "ground truth" and assessed how well Capsule and the baseline methods were able to recover them.

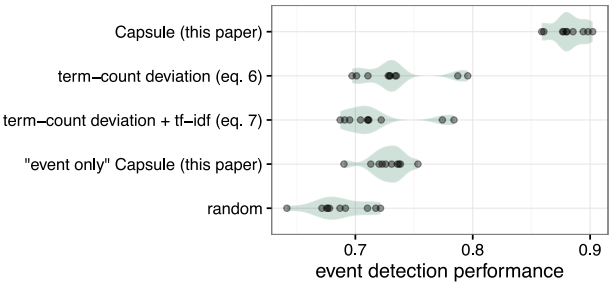

Figure 6: Event detection performance using ten simulated data sets. Each dot represents the performance (equation (8); higher is better) of a single method on a single data set; each shaded green area summarizes the distribution of performance for a single method. Capsule outperforms all four baseline methods.

For Capsule, we used our approximate inference algorithm to obtain a fitted variational distribution for each data set, and then, for each time interval, ordered the messages according to $m_{dt} = f(t_d, t)\,\mathbb{E}[\epsilon_{dt}]$. For our second and third baselines, we ordered the messages sent during each time interval according message-specific versions of equations (6) and (7).

For each data set, we compared each method's ranked list of messages for each time interval to the corresponding "ground-truth" list, by computing precision at ten messages. The average precision for Capsule was was 0.44, while the average precision for the "event-only" version of the model was 0.09. The other baselines recovered zero relevant messages.

5 Exploratory Analysis

Capsule is intended to help analysts explore and understand their data. In this section, we demonstrate its capabilities by analyzing a corpus of over two million U.S. State Department cables from the 1970s.

5.1 Data

The National Archive collects diplomatic cables sent between the U.S. State Department and its foreign embassies. We obtained a subset of this corpus from the Central Foreign Policy Files at the National Archives, via the History Lab at Columbia Univer-

sity;[7] the subset contains cables sent between 1973 and 1978. In addition to the text of the cables, each message is labeled with its author (e.g., the U.S. State Department, a particular embassy, or an individual), the date the cable was sent, and other metadata. We used a vocabulary of 6,293 terms and omitted cables with fewer than three terms, resulting in 2,021,852 cables sent by 22,961 entities. We used weekly time intervals, as few cables were sent on weekends.

5.2 Model Settings

We ran our approximate inference algorithm for Capsule to obtain a fitted variational distribution. We used $K = 100$ general topics, the exponential decay function in equation (3) with $\tau = 4$, and top-level hyperparameters $s = r = 0.3$. With these settings, a single iteration of the algorithm took about an hour.[8]

5.3 Detecting Well-Known Events

To evaluate Capsule's ability to detect well-known events, we used a list, provided to us by the History Lab, of thirty-nine well-known events that took place between 1973 and 1978. Each event is present in at least one of six reputable collections of historic events, such as the Office of the Historian's Milestones in the History of U.S. Foreign Relations.[9] We treated this list of events as "ground truth" and assessed how well Capsule and each of the baselines described in section 4.1 were able to recover them—or, in other words, how well the methods identify these eventful weeks, compared to more typical weeks.

Specifically, we used each method to construct a ranked list of time intervals. Then, for each method, we computed the discounted cumulative gain (DCG), which, in this context, is equivalent to computing

$$\sum_{e=1}^{39} \frac{1}{\log\left(\text{rank}\left(e, L_T^{\text{method}}\right)\right)}, \tag{9}$$

where L_T^{method} is the method's ranked list of time intervals and $\text{rank}\left(e, L_T^{\text{method}}\right)$ is the rank of the e^{th} well-known event in L_T^{method}. Finally, we divided the DCG by the ideal DCG—i.e., $\sum_{e=1}^{39} \frac{1}{\log(e)}$—to obtain the normalized DCG (nDCG). Table 2 shows that Capsule outperforms all four baseline methods.

Method	nDCG
Capsule (this paper)	0.693
term-count deviation + tf-idf (equation (7))	0.652
term-count deviation (equation (6))	0.642
random	0.557
"event-only" Capsule (this paper)	0.426

Table 2: Event detection performance (nDCG; higher is better) using thirty-nine well-known events that took place between 1973 and 1978. Capsule outperforms all four baseline methods.

5.4 Exploration

We now turn to our primary goal—using Capsule to explore and understand a corpus of messages. Figure 1 shows our "eventness" measure (equation (5)) over time. One of the tallest peaks occurs during the week of December 1, 1975, when the United Nations General Assembly discussed omnibus decolonization. As described in section 3.3, we can characterize this event by computing $m_{dt} = f(t_d, t)\,\mathbb{E}[\epsilon_{dt}]$ for each message d and then ordering the messages accordingly. Table 3 lists the highest-ranked messages.

Another notable event was the seizure of the S.S. Mayaguez, an American merchant vessel, during May, 1975, at the end of the Vietnam War. Table 4 lists the highest-ranked messages for this event. We can examine these messages to confirm their relevancy and learn more about the event. For example, here is the content of the most relevant message:

> In absence of MFA Chief of Eighth Department Avramov, I informed American desk officer Yankov of circumstances surrounding seizure and recovery of merchant ship Mayaguez and its crew. Yankov promised to inform the Foreign Minister of US statement today (May 15). Batjer

A third week of interest occurs in early July, 1976. On July 4, the U.S. celebrated its Bicentennial, but on the same day, Israeli forces completed a hostage rescue mission because an Air France flight from Tel Aviv had been hijacked and taken to Entebbe, Uganda.[10] This event was mostly discussed the week

[7] http://history-lab.org

[8] Each iteration of our algorithm considers all messages. Modifying it to stochastically sample the data would reduce the time required to obtain an equivalent fitted variational distribution.

[9] https://history.state.gov/milestones/1969-1976

[10] Capsule assumes that only one event occurs during each

after the event took place; the most relevant messages are listed in appendix B (table 5). The cable from Stockholm describing the "Ugandan role in Air France hijacking" begins with the following content, which reveals further information about this event:

> 1. We provided MFA Director of Political Affairs Leifland with Evidence of Ugandan assistance to hijackers contained in Ref A. After reading material, Leifland described it a "quite good", and said it would be helpful for meeting MFA has scheduled for early this morning to determine position GOS will take at July 8 UNSC consideration of Israeli Rescue Operation. ...

In addition to detecting and characterizing well-known events, such the S.S. Mayaguez incident and Operation Entebbe, Capsule can detect and characterize obscure, but significant, events, such as when Eritrean rebels kidnapped Tenneco oil employees (April 8, 1974) and when the U.S. Navy evacuated citizens from Lebanon ("Operation Fluid Drive," June 20, 1976). Both events appear in figure 1. Capsule uncovers events where analysts might not otherwise look.

Capsule also provides a way to explore "business-as-usual" discussion using the posterior expected values of the general topics $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_K$ and the entity topics $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_A$. Examples of each of these types of topics are in appendix B (tables 6 and 7, respectively); these examples illustrate that, as desired, the entity topics absorb location-specific terms, preventing them from overwhelming the general topics.

6 Conclusion

We presented Capsule, a Bayesian model for detecting and characterizing potentially significant events. We evaluated Capsule's ability to detect events and identify relevant messages; it outperformed four baseline methods. We used Capsule to analyze a large corpus of U.S. State Department cables from the 1970s, demonstrating that it can discover both well-known and obscure (but significant) events, as well as relevant documents. We anticipate that Capsule, and our visualization tool, will be useful for historians, political scientists, and journalists who wish to explore and understand large corpora of documents. This is increasingly important—the U.S. State Department alone produces around two billion e-mails annually.

Abstract

Convolutional Neural Networks (CNNs) have shown to yield very strong results in several Computer Vision tasks. Their application to language has received much less attention, and it has mainly focused on static classification tasks, such as sentence classification for Sentiment Analysis or relation extraction. In this work, we study the application of CNNs to language modeling, a dynamic, sequential prediction task that needs models to capture local as well as long-range dependency information. Our contribution is twofold. First, we show that CNNs achieve 11-26% better absolute performance than feed-forward neural language models, demonstrating their potential for language representation even in sequential tasks. As for recurrent models, our model outperforms RNNs but is below state of the art LSTM models. Second, we gain some understanding of the behavior of the model, showing that CNNs in language act as feature detectors at a high level of abstraction, like in Computer Vision, and that the model can profitably use information from as far as 16 words before the target.

1 Introduction

Convolutional Neural Networks (CNNs) are the family of neural network models that feature a type of layer known as the convolutional layer. This layer can extract features by convolving a learnable filter (or kernel) along different positions of a vectorial input.

CNNs have been successfully applied in Computer Vision in many different tasks, including object recognition, scene parsing, and action recognition (Gu et al., 2015), but they have received less attention in NLP. They have been somewhat explored in *static classification tasks* where the model is provided with a full linguistic unit as input (e.g. a sentence) and classes are treated as independent of each other. Examples of this are sentence or document classification for tasks such as Sentiment Analysis or Topic Categorization (Kalchbrenner et al., 2014; Kim, 2014), sentence matching (Hu et al., 2014), and relation extraction (Nguyen and Grishman, 2015). However, their application to *sequential prediction tasks*, where the input is construed to be part of a sequence (for example, language modeling or POS tagging), has been rather limited (with exceptions, such as Collobert et al. (2011)). The main contribution of this paper is a systematic evaluation of CNNs in the context of a prominent sequential prediction task, namely, language modeling.

Statistical language models are a crucial component in many NLP applications, such as Automatic Speech Recognition, Machine Translation, and Information Retrieval. Here, we study the problem under the standard formulation of learning to predict the upcoming token given its previous context. One successful approach to this problem relies on counting the number of occurrences of n-grams while using smoothing and back-off techniques to estimate the probability of an upcoming word (Kneser and Ney, 1995). However, since each individual word is treated independently of the others, n-gram models fail to capture semantic relations between words. In contrast, neural network language models (Bengio et al., 2006) learn to predict the up-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1153–1162,
Austin, Texas, November 1-5, 2016.

coming word given the previous context while embedding the vocabulary in a continuous space that can represent the similarity structure between words. Both feed-forward (Schwenk, 2007) and recurrent neural networks (Mikolov et al., 2010) have been shown to outperform n-gram models in various setups (Mikolov et al., 2010; Hai Son et al., 2011). These two types of neural networks make different architectural decisions. Recurrent networks take one token at a time together with a hidden "memory" vector as input and produce a prediction and an updated hidden vector for the next time step. In contrast, feed-forward language models take as input the last n tokens, where n is a fixed window size, and use them jointly to predict the upcoming word.

In this paper we define and explore CNN-based language models and compare them with both feed-forward and recurrent neural networks. Our results show a 11-26% perplexity reduction of the CNN with respect to the feed-forward language model, comparable or higher performance compared to similarly-sized recurrent models, and lower performance with respect to larger, state-of-the-art recurrent language models (LSTMs as trained in Zaremba et al. (2014)).

Our second contribution is an analysis of the kind of information learned by the CNN, showing that the network learns to extract a combination of grammatical, semantic, and topical information from tokens of all across the input window, even those that are the farthest from the target.

2 Related Work

Convolutional Neural Networks (CNNs) were originally designed to deal with hierarchical representation in Computer Vision (LeCun and Bengio, 1995). Deep convolutional networks have been successfully applied in image classification and understanding (Simonyan and Zisserman, 2014; He et al., 2015). In such systems the convolutional kernels learn to detect visual features at both local and more abstract levels.

In NLP, CNNs have been mainly applied to static classification tasks for discovering latent structures in text. Kim (2014) uses a CNN to tackle sentence classification, with competitive results. The same work also introduces kernels with varying window sizes to learn complementary features at different aggregation levels. Kalchbrenner et al. (2014) propose a convolutional architecture for sentence representation that vertically stacks multiple convolution layers, each of which can learn independent convolution kernels. CNNs with similar structures have also been applied to other classification tasks, such as semantic matching (Hu et al., 2014), relation extraction (Nguyen and Grishman, 2015), and information retrieval (Shen et al., 2014). In contrast, Collobert et al. (2011) explore a CNN architecture to solve various sequential and non-sequential NLP tasks such as part-of-speech tagging, named entity recognition and also language modeling. This is perhaps the work that is closest to ours in the existing literature. However, their model differs from ours in that it uses a max-pooling layer that picks the most activated feature across time, thus ignoring temporal information, whereas we explicitly avoid doing so. More importantly, the language models trained in that work are only evaluated through downstream tasks and through the quality of the learned word embeddings, but not on the sequence prediction task itself, as we do here.

Besides being applied to word-based sequences, the convolutional layers have also been used to model sequences at the character level. Kim et al. (2015) propose a recurrent language model that replaces the word-indexed projection matrix with a convolution layer fed with the character sequence that constitutes each word to find morphological patterns. The main difference between that work and ours is that we consider words as the smallest linguistic unit, and thus apply the convolutional layer at the word level.

Statistical language modeling, the task we tackle, differs from most of the tasks where CNNs have been applied before in multiple ways. First, the input typically consists of incomplete sequences of words rather than complete sentences. Second, as a classification problem, it features an extremely large number of classes (the words in a large vocabulary). Finally, temporal information, which can be safely discarded in many settings with little impact in performance, is critical here: An n-gram appearing close to the predicted word may be more informative, or yield different information, than the same n-gram appearing several tokens earlier.

3 Models

Our model is constructed by extending a feed-forward language model (FFLM) with convolutional layers. In what follows, we first explain the implementation of the base FFLM and then describe the CNN model that we study.

3.1 Baseline FFLM

Our baseline feed-forward language model (FFLM) is almost identical to the original model proposed by Bengio et al. (2006), with only slight changes to push its performance as high as we can, producing a very strong baseline. In particular, we extend it with highway layers and use Dropout as regularization. The model is illustrated in Figure 1 and works as follows. First, each word in the input n-gram is mapped to a low-dimensional vector (viz. embedding) though a shared lookup table. Next, these word vectors are concatenated and fed to a highway layer (Srivastava et al., 2015). Highway layers improve the gradient flow of the network by computing as output a convex combination between its input (called the *carry*) and a traditional non-linear transformation of it (called the *transform*). As a result, if there is a neuron whose gradient cannot flow through the transform component (e.g., because the activation is zero), it can still receive the back-propagation update signal through the carry gate. We empirically observed the usage of a single highway layer to significantly improve the performance of the model. Even though a systematic evaluation of this aspect is beyond the scope of the current paper, our empirical results demonstrate that the resulting model is a very competitive one (see Section 4).

Finally, a softmax layer computes the model prediction for the upcoming word. We use ReLU for all non-linear activations, and Dropout (Hinton et al., 2012) is applied between each hidden layer.

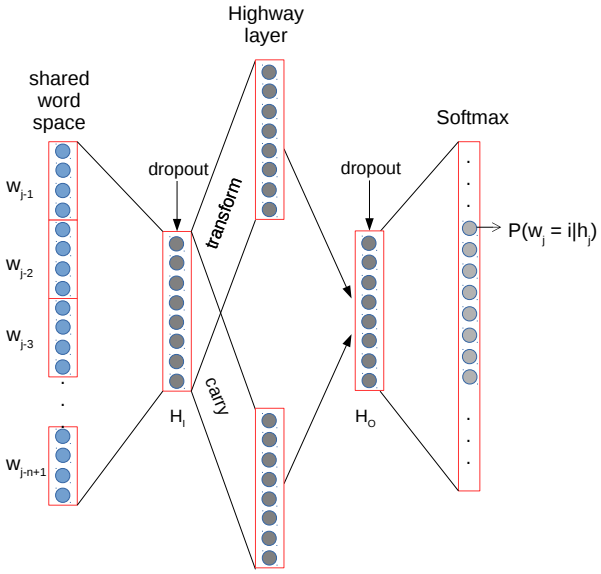

Figure 1: Overview of baseline FFLM.

3.2 CNN and variants

The proposed CNN network is produced by injecting a convolutional layer right after the words in the input are projected to their embeddings (Figure 2). Rather than being concatenated into a long vector, the embeddings $x_i \in \mathbb{R}^k$ are concatenated transversally producing a matrix $x_{1:n} \in \mathbb{R}^{n \times k}$, where n is the size of the input and k is the embedding size. This matrix is fed to a time-delayed layer, which convolves a sliding window of w input vectors centered on each word vector using a parameter matrix $W \in \mathbb{R}^{w \times k}$. Convolution is performed by taking the dot-product between the kernel matrix W and each sub-matrix $x_{i-w/2:i+w/2}$ resulting in a scalar value for each position i in input context. This value represents how much the words encompassed by the window match the feature represented by the filter W. A ReLU activation function is applied subsequently so negative activations are discarded. This operation is repeated multiple times using various kernel matrices W, learning different features independently. We tie the number of learned kernels to be the same as the embedding dimensionality k, such that the output of this stage will be another matrix of dimensions $n \times k$ containing the activations for each kernel at each time step. The number of kernels was tied to the embedding size for two reasons, one practical, namely, to limit the hyper parameter search, one methodological, namely, to keep the network structure identical to that of the baseline feed-forward model.

Next, we add a batch normalization stage immediately after the convolutional output, which facilitates learning by addressing the internal covariate

shift problem and regularizing the learned representations (Ioffe and Szegedy, 2015).

Finally, this feature matrix is directly fed into a fully connected layer that can project the extracted features into a lower-dimensional representation. This is different from previous work, where a max-over-time pooling operation was used to find the most activated feature in the time series. Our choice is motivated by the fact that the max pooling operator loses the specific position where the feature was detected, which is important for word prediction.

After this initial convolutional layer, the network proceeds identically to the FFNN by feeding the produced features into a highway layer, and then, to a softmax output.

This is our basic CNN architecture. We also experiment with three expansions to the basic model, as follows. First, we generalize the CNN by extending the shallow linear kernels with deeper multilayer perceptrons, in what is called a MLP Convolution (**MLPConv**) structure (Lin et al., 2013). This allows the network to produce non-linear filters, and it has achieved state-of-the-art performance in object recognition while reducing the number of total layers compared to other mainstream networks. Concretely, we implement MLPConv networks by using another convolutional layer with a 1×1 kernel on top of the convolutional layer output. This results in an architecture that is exactly equivalent to sliding a one-hidden-layer MLP over the input. Notably, we do not include the global pooling layer in the original Network-in-Network structure (Lin et al., 2013).

Second, we explore stacking convolutional layers on top of each other (Multi-layer CNN or **ML-CNN**) to connect the local features into broader regional representations, as commonly done in computer vision. While this proved to be useful for sentence representation (Kalchbrenner et al., 2014), here we have found it to be rather harmful for language modeling, as shown in Section 4. It is important to note that, in ML-CNN experiments, we stack convolutions with the same kernel size and number of kernels on top of each other, which is to be distinguished from the MLPConv that refers to the deeper structure in each CNN layer mentioned above.

Finally, we consider combining features learned through different kernel sizes (**COM**), as depicted in Figure 3. For example, we can have a combination of kernels that learn filters over 3-grams with others that learn over 5-grams. This is achieved simply by applying in parallel two or more sets of kernels to the input and concatenating their respective outputs (Kim, 2014).

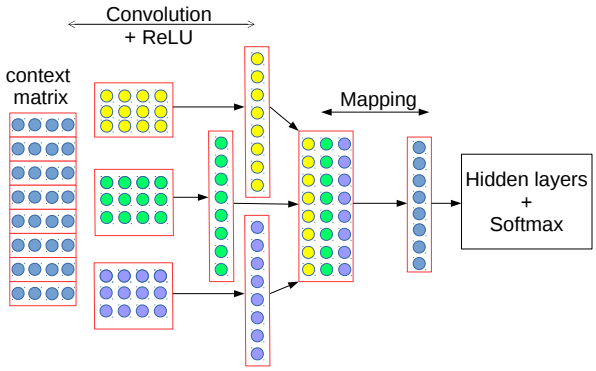

Figure 2: Convolutional layer on top of the context matrix.

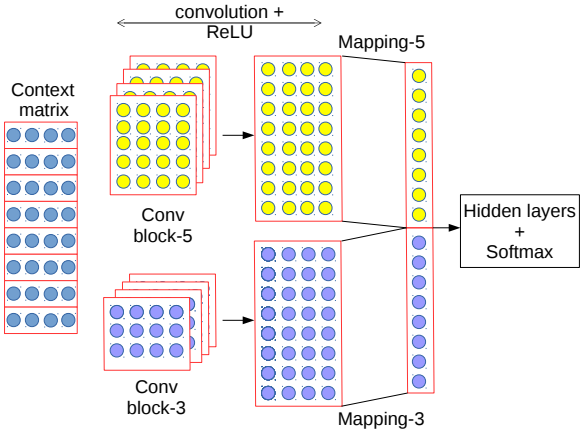

Figure 3: Combining kernels with different sizes. We concatenate the outputs of 2 convolutional blocks with kernel size of 5 and 3 respectively.

4 Experiments

We evaluate our model on three English corpora of different sizes and genres, the first two of which have been used for language modeling evaluation before. The **Penn Treebank** contains one million words of newspaper text with 10K words in the vocabulary. We reuse the preprocessing and training/test/validation division from Mikolov et

al. (2014). **Europarl-NC** is a 64-million word corpus that was developed for a Machine Translation shared task (Bojar et al., 2015), combining Europarl data (from parliamentary debates in the European Union) and News Commentary data. We preprocessed the corpus with tokenization and true-casing tools from the Moses toolkit (Koehn et al., 2007). The vocabulary is composed of words that occur at least 3 times in the training set and contains approximately 60K words. We use the validation and test set of the MT shared task. Finally, we took a subset of the **ukWaC** corpus, which was constructed by crawling UK websites (Baroni et al., 2009). The training subset contains 200 million words and the vocabulary consists of the 200K words that appear more than 5 times in the training subset. The validation and test sets are different subsets of the ukWaC corpus, both containing 120K words. We preprocessed the data similarly to what we did for Europarl-NC.

We train our models using Stochastic Gradient Descent (SGD), which is relatively simple to tune compared to other optimization methods that involve additional hyper parameters (such as alpha in RMSprop) while being still fast and effective. SGD is commonly used in similar work (Devlin et al., 2014; Zaremba et al., 2014; Sukhbaatar et al., 2015). The learning rate is kept fixed during a single epoch, but we reduce it by a fixed proportion every time the validation perplexity increases by the end of the epoch. The values for learning rate, learning rate shrinking and mini-batch sizes as well as context size are fixed once and for all based on insights drawn from previous work (Hai Son et al., 2011; Sukhbaatar et al., 2015; Devlin et al., 2014) as well as experimentation with the Penn Treebank validation set.

Specifically, the learning rate is set to 0.05, with mini-batch size of 128 (we do not take the average of loss over the batch, and the training set is shuffled). We multiply the learning rate by 0.5 every time we shrink it and clip the gradients if their norm is larger than 12. The network parameters are initialized randomly on a range from -0.01 to 0.01 and the context size is set to 16. In Section 6 we show that this large context window is fully exploited.

For the base FFNN and CNN we varied embedding sizes (and thus, number of kernels) $k = 128, 256$. For $k = 128$ we explore the simple CNN, incrementally adding MLPConv and COM variations (in that order) and, alternatively, using a ML-CNN. For $k = 256$, we only explore the former three alternatives (i.e. all but the ML-CNN). For the kernel size, we set it to $w = 3$ words for the simple CNN (out of options $3, 5, 7, 9$), whereas for the COM variant we use $w = 3$ and 5, based on experimentation on PTB. However, we observed the models to be generally robust to this parameter. Dropout rates are tuned specifically for each combination of model and dataset based on the validation perplexity. We also add small dropout ($p = 0.05$–0.15) when we train the networks on the smaller corpus (Penn Treebank).

The experimental results for recurrent neural network language models, such as Recurrent Neural Networks (RNN) and Long-Short Term Memory models (LSTM), on the Penn Treebank are quoted from previous work; for Europarl-NC, we train our own models (we also report the performance of these in-house trained RNN and LSTM models on the Penn Treebank for reference). Specifically, we train LSTMs with embedding size $k = 256$ and number of layers $L = 2$ as well as $k = 512$ with $L = 1, 2$. We train one RNN with $k = 512$ and $L = 2$. To train these models, we use the published source code from Zaremba et al. (2014). Our own models are also implemented in Torch7 for easier comparison.[1] Finally, we selected the best performing convolutional and recurrent language models on Europarl-NC and the Baseline FFLM to be evaluated on the ukWaC corpus.

For all models trained on Europarl-NC and ukWaC, we speed up training by approximating the softmax with Noise Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2010), with the parameters being set following previous work (Chen et al., 2015). Concretely, for each predicted word, we sample 10 words from the unigram distribution, and the normalization factor is such that $\ln Z = 9$. [2]

For comparison, we also implemented a simpler version of the FFNN without dropout and highway layers (Bengio et al., 2006). These networks have two hidden layers (Arisoy et al., 2012) with the size

[1] Available at https://github.com/quanpn90/NCE_CNNLM.

[2] We also experimented with Hierarchical Softmax (Mikolov et al., 2011) and found out that the NCE gave better performance in terms of speed and perplexity.

of 2 times the embedding size (k), thus having the same number of parameters as our baseline.

5 Results

Our experimental results are summarized in Table 1.

First of all, we can see that, even though the FFNN gives a very competitive performance,[3] the addition of convolutional layers clearly improves it even further. Concretely, we observe a solid 11-26% reduction of perplexity compared to the feed-forward network after using MLP Convolution, depending on the setup and corpus. CNN alone yields a sizable improvement (5-24%), while MLP-Conv, in line with our expectations, adds another approximately 2-5% reduction in perplexity. A final (smaller) improvement comes from combining kernels of size 3 and 5, which can be attributed to a more expressive model that can learn patterns of n-grams of different sizes. In contrast to the successful two variants above, the multi-layer CNN did not help in better capturing the regularities of text, but rather the opposite: the more convolutional layers were stacked, the worse the performance. This also stands in contrast to the tradition of convolutional networks in Computer Vision, where using very deep convolutional neural networks is key to having better models. Deep convolution for text representation is in contrast rather rare, and to our knowledge it has only been successfuly applied to sentence representation (Kalchbrenner et al., 2014). We conjecture that the reason why deep CNNs may not be so effective for language could be the effect of the convolution on the data: The convolution output for an image is akin to a new, more abstract image, which yet again can be subject to new convolution operations, whereas the textual counterpart may no longer have the same properties, in the relevant aspects, as the original linguistic input.

Regarding the comparison with a stronger LSTM, our models can perform competitively under the same embedding dimension (e.g. see $k = 256$ of $k = 512$) on the first two datasets. However, the LSTM can be easily scaled using larger models, as shown in Zaremba et al. (2014), which gives the best known results to date. This is not an option for our model, which heavily overfits with large hidden layers (around 1000) even with very large dropout values. Furthermore, the experiments on the larger ukWaC corpus show an even clearer advantage for the LSTM, which seems to be more efficient at harnessing this volume of data, than in the case of the two smaller corpora.

To sum up, we have established that the results of our CNN model are well above those of simple feed forward networks and recurrent neural networks. While they are below state of the art LSTMs, they are able to perform competitively with them for small and moderate-size models. Scaling to larger sizes may be today the main roadblock for CNNs to reach the same performances as large LSTMs in language modeling.

6 Model Analysis

In what follows, we obtain insights into the inner workings of the CNN by looking into the linguistic patterns that the kernels learn to extract and also studying the temporal information extracted by the network in relation to its prediction capacity.

Learned patterns To get some insight into the kind of patterns that each kernel is learning to detect, we fed trigrams from the validation set of the Penn Treebank to each of the kernels, and extracted the ones that most highly activated the kernel, similarly to what was done in Kalchbrenner et al. (2014). Some examples are shown in Figure 4. Since the word windows are made of embeddings, we can expect patterns with similar embeddings to have close activation outputs. This is borne out in the analysis: The kernels specialize in distinct features of the data, including more syntactic-semantic constructions (cf. the "comparative kernel" including *as ... as* patterns, but also *of more than*) and more lexical or topical features (cf. the "ending-in-month-name" kernel). Even in the more lexicalized features, however, we see linguistic regularities at different levels being condensed in a single kernel: For instance, the "spokesman" kernel detects phrases consisting of an indefinite determiner, a company name (or the word *company* itself) and the word "spokesman". We hypothesize that the convolutional layer adds an "I identify one specific feature, but at a high level of

[3] In our experiments, increasing the number of fully connected layers of the FFNN is harmful. Two hidden layers with highway connections is the best setting we could find.

abstraction" dimension to a feed-forward neural network, similarly to what has been observed in image classification (Krizhevsky et al., 2012).

Temporal information To the best of our knowledge, the longest context used in feed-forward language models is 10 tokens (Hai Son et al., 2012),

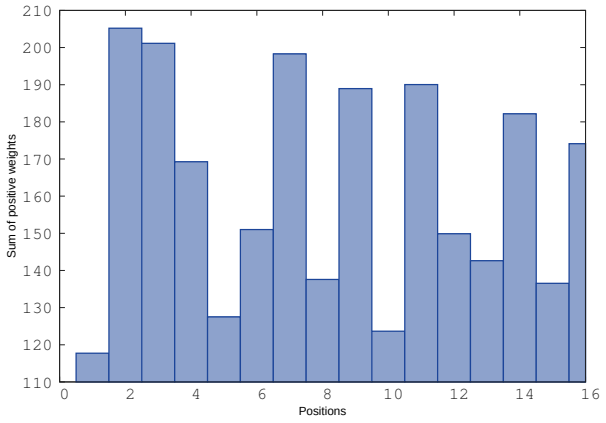

Figure 5: The distribution of positive weights over context positions, where 1 is the position closest to the predicted word.

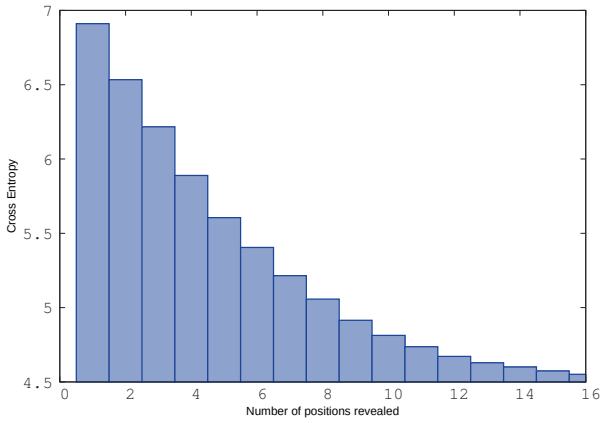

Figure 6: Perplexity change over position, by incrementally revealing the Mapping's weights corresponding to each position.

where no significant change in terms of perplexity was observed for bigger context sizes, even though in that work only same-sentence contexts were considered. In our experiments, we use a larger context size of 16 while removing the sentence boundary limit (as commonly done in n-gram language models) such that the network can take into account the words in the previous sentences.

To analyze whether all this information was effectively used, we took our best model, the CNN+MLPConv+COM model with embedding size of 256 (fifth line of second block in Table 1), and we identified the weights in the model that map the convolutional output (of size $n \times k$) to a lower dimensional vector (the "mapping" layer in Figure 2). Recall that the output of the convolutional layer is a matrix indexed by time step and kernel index containing the activation of the kernel when convolved with a window of text centered around the word at the given time step. Thus, output units of the above mentioned mapping predicate over an ensemble of kernel activations for each time step. We can identify the patterns that they learn to detect by extracting the time-kernel combinations for which they have positive weights (since we have ReLU activations, negative weights are equivalent to ignoring a feature). First, we asked ourselves whether these units tend to be more focused on the time steps closer to the target or not. To test this, we calculated the sum of the positive weights for each position in time using an average of the mappings that correspond to each output unit. The results are shown in Figure 5. As could be expected, positions that are close to the token to be predicted have many active units (local context is very informative; see positions 2-4). However, surprisingly, positions that are actually far from the target are also quite active. It seems like the CNN is putting quite a lot of effort on characterizing long-range dependencies.

Next, we checked that the information extracted from the positions that are far in the past are actually used for prediction. To measure this, we artificially lesioned the network so it would only read the features from a given range of time steps (words in the context). To lesion the network we manually masked the weights of the mapping that focus on times outside of the target range by setting them to zero. We started using only the word closest to the final position and sequentially unmasked earlier positions until the full context was used again. The result of this experiment is presented in Figure 6, and it confirms our previous observation that positions that are the farthest away contribute to the predictions of the model. The perplexity drops dramatically as the first positions are unmasked, and then decreases more slowly, approximately in the form of a power law ($f(x) \propto x^{-0.9}$). Even though the effect is smaller, the last few positions still contribute to the final perplexity.

7 Conclusion

In this work, we have investigated the potential of Convolutional Neural Networks for one prominent NLP task, language modeling, a sequential predic-

tion task. We incorporate a CNN layer on top of a strong feed-forward model enhanced with modern techniques like Highway Layers and Dropout. Our results show a solid 11-26% reduction in perplexity with respect to the feed-forward model across three corpora of different sizes and genres when the model uses MLP Convolution and combines kernels of different window sizes. However, even without these additions we show CNNs to effectively learn language patterns that allow it to significantly decrease the model perplexity.

In our view, this improvement responds to two key properties of CNNs, highlighted in the analysis. First, as we have shown, they are able to integrate information from larger context windows, using information from words that are as far as 16 positions away from the predicted word. Second, as we have qualitatively shown, the kernels learn to detect specific patterns at a high level of abstraction. This is analogous to the role of convolutions in Computer Vision. The analogy, however, has limits; for instance, a deeper model stacking convolution layers harms performance in language modeling, while it greatly helps in Computer Vision. We conjecture that this is due to the differences in the nature of visual vs. linguistic data. The convolution creates sort of abstract images that still retain significant properties of images. When applied to language, it detects important textual features but distorts the input, such that it is not text anymore.

As for recurrent models, even if our model outperforms RNNs, it is well below state-of-the-art LSTMs. Since CNNs are quite different in nature, we believe that a fruitful line of future research could focus on integrating the convolutional layer into a recurrent structure for language modeling, as well as other sequential problems, perhaps capturing the best of both worlds.

Acknowledgments

Generalizing and Hybridizing Count-based and Neural Language Models

Graham Neubig[†] and **Chris Dyer**[‡]

[‡]Google DeepMind, United Kingdom

Abstract

Language models (LMs) are statistical models that calculate probabilities over sequences of words or other discrete symbols. Currently two major paradigms for language modeling exist: count-based n-gram models, which have advantages of scalability and test-time speed, and neural LMs, which often achieve superior modeling performance. We demonstrate how both varieties of models can be unified in a single modeling framework that defines a set of probability distributions over the vocabulary of words, and then dynamically calculates mixture weights over these distributions. This formulation allows us to create novel hybrid models that combine the desirable features of count-based and neural LMs, and experiments demonstrate the advantages of these approaches.[1]

1 Introduction

Language models (LMs) are statistical models that, given a sentence $w_1^I := w_1, \ldots, w_I$, calculate its probability $P(w_1^I)$. LMs are widely used in applications such as machine translation and speech recognition, and because of their broad applicability they have also been widely studied in the literature. The most traditional and broadly used language modeling paradigm is that of count-based LMs, usually smoothed n-grams (Witten and Bell, 1991; Chen and Goodman, 1996). Recently, there has been a focus on LMs based on neural networks (Nakamura et al., 1990; Bengio et al., 2006; Mikolov et al., 2010), which have shown impressive improvements in performance over count-based LMs. On the other hand, these neural LMs also come at the cost of increased computational complexity at both training and test time, and even the largest reported neural LMs (Chen et al., 2015; Williams et al., 2015) are trained on a fraction of the data of their count-based counterparts (Brants et al., 2007).

In this paper we focus on a class of LMs, which we will call *mixture of distributions LMs* (MODLMs; §2). Specifically, we define MODLMs as all LMs that take the following form, calculating the probabilities of the next word in a sentence w_i given preceding context $\boldsymbol{c}$ according to a mixture of several component probability distributions $P_k(w_i|\boldsymbol{c})$:

$$P(w_i|\boldsymbol{c}) = \sum_{k=1}^{K} \lambda_k(\boldsymbol{c}) P_k(w_i|\boldsymbol{c}). \quad (1)$$

Here, $\lambda_k(\boldsymbol{c})$ is a function that defines the mixture weights, with the constraint that $\sum_{k=1}^{K} \lambda_k(\boldsymbol{c}) = 1$ for all $\boldsymbol{c}$. This form is not new in itself, and widely used both in the calculation of smoothing coefficients for n-gram LMs (Chen and Goodman, 1996), and interpolation of LMs of various varieties (Jelinek and Mercer, 1980).

The main contribution of this paper is to demonstrate that depending on our definition of $\boldsymbol{c}$, $\lambda_k(\boldsymbol{c})$, and $P_k(w_i|\boldsymbol{c})$, Eq. 1 can be used to describe not only n-gram models, but also feed-forward (Nakamura et al., 1990; Bengio et al., 2006; Schwenk, 2007) and

Austin, Texas, November 1-5, 2016.

recurrent (Mikolov et al., 2010; Sundermeyer et al., 2012) neural network LMs (§3). This observation is useful theoretically, as it provides a single mathematical framework that encompasses several widely used classes of LMs. It is also useful practically, in that this new view of these traditional models allows us to create new models that combine the desirable features of n-gram and neural models, such as:

neurally interpolated n-gram LMs (§4.1), which learn the interpolation weights of n-gram models using neural networks, and

neural/n-gram hybrid LMs (§4.2), which add a count-based n-gram component to neural models, allowing for flexibility to add large-scale external data sources to neural LMs.

We discuss learning methods for these models (§5) including a novel method of randomly dropping out more easy-to-learn distributions to prevent the parameters from falling into sub-optimal local minima.

Experiments on language modeling benchmarks (§6) find that these models outperform baselines in terms of performance and convergence speed.

2 Mixture of Distributions LMs

As mentioned above, MODLMs are LMs that take the form of Eq. 1. This can be re-framed as the following matrix-vector multiplication:

$$\boldsymbol{p}_{\boldsymbol{c}}^\intercal = D_{\boldsymbol{c}} \boldsymbol{\lambda}_{\boldsymbol{c}}^\intercal,$$

where $\boldsymbol{p}_{\boldsymbol{c}}$ is a vector with length equal to vocabulary size, in which the jth element $p_{\boldsymbol{c},j}$ corresponds to $P(w_i = j|\boldsymbol{c})$, $\boldsymbol{\lambda}_{\boldsymbol{c}}$ is a size K vector that contains the mixture weights for the distributions, and $D_{\boldsymbol{c}}$ is a J-by-K matrix, where element $d_{\boldsymbol{c},j,k}$ is equivalent to the probability $P_k(w_i = j|\boldsymbol{c})$.[2] An example of this formulation is shown in Fig. 1.

Note that all columns in D represent probability distributions, and thus must sum to one over the J words in the vocabulary, and that all $\boldsymbol{\lambda}$ must sum to 1 over the K distributions. Under this condition, the vector $\boldsymbol{p}$ will represent a well-formed probability distribution as well. This conveniently allows us to calculate the probability of a single word $w_i = j$ by calculating the product of the jth row of $D_{\boldsymbol{c}}$ and $\boldsymbol{\lambda}_{\boldsymbol{c}}^\intercal$

$$P_k(w_i = j|\boldsymbol{c}) = \boldsymbol{d}_{\boldsymbol{c},j} \boldsymbol{\lambda}_{\boldsymbol{c}}^\intercal.$$

In the sequel we show how this formulation can be used to describe several existing LMs (§3) as well as several novel model structures that are more powerful and general than these existing models (§4).

[2] We omit the subscript $\boldsymbol{c}$ when appropriate.

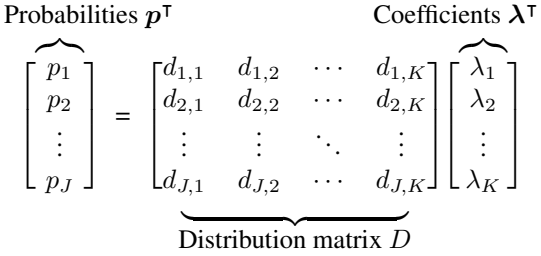

Figure 1: MODLMs as linear equations

3 Existing LMs as Linear Mixtures

3.1 n-gram LMs as Mixtures of Distributions

First, we discuss how count-based interpolated n-gram LMs fit within the MODLM framework.

Maximum likelihood estimation: n-gram models predict the next word based on the previous N-1 words. In other words, we set $\boldsymbol{c} = w_{i-N+1}^{i-1}$ and calculate $P(w_i|w_{i-N+1}^{i-1})$. The maximum-likelihood (ML) estimate for this probability is

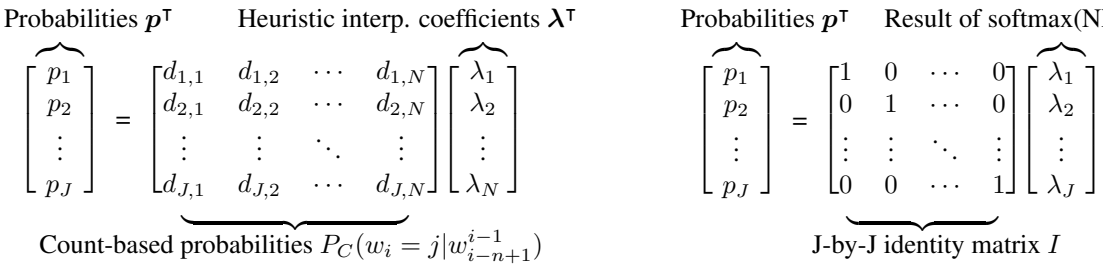
$$P_{ML}(w_i|w_{i-N+1}^{i-1}) = c(w_{i-N+1}^{i})/c(w_{i-N+1}^{i-1}),$$

where $c(\cdot)$ counts frequency in the training corpus.

Interpolation: Because ML estimation assigns zero probability to word sequences where $c(w_{i-N+1}^{i}) = 0$, n-gram models often interpolate the ML distributions for sequences of length 1 to N. The simplest form is static interpolation

$$P(w_i|w_{i-n+1}^{i-1}) = \sum_{n=1}^{N} \lambda_{S,n} P_{ML}(w_i|w_{i-n+1}^{i-1}). \quad (2)$$

$\boldsymbol{\lambda}_S$ is a vector where $\lambda_{S,n}$ represents the weight put on the distribution $P_{ML}(w_i|w_{i-n+1}^{i-1})$. This can be expressed as linear equations (Fig. 2a) by setting the nth column of D to the ML distribution $P_{ML}(w_i|w_{i-n+1}^{i-1})$, and $\boldsymbol{\lambda}(\boldsymbol{c})$ equal to $\boldsymbol{\lambda}_S$.



(a) Interpolated n-grams as MODLMs

(b) Neural LMs as MODLMs

Figure 2: Interpretations of existing models as mixtures of distributions

Static interpolation can be improved by calculating $\boldsymbol{\lambda}(\boldsymbol{c})$ dynamically, using heuristics based on the frequency counts of the context (Good, 1953; Katz, 1987; Witten and Bell, 1991). These methods define a context-sensitive fallback probability $\alpha(w_{i-n+1}^{i-1})$ for order n models, and recursively calculate the probability of the higher order models from the lower order models:

$$P(w_i|w_{i-n+1}^{i-1}) = \alpha(w_{i-n+1}^{i-1})P(w_i|w_{i-n+2}^{i-1}) + (1 - \alpha(w_{i-n+1}^{i-1}))P_{ML}(w_i|w_{i-n+1}^{i-1}). \quad (3)$$

To express this as a linear mixture, we convert $\alpha(w_{i-n+1}^{i-1})$ into the appropriate value for $\lambda_n(w_{i-N+1}^{i-1})$. Specifically, the probability assigned to each $P_{ML}(w_i|w_{i-n+1}^{i-1})$ is set to the product of the fallbacks α for all higher orders and the probability of not falling back $(1 - \alpha)$ at the current level:

$$\lambda_n(w_{i-N+1}^{i-1}) = (1-\alpha(w_{i-n+1}^{i-1})) \prod_{\tilde{n}=n+1}^{N} \alpha(w_{i-\tilde{n}+1}^{i-1}).$$

Discounting: The widely used technique of discounting (Ney et al., 1994) defines a fixed discount d and subtracts it from the count of each word before calculating probabilities:

$$P_D(w_i|w_{i-n+1}^{i-1}) = (c(w_{i-n+1}^{i}) - d)/c(w_{i-n+1}^{i-1}).$$

Discounted LMs then assign the remaining probability mass after discounting as the fallback probability

$$\beta_D(w_{i-n+1}^{i-1}) = 1 - \sum_{j=1}^{J} P_D(w_i = j|w_{i-n+1}^{i-1}),$$
$$P(w_i|w_{i-n+1}^{i-1}) = \beta_D(w_{i-n+1}^{i-1})P(w_i|w_{i-n+2}^{i-1}) + P_D(w_i|w_{i-n+1}^{i-1}). \quad (4)$$

In this case, $P_D(\cdot)$ does not add to one, and thus violates the conditions for MODLMs stated in §2, but it is easy to turn discounted LMs into interpolated LMs by normalizing the discounted distribution:

$$P_{ND}(w_i|w_{i-n+1}^{i-1}) = \frac{P_D(w_i|w_{i-n+1}^{i-1})}{\sum_{j=1}^{J} P_D(w_i = j|w_{i-n+1}^{i-1})},$$

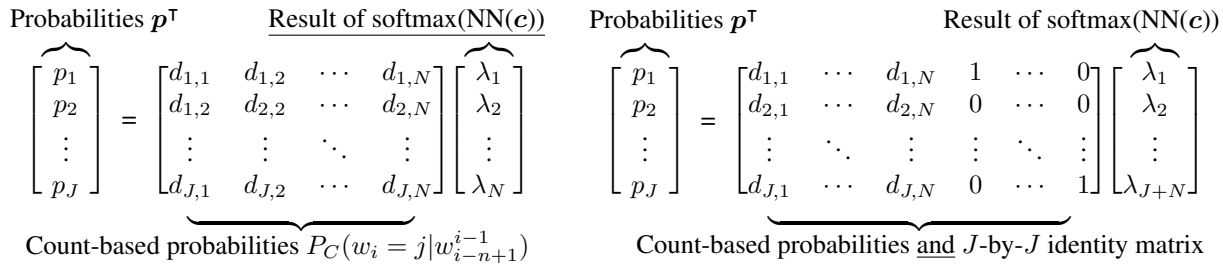
which allows us to replace $\beta(\cdot)$ for $\alpha(\cdot)$ and $P_{ND}(\cdot)$ for $P_{ML}(\cdot)$ in Eq. 3, and proceed as normal.

Kneser–Ney (KN; Kneser and Ney (1995)) and Modified KN (Chen and Goodman, 1996) smoothing further improve discounted LMs by adjusting the counts of lower-order distributions to more closely match their expectations as fallbacks for higher order distributions. Modified KN is currently the defacto standard in n-gram LMs despite occasional improvements (Teh, 2006; Durrett and Klein, 2011), and we will express it as $P_{KN}(\cdot)$.

3.2 Neural LMs as Mixtures of Distributions

In this section we demonstrate how neural network LMs can also be viewed as an instantiation of the MODLM framework.

Feed-forward neural network LMs: Feed-forward LMs (Bengio et al., 2006; Schwenk, 2007) are LMs that, like n-grams, calculate the probability of the next word based on the previous words. Given context w_{i-N+1}^{i-1}, these words are converted into real-valued word representation vectors $\boldsymbol{r}_{i-N+1}^{i-1}$, which are concatenated into an overall representation vector $\boldsymbol{q} = \oplus(\boldsymbol{r}_{i-N+1}^{i-1})$, where $\oplus(\cdot)$ is the vector concatenation function. $\boldsymbol{q}$ is then run through a series of affine transforms and nonlinearities defined as function NN($\boldsymbol{q}$) to obtain a vector $\boldsymbol{h}$. For example, for a one-layer neural net-



(a) Neurally interpolated n-gram LMs

(b) Neural/n-gram hybrid LMs

Figure 3: Two new expansions to n-gram and neural LMs made possible in the MODLM framework

work with a tanh non-linearity we can define

$$\text{NN}(\boldsymbol{q}) := \tanh(\boldsymbol{q}W_q + \boldsymbol{b}_q), \tag{5}$$

where W_q and $\boldsymbol{b}_q$ are weight matrix and bias vector parameters respectively. Finally, the probability vector $\boldsymbol{p}$ is calculated using the softmax function $\boldsymbol{p} = \text{softmax}(\boldsymbol{h}W_s + \boldsymbol{b}_s)$, similarly parameterized.

As these models are directly predicting $\boldsymbol{p}$ with no concept of mixture weights $\boldsymbol{\lambda}$, they cannot be interpreted as MODLMs as-is. However, we can perform a trick shown in Fig. 2b, not calculating $\boldsymbol{p}$ directly, but instead calculating mixture weights $\boldsymbol{\lambda} = \text{softmax}(\boldsymbol{h}W_s + \boldsymbol{b}_s)$, and defining the MODLM's distribution matrix D as a J-by-J identity matrix. This is equivalent to defining a linear mixture of J Kronecker δ_j distributions, the jth of which assigns a probability of 1 to word j and zero to everything else, and estimating the mixture weights with a neural network. While it may not be clear why it is useful to define neural LMs in this somewhat roundabout way, we describe in §4 how this opens up possibilities for novel expansions to standard models.

Recurrent neural network LMs: LMs using recurrent neural networks (RNNs) (Mikolov et al., 2010) consider not the previous few words, but also maintain a hidden state summarizing the sentence up until this point by re-defining the net in Eq. 5 as

$$\text{RNN}(\boldsymbol{q}_i) := \tanh(\boldsymbol{q}_i W_q + \boldsymbol{h}_{i-1} W_h + \boldsymbol{b}_q),$$

where $\boldsymbol{q}_i$ is the current input vector and $\boldsymbol{h}_{i-1}$ is the hidden vector at the previous time step. This allows for consideration of long-distance dependencies beyond the scope of standard n-grams, and LMs using RNNs or long short-term memory (LSTM) networks (Sundermeyer et al., 2012) have posted large improvements over standard n-grams and feed-forward models. Like feed-forward LMs, LMs using RNNs can be expressed as MODLMs by predicting $\boldsymbol{\lambda}$ instead of predicting $\boldsymbol{p}$ directly.

4 Novel Applications of MODLMs

This section describes how we can use this framework of MODLMs to design new varieties of LMs that combine the advantages of both n-gram and neural network LMs.

4.1 Neurally Interpolated n-gram Models

The first novel instantiation of MODLMs that we propose is *neurally interpolated n-gram models*, shown in Fig. 3a. In these models, we set D to be the same matrix used in n-gram LMs, but calculate $\boldsymbol{\lambda}(\boldsymbol{c})$ using a neural network model. As $\boldsymbol{\lambda}(\boldsymbol{c})$ is learned from data, this framework has the potential to allow us to learn more intelligent interpolation functions than the heuristics described in §3.1. In addition, because the neural network only has to calculate a softmax over N distributions instead of J vocabulary words, training and test efficiency of these models can be expected to be much greater than that of standard neural network LMs.

Within this framework, there are several design decisions. First, how we decide D: do we use the maximum likelihood estimate P_{ML} or KN estimated distributions P_{KN}? Second, what do we provide as input to the neural network to calculate the mixture weights? To provide the neural net with the same information used by interpolation heuristics used in traditional LMs, we first calculate three features for each of the N contexts w_{i-n+1}^{i-1}: a binary feature indicating whether the context has been observed in the training corpus ($c(w_{i-n+1}^{i-1}) > 0$), the log frequency of the context counts ($\log(c(w_{i-n+1}^{i-1}))$ or

zero for unobserved contexts), and the log frequency of the number of unique words following the context ($\log(u(w_{i-n+1}^{i-1}))$ or likewise zero). When using discounted distributions, we also use the log of the sum of the discounted counts as a feature. We can also optionally use the word representation vector $\boldsymbol{q}$ used in neural LMs, allowing for richer representation of the input, but this may or may not be necessary in the face of the already informative count-based features.

4.2 Neural/n-gram Hybrid Models

Our second novel model enabled by MODLMs is *neural/n-gram hybrid models*, shown in Fig. 3b. These models are similar to neurally interpolated n-grams, but D is augmented with J additional columns representing the Kronecker δ_j distributions used in the standard neural LMs. In this construction, $\boldsymbol{\lambda}$ is still a stochastic vector, but its contents are both the mixture coefficients for the count-based models and direct predictions of the probabilities of words. Thus, the learned LM can use count-based models when they are deemed accurate, and deviate from them when deemed necessary.

This model is attractive conceptually for several reasons. First, it has access to all information used by both neural and n-gram LMs, and should be able to perform as well or better than both models. Second, the efficiently calculated n-gram counts are likely sufficient to capture many phenomena necessary for language modeling, allowing the neural component to focus on learning only the phenomena that are not well modeled by n-grams, requiring fewer parameters and less training time. Third, it is possible to train n-grams from much larger amounts of data, and use these massive models to bootstrap learning of neural nets on smaller datasets.

5 Learning Mixtures of Distributions

While the MODLM formulations of standard heuristic n-gram LMs do not require learning, the remaining models are parameterized. This section discusses the details of learning these parameters.

5.1 Learning MODLMs

The first step in learning parameters is defining our training objective. Like most previous work on LMs (Bengio et al., 2006), we use a negative log-likelihood loss summed over words w_i in every sentence $\boldsymbol{w}$ in corpus $\mathcal{W}$

$$L(\mathcal{W}) = -\sum_{\boldsymbol{w}\in\mathcal{W}}\sum_{w_i\in\boldsymbol{w}} \log P(w_i|\boldsymbol{c}),$$

where $\boldsymbol{c}$ represents all words preceding w_i in $\boldsymbol{w}$ that are used in the probability calculation. As noted in Eq. 2, $P(w_i = j|\boldsymbol{c})$ can be calculated efficiently from the distribution matrix $D_{\boldsymbol{c}}$ and mixture function output $\boldsymbol{\lambda}_{\boldsymbol{c}}$.

Given that we can calculate the log likelihood, the remaining parts of training are similar to training for standard neural network LMs. As usual, we perform forward propagation to calculate the probabilities of all the words in the sentence, back-propagate the gradients through the computation graph, and perform some variant of stochastic gradient descent (SGD) to update the parameters.

5.2 Block Dropout for Hybrid Models

While the training method described in the previous section is similar to that of other neural network models, we make one important modification to the training process specifically tailored to the hybrid models of §4.2.

This is motivated by our observation (detailed in §6.3) that the hybrid models, despite being strictly more expressive than the corresponding neural network LMs, were falling into poor local minima with higher training error than neural network LMs. This is because at the very beginning of training, the count-based elements of the distribution matrix in Fig. 3b are already good approximations of the target distribution, while the weights of the single-word δ_j distributions are not yet able to provide accurate probabilities. Thus, the model learns to set the mixture proportions of the δ elements to near zero and rely mainly on the count-based n-gram distributions.

To encourage the model to use the δ mixture components, we adopt a method called *block dropout* (Ammar et al., 2016). In contrast to standard dropout (Srivastava et al., 2014), which drops out single nodes or connections, block dropout randomly drops out entire subsets of network nodes. In our case, we want to prevent the network from overusing the count-based n-gram distributions, so for a randomly selected portion of the training examples (here, 50%) we disable all n-gram distributions and

force the model to rely on only the δ distributions. To do so, we zero out all elements in $\boldsymbol{\lambda}(\boldsymbol{c})$ that correspond to n-gram distributions, and re-normalize over the rest of the elements so they sum to one.

5.3 Network and Training Details

Finally, we note design details that were determined based on preliminary experiments.

Network structures: We used both feed-forward networks with $\tanh$ non-linearities and LSTM (Hochreiter and Schmidhuber, 1997) networks. Most experiments used single-layer 200-node networks, and 400-node networks were used for experiments with larger training data. Word representations were the same size as the hidden layer. Larger and multi-layer networks did not yield improvements.

Training: We used ADAM (Kingma and Ba, 2015) with a learning rate of 0.001, and minibatch sizes of 512 words. This led to faster convergence than standard SGD, and more stable optimization than other update rules. Models were evaluated every 500k-3M words, and the model with the best development likelihood was used. In addition to the block dropout of §5.2, we used standard dropout with a rate of 0.5 for both feed-forward (Srivastava et al., 2014) and LSTM (Pham et al., 2014) nets in the neural LMs and neural/n-gram hybrids, but not in the neurally interpolated n-grams, where it resulted in slightly worse perplexities.

Features: If parameters are learned on the data used to train count-based models, they will heavily over-fit and learn to trust the count-based distributions too much. To prevent this, we performed 10-fold cross validation, calculating count-based elements of D for each fold with counts trained on the other 9/10. In addition, the count-based contextual features in §4.1 were normalized by subtracting the training set mean, which improved performance.

6 Experiments

6.1 Experimental Setup

In this section, we perform experiments to evaluate the neurally interpolated n-grams (§6.2) and neural/n-gram hybrids (§6.3), the ability of our models to take advantage of information from large data sets (§6.4), and the relative performance compared to post-facto static interpolation of already-trained models (§6.5). For the main experiments, we evaluate on two corpora: the Penn Treebank (PTB) data set prepared by Mikolov et al. (2010),[3] and the first 100k sentences in the English side of the ASPEC corpus (Nakazawa et al., 2015)[4] (details in Tab. 1). The PTB corpus uses the standard vocabulary of 10k words, and for the ASPEC corpus we use a vocabulary of the 20k most frequent words. Our implementation is included as supplementary material.

PTB	Sent	Word	ASP	Sent	Word
train	42k	890k	train	100k	2.1M
valid	3.4k	70k	valid	1.8k	45k
test	3.8k	79k	test	1.8k	46k

Table 1: Data sizes for the PTB and ASPEC corpora.

Dst./Ft.	HEUR	FF	LSTM
ML/C	220.5/265.9	146.6/164.5	144.4/162.7
ML/CR	-	145.7/163.9	142.6/158.4
KN/C	140.8/156.5	138.9/152.5	136.8/151.1
KN/CR	-	136.9/153.0	**135.2/149.1**

Table 2: PTB/ASPEC perplexities for traditional heuristic (HEUR) and proposed neural net (FF or LSTM) interpolation methods using ML or KN distributions, and count (C) or count+word representation (CR) features.

6.2 Results for Neurally Interpolated n-grams

First, we investigate the utility of neurally interpolated n-grams. In all cases, we use a history of $N = 5$ and test several different settings for the models:

Estimation type: $\boldsymbol{\lambda}(\boldsymbol{c})$ is calculated with heuristics (HEUR) or by the proposed method using feed-forward (FF), or LSTM nets.

Distributions: We compare $P_{ML}(\cdot)$ and $P_{KN}(\cdot)$. For heuristics, we use Witten-Bell for ML and the appropriate discounted probabilities for KN.

Input features: As input features for the neural network, we either use only the count-based features (C) or count-based features together with the word representation for the single previous word (CR).

From the results shown in Tab. 2, we can first see that when comparing models using the same set of

[3] http://rnnlm.org/simple-examples.tgz
[4] http://lotus.kuee.kyoto-u.ac.jp/ASPEC/

input distributions, the neurally interpolated model outperforms corresponding heuristic methods. We can also see that LSTMs have a slight advantage over FF nets, and models using word representations have a slight advantage over those that use only the count-based features. Overall, the best model achieves a relative perplexity reduction of 4-5% over KN models. Interestingly, even when using simple ML distributions, the best neurally interpolated n-gram model nearly matches the heuristic KN method, demonstrating that the proposed model can automatically learn interpolation functions that are nearly as effective as carefully designed heuristics.[5]

6.3 Results for Neural/n-gram Hybrids

In experiments with hybrid models, we test a neural/n-gram hybrid LM using LSTM networks with both Kronecker δ and KN smoothed 5-gram distributions, trained either with or without block dropout. As our main baseline, we compare to LSTMs with only δ distributions, which have reported competitive numbers on the PTB data set (Zaremba et al., 2014).[6] We also report results for heuristically smoothed KN 5-gram models, and the best neurally interpolated n-grams from the previous section for reference.

The results, shown in Tab. 3, demonstrate that similarly to previous research, LSTM LMs (2) achieve a large improvement in perplexity over n-gram models, and that the proposed neural/n-gram hybrid method (5) further reduces perplexity by 10-11% relative over this strong baseline.

Comparing models without (4) and with (5) the proposed block dropout, we can see that this method contributes significantly to these gains. To examine this more closely, we show the test perplexity for the three models using δ distributions in Fig. 5, and the amount of the probability mass in $\boldsymbol{\lambda}(\boldsymbol{c})$ assigned to the non-δ distributions in the hybrid models. From this, we can see that the model with block dropout quickly converges to a better result than the LSTM LM, but the model without converges to a worse result, assigning too much probability mass to the dense count-based distributions, demonstrating the learning problems mentioned in §5.2.

It is also of interest to examine exactly why the proposed model is doing better than the more standard methods. One reason can be found in the behavior with regards to low-frequency words. In Fig. 4, we show perplexities for words that appear n times or less in the training corpus, for $n = 10$, $n = 100$, $n = 1000$ and $n = \infty$ (all words). From the results, we can first see that if we compare the baselines, LSTM language models achieve better perplexities overall but n-gram language models tend to perform better on low-frequency words, corroborating the observations of Chen et al. (2015).

	Dist.	Interp.	PPL
(1)	KN	HEUR	140.8/156.5
(2)	δ	LSTM	105.9/116.9
(3)	KN	LSTM	135.2/149.1
(4)	KN,δ	LSTM -BIDO	108.4/130.4
(5)	KN,δ	LSTM +BIDO	95.3 /104.5

Table 3: PTB/ASPEC perplexities for traditional KN (1) and LSTM LMs (2), neurally interpolated n-grams (3), and neural/n-gram hybrid models without (4) and with (5) block dropout.

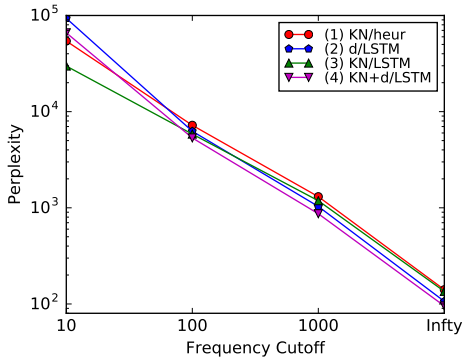


Figure 4: Perplexities of (1) standard n-grams, (2) standard LSTMs, (3) neurally interpolated n-grams, and (4) neural/n-gram hybrids on lower frequency words.

[5]Neurally interpolated n-grams are also more efficient than standard neural LMs, as mentioned in §4.1. While a standard LSTM LM calculated 1.4kw/s on the PTB data, the neurally interpolated models using LSTMs and FF nets calculated 11kw/s and 58kw/s respectively, only slightly inferior to 140kw/s of heuristic KN.

[6]Note that unlike this work, we opt to condition only on in-sentence context, not inter-sentential dependencies, as training through gradient calculations over sentences is more straightforward and because examining the effect of cross-boundary information is not central to the proposed method. Thus our baseline numbers are not directly comparable (i.e. have higher perplexity) to previous reported results on this data, but we still feel that the comparison is appropriate.

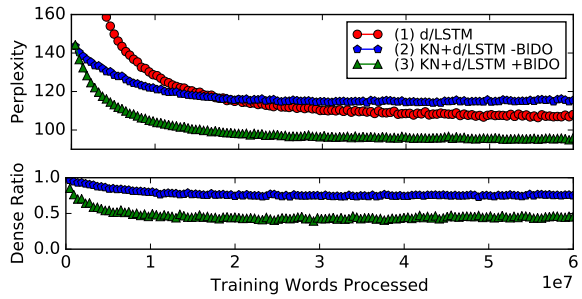

Figure 5: Perplexity and dense distribution ratio of the baseline LSTM LM (1), and the hybrid method without (2) and with (3) block dropout.

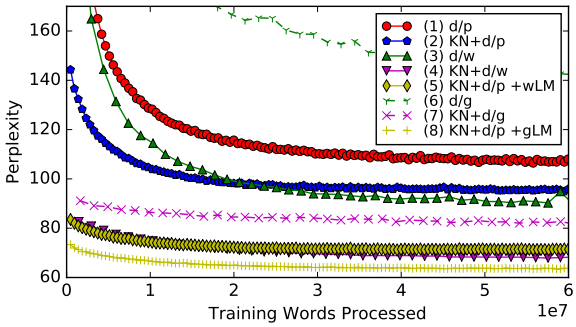

Figure 6: Models trained on PTB (1,2), PTB+WSJ (3,4,5) or PTB+WSJ+GW (6,7,8) using standard neural LMs (1,3,6), neural/n-gram hybrids trained all data (2,4,7), or hybrids trained on PTB with additional n-gram distributions (5,8).

The neurally interpolated n-gram models consistently outperform standard KN-smoothed n-grams, demonstrating their superiority within this model class. In contrast, the neural/n-gram hybrid models tend to follow a pattern more similar to that of LSTM language models, similarly with consistently higher performance.

6.4 Results for Larger Data Sets

To examine the ability of the hybrid models to use counts trained over larger amounts of data, we perform experiments using two larger data sets:

WSJ: The PTB uses data from the 1989 Wall Street Journal, so we add the remaining years between 1987 and 1994 (1.81M sents., 38.6M words).

GW: News data from the English Gigaword 5th Edition (LDC2011T07, 59M sents., 1.76G words).

We incorporate this data either by training net parameters over the whole large data, or by separately training count-based n-grams on each of PTB, WSJ, and GW, and learning net parameters on only PTB data. The former has the advantage of training the net on much larger data. The latter has two main advantages: 1) when the smaller data is of a particular domain the mixture weights can be learned to match this in-domain data; 2) distributions can be trained on data such as Google n-grams (LDC2006T13), which contain n-gram counts but not full sentences.

In the results of Fig. 6, we can first see that the neural/n-gram hybrids significantly outperform the traditional neural LMs in the scenario with larger data as well. Comparing the two methods for incorporating larger data, we can see that the results are mixed depending on the type and size of the data being used. For the WSJ data, training on all data slightly outperforms the method of adding distributions, but when the GW data is added this trend reverses. This can be explained by the fact that the GW data differs from the PTB test data, and thus the effect of choosing domain-specific interpolation coefficients was more prominent.

6.5 Comparison with Static Interpolation

Finally, because the proposed neural/n-gram hybrid models combine the advantages of neural and n-gram models, we compare with the more standard method of training models independently and combining them with static interpolation weights tuned on the validation set using the EM algorithm. Tab. 4 shows perplexities for combinations of a standard neural model (or δ distributions) trained on PTB, and count based distributions trained on PTB, WSJ, and GW are added one-by-one using the standard static and proposed LSTM interpolation methods. From the results, we can see that when only PTB data is used, the methods have similar results, but with the more diverse data sets the proposed method edges out its static counterpart.[7]

[7] In addition to better perplexities, neural/n-gram hybrids are trained in a single pass instead of performing post-facto interpolation, which may give advantages when training for other objectives (Auli and Gao, 2014; Li et al., 2015).

Interp	δ+PTB	+WSJ	+GW
Lin.	**95.1**	70.5	65.8
LSTM	95.3	**68.3**	**63.5**

Table 4: PTB perplexity for interpolation between neural (δ) LMs and count-based models.

7 Related Work

A number of alternative methods focus on interpolating LMs of multiple varieties such as in-domain and out-of-domain LMs (Bulyko et al., 2003; Bacchiani et al., 2006; Gülçehre et al., 2015). Perhaps most relevant is Hsu (2007)'s work on learning to interpolate multiple LMs using log-linear models. This differs from our work in that it learns functions to estimate the fallback probabilities $\alpha_n(\boldsymbol{c})$ in Eq. 3 instead of $\boldsymbol{\lambda}(\boldsymbol{c})$, and does not cover interpolation of n-gram components, non-linearities, or the connection with neural network LMs. Also conceptually similar is work on adaptation of n-gram LMs, which start with n-gram probabilities (Della Pietra et al., 1992; Kneser and Steinbiss, 1993; Rosenfeld, 1996; Iyer and Ostendorf, 1999) and adapt them based on the distribution of the current document, albeit in a linear model. There has also been work incorporating binary n-gram features into neural language models, which allows for more direct learning of n-gram weights (Mikolov et al., 2011), but does not afford many of the advantages of the proposed model such as the incorporation of count-based probability estimates. Finally, recent works have compared n-gram and neural models, finding that neural models often perform better in perplexity, but n-grams have their own advantages such as effectiveness in extrinsic tasks (Baltescu and Blunsom, 2015) and better modeling of rare words (Chen et al., 2015).

8 Conclusion and Future Work

In this paper, we proposed a framework for language modeling that generalizes both neural network and count-based n-gram LMs. This allowed us to learn more effective interpolation functions for count-based n-grams, and to create neural LMs that incorporate information from count-based models.

As the framework discussed here is general, it is also possible that they could be used in other tasks that perform sequential prediction of words such as neural machine translation (Sutskever et al., 2014) or dialog response generation (Sordoni et al., 2015). In addition, given the positive results using block dropout for hybrid models, we plan to develop more effective learning methods for mixtures of sparse and dense distributions.

Reasoning about Pragmatics with Neural Listeners and Speakers

Jacob Andreas and **Dan Klein**
Computer Science Division
University of California, Berkeley
{jda,klein}@cs.berkeley.edu

Abstract

We present a model for contrastively describing scenes, in which context-specific behavior results from a combination of inference-driven pragmatics and learned semantics. Like previous learned approaches to language generation, our model uses a simple feature-driven architecture (here a pair of neural "listener" and "speaker" models) to ground language in the world. Like inference-driven approaches to pragmatics, our model actively reasons about listener behavior when selecting utterances. For training, our approach requires only ordinary captions, annotated *without* demonstration of the pragmatic behavior the model ultimately exhibits. In human evaluations on a referring expression game, our approach succeeds 81% of the time, compared to 69% using existing techniques.

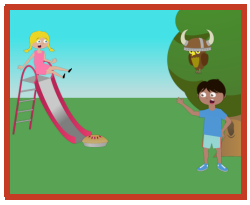
1 Introduction

We present a model for describing scenes and objects by reasoning about context and listener behavior. By incorporating standard neural modules for image retrieval and language modeling into a probabilistic framework for pragmatics, our model generates rich, contextually appropriate descriptions of structured world representations.

This paper focuses on a *reference game* RG played between a listener L and a speaker S.

1. Reference candidates r_1 and r_2 are revealed to both players.
2. S is secretly assigned a random target $t \in \{1, 2\}$.
3. S produces a description $d = S(t, r_1, r_2)$, which is shown to L.
4. L chooses $c = L(d, r_1, r_2)$.
5. Both players win if $c = t$.

(RG)



(a) target

(b) distractor

the owl is sitting in the tree

(c) description

Figure 1: Sample output from our model. When presented with a target image (a) in contrast with a distractor image (b), the model generates a description (c). This description mentions a *tree*, the distinguishing object present in (a) but not in (b), and situates it with respect to other objects and events in the scene.

Figure 1 shows an example drawn from a standard captioning dataset (Zitnick et al., 2014).

In order for the players to win, S's description d must be *pragmatic*: it must be informative, fluent, concise, and must ultimately encode an understanding of L's behavior. In Figure 1, for example, *the owl is wearing a hat* and *the owl is sitting in the tree* are both accurate descriptions of the target image, but only the second allows a human listener to succeed with high probability. RG is the focus of many papers in the computational pragmatics literature: it provides a concrete generation task while eliciting a broad range of pragmatic behaviors, including conversational implicature (Benotti and Traum, 2009) and context dependence (Smith et al., 2013). Existing computational models of pragmatics can be divided into two broad lines of work, which we term the *direct* and *derived* approaches.

Direct models (see Section 2 for examples) are based on a representation of S. They learn pragmatic behavior by example. Beginning with datasets annotated for the specific task they are trying to

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1173–1182,
Austin, Texas, November 1-5, 2016.

solve (e.g. examples of humans playing RG), direct models use feature-based architectures to predict appropriate behavior without a listener representation. While quite general in principle, such models require training data annotated specifically with pragmatics in mind; such data is scarce in practice.

Derived models, by contrast, are based on a representation of L. They first instantiate a *base listener* L0 (intended to simulate a naïve, non-pragmatic listener). They then form a *reasoning speaker* S1, which chooses a description that causes L0 to behave correctly. Existing derived models couple hand-written grammars and hand-engineered listener models with sophisticated inference procedures. They exhibit complex behavior, but are restricted to small domains where grammar engineering is practical.

The approach we present in this paper aims to capture the best aspects of both lines of work. Like direct approaches, we use machine learning to acquire a complete grounded generation model from data, without domain knowledge in the form of a hand-written grammar or hand-engineered listener model. But like derived approaches, we use this learning to construct a *base* model, and embed it within a higher-order model that reasons about listener responses. As will be seen, this reasoning step allows the model to make use of weaker supervision than previous data-driven approaches, while exhibiting robust behavior in a variety of contexts.

Our goal is to build a derived model that scales to real-world datasets without domain engineering. Independent of the application to RG, our model also belongs to the family of neural image captioning models that have been a popular subject of recent study (Xu et al., 2015). Nevertheless, our approach appears to be:

- the first such captioning model to reason explicitly about listeners
- the first learned approach to pragmatics that requires only *non-pragmatic* training data

Following previous work, we evaluate our model on RG, though the general architecture could be applied to other tasks where pragmatics plays a core role. Using a large dataset of abstract scenes like the one shown in Figure 1, we run a series of games with humans in the role of L and our system in the role of S. We find that the descriptions generated by our model result in correct interpretation 17% more often than a recent learned baseline system. We use these experiments to explore various other aspects of computational pragmatics, including tradeoffs between adequacy and fluency, and between computational efficiency and expressive power.[1]

2 Related Work

Direct pragmatics As an example of the direct approach mentioned in the introduction, FitzGerald et al. (2013) collect a set of human-generated referring expressions about abstract representations of sets of colored blocks. Given a set of blocks to describe, their model directly learns a maximum-entropy distribution over the set of logical expressions whose denotation is the target set. Other research, focused on referring expression generation from a computer vision perspective, includes that of Mao et al. (2015) and Kazemzadeh et al. (2014).

Derived pragmatics Derived approaches, sometimes referred to as "rational speech acts" models, include those of Smith et al. (2013), Vogel et al. (2013), Golland et al. (2010), and Monroe and Potts (2015). These couple template-driven language generation with probabilistic or game-theoretic reasoning frameworks to produce contextually appropriate language: intelligent listeners reason about the behavior of reflexive speakers, and even higher-order speakers reason about these listeners. Experiments (Frank et al., 2009) show that derived approaches explain human behavior well, but both computational and representational issues restrict their application to simple reference games. They require domain-specific engineering, controlled world representations, and pragmatically annotated training data.

An extensive literature on computational pragmatics considers its application to tasks other than RG, including instruction following (Anderson et al., 1991) and discourse analysis (Jurafsky et al., 1997).

[1] Models, human annotations, and code to generate all tables and figures in this paper can be found at `http://github.com/jacobandreas/pragma`.

Representing language and the world In addition to the pragmatics literature, the approach proposed in this paper relies extensively on recently developed tools for multimodal processing of language and unstructured representations like images. These includes both image retrieval models, which select an image from a collection given a textual description (Socher et al., 2014), and neural conditional language models, which take a content representation and emit a string (Donahue et al., 2015).

3 Approach

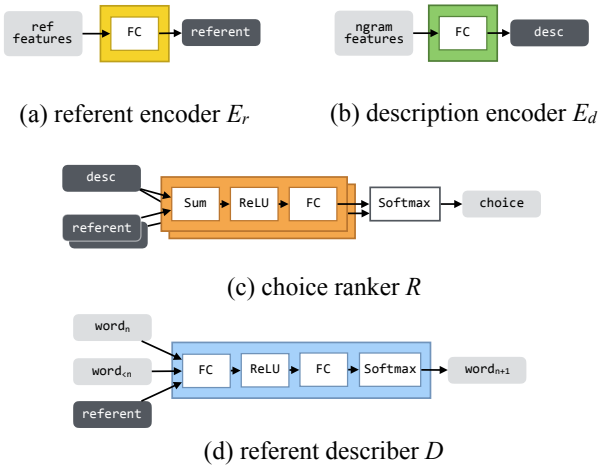
Our goal is to produce a model that can play the role of the speaker S in RG. Specifically, given a target referent (e.g. scene or object) r and a distractor r', the model must produce a description d that uniquely identifies r. For training, we have access to a set of *non-contrastively* captioned referents $\{(r_i, d_i)\}$: each training description d_i is generated for its associated referent r_i in isolation. There is no guarantee that d_i would actually serve as a good referring expression for r_i in any particular context. We must thus use the training data to ground language in referent representations, but rely on reasoning to produce pragmatics.

Our model architecture is compositional and hierarchical. We begin in Section 3.2 by describing a collection of "modules": basic computational primitives for mapping between referents, descriptions, and reference judgments, here implemented as linear operators or small neural networks. While these modules appear as substructures in neural architectures for a variety of tasks, we put them to novel use in constructing a reasoning pragmatic speaker.

Section 3.3 describes how to assemble two base models: a *literal speaker*, which maps from referents to strings, and a *literal listener*, which maps from strings to reference judgments. Section 3.4 describes how these base models are used to implement a top-level *reasoning speaker*: a learned, probabilistic, derived model of pragmatics.

3.1 Preliminaries

Formally, we take a description d to consist of a sequence of words $d_1, d_2, \ldots, d_n$, drawn from a vocabulary of known size. For encoding, we also assume access to a feature representation $f(d)$ of the sentence (for purposes of this paper, a vector of indicator features on n-grams). These two views—as a sequence of words d_i and a feature vector $f(d)$—form the basis of module interactions with language.



(a) referent encoder E_r (b) description encoder E_d

(c) choice ranker R

(d) referent describer D

Figure 2: Diagrams of modules used to construct speaker and listener models. "FC" is a fully-connected layer (a matrix multiply) and "ReLU" is a rectified linear unit. The encoder modules (a,b) map from feature representations (in gray) to embeddings (in black), while the ranker (c) and describer modules (d) respectively map from embeddings to decisions and strings.

Referent representations are similarly simple. Because the model never generates referents—only conditions on them and scores them—a vector-valued feature representation of referents suffices. Our approach is completely indifferent to the nature of this representation. While the experiments in this paper use a vector of indicator features on objects and actions present in abstract scenes (Figure 1), it would be easy to instead use pre-trained convolutional representations for referring to natural images. As with descriptions, we denote this feature representation $f(r)$ for referents.

3.2 Modules

All listener and speaker models are built from a kit of simple building blocks for working with multimodal representations of images and text:

1. a **referent encoder** E_r
2. a **description encoder** E_d
3. a **choice ranker** R
4. a **referent describer** D

These are depicted in Figure 2, and specified more formally below. All modules are parameterized by weight matrices, written with capital letters W_1, W_2, etc.; we refer to the collection of weights for all modules together as W.

Encoders The referent and description encoders produce a linear embedding of referents and descriptions in a common vector space.

$$\text{Referent encoder:} \quad E_r(r) = W_1 f(r) \tag{1}$$

$$\text{Description encoder:} \quad E_d(d) = W_2 f(d) \tag{2}$$

Choice ranker The choice ranker takes a string encoding and a collection of referent encodings, assigns a score to each (string, referent) pair, and then transforms these scores into a distribution over referents. We write $R(e_i|e_{-i}, e_d)$ for the probability of choosing i in contrast to the alternative; for example, $R(e_2|e_1, e_d)$ is the probability of answering "2" when presented with encodings e_1 and e_2.

$$\begin{aligned} s_1 &= w_3^\top \rho(W_4 e_1 + W_5 e_d) \\ s_2 &= w_3^\top \rho(W_4 e_2 + W_5 e_d) \\ R(e_i|e_{-i}, e_d) &= \frac{e^{s_i}}{e^{s_1} + e^{s_2}} \end{aligned} \tag{3}$$

(Here ρ is a rectified linear activation function.)

Referent describer The referent describer takes an image encoding and outputs a description using a (feedforward) conditional neural language model. We express this model as a distribution $p(d_{n+1}|d_n, d_{<n}, e_r)$, where d_n is an indicator feature on the last description word generated, $d_{<n}$ is a vector of indicator features on all other words previously generated, and e_r is a referent embedding. This is a "2-plus-skip-gram" model, with local positional history features, global position-independent history features, and features on the referent being described. To implement this probability distribution, we first use a multilayer perceptron to compute a vector of scores s (one s_i for each vocabulary item): $s = W_6 \rho(W_7[d_n, d_{<n}, e_i])$. We then normalize these to obtain probabilities: $p_i = e^{s_i} / \sum_j e^{s_j}$. Finally, $p(d_{n+1}|d_n, d_{<n}, e_r) = p_{d_{n+1}}$.

3.3 Base models

From these building blocks, we construct a pair of base models. The first of these is a **literal listener** L0, which takes a description and a set of referents, and chooses the referent most likely to be described. This serves the same purpose as the base listener in the general derived approach described in the introduction. We additionally construct a **literal speaker** S0, which takes a referent in isolation and outputs a description. The literal speaker is used for efficient inference over the space of possible descriptions, as described in Section 3.4. L0 is, in essence, a retrieval model, and S0 is neural captioning model.

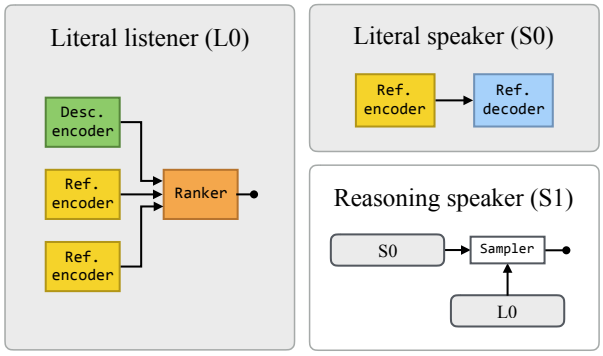


Figure 3: Schematic depictions of models. The literal listener L0 maps from descriptions and reference candidates to reference decisions. The literal speaker S0 maps directly from scenes to descriptions, ignoring context, while the reasoning speaker uses samples from S0 and scores from both L0 and S0 to produce contextually-appropriate captions.

Both of the base models are probabilistic: L0 produces a distribution over referent choices, and S0 produces a distribution over strings. They are depicted with shaded backgrounds in Figure 3.

Literal listener Given a description d and a pair of candidate referents r_1 and r_2, the literal listener embeds both referents and passes them to the ranking module, producing a distribution over choices i.

$$\begin{aligned} e_d &= E_d(d) \\ e_1 &= E_r(r_1) \\ e_2 &= E_r(r_2) \\ p_{\text{L0}}(i|d, r_1, r_2) &= R(e_i|e_{-i}, e_d) \end{aligned} \tag{4}$$

That is, $p_{\text{L0}}(1|d, r_1, r_2) = R(e_1|e_2, e_d)$ and vice-versa. This model is trained contrastively, by solving the following optimization problem:

$$\max_W \sum_j \log p_{\text{L0}}(1|d_j, r_j, r') \tag{5}$$

Here r' is a random distractor chosen uniformly from the training set. For each training example (r_i, d_i), this objective attempts to maximize the probability that the model chooses r_i as the referent of d_i over a random distractor.

This contrastive objective ensures that our approach is applicable even when there is not a naturally-occurring source of target–distractor pairs, as previous work (Golland et al., 2010; Monroe and Potts, 2015) has required. Note that this can also be viewed as a version of the loss described by Smith and Eisner (2005), where it approximates a likelihood objective that encourages L0 to prefer r_i to every other possible referent simultaneously.

Literal speaker As in the figure, the literal speaker is obtained by composing a referent encoder with a describer, as follows:

$$e = E_r(f(r))$$
$$p_{\text{S0}}(d|r) = D_d(d|e)$$

As with the listener, the literal speaker should be understood as producing a distribution over strings. It is trained by maximizing the conditional likelihood of captions in the training data:

$$\max_W \sum_i \log p_{\text{S0}}(d_i|r_i) \tag{6}$$

These base models are intended to be the minimal learned equivalents of the hand-engineered speakers and hand-written grammars employed in previous derived approaches (Golland et al., 2010). The neural encoding/decoding framework implemented by the modules in the previous subsection provides a simple way to map from referents to descriptions and descriptions to judgments without worrying too much about the details of syntax or semantics. Past work amply demonstrates that neural conditional language models are powerful enough to generate fluent and accurate (though not necessarily pragmatic) descriptions of images or structured representations (Donahue et al., 2015).

3.4 Reasoning model

As described in the introduction, the general derived approach to pragmatics constructs a base listener and then selects a description that makes it behave correctly. Since the assumption that listeners will behave deterministically is often a poor one, it is common for such derived approaches to implement *probabilistic* base listeners, and maximize the probability of correct behavior.

The neural literal listener L0 described in the preceding section is such a probabilistic listener. Given a target i and a pair of candidate referents r_1 and r_2, it is natural to specify the behavior of a reasoning speaker as simply:

$$\max_d p_{\text{L0}}(i|d, r_1, r_2) \tag{7}$$

At a first glance, the only thing necessary to implement this model is the representation of the literal listener itself. When the set of possible utterances comes from a fixed vocabulary (Vogel et al., 2013) or a grammar small enough to exhaustively enumerate (Smith et al., 2013) the operation $\max_d$ in Equation 7 is practical.

For our purposes, however, we would like the model to be capable of producing arbitrary utterances. Because the score p_{L0} is produced by a discriminative listener model, and does not factor along the words of the description, there is no dynamic program that enables efficient inference over the space of all strings.

We instead use a sampling-based optimization procedure. The key ingredient here is a good *proposal distribution* from which to sample sentences likely to be assigned high weight by the model listener. For this we turn to the literal speaker S0 described in the previous section. Recall that this speaker produces a distribution over plausible descriptions of isolated images, while ignoring pragmatic context. We can use it as a source of candidate descriptions, to be reweighted according to the expected behavior of L0. The full specification of a sampling neural reasoning speaker is as follows:

1. Draw samples $d_1, \ldots d_n \sim p_{\text{S0}}(\cdot|r_i)$.
2. Score samples: $p_k = p_{\text{L0}}(i|d_k, r_1, r_2)$.
3. Select d_k with $k = \arg\max p_k$.

While primarily to enable efficient inference, we can also use the literal speaker to serve a different purpose: "regularizing" model behavior towards choices that are adequate and fluent, rather than exploiting strange model behavior. Past work has re-

stricted the set of utterances in a way that guarantees fluency. But with an imperfect learned listener model, and a procedure that optimizes this listener's judgments directly, the speaker model might accidentally discover the kinds of pathological optima that neural classification models are known to exhibit (Goodfellow et al., 2014)—in this case, sentences that cause exactly the right response from L0, but no longer bear any resemblance to human language use. To correct this, we allow the model to consider two questions: as before, "how likely is it that a listener would interpret this sentence correctly?", but additionally "how likely is it that a speaker would produce it?"

Formally, we introduce a parameter λ that trades off between L0 and S0, and take the reasoning model score in step 2 above to be:

$$p_k = p_{\text{S0}}(d_k|r_i)^{\lambda} \cdot p_{\text{L0}}(i|d_k, r_1, r_2)^{1-\lambda} \quad (8)$$

This can be viewed as a weighted *joint* probability that a sentence is both uttered by the literal speaker and correctly interpreted by the literal listener, or alternatively in terms of Grice's conversational maxims (Grice, 1970): L0 encodes the maxims of *quality* and *relation*, ensuring that the description contains enough information for L to make the right choice, while S0 encodes the maxim of *manner*, ensuring that the description conforms with patterns of human language use. Responsibility for the maxim of *quantity* is shared: L0 ensures that the model doesn't say too little, and S0 ensures that the model doesn't say too much.

4 Evaluation

We evaluate our model on the reference game RG described in the introduction. In particular, we construct instances of RG using the Abstract Scenes Dataset introduced by Zitnick and Parikh (2013). Example scenes are shown in Figure 1 and Figure 4. The dataset contains pictures constructed by humans and described in natural language. Scene representations are available both as rendered images and as feature representations containing the identity and location of each object; as noted in Section 3.1, we use this feature set to produce our referent representation $f(r)$. This dataset was previously used for a variety of language and vision tasks (e.g. Ortiz et al. (2015), Zitnick et al. (2014)). It consists of 10,020 scenes, each annotated with up to 6 captions.

The abstract scenes dataset provides a more challenging version of RG than anything we are aware of in the existing computational pragmatics literature, which has largely used the TUNA corpus of isolated object descriptions (Gatt et al., 2007) or small synthetic datasets (Smith et al., 2013). By contrast, the abstract scenes data was generated by humans looking at complex images with numerous objects, and features grammatical errors, misspellings, and a vocabulary an order of magnitude larger than TUNA. Unlike previous work, we have no prespecified in-domain grammar, and no direct supervision of the relationship between scene features and lexemes.

We perform a human evaluation using Amazon Mechanical Turk. We begin by holding out a development set and a test set; each held-out set contains 1000 scenes and their accompanying descriptions. For each held-out set, we construct two sets of 200 paired (target, distractor) scenes: **All**, with up to four differences between paired scenes, and **Hard**, with exactly one difference between paired scenes. (We take the number of differences between scenes to be the number of objects that appear in one scene but not the other.)

We report two evaluation metrics. *Fluency* is determined by showing human raters isolated sentences, and asking them to rate linguistic quality on a scale from 1–5. *Accuracy* is success rate at RG: as in Figure 1, humans are shown two images and a model-generated description, and asked to select the image matching the description.

In the remainder of this section, we measure the tradeoff between fluency and accuracy that results from different mixtures of the base models (Section 4.1), measure the number of samples needed to obtain good performance from the reasoning listener (Section 4.2), and attempt to approximate the reasoning listener with a monolithic "compiled" listener (Section 4.3). In Section 4.4 we report final accuracies for our approach and baselines.

# samples	1	10	100	1000
Accuracy (%)	66	75	83	85

Table 1: S1 accuracy vs. number of samples.

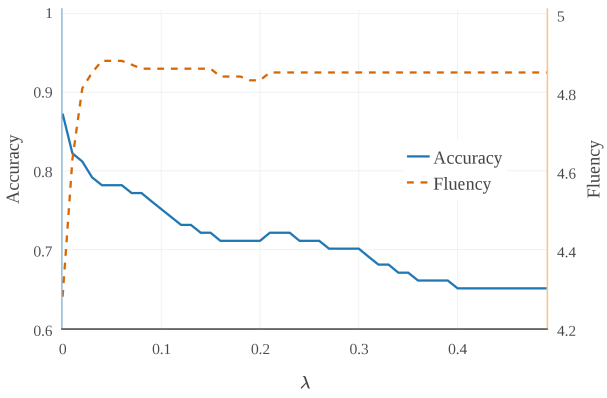

Figure 5: Tradeoff between speaker and listener models, controlled by the parameter λ in Equation 8. With $\lambda = 0$, all weight is placed on the literal listener, and the model produces highly discriminative but somewhat disfluent captions. With $\lambda = 1$, all weight is placed on the literal speaker, and the model produces fluent but generic captions.

4.1 How good are the base models?

To measure the performance of the base models, we draw 10 samples d_{jk} for a subset of 100 pairs $(r_{1,j}, r_{2,j})$ in the Dev-All set. We collect human fluency and accuracy judgments for each of the 1000 total samples. This allows us to conduct a post-hoc search over values of λ: for a range of λ, we compute the average accuracy and fluency of the highest scoring sample. By varying λ, we can view the tradeoff between accuracy and fluency that results from interpolating between the listener and speaker model—setting $\lambda = 0$ gives samples from p_{L0}, and $\lambda = 1$ gives samples from p_{S0}.

Figure 5 shows the resulting accuracy and fluency for various values of λ. It can be seen that relying entirely on the listener gives the highest accuracy but degraded fluency. However, by adding only a very small weight to the speaker model, it is possible to achieve near-perfect fluency without a substantial decrease in accuracy. Example sentences for an individual reference game are shown in Figure 5; increasing λ causes captions to become more generic. For the remaining experiments in this paper, we take $\lambda = 0.02$, finding that this gives excellent performance on both metrics.

On the development set, $\lambda = 0.02$ results in an **average fluency of 4.8** (compared to 4.8 for the literal speaker $\lambda = 1$). This high fluency can be confirmed by inspection of model samples (Figure 4). We thus focus on **accuracy** or the remainder of the evaluation.

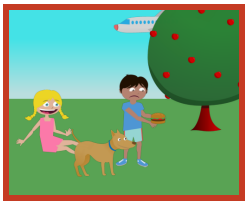
4.2 How many samples are needed?

Next we turn to the computational efficiency of the reasoning model. As in all sampling-based inference, the number of samples that must be drawn from the proposal is of critical interest—if too many samples are needed, the model will be too slow to use in practice. Having fixed $\lambda = 0.02$ in the preceding section, we measure accuracy for versions of the reasoning model that draw 1, 10, 100, and 1000 samples. Results are shown in Table 1. We find that gains continue up to 100 samples.

4.3 Is reasoning necessary?

Because they do not require complicated inference procedures, direct approaches to pragmatics typically enjoy better computational efficiency than derived ones. Having built an accurate derived speaker, can we bootstrap a more efficient direct speaker?

To explore this, we constructed a "compiled" speaker model as follows: Given reference candidates r_1 and r_2 and target t, this model produces embeddings e_1 and e_2, concatenates them together into a "contrast embedding" $[e_t, e_{-t}]$, and then feeds this whole embedding into a string decoder module. Like S0, this model generates captions without the need for discriminative rescoring; unlike S0, the contrast embedding means this model can in principle learn to produce pragmatic captions, if given access to pragmatic training data. Since no such training data exists, we train the compiled model on

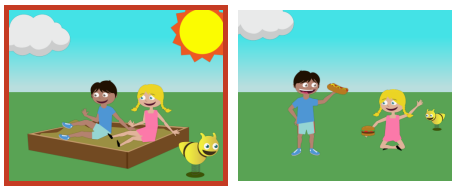


(a) target

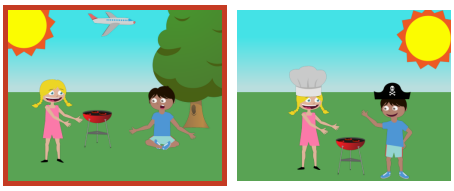
(b) distractor

(prefer L0)	`0.0`	*a hamburger on the ground*
	`0.1`	*mike is holding the burger*
(prefer S0)	`0.2`	*the airplane is in the sky*

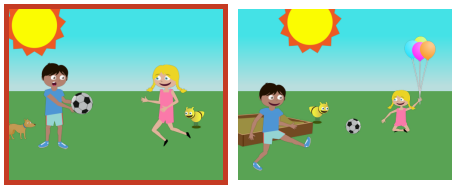
Figure 5: Captions for the same pair with varying λ. Changing λ alters both the naturalness and specificity of the output.



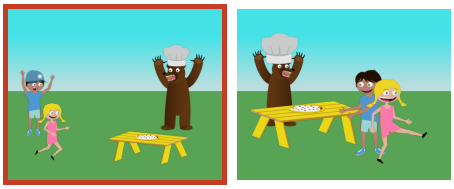
(a) *the sun is in the sky*
[contrastive]



(d) *the plane is flying in the sky*
[contrastive]



(c) *the dog is standing beside jenny*
[contrastive]



(b) *mike is wearing a chef's hat*
[non-contrastive]

Figure 4: Figure 4: Four randomly-chosen samples from our model. For each, the target image is shown on the left, the distractor image is shown on the right, and description generated by the model is shown below. All descriptions are fluent, and generally succeed in uniquely identifying the target scene, even when they do not perfectly describe it (e.g. (c)). These samples are broadly representative of the model's performance (Table 2).

	Dev acc. (%)		Test acc. (%)	
Model	All	Hard	All	Hard
Literal (S0)	66	54	64	53
Contrastive	71	54	69	58
Reasoning (S1)	**83**	**73**	**81**	**68**

Table 2: Success rates at RG on abstract scenes. "Literal" is a captioning baseline corresponding to the base speaker S0. "Contrastive" is a reimplementation of the approach of Mao et al. (2015). "Reasoning" is the model from this paper. All differences between our model and baselines are significant ($p < 0.05$, Binomial).

	# of differences				
	1	2	3	4	Mean
Literal (S0)	50	66	70	78	66 (%)
Reasoning	64	86	88	94	83
Compiled (S1)	44	72	80	80	69

Table 3: Comparison of the "compiled" pragmatic speaker model with literal and explicitly reasoning speakers. The models are evaluated on subsets of the development set, arranged by difficulty: column headings indicate the number of differences between the target and distractor scenes.

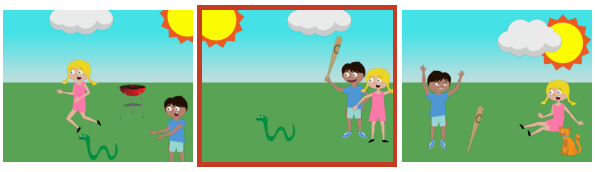
captions sampled from the reasoning speaker itself.

This model is evaluated in Table 3. While the distribution of scores is quite different from that of the base model (it improves noticeably over S0 on scenes with 2–3 differences), the overall gain is negligible (the difference in mean scores is not significant). The compiled model significantly underperforms the reasoning model. These results suggest either that the reasoning procedure is not easily approximated by a shallow neural network, or that example descriptions of randomly-sampled training pairs (which are usually easy to discriminate) do not provide a strong enough signal for a reflex learner to recover pragmatic behavior.

4.4 Final evaluation

Based on the following sections, we keep $\lambda = 0.02$ and use 100 samples to generate predictions. We evaluate on the test set, comparing this **Reasoning** model S1 to two baselines: **Literal**, an image captioning model trained normally on the abstract scene captions (corresponding to our L0), and **Contrastive**, a model trained with a soft contrastive objective, and previously used for visual referring expression generation (Mao et al., 2015).

Results are shown in Table 2. Our reasoning model outperforms both the literal baseline and previous work by a substantial margin, achieving an improvement of 17% on all pairs set and 15% on hard



(a) (b) (c)

(b vs. a) *mike is holding a baseball bat*
(b vs. c) *the snake is slithering away from mike and jenny*

Figure 6: Descriptions of the same image in different contexts. When the target scene (b) is contrasted with the left (a), the system describes a bat; when the target scene is contrasted with the right (c), the system describes a snake.

pairs.[2] Figures 4 and 6 show various representative descriptions from the model.

5 Conclusion

We have presented an approach for learning to generate pragmatic descriptions about general referents, even without training data collected in a pragmatic context. Our approach is built from a pair of simple neural base models, a listener and a speaker, and a high-level model that reasons about their outputs in order to produce pragmatic descriptions. In an evaluation on a standard referring expression game, our model's descriptions produced correct behavior in human listeners significantly more often than existing baselines.

It is generally true of existing derived approaches to pragmatics that much of the system's behavior requires hand-engineering, and generally true of direct approaches (and neural networks in particular) that training is only possible when supervision is available for the precise target task. By synthesizing these two approaches, we address both problems, obtaining pragmatic behavior without domain knowledge and without targeted training data. We believe that this general strategy of using reasoning to obtain novel contextual behavior from neural decoding models might be more broadly applied.

[2] For comparison, a model with hand-engineered pragmatic behavior—trained using a feature representation with indicators on only those objects that appear in the target image but not the distractor—produces an accuracy of 78% and 69% on all and hard development pairs respectively. In addition to performing slightly worse than our reasoning model, this alternative approach relies on the structure of scene representations and cannot be applied to more general pragmatics tasks.

Abstract

We describe Hafez, a program that generates any number of distinct poems on a user-supplied topic. Poems obey rhythmic and rhyme constraints. We describe the poetry-generation algorithm, give experimental data concerning its parameters, and show its generality with respect to language and poetic form.

1 Introduction

Automatic algorithms are starting to generate interesting, creative text, as evidenced by recent distinguishability tests that ask whether a given story, poem, or song was written by a human or a computer.[1] In this paper, we describe Hafez, a program that generates any number of distinct poems on a user-supplied topic. Figure 1 shows an overview of the system, which sets out these tasks:

- Vocabulary. We select a specific, large vocabulary of words for use in our generator, and we compute stress patterns for each word.
- Related words. Given a user-supplied topic, we compute a large set of related words.
- Rhyme words. From the set of related words, we select pairs of rhyming words to end lines.
- Finite-state acceptor (FSA). We build an FSA with a path for every conceivable sequence of vocabulary words that obeys formal rhythm constraints, with chosen rhyme words in place.
- Path extraction. We select a fluent path through the FSA, using a recurrent neural network (RNN) for scoring.

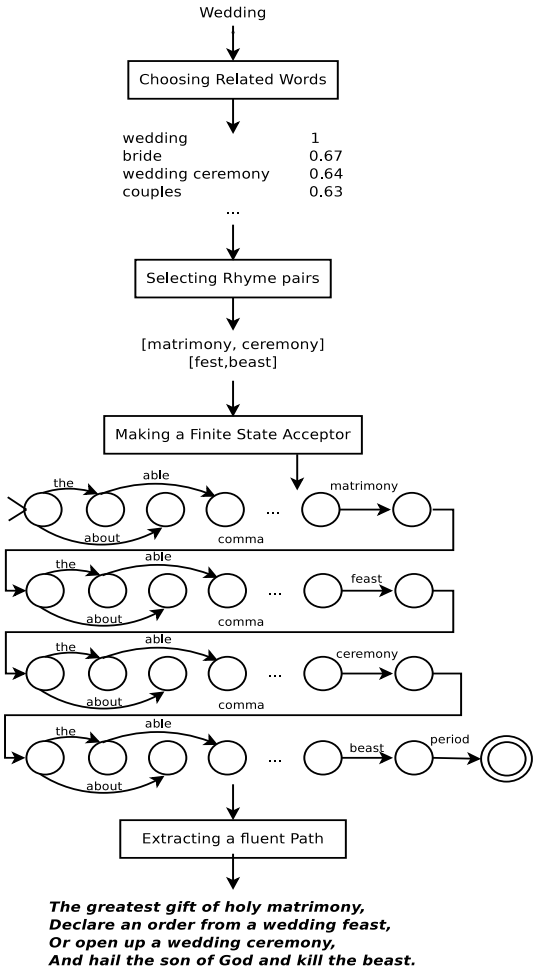

Figure 1: Overview of Hafez converting a user-supplied topic word (*wedding*) into a four-line iambic pentameter stanza.

[1]For example, in the 2016 Dartmouth test *bit.ly/20WGLF3*, no automatic sonnet-writing system passed indistinguishability, though ours was selected as the best of the submitted systems.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1183–1191,
Austin, Texas, November 1-5, 2016.

Sections 3-7 describe how we address these tasks. After this, we show results of Hafez generating 14-line classical sonnets with rhyme scheme ABAB CDCD EFEF GG, written in iambic pentameter (ten syllables per line with alternating stress: "da-DUM da-DUM da-DUM . . . "). We then show experiments on Hafez's parameters and conclude by showing the generality of the approach with respect to language and poetic form.

2 Prior Work

Automated poem generation has been a popular but challenging research topic (Manurung et al., 2000; Gervas, 2001; Diaz-Agudo et al., 2002; Manurung, 2003; Wong and Chun, 2008; Jiang and Zhou, 2008; Netzer et al., 2009). Recent work attempts to solve this problem by applying grammatical and semantic templates (Oliveira, 2009; Oliveira, 2012), or by modeling the task as statistical machine translation, in which each line is a "translation" of the previous line (Zhou et al., 2009; He et al., 2012). Yan et al. (2013) proposes a method based on summarization techniques for poem generation, retrieving candidate sentences from a large corpus of poems based on a user's query and clustering the constituent terms, summarizing each cluster into a line of a poem. Greene et al. (2010) use unsupervised learning to estimate the stress patterns of words in a poetry corpus, then use these in a finite-state network to generate short English love poems.

Several deep learning methods have recently been proposed for generating poems. Zhang and Lapata (2014) use an RNN model to generate 4-line Chinese poems. They force the decoder to rhyme the second and fourth lines, trusting the RNN to control rhythm. Yi et al. (2016) also propose an attention-based bidirectional RNN model for generating 4-line Chinese poems. The only such work which tries to generate longer poems is from Wang et al. (2016), who use an attention-based LSTM model for generation iambic poems. They train on a small dataset and do not use an explicit system for constraining rhythm and rhyme in the poem.

Novel contributions of our work are:

- We combine finite-state machinery with deep learning, guaranteeing formal correctness of our poems, while gaining coherence of long-distance RNNs.
- By using words related to the user's topic as rhyme words, we design a system that can generate poems with topical coherence. This allows us to generate longer topical poems.
- We extend our method to other poetry formats and languages.

3 Vocabulary

To generate a line of iambic pentameter poetry, we arrange words to form a sequence of ten syllables alternating between stressed and unstressed. For example:

```
   010     1  0    10      101
Attending on his golden pilgramage
```

Following Ghazvininejad and Knight (2015), we refer to unstressed syllables with 0 and stressed syllables with 1, so that the form of a Shakespearean sonnet is $((01)^5)^{14}$. To get stress patterns for individual words, we use CMU pronunciation dictionary,[2] collapsing primary and secondary stresses. For example:

```
CAFETERIA  K AE2 F AH0 T IH1 R IY0 AH0
```

becomes

```
CAFETERIA 10100
```

The first two columns of Table 1 show other examples. From the 125,074 CMU dictionary word types, we can actually only use words whose stress pattern matches the iambic pattern (alternating 1s and 0s). However, we make an exception for words that end in ...100 (such as *spatula*). To mimic how human poets employ such words, we convert all "...100" patterns to "...101". This leaves us with a 106,019 word types.

Words with multiple syllable-stress patterns present a challenge. For example, our program may use the word *record* in a "...10..." context, but if it is a verb in that context, a human reader will pronounce it as "01", breaking the intended rhythm. To guarantee that our poems scan properly, we eject all ambiguous words from our vocabulary. This problem is especially acute with monosyllabic words, as most have a stress that depends on context. Greene et al. (2010) apply the EM algorithm to align

[2] http://www.speech.cs.cmu.edu/cgi-bin/cmudict

word	stress pattern	strict rhyme class	slant rhyme class (coarse version)
needing	10	IY1 D IH0 NG	IY1 * IH0 NG
ordinary	1010	EH1 R IY0	EH1 * IY0
obligate	101	EY1 T	last syllable stressed, no slant rhyme

Table 1: Sample word analyses.

human-written sonnets with assumed meter, extracting P(0|word) and P(1|word) probabilities. Using their method, we eject all monosyllabic words except those with P(0|word) > 0.9 or P(1|word) > 0.9. A consequence is that our poetry generator avoids the words *to*, *it*, *in*, and *is*, which actually forces the system into novel territory. This yields 16,139 monosyllabic and 87,282 multisyllabic words.

Because our fluency module (Section 7) is restricted to 20,000 word types, we further pare down our vocabulary by removing words that are not found in the 20k-most-frequent list derived from the song lyrics corpus we use for fluency. After this step, our final vocabulary contains 14,368 words (4833 monosyllabic and 9535 multisyllabic).

4 Topically Related Words and Phrases

After we receive a user-supplied topic, the first step in our poem generation algorithm is to build a scored list of 1000 words/phrases that are related to that topic. For example:

- **User-supplied input topic:** *colonel*
- **Output:** *colonel* (1.00), *lieutenant_colonel* (0.77), *brigadier_general* (0.73), *commander* (0.67) ... *army* (0.55) ...

This problem is different from finding synonyms or hypernyms in WordNet (Miller, 1995). For example, while Banerjee and Pedersen (2003) use WordNet to assign a 1.0 similarity score between *car* and *automobile*, they only give a 0.3 similarity between *car* and *gasoline*.

A second method is to use pointwise mutual information (PMI). Let t be the topic/phrase, and let w be a candidate related word. We collect a set of sentences S that contain t, and sort candidates by

$$\frac{\text{Proportion of sentences in } S \text{ containing } w}{\text{P}(w) \text{ in general text}}$$

Table 2 shows that PMI has a tendency to assign a high score to low frequency words (Bouma, 2009; Role and Nadif, 2011; Damani, 2013).

A third method is word2vec (Mikolov et al., 2013a), which provides distributed word representations. We train a continuous-bag-of-words model[3] with window size 8 and 40 and word vector dimension 200. We score candidate related words/phrases with cosine to topic-word vector. We find that a larger window size works best (Pennington et al., 2014; Levy and Goldberg, 2014).

Table 2 shows examples. The training corpus for word2vec has a crucial effect on the quality of the related words. We train word2vec models on the English Gigaword corpus,[4] a song lyrics corpus, and the first billion characters from Wikipedia.[5] The Gigaword corpus produces related words that are too newsy, while the song lyrics corpus does not cover enough topics. Hence, we train on Wikipedia. To obtain related phrases as well as words, we apply the method of Mikolov et al. (2013b) to the Wikipedia corpus, which replaces collocations like *Los Angeles* with single tokens like *Los_Angeles*. Word2vec then builds vectors for phrases as well as words. When the user supplies a multi-word topic, we use its phrase vector if available. Otherwise, we create the vector topic by element wise addition of its words' vectors.

5 Choosing Rhyme Words

We next fill in the right-hand edge of our poem by selecting pairs of rhyming words/phrases and assigning them to lines. In a Shakespearean sonnet with rhyme scheme ABAB CDCD EFEF GG, there are seven pairs of rhyme words to decide on.

5.1 Strict Rhyme

The strict definition of English rhyme is that the sounds of two words must match from the last stressed vowel onwards. In a masculine rhyme,

[3] https://code.google.com/archive/p/word2vec/
[4] https://catalog.ldc.upenn.edu/LDC2011T07
[5] http://mattmahoney.net/dc/enwik9.zip

Method	Window	Corpus	Phrases?	Related words
PMI	n/a	Gigaword	no	*croquet, Romai, Carisbo, NTTF, showcourts ...*
CBOW	8	Gigaword	no	*squash, badminton, golf, soccer, racquetball ...*
CBOW	40	Gigaword	no	*singles, badminton, squash, ATP, WTA ...*
CBOW	40	Song Lyrics	no	*high-heel, Reebok, steel-toed, basketball, Polos ...*
CBOW	40	Wikipedia	no	*volleyball, racquet, Wimbledon, athletics, doubles ...*
CBOW	40	Wikipedia	yes	*singles titles, grass courts, tennis club, hardcourt ...*

Table 2: Different methods for extracting words related to the topic *tennis*.

the last syllable is stressed; in a feminine rhyme, the penultimate syllable is stressed. We collect phoneme and stress information from the CMU pronunciation dictionary. We pre-compute strict rhyme classes for words (see Table 1) and hash the vocabulary into those classes.

5.2 Slant Rhyme

In practice, human poets do not always use strict rhymes. To give ourselves more flexibility in choosing rhyme pairs, we allow for slant (or half) rhymes. By inspecting human rhyming data, we develop this operational definition of slant rhyme:

1. Let s1 and s2 be two potentially-rhyming phoneme sequences.
2. Replace ER with UH R in both sequences.
3. Let v1 and v2 be the last stressed vowels in s1 and s2.
4. Let w1 and w2 be last vowels in s1 and s2.
5. Let s1 = a1 v1 x1 w1 c1. Likewise, let s2 = a2 v2 x2 w2 c2.
6. Output NO under any of these circumstances: (a) v1 $\neq$ v2, (b) w1 $\neq$ w2, (c) c1 $\neq$ c2, (d) a1 $\neq$ NULL and a2 $\neq$ NULL and a1 = a2.
7. If x1 and x2 are single phonemes:
   (a) If x1 $\sim$ x2, then output YES.[6]
   (b) Otherwise, output NO.
8. If x1 and x2 contain different numbers of vowels, output NO.
9. Let p1 and q1 be the first and last phonemes of x1. Let p2 and q2 be the same for x2.
10. If (p1 = p2) and (q1 $\sim$ q2), output YES.
11. If (p1 $\sim$ p2) and (q1 = q1), output YES.
12. Otherwise, output NO.

[6] x $\sim$ y if phonemes x and y are similar. Two phonemes are similar if their pairwise score according to (Hirjee and Brown, 2010) is greater than -0.6. This includes 98 pairs, such as L/R, S/SH, and OY/UH.

Words whose last syllable is stressed do not participate in slant rhymes.

Example slant rhymes taken from our generated poems include *Viking/fighting*, *snoopy/spooky*, *baby/crazy* and *comic/ironic*. We pre-compute a coarse version of slant rhyme classes (Table 1) with the pattern "v_i * w_i c_i". If two words hash to the same coarse class, then we subsequently accept or reject depending on the similarity of the intermediate phonemes.

5.3 Non-Topical Rhyming Words

For rare topics, we may not have enough related words to locate seven rhyming pairs. For example, we generate 1000 related words for the topic *Viking*, but only 32 of them are found in our 14,368-word vocabulary. To give a chance for all topical words/phrases to be used as rhyme words, for each strict rhyme class, we add the most common word in our song lyric corpus to the list of related words. In addition, we add words from popular rhyme pairs[7] (like *do/you* and *go/know*) to the list of related words with a low topic similarity score.

5.4 Rhyme word selection

We first hash all related words/phrases into rhyme classes. Each collision generates a candidate rhyme pair (s1, s2), which we score with the maximum of cosine(s1, topic) and cosine(s2, topic). So that we can generate many different sonnets on the same topic, we choose rhyme pairs randomly with probability proportional to their score. After choosing a pair (s1, s2), we remove it, along with any other candidate pair that contains s1 or s2. Because a poem's beginning and ending are more important, we assign the first rhyme pair to the last two lines of the sonnet,

[7] http://slate.me/OhTKCA

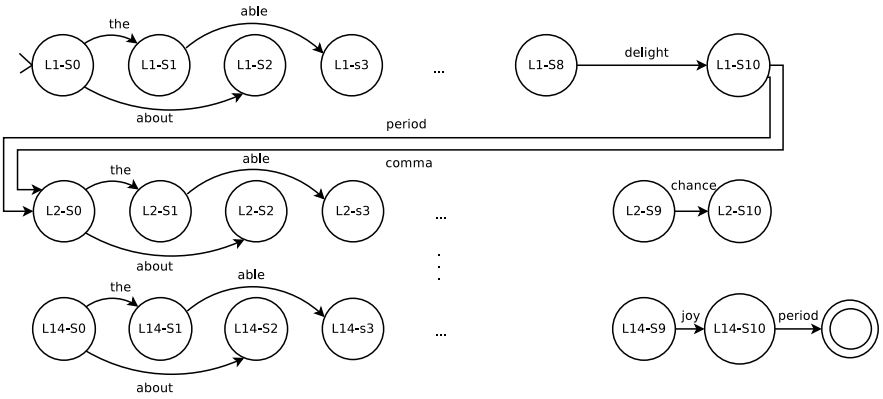

Figure 2: An FSA compactly encoding all word sequences that obey formal sonnet constraints, and dictating the right-hand edge of the poem via rhyming, topical words *delight*, *chance*, ... and *joy*.

then assign other pairs from beginning of the sonnet towards the end.

6 Constructing FSA of Possible Poems

After choosing rhyme words, we create a large finite-state acceptor (FSA) that compactly encodes all word sequences that use these rhyme words and also obey formal sonnet constraints:

- Each sonnet contains 14 lines.
- Lines are in iambic pentameter, with stress pattern $(01)^5$. Following poetic convention, we also use $(01)^50$, allowing feminine rhyming.
- Each line ends with the chosen rhyme word/phrase for that line.
- Each line is punctuated with comma or period, except for the 4th, 8th, 12th, and 14th lines, which are punctuated with period.

To implement these constraints, we create FSA states that record line number and syllable count. For example, FSA state L2-S3 (Figure 2) signifies "I am in line 2, and I have seen 3 syllables so far". From each state, we create arcs for each feasible word in the vocabulary. For example, we can move from state L1-S1 to state L1-S3 by consuming any word with stress pattern 10 (such as *table* or *active*). When moving between lines (e.g., from L1-S10 to L2-S1), we employ arcs labeled with punctuation marks.

To fix the rhyme words at the end of each line, we delete all arcs pointing to the line-final state, except for the arc labeled with the chosen rhyme word. For speed, we pre-compute the entire FSA; once we receive the topic and choose rhyme words, we only need to carry out the deletion step.

In the resulting FSA, each path is *formally* a sonnet. However, most of the paths through the FSA are meaningless. One FSA generated from the topic *natural language* contains 10^{229} paths, including this randomly-selected one:

Of pocket solace ammunition grammar.
An tile pretenders spreading logical.
An stories Jackie gallon posing banner.
An corpses Kato biological ...

Hence, we need a way to search and rank this large space.

7 Path extraction through FSA with RNN

To locate fluent paths, we need a scoring function and a search procedure. For example, we can build a n-gram word language model (LM)—itself a large weighted FSA. Then we can take a weighted intersection of our two FSAs and return the highest-scoring path. While this can be done efficiently with dynamic programming, we find that n-gram models have a limited attention span, yielding poor poetry.

Instead, we use an RNN language model (LM). We collect 94,882 English songs (32m word tokens) as our training corpus,[8] and train[9] a two-layer recurrent network with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997).[10]

When decoding with the LM, we employ a beam

[8] http://www.mldb.org/

[9] We use the toolkit: https://github.com/isi-nlp/Zoph_RNN

[10] We use a minibatch of 128, a hidden state size of 1000, and a dropout rate of 0.2. The output vocabulary size is 20,000. The learning rate is initially set as 0.7 and starts to decay by 0.83 once the perplexity on a development set starts to increase. All parameters are initialized within range $[-0.08, +0.08]$, and the gradients are re-scaled when the global norm is larger than 5.

search that is further guided by the FSA. Each beam state $C_{t,i}$ is a tuple of $(h, s, word, score)$, where h is the hidden states of LSTM at step t in ith state, and s is the FSA state at step t in ith state. The model generates one word at each step.

At the beginning, $h_{0,0}$ is the initial hidden state of LSTM, $s_{0,0}$ is the start state of FSA, $word_{0,0}$ = <START> and $score_{0,0} = 0$. To expand a beam state $C_{t,i}$, we first feed $h_{t,i}$ and $word$ into the LM and get an updated hidden state h_{next}. The LM also returns a probability distribution $P(V)$ over the entire vocabulary V for next word. Then, for each succeeding state s_{suc} of $s_{t,i}$ in the FSA and the word w_{next} over each edge from $s_{t,i}$ to s_{suc}, we form a new state $(h_{next}, s_{suc}, w_{next}, score_{t,i} + log(P(w_{next})))$ and push it into next beam.

Because we fix the rhyme word at the end of each line, when we expand the beam states immediately before the rhyme word, the FSA states in those beam states have only one succeeding state—LN-S10, where $N = [1, 14]$, and only one succeeding word, the fixed rhyme word. For our beam size b = 50, the chance is quite low that in those b words there exists any suitable word to precede that rhyme word. We solve this by generating the whole sonnet *in reverse*, starting from the final rhyme word. Thus, when we expand the state L1-S8, we can choose from almost every word in vocabulary instead of just b possible words. The price to pay is that at the beginning of each line, we need to hope in those b words there exists some that are suitable to succeed comma or period.

Because we train on song lyrics, our LM tends to generate repeating words, like *never ever ever ever ever*. To solve this problem, we apply a penalty to those words that already generated in previous steps during the beam search.

To create a poem that fits well with the predetermined rhyme words at the end of each line, the LM model tends to choose "safe" words that are frequent and suitable for any topic, such as pronouns, adverbs, and articles. During decoding, we apply a reward on all topically related words (generated in Section 4) in the non-rhyming portion of the poem.

Finally, to further encourage the system to follow the topic, we train an encoder-decoder sequence-to-sequence model (Sutskever et al., 2014). For training, we select song lyric rhyme words and assemble them in reverse order (encoder side), and we pair this with the entire reversed lyric (decoder side). At generation time, we put all the selected rhyme words on the source side, and let the model to generate the poem conditioned on those rhyme words. In this way, when the model tries to generate the last line of the poem, it already knows all fourteen rhyme words, thus possessing better knowledge of the requested topic. We refer to generating poems using the RNN LM as the "generation model" and to this model as the "translation model".

Bipolar Disorder

Existence enters your entire nation.
A twisted mind reveals becoming manic,
An endless modern ending medication,
Another rotten soul becomes dynamic.

Or under pressure on genetic tests.
Surrounded by controlling my depression,
And only human torture never rests,
Or maybe you expect an easy lesson.

Or something from the cancer heart disease,
And I consider you a friend of mine.
Without a little sign of judgement please,
Deliver me across the borderline.

An altered state of manic episodes,
A journey through the long and winding roads.

Figure 3: Sample sonnet generated from the topic phrase *bipolar disorder*.

8 Results and Analysis

Sample outputs produced by our best system are shown in Figures 3 and 4. We find that they generally stay on topic and are fairly creative. If we request a poem on the topic *Vietnam*, we may see the phrase *Honky Tonkin Resolution*; a different topic leads the system to rhyme *Dirty Harry* with *Bloody Mary*. In this section, we present experiments we used to select among different versions of our poem generator.

The first experiment tests the effect of encouraging topical words in the body of the poem, via a direct per-word bonus. For 40 different topics, we generate 2 sonnets with and without encouragement, using the same set of rhyme words. Then we ask 23 human judges to choose the better sonnet. Each judge compares sonnets for 10 different topics. Table 3 shows that using topical words increases the

Love at First Sight

An early morning on a rainy night,
Relax and make the other people happy,
Or maybe get a little out of sight,
And wander down the streets of Cincinnati.

Girlfriend

Another party started getting heavy.
And never had a little bit of Bobby,
Or something going by the name of Eddie,
And got a finger on the trigger sloppy.

Noodles

The people wanna drink spaghetti alla,
And maybe eat a lot of other crackers,
Or sit around and talk about the salsa,
A little bit of nothing really matters.

Civil War

Creating new entire revolution,
An endless nation on eternal war,
United as a peaceful resolution,
Or not exist together any more.

Figure 4: Sample stanzas generated from different topic phrases.

Preference	Encourages	Does Not Encourage	Cannot Decide
Sonnets	**54**%	18%	28%

Table 3: Users prefer the system that encourages the use of related words in the body (non-rhyme) portion of the poem. 40 poems are tested with 23 judges.

quality of the sonnets.

Next, we compare the translation model with generation model. For each of 40 topics, we generate one poem with generation model and one poem with translation model, using the same set of rhyme words. We ask 25 human judges to chose the better poem. Each judge compares sonnets for 10 different topics. This experiment is run separately for sonnets and stanzas. Table 4 shows how the translation model generates better poems, and Figure 5 compares two stanzas.

We check for plagiarism, as it is common for optimal-searching RNNs to repeat large sections of the training data. We hypothesize that strong conditions on rhyme, meter, repetition, and ambiguously-stressed words will all mitigate against plagiarism.

Gen	Another tiny thousand ashes scattered. And never hardly ever really own, Or many others have already gathered, The only human being left alone.
Trans	Being **buried** under ashes scattered, Many faces we forgotten own, About a hundred thousand **soldiers** gathered, And I remember standing all alone.

Figure 5: Stanzas generated with and without a encoder-decoder translation model for topic *death*.

Preference	Generation Model	Translation Model	Cannot Decide
Stanzas	26%	**43**%	31%
Sonnets	21%	**57**%	22%

Table 4: Users prefer poems created with the encoder-decoder translation model over those that use only the RNN language model in generation mode. 40 poems are tested with 25 judges.

We find that on average, each sonnet copies only 1.2 5-grams from the training data. If we relax the repeated-word penalty and the iambic meter, this number increases to 7.9 and 10.6 copied 5-grams, respectively. Considering the lack of copying, we find the RNN-generated grammar to be quite good. The most serious—and surprisingly common—grammatical error is the wrong use of *a* and *an*, which we fix in a post-processing step.

9 Other Languages and Formats

To show the generality of our approach, we modify our system to generate Spanish-language poetry from a Spanish topic. We use these resources:

- A song lyric corpus for training our RNN. We download 97,775 Spanish song lyrics from LyricWikia,[11] which amounts to 20m word tokens and 219k word types.
- A Spanish Wikipedia dump[12] consisting of 885m word tokens, on which we run word2vec to find words and phrases related to the topic.

Our vocabulary consists of the 20k most frequent lyric words. For each word, we compute its syllable-stress pattern and its rhyme class (see Figure 6). Because Spanish writing is quite phonetic, we can retrieve this from the letter strings of the vocabulary.

[11] http://lyrics.wikia.com/wiki/Category:Language/Spanish

[12] https://dumps.wikimedia.org/eswiki/20160305/eswiki-20160305-pages-meta-current.xml.bz2

word	stress	rhyme	v-	-v
consultado	0010	-ado		yes
aduciendo	0010	-endo	yes	yes
régimen	100	-egimen		
hospital	001	-al	yes	

Figure 6: Sample word analyses needed to construct Spanish Hafez. v- and -v indicate whether the word starts and/or ends with a vowel sound.

For any given vocabulary word:[13]

1. We remove silent h, and convert y into i.
2. We count the number of syllables by isolating vowel groups. In such groups, weak vowels (i, u) attached to strong vowels (a, e, o) do not form separate syllables, unless they are accented (*dí-as* versus *dios*). Strong clusters are broken into separate syllables (eg, *ca-er*).
3. We determine which vowel (and therefore syllable) is stressed. If any vowel is accented, it is stressed. If the word is accent-free, then the second-to-last syllable is stressed, unless the word ends in a consonant other than n or s, in which case the last syllable is stressed.
4. We form the word's rhyme class by breaking off a letter suffix starting at the last stressed vowel (as in English). Weak vowels do not participate (e.g., *tienda* $\rightarrow$ *-enda*, not *-ienda*). We remove h from the rhyme, so *búho* rhymes with *continúo*. Because rhyming is easier in Spanish than English, we do not need slant rhyme.

Most Spanish poetic formats enforce some number of syllables per line, without meter. However, there are two caveats when counting syllables:

1. *Sinalefa* merges vowels across word boundaries. Thus, *la_obra* is counted as two syllables instead of three, and *va_a_hacer* is counted as two syllables instead of four. A line may therefore have more words than syllables.
2. For the last word of a line (only), we count up to its last stressed syllable, then add one. This means that even though iambic meter is not employed, we still need stress patterns to correctly count syllables.

We implement these constraints in the FSA framework, now with separate states for "I have seen M syllables, and the last word ended in a vowel sound" and "I have seen M syllables, and the last word ended in a consonant sound." Technically speaking, the FSA includes single-state cycles for the Spanish word a, due to *sinalefa*. Line-ending states can only be reached by words that have their syllable count adjusted as in point 2 above.

[13] http://community.dur.ac.uk/m.p.thompson/verse.htm

Mariposa

Quieres saber dónde está el escorpión,
Ni ayer ni antes vos sos corona dorada.
Ya os ves más tal cual tortuga pintada,
A él nos gusta andar con cola marrón.

Ella es quién son las alas de algún gorrión.
Si al fin podés ver tu imagen manchada,
O hoy vas bajo un cielo azul plateada,
Por qué estás tan lejos del aguijón.

No hay luz que al sol se enreda en tus palmera.
Ay por qué eres víbora venenosa,
Sin querer igual a un enredadera.

Y si aún sueñas con ser mariposa,
En vez de abrir los ojos y espera,
Sabes muy bien que el amor no es gran cosa.

Figure 7: Sample Spanish poem generated in classical *soneta* form, on the topic *mariposa* (butterfly).

Figure 7 shows a sample Spanish output. The format is the classical Spanish *soneta*, which consists of 14 eleven-syllable lines under the rhyme scheme ABBA ABBA CDC DCD. This scheme requires us to choose up to four words with the same rhyme.

Overall, we also find Spanish outputs to be fluent, fairly creative, and on topic. Grammatical problems are a bit more common than in our English generator—for example, adjacent words sometimes disagree in number or gender. The RNN generalizations that permit these errors no doubt also permit creative phrasings.

10 Conclusion

We have described Hafez, a poetry generation system that combines hard format constraints with a deep-learning recurrent network. The system uses special techniques, such as rhyme-word choice and encoder-decoder modeling, to keep the poem on topic. We hope that future work will provide more discourse structure and function to automatic poetry, while maintaining the syntax, semantics, and creative phrasing we observe.

Abstract

Recent neural models of dialogue generation offer great promise for generating responses for conversational agents, but tend to be shortsighted, predicting utterances one at a time while ignoring their influence on future outcomes. Modeling the future direction of a dialogue is crucial to generating coherent, interesting dialogues, a need which led traditional NLP models of dialogue to draw on reinforcement learning. In this paper, we show how to integrate these goals, applying deep reinforcement learning to model future reward in chatbot dialogue. The model simulates dialogues between two virtual agents, using policy gradient methods to reward sequences that display three useful conversational properties: informativity, coherence, and ease of answering (related to forward-looking function). We evaluate our model on diversity, length as well as with human judges, showing that the proposed algorithm generates more interactive responses and manages to foster a more sustained conversation in dialogue simulation. This work marks a first step towards learning a neural conversational model based on the long-term success of dialogues.

1 Introduction

Neural response generation (Sordoni et al., 2015; Shang et al., 2015; Vinyals and Le, 2015; Li et al., 2016a; Wen et al., 2015; Yao et al., 2015; Luan et al., 2016; Xu et al., 2016; Wen et al., 2016; Li et al., 2016b; Su et al., 2016) is of growing interest. The LSTM sequence-to-sequence (SEQ2SEQ) model (Sutskever et al., 2014) is one type of neural generation model that maximizes the probability of generating a response given the previous dialogue turn. This approach enables the incorporation of rich context when mapping between consecutive dialogue turns (Sordoni et al., 2015) in a way not possible, for example, with MT-based dialogue models (Ritter et al., 2011).

Despite the success of SEQ2SEQ models in dialogue generation, two problems emerge: First, SEQ2SEQ models are trained by predicting the next dialogue turn in a given conversational context using the maximum-likelihood estimation (MLE) objective function. However, it is not clear how well MLE approximates the real-world goal of chatbot development: teaching a machine to converse with humans, while providing interesting, diverse, and informative feedback that keeps users engaged. One concrete example is that SEQ2SEQ models tend to generate highly generic responses such as "*I don't know*" regardless of the input (Sordoni et al., 2015; Serban et al., 2016; Li et al., 2016a). This can be ascribed to the high frequency of generic responses found in the training set and their compatibility with a diverse range of conversational contexts. Yet *"I don't know"* is apparently not a good action to take, since it closes the conversation down.

Another common problem, illustrated in the two sample conversations on the left of Table 1, is that the system becomes stuck in an infinite loop of repetitive responses. This is due to MLE-based SEQ2SEQ models' inability to account for repetition. In example 2 (bottom left), the dialogue falls into an infinite loop after three turns, with both agents generating dull, generic utterances like *i don't know what you are talking about* and *you don't know what you are saying*. Looking at the entire conversation, utterance (4) turns out to be a bad action to take because it offers no way of continuing the conversation.[1]

[1]A similar rule is often suggested in improvisational comedy: https://en.wikipedia.org/wiki/Yes,_and...

Table 1: **Left Column**: Dialogue simulation between two agents using a 4-layer LSTM encoder-decoder trained on the OpenSubtitles dataset. The first turn (index 1) is input by the authors. Then the two agents take turns conversing, taking as input the other agent's prior generated turn. The output is generated using the mutual information model (Li et al., 2015) in which an N-best list is first obtained using beam search based on p(t|s) and reranked by linearly combining the backward probability p(s|t), where t and s respectively denote targets and sources. **Right Column**: Dialogue simulated using the proposed reinforcement learning model. The new model has more forward-looking utterances (questions like "Why are you asking?" and offers like "I'll come with you") and lasts longer before it falls into conversational black holes.

These challenges suggest we need a conversation framework that has the ability to (1) integrate developer-defined rewards that better mimic the true goal of chatbot development and (2) model the long-term influence of a generated response in an ongoing dialogue.

To achieve these goals, we draw on the insights of reinforcement learning, which have been widely applied in MDP and POMDP dialogue systems (see Related Work section for details). We introduce a neural reinforcement learning (RL) generation method, which can optimize long-term rewards designed by system developers. Our model uses the encoder-decoder architecture as its backbone, and simulates conversation between two virtual agents to explore the space of possible actions while learning to maximize expected reward. We define simple heuristic approximations to rewards that characterize good conversations: good conversations are forward-looking (Allwood et al., 1992) or interactive (a turn suggests a following turn), informative, and coherent. The parameters of an encoder-decoder RNN define a policy over an infinite action space consisting of all possible utterances. The agent learns a policy by optimizing the long-term developer-defined reward from ongoing dialogue simulations using policy gradient methods (Williams, 1992), rather than the MLE objective defined in standard SEQ2SEQ models.

Our model thus integrates the power of SEQ2SEQ systems to learn compositional semantic meanings of utterances with the strengths of reinforcement learning in optimizing for long-term goals across a conversation. Experimental results (sampled results at the right panel of Table 1) demonstrate that our approach fosters a more sustained dialogue and manages to produce more interactive responses than standard SEQ2SEQ models trained using the MLE objective.

2 Related Work

Efforts to build statistical dialog systems fall into two major categories.

The first treats dialogue generation as a source-to-target transduction problem and learns mapping rules between input messages and responses from a massive amount of training data. Ritter et al. (2011) frames the response generation problem as a statisti-

cal machine translation (SMT) problem. Sordoni et al. (2015) improved Ritter et al.'s system by rescoring the outputs of a phrasal SMT-based conversation system with a neural model that incorporates prior context. Recent progress in SEQ2SEQ models inspire several efforts (Vinyals and Le, 2015) to build end-to-end conversational systems which first apply an encoder to map a message to a distributed vector representing its semantics and generate a response from the message vector. Serban et al. (2016) propose a hierarchical neural model that captures dependencies over an extended conversation history. Li et al. (2016a) propose mutual information between message and response as an alternative objective function in order to reduce the proportion of generic responses produced by SEQ2SEQ systems.

The other line of statistical research focuses on building task-oriented dialogue systems to solve domain-specific tasks. Efforts include statistical models such as Markov Decision Processes (MDPs) (Levin et al., 1997; Levin et al., 2000; Walker et al., 2003; Pieraccini et al., 2009), POMDP (Young et al., 2010; Young et al., 2013; Gašic et al., 2013a; Gašic et al., 2014) models, and models that statistically learn generation rules (Oh and Rudnicky, 2000; Ratnaparkhi, 2002; Banchs and Li, 2012; Nio et al., 2014). This dialogue literature thus widely applies reinforcement learning (Walker, 2000; Schatzmann et al., 2006; Gasic et al., 2013b; Singh et al., 1999; Singh et al., 2000; Singh et al., 2002) to train dialogue policies. But task-oriented RL dialogue systems often rely on carefully limited dialogue parameters, or hand-built templates with state, action and reward signals designed by humans for each new domain, making the paradigm difficult to extend to open-domain scenarios.

Also relevant is prior work on reinforcement learning for language understanding - including learning from delayed reward signals by playing text-based games (Narasimhan et al., 2015; He et al., 2016), executing instructions for Windows help (Branavan et al., 2011), or understanding dialogues that give navigation directions (Vogel and Jurafsky, 2010).

Our goal is to integrate the SEQ2SEQ and reinforcement learning paradigms, drawing on the advantages of both. We are thus particularly inspired by recent work that attempts to merge these paradigms, including Wen et al. (2016)— training an end-to-end task-oriented dialogue system that links input representations to slot-value pairs in a database— or Su et al. (2016), who combine reinforcement learning with neural generation on tasks with real users, showing that reinforcement learning improves dialogue performance.

3 Reinforcement Learning for Open-Domain Dialogue

In this section, we describe in detail the components of the proposed RL model.

The learning system consists of two agents. We use p to denote sentences generated from the first agent and q to denote sentences from the second. The two agents take turns talking with each other. A dialogue can be represented as an alternating sequence of sentences generated by the two agents: $p_1, q_1, p_2, q_2, ..., p_i, q_i$. We view the generated sentences as actions that are taken according to a policy defined by an encoder-decoder recurrent neural network language model.

The parameters of the network are optimized to maximize the expected future reward using policy search, as described in Section 4.3. Policy gradient methods are more appropriate for our scenario than Q-learning (Mnih et al., 2013), because we can initialize the encoder-decoder RNN using MLE parameters that already produce plausible responses, before changing the objective and tuning towards a policy that maximizes long-term reward. Q-learning, on the other hand, directly estimates the future expected reward of each action, which can differ from the MLE objective by orders of magnitude, thus making MLE parameters inappropriate for initialization. The components (states, actions, reward, etc.) of our sequential decision problem are summarized in the following sub-sections.

3.1 Action

An action a is the dialogue utterance to generate. The action space is infinite since arbitrary-length sequences can be generated.

3.2 State

A state is denoted by the previous two dialogue turns $[p_i, q_i]$. The dialogue history is further transformed to a vector representation by feeding the concatenation of p_i and q_i into an LSTM encoder model as

described in Li et al. (2016a).

3.3 Policy

A policy takes the form of an LSTM encoder-decoder (i.e., $p_{RL}(p_{i+1}|p_i, q_i)$) and is defined by its parameters. Note that we use a stochastic representation of the policy (a probability distribution over actions given states). A deterministic policy would result in a discontinuous objective that is difficult to optimize using gradient-based methods.

3.4 Reward

r denotes the reward obtained for each action. In this subsection, we discuss major factors that contribute to the success of a dialogue and describe how approximations to these factors can be operationalized in computable reward functions.

Ease of answering A turn generated by a machine should be easy to respond to. This aspect of a turn is related to its *forward-looking function*: the constraints a turn places on the next turn (Schegloff and Sacks, 1973; Allwood et al., 1992). We propose to measure the ease of answering a generated turn by using the negative log likelihood of responding to that utterance with a dull response. We manually constructed a list of dull responses $\mathbb{S}$ consisting 8 turns such as "I don't know what you are talking about", "I have no idea", etc., that we and others have found occur very frequently in SEQ2SEQ models of conversations. The reward function is given as follows:

$$r_1 = -\frac{1}{N_{\mathbb{S}}} \sum_{s \in \mathbb{S}} \frac{1}{N_s} \log p_{\text{seq2seq}}(s|a) \qquad (1)$$

where $N_{\mathbb{S}}$ denotes the cardinality of $N_{\mathbb{S}}$ and N_s denotes the number of tokens in the dull response s. Although of course there are more ways to generate dull responses than the list can cover, many of these responses are likely to fall into similar regions in the vector space computed by the model. A system less likely to generate utterances in the list is thus also less likely to generate other dull responses.

p_{seq2seq} represents the likelihood output by SEQ2SEQ models. It is worth noting that p_{seq2seq} is different from the stochastic policy function $p_{RL}(p_{i+1}|p_i, q_i)$, since the former is learned based on the MLE objective of the SEQ2SEQ model while the latter is the policy optimized for long-term future reward in the RL setting. r_1 is further scaled by the length of target $\mathbb{S}$.

Information Flow We want each agent to contribute new information at each turn to keep the dialogue moving and avoid repetitive sequences. We therefore propose penalizing semantic similarity between consecutive turns from the same agent. Let h_{p_i} and $h_{p_{i+1}}$ denote representations obtained from the encoder for two consecutive turns p_i and p_{i+1}. The reward is given by the negative log of the cosine similarity between them:

$$r_2 = -\log \cos(h_{p_i}, h_{p_{i+1}}) = -\log \frac{h_{p_i} \cdot h_{p_{i+1}}}{\|h_{p_i}\| \|h_{p_{i+1}}\|} \qquad (2)$$

Semantic Coherence We also need to measure the adequacy of responses to avoid situations in which the generated replies are highly rewarded but are ungrammatical or not coherent. We therefore consider the mutual information between the action a and previous turns in the history to ensure the generated responses are coherent and appropriate:

$$r_3 = \frac{1}{N_a} \log p_{\text{seq2seq}}(a|q_i, p_i) + \frac{1}{N_{q_i}} \log p^{\text{backward}}_{\text{seq2seq}}(q_i|a) \qquad (3)$$

$p_{\text{seq2seq}}(a|p_i, q_i)$ denotes the probability of generating response a given the previous dialogue utterances $[p_i, q_i]$. $p^{\text{backward}}_{\text{seq2seq}}(q_i|a)$ denotes the backward probability of generating the previous dialogue utterance q_i based on response a. $p^{\text{backward}}_{\text{seq2seq}}$ is trained in a similar way as standard SEQ2SEQ models with sources and targets swapped. Again, to control the influence of target length, both $\log p_{\text{seq2seq}}(a|q_i, p_i)$ and $\log p^{\text{backward}}_{\text{seq2seq}}(q_i|a)$ are scaled by the length of targets.

The final reward for action a is a weighted sum of the rewards discussed above:

$$r(a, [p_i, q_i]) = \lambda_1 r_1 + \lambda_2 r_2 + \lambda_3 r_3 \qquad (4)$$

where $\lambda_1 + \lambda_2 + \lambda_3 = 1$. We set $\lambda_1 = 0.25$, $\lambda_2 = 0.25$ and $\lambda_3 = 0.5$. A reward is observed after the agent reaches the end of each sentence.

4 Simulation

The central idea behind our approach is to simulate the process of two virtual agents taking turns talking with each other, through which we can explore the

state-action space and learn a policy $p_{RL}(p_{i+1}|p_i, q_i)$ that leads to the optimal expected reward. We adopt an AlphaGo-style strategy (Silver et al., 2016) by initializing the RL system using a general response generation policy which is learned from a fully supervised setting.

4.1 Supervised Learning

For the first stage of training, we build on prior work of predicting a generated target sequence given dialogue history using the supervised SEQ2SEQ model (Vinyals and Le, 2015). Results from supervised models will be later used for initialization.

We trained a SEQ2SEQ model with attention (Bahdanau et al., 2015) on the OpenSubtitles dataset, which consists of roughly 80 million source-target pairs. We treated each turn in the dataset as a target and the concatenation of two previous sentences as source inputs.

4.2 Mutual Information

Samples from SEQ2SEQ models are often times dull and generic, e.g., "*i don't know*" (Li et al., 2016a) We thus do not want to initialize the policy model using the pre-trained SEQ2SEQ models because this will lead to a lack of diversity in the RL models' experiences. Li et al. (2016a) showed that modeling mutual information between sources and targets will significantly decrease the chance of generating dull responses and improve general response quality. We now show how we can obtain an encoder-decoder model which generates maximum mutual information responses.

As illustrated in Li et al. (2016a), direct decoding from Eq 3 is infeasible since the second term requires the target sentence to be completely generated. Inspired by recent work on sequence level learning (Ranzato et al., 2015), we treat the problem of generating maximum mutual information response as a reinforcement learning problem in which a reward of mutual information value is observed when the model arrives at the end of a sequence.

Similar to Ranzato et al. (2015), we use policy gradient methods (Sutton et al., 1999; Williams, 1992) for optimization. We initialize the policy model p_{RL} using a pre-trained $p_{\text{SEQ2SEQ}}(a|p_i, q_i)$ model. Given an input source $[p_i, q_i]$, we generate a candidate list $A = \{\hat{a}|\hat{a} \sim p_{RL}\}$. For each generated candidate $\hat{a}$, we will obtain the mutual information score $m(\hat{a}, [p_i, q_i])$ from the pre-trained $p_{\text{SEQ2SEQ}}(a|p_i, q_i)$ and $p^{\text{backward}}_{\text{SEQ2SEQ}}(q_i|a)$. This mutual information score will be used as a reward and back-propagated to the encoder-decoder model, tailoring it to generate sequences with higher rewards. We refer the readers to Zaremba and Sutskever (2015) and Williams (1992) for details. The expected reward for a sequence is given by:

$$J(\theta) = \mathbb{E}[m(\hat{a}, [p_i, q_i])] \tag{5}$$

The gradient is estimated using the likelihood ratio trick:

$$\nabla J(\theta) = m(\hat{a}, [p_i, q_i]) \nabla \log p_{RL}(\hat{a}|[p_i, q_i]) \tag{6}$$

We update the parameters in the encoder-decoder model using stochastic gradient descent. A curriculum learning strategy is adopted (Bengio et al., 2009) as in Ranzato et al. (2015) such that, for every sequence of length T we use the MLE loss for the first L tokens and the reinforcement algorithm for the remaining $T - L$ tokens. We gradually anneal the value of L to zero. A baseline strategy is employed to decrease the learning variance: an additional neural model takes as inputs the generated target and the initial source and outputs a baseline value, similar to the strategy adopted by Zaremba and Sutskever (2015). The final gradient is thus:

$$\nabla J(\theta) = \nabla \log p_{RL}(\hat{a}|[p_i, q_i])[m(\hat{a}, [p_i, q_i]) - b] \tag{7}$$

4.3 Dialogue Simulation between Two Agents

We simulate conversations between the two virtual agents and have them take turns talking with each other. The simulation proceeds as follows: at the initial step, a message from the training set is fed to the first agent. The agent encodes the input message to a vector representation and starts decoding to generate a response output. Combining the immediate output from the first agent with the dialogue history, the second agent updates the state by encoding the dialogue history into a representation and uses the decoder RNN to generate responses, which are subsequently fed back to the first agent, and the process is repeated.

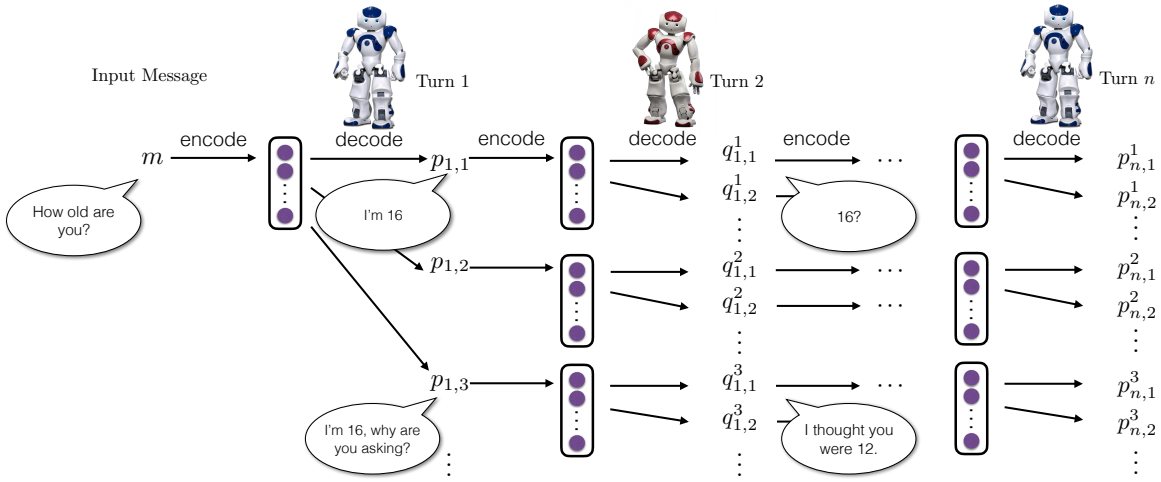

Figure 1: Dialogue simulation between the two agents.

Optimization We initialize the policy model p_{RL} with parameters from the mutual information model described in the previous subsection. We then use policy gradient methods to find parameters that lead to a larger expected reward. The objective to maximize is the expected future reward:

$$J_{RL}(\theta) = \mathbb{E}_{p_{RL}(a_{1:T})}[\sum_{i=1}^{i=T} R(a_i, [p_i, q_i])] \quad (8)$$

where $R(a_i, [p_i, q_i])$ denotes the reward resulting from action a_i. We use the likelihood ratio trick (Williams, 1992; Glynn, 1990; Aleksandrov et al., 1968) for gradient updates:

$$\nabla J_{RL}(\theta) \approx \sum_i \nabla \log p(a_i|p_i, q_i) \sum_{i=1}^{i=T} R(a_i, [p_i, q_i]) \quad (9)$$

We refer readers to Williams (1992) and Glynn (1990) for more details.

4.4 Curriculum Learning

A curriculum Learning strategy is again employed in which we begin by simulating the dialogue for 2 turns, and gradually increase the number of simulated turns. We generate 5 turns at most, as the number of candidates to examine grows exponentially in the size of candidate list. Five candidate responses are generated at each step of the simulation.

5 Experimental Results

In this section, we describe experimental results along with qualitative analysis. We evaluate dialogue generation systems using both human judgments and two automatic metrics: conversation length (number of turns in the entire session) and diversity.

5.1 Dataset

The dialogue simulation requires high-quality initial inputs fed to the agent. For example, an initial input of "why ?" is undesirable since it is unclear how the dialogue could proceed. We take a subset of 10 million messages from the OpenSubtitles dataset and extract 0.8 million sequences with the lowest likelihood of generating the response "*i don't know what you are taking about*" to ensure initial inputs are easy to respond to.

5.2 Automatic Evaluation

Evaluating dialogue systems is difficult. Metrics such as BLEU (Papineni et al., 2002) and perplexity have been widely used for dialogue quality evaluation (Li et al., 2016a; Vinyals and Le, 2015; Sordoni et al., 2015), but it is widely debated how well these automatic metrics are correlated with true response quality (Liu et al., 2016; Galley et al., 2015). Since the goal of the proposed system is not to predict the highest probability response, but rather the long-term success of the dialogue, we do not employ BLEU or perplexity for evaluation[2].

[2]We found the RL model performs worse on BLEU score. On a random sample of 2,500 conversational pairs, single reference BLEU scores for RL models, mutual information models and vanilla SEQ2SEQ models are respectively 1.28, 1.44 and 1.17. BLEU is highly correlated with perplexity in generation tasks.

Model	# of simulated turns
SEQ2SEQ	2.68
mutual information	3.40
RL	4.48

Table 2: The average number of simulated turns from standard SEQ2SEQ models, mutual information model and the proposed RL model.

Length of the dialogue The first metric we propose is the length of the simulated dialogue. We say a dialogue ends when one of the agents starts generating dull responses such as "*i don't know*" [3] or two consecutive utterances from the same user are highly overlapping[4].

The test set consists of 1,000 input messages. To reduce the risk of circular dialogues, we limit the number of simulated turns to be less than 8. Results are shown in Table 2. As can be seen, using mutual information leads to more sustained conversations between the two agents. The proposed RL model is first trained based on the mutual information objective and thus benefits from it in addition to the RL model. We observe that the RL model with dialogue simulation achieves the best evaluation score.

Diversity We report degree of diversity by calculating the number of distinct unigrams and bigrams in generated responses. The value is scaled by the total number of generated tokens to avoid favoring long sentences as described in Li et al. (2016a). The resulting metric is thus a type-token ratio for unigrams and bigrams.

For both the standard SEQ2SEQ model and the proposed RL model, we use beam search with a beam size 10 to generate a response to a given input message. For the mutual information model, we first generate n-best lists using $p_{\text{SEQ2SEQ}}(t|s)$ and then linearly re-rank them using $p_{\text{SEQ2SEQ}}(s|t)$. Results are presented in Table 4. We find that the proposed RL model generates more diverse outputs when compared against both the vanilla SEQ2SEQ model and the mutual information model.

Human Evaluation We explore three settings for human evaluation: the first setting is similar to what was described in Li et al. (2016a), where we employ crowdsourced judges to evaluate a random sample of 500 items. We present both an input message and the generated outputs to 3 judges and ask them to decide which of the two outputs is better (denoted as *single-turn general quality*). Ties are permitted. Identical strings are assigned the same score. We measure the improvement achieved by the RL model over the mutual information model by the mean difference in scores between the models.

For the second setting, judges are again presented with input messages and system outputs, but are asked to decide which of the two outputs is easier to respond to (denoted as *single-turn ease to answer*). Again we evaluate a random sample of 500 items, each being assigned to 3 judges.

For the third setting, judges are presented with simulated conversations between the two agents (denoted as *multi-turn general quality*). Each conversation consists of 5 turns. We evaluate 200 simulated conversations, each being assigned to 3 judges, who are asked to decide which of the simulated conversations is of higher quality.

Results for human evaluation are shown in Table 5. The proposed RL system does not introduce a significant boost in single-turn response quality (winning 40 percent of time and losing 36 percent of time). This is in line with our expectations, as the RL model is not optimized to predict the next utterance, but rather to increase long-term reward. The RL system produces responses that are significantly easier to answer than does the mutual information system, as demonstrated by the *single-turn ease to answer* setting (winning 52 percent of time and losing 23 percent of time), and also significantly higher quality multi-turn dialogues, as demonstrated by the *multi-turn general quality* setting (winning 72 percent of time).

Qualitative Analysis and Discussion We show a random sample of generated responses in Table 3 and simulated conversations in Table 1 at the beginning of the paper. From Table 3, we can see that the RL based agent indeed generates more interactive

Since the RL model is trained based on future reward rather than MLE, it is not surprising that the RL based models achieve lower BLEU score.

[3] We use a simple rule matching method, with a list of 8 phrases that count as dull responses. Although this can lead to both false-positives and -negatives, it works pretty well in practice.

[4] Two utterances are considered to be repetitive if they share more than 80 percent of their words.

Input Message	Mutual Information Model	RL
How old are you?	I'm 16.	I'm 16, why are you asking?
What's your full name?	I have no idea.	What's yours?
I don't want to go home tonight.	Really?	Why?
Do you have any feelings for me?	I don't know what you are talking about.	I don't want to hurt your feelings.
How much time do you have here?	Not long enough. Sorry, sir.	Ten seconds.
Shall we get started?	Of course!	Yes. We've got a lot of work to do here.
Do you play football?	No, i don't	Yes. I love football!
We'd have to talk to him.	I mean, he's a good guy	About what ?
How come you never say it?	Because I don't want to hurt you.	I don't think it's a good idea to say it.

Table 3: Sampled responses generated from the mutual information models and the proposed RL model.

Model	Unigram	Bigram
SEQ2SEQ	0.0062	0.015
mutual information	0.011	0.031
RL	0.017	0.041

Table 4: Diversity scores (type-token ratios) for the standard SEQ2SEQ model, mutual information model and the proposed RL model.

Setting	RL-win	RL-lose	Tie
single-turn general quality	0.40	0.36	0.24
single-turn ease to answer	0.52	0.23	0.25
multi-turn general quality	0.72	0.12	0.16

Table 5: RL gains over the mutual information system based on pairwise human judgments.

responses than the other baselines. We also find that the RL model has a tendency to end a sentence with another question and hand the conversation over to the user. From Table 1, we observe that the RL model manages to produce more interactive and sustained conversations than the mutual information model.

During error analysis, we found that although we penalize repetitive utterances in consecutive turns, the dialogue sometimes enters a cycle with length greater than one, as shown in Table 6. This can be ascribed to the limited amount of conversational history we consider. Another issue observed is that the model sometimes starts a less relevant topic during the conversation. There is a tradeoff between relevance and less repetitiveness, as manifested in the reward function we define in Eq 4.

The fundamental problem, of course, is that the manually defined reward function can't possibly cover the crucial aspects that define an ideal conversation. While the heuristic rewards that we defined are amenable to automatic calculation, and do capture some aspects of what makes a good conversation, ideally the system would instead receive real rewards from humans. Another problem with the current model is that we can only afford to explore a very small number of candidates and simulated turns since the number of cases to consider grow exponentially.

A: What's your name ?
B: Daniel.
A: How old are you ?
B. Twelve. What's your name ?
A. Daniel.
B: How old are you ?
A: Twelve. What's your name ?
B: Daniel.
A: How old are you ?
B ...

Table 6: An simulated dialogue with a cycle longer than one.

6 Conclusion

We introduce a reinforcement learning framework for neural response generation by simulating dialogues between two agents, integrating the strengths of neural SEQ2SEQ systems and reinforcement learning for dialogue. Like earlier neural SEQ2SEQ models, our framework captures the compositional models of the meaning of a dialogue turn and generates semantically appropriate responses. Like reinforcement learning dialogue systems, our framework is able to generate utterances that optimize future reward, successfully capturing global properties of a good conversation. Despite the fact that our model uses very simple, operationable heuristics for capturing these global properties, the framework generates more diverse, interactive responses that foster a more sustained conversation.

Neural Text Generation from Structured Data with Application to the Biography Domain

Rémi Lebret* EPFL, Switzerland
David Grangier Facebook AI Research
Michael Auli Facebook AI Research

Abstract

This paper introduces a neural model for concept-to-text generation that scales to large, rich domains. It generates biographical sentences from fact tables on a new dataset of biographies from Wikipedia. This set is an order of magnitude larger than existing resources with over 700k samples and a 400k vocabulary. Our model builds on conditional neural language models for text generation. To deal with the large vocabulary, we extend these models to mix a fixed vocabulary with *copy actions* that transfer sample-specific words from the input database to the generated output sentence. To deal with structured data, we allow the model to embed words differently depending on the data fields in which they occur. Our neural model significantly outperforms a Templated Kneser-Ney language model by nearly 15 BLEU.

1 Introduction

Concept-to-text generation renders structured records into natural language (Reiter et al., 2000). A typical application is to generate a weather forecast based on a set of structured meteorological measurements. In contrast to previous work, we scale to the large and very diverse problem of generating biographies based on Wikipedia infoboxes. An infobox is a fact table describing a person, similar to a person subgraph in a knowledge base (Bollacker et al., 2008; Ferrucci, 2012). Similar generation applications include the generation of product descriptions based on a catalog of millions of items with dozens of attributes each.

Previous work experimented with datasets that contain only a few tens of thousands of records such as WEATHERGOV or the ROBOCUP dataset, while our dataset contains over 700k biographies from Wikipedia. Furthermore, these datasets have a limited vocabulary of only about 350 words each, compared to over 400k words in our dataset.

To tackle this problem we introduce a statistical generation model conditioned on a Wikipedia infobox. We focus on the generation of the first sentence of a biography which requires the model to select among a large number of possible fields to generate an adequate output. Such diversity makes it difficult for classical count-based models to estimate probabilities of rare events due to data sparsity. We address this issue by parameterizing words and fields as embeddings, along with a neural language model operating on them (Bengio et al., 2003). This factorization allows us to scale to a larger number of words and fields than Liang et al. (2009), or Kim and Mooney (2010) where the number of parameters grows as the product of the number of words and fields.

Moreover, our approach does not restrict the relations between the field contents and the generated text. This contrasts with less flexible strategies that assume the generation to follow either a hybrid alignment tree (Kim and Mooney, 2010), a probabilistic context-free grammar (Konstas and Lapata, 2013), or a tree adjoining grammar (Gyawali and Gardent, 2014).

Our model exploits structured data both globally and locally. Global conditioning summarizes all information about a personality to understand high-level themes such as that the biography is about a scientist or an artist, while as local conditioning describes the previously generated tokens in terms of the their relationship to the infobox. We analyze the effectiveness of each and demonstrate their complementarity.

2 Related Work

Traditionally, generation systems relied on rules and hand-crafted specifications (Dale et al., 2003; Reiter et al., 2005; Green, 2006; Galanis and Androut-

*Rémi performed this work while interning at Facebook.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1203–1213,
Austin, Texas, November 1-5, 2016.

sopoulos, 2007; Turner et al., 2010). Generation is divided into modular, yet highly interdependent, decisions: (1) *content planning* defines which parts of the input fields or meaning representations should be selected; (2) *sentence planning* determines which selected fields are to be dealt with in each output sentence; and (3) *surface realization* generates those sentences.

Data-driven approaches have been proposed to automatically learn the individual modules. One approach first aligns records and sentences and then learns a content selection model (Duboue and McKeown, 2002; Barzilay and Lapata, 2005). Hierarchical hidden semi-Markov generative models have also been used to first determine which facts to discuss and then to generate words from the predicates and arguments of the chosen facts (Liang et al., 2009). Sentence planning has been formulated as a supervised set partitioning problem over facts where each partition corresponds to a sentence (Barzilay and Lapata, 2006). End-to-end approaches have combined sentence planning and surface realization by using explicitly aligned sentence/meaning pairs as training data (Ratnaparkhi, 2002; Wong and Mooney, 2007; Belz, 2008; Lu and Ng, 2011). More recently, content selection and surface realization have been combined (Angeli et al., 2010; Kim and Mooney, 2010; Konstas and Lapata, 2013).

At the intersection of rule-based and statistical methods, hybrid systems aim at leveraging human contributed rules and corpus statistics (Langkilde and Knight, 1998; Soricut and Marcu, 2006; Mairesse and Walker, 2011).

Our approach is inspired by the recent success of neural language models for image captioning (Kiros et al., 2014; Karpathy and Fei-Fei, 2015; Vinyals et al., 2015; Fang et al., 2015; Xu et al., 2015), machine translation (Devlin et al., 2014; Bahdanau et al., 2015; Luong et al., 2015), and modeling conversations and dialogues (Shang et al., 2015; Wen et al., 2015; Yao et al., 2015).

Our model is most similar to Mei et al. (2016) who use an encoder-decoder style neural network model to tackle the WEATHERGOV and ROBOCUP tasks. Their architecture relies on LSTM units and an attention mechanism which reduces scalability compared to our simpler design.

3 Language Modeling for Constrained Sentence generation

Conditional language models are a popular choice to generate sentences. We introduce a table-conditioned language model for constraining text generation to include elements from fact tables.

3.1 Language model

Given a sentence $s = w_1, \ldots, w_T$ with T words from vocabulary $\mathcal{W}$, a language model estimates:

$$P(s) = \prod_{t=1}^{T} P(w_t | w_1, \ldots, w_{t-1}) \,. \quad (1)$$

Let $c_t = w_{t-(n-1)}, \ldots, w_{t-1}$ be the sequence of $n-1$ context words preceding w_t. An n-gram language model makes an order n Markov assumption,

$$P(s) \approx \prod_{t=1}^{T} P(w_t | c_t) \,. \quad (2)$$

3.2 Language model conditioned on tables

A table is a set of field/value pairs, where values are sequences of words. We therefore propose language models that are conditioned on these pairs.

Local conditioning refers to the information from the table that is applied to the description of the words which have already generated, i.e. the previous words that constitute the context of the language

Table (g_f, g_w)

name	John Doe
birthdate	18 April 1352
birthplace	Oxford UK
occupation	placeholder
spouse	Jane Doe
children	Johnnie Doe

input text (c_t, z_{c_t})

	John	Doe	(	18	April	1352	)	is	a
c_t	13944	unk	17	37	92	25	18	12	4
z_{c_t}	(name,1,2)	(name,2,1) (spouse,2,1) (children,2,1)	$\emptyset$	(birthd.,1,3)	(birthd.,2,2)	(birthd.,3,1)	$\emptyset$	$\emptyset$	$\emptyset$

output candidates $(w \in \mathcal{W} \cup \mathcal{Q})$

	the	...	april	...	placeholder	...	john	...	doe
w	1	...	92	...	5302	...	13944	...	unk
z_w	$\emptyset$		(birthd.,2,2)		(occupation,1,1)		(name,1,2)		(name,2,1) (spouse,2,1) (children,2,1)

Figure 2: Table features (right) for an example table (left); $\mathcal{W} \cup \mathcal{Q}$ is the set of all output words as defined in Section 3.3.

model. The table allows us to describe each word not only by its string (or index in the vocabulary) but also by a descriptor of its occurrence in the table. Let $\mathcal{F}$ define the set of all possible fields f. The occurrence of a word w in the table is described by a set of (field, position) pairs.

$$z_w = \left\{(f_i, p_i)\right\}_{i=1}^{m}, \tag{3}$$

where m is the number of occurrences of w. Each pair (f, p) indicates that w occurs in field f at position p. In this scheme, most words are described by the empty set as they do not occur in the table. For example, the word *linguistics* in the table of Figure 1 is described as follows:

$$z_{\text{linguistics}} = \{(\text{fields}, 8); (\text{known for}, 4)\}, \tag{4}$$

assuming words are lower-cased and commas are treated as separate tokens.

Conditioning both on the field type and the position within the field allows the model to encode field-specific regularities, e.g., a number token in a date field is likely followed by a month token; knowing that the number is the first token in the date field makes this even more likely.

The (field, position) description scheme of the table does not allow to express that a token terminates a field which can be useful to capture field transitions. For biographies, the last token of the name field is often followed by an introduction of the birth date like '(' or 'was born'. We hence extend our descriptor to a triplet that includes the position of the token counted from the end of the field:

$$z_w = \left\{(f_i, p_i^+, p_i^-)\right\}_{i=1}^{m}, \tag{5}$$

where our example becomes:

$$z_{\text{linguistics}} = \{(\text{fields}, 8, 4); (\text{known for}, 4, 13)\}.$$

We extend Equation 2 to use the above information as additional conditioning context when generating a sentence s:

$$P(s|z) = \prod_{t=1}^{T} P(w_t|c_t, z_{c_t}), \tag{6}$$

where $z_{c_t} = z_{w_{t-(n-1)}}, \ldots, z_{w_{t-1}}$ are referred to as the local conditioning variables since they describe the local context (previous word) relations with the table.

Global conditioning refers to information from all tokens and fields of the table, regardless whether they appear in the previous generated words or not. The set of fields available in a table often impacts the structure of the generation. For biographies, the fields used to describe a politician are different from the ones for an actor or an athlete. We introduce global conditioning on the available fields g_f as

$$P(s|z, g_f) = \prod_{t=1}^{T} P(w_t|c_t, z_{c_t}, g_f). \tag{7}$$

Similarly, global conditioning g_w on the available

words occurring in the table is introduced:

$$P(s|z, g_f, g_w) = \prod_{t=1}^{T} P(w_t|c_t, z_{c_t}, g_f, g_w). \quad (8)$$

Tokens provide information complementary to fields. For example, it may be hard to distinguish a basketball player from a hockey player by looking only at the field names, e.g. teams, league, position, weight and height, etc. However the actual field tokens such as team names, league name, player's position can help the model to give a better prediction. Here, $g_f \in \{0,1\}^{\mathcal{F}}$ and $g_w \in \{0,1\}^{\mathcal{W}}$ are binary indicators over fixed field and word vocabularies.

Figure 2 illustrates the model with a schematic example. For predicting the next word w_t after a given context c_t, the language model is conditioned on sets of triplets for each word occurring in the table z_{c_t}, along with all fields and words from this table.

3.3 Copy actions

So far we extended the model conditioning with features derived from the fact table. We now turn to using table information when scoring output words. In particular, sentences which express facts from a given table often copy words from the table. We therefore extend our model to also score special field tokens such as `name_1` or `name_2` which are subsequently added to the score of the corresponding words from the field value.

Our model reads a table and defines an output domain $\mathcal{W} \cup \mathcal{Q}$. $\mathcal{Q}$ defines all tokens in the table, which might include out of vocabulary words ($\notin \mathcal{W}$). For instance *Park-Rhodes* in Figure 1 is not in $\mathcal{W}$. However, *Park-Rhodes* will be included in $\mathcal{Q}$ as `name_2` (since it is the second token of the name field) which allows our model to generate it. This mechanism is inspired by recent work on attention based word copying for neural machine translation (Luong et al., 2015) as well as delexicalization for neural dialog systems (Wen et al., 2015). It also builds upon older work such as class-based language models for dialog systems (Oh and Rudnicky, 2000).

4 A Neural Language Model Approach

A feed-forward neural language model (NLM) estimates $P(w_t|c_t)$ with a parametric function $\boldsymbol{\phi}_\theta$ (Equation 1), where θ refers to all learnable parameters of the network. This function is a composition of simple differentiable functions or *layers*.

4.1 Mathematical notations and layers

We denote matrices as bold upper case letters ($\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z}$), and vectors as bold lower-case letters ($\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$). $\mathbf{A}_i$ represents the i^{th} row of matrix $\mathbf{A}$. When $\mathbf{A}$ is a 3-d matrix, then $\mathbf{A}_{i,j}$ represents the vector of the i^{th} first dimension and j^{th} second dimension. Unless otherwise stated, vectors are assumed to be column vectors. We use $[\mathbf{v}_1; \mathbf{v}_2]$ to denote vector concatenation. Next, we introduce the notation for the different layers used in our approach.

Embedding layer. Given a parameter matrix $\mathbf{X} \in \mathbb{R}^{N \times d}$, the *embedding layer* is a lookup table that performs an array indexing operation:

$$\boldsymbol{\psi}_{\mathbf{X}}(x_i) = \mathbf{X}_i \in \mathbb{R}^d, \quad (9)$$

where $\mathbf{X}_i$ corresponds to the embedding of the element x_i at row i. When $\mathbf{X}$ is a 3-d matrix, the lookup table takes two arguments:

$$\boldsymbol{\psi}_{\mathbf{X}}(x_i, x_j) = \mathbf{X}_{i,j} \in \mathbb{R}^d, \quad (10)$$

where $\mathbf{X}_{i,j}$ corresponds to the embedding of the pair (x_i, x_j) at index (i, j). The lookup table operation can be applied for a sequence of elements $s = x_1, \ldots, x_T$. A common approach is to concatenate all resulting embeddings:

$$\boldsymbol{\psi}_{\mathbf{X}}(s) = \left[\boldsymbol{\psi}_{\mathbf{X}}(x_1); \ldots; \boldsymbol{\psi}_{\mathbf{X}}(x_T)\right] \in \mathbb{R}^{T \times d}. \quad (11)$$

Linear layer. This layer applies a linear transformation to its inputs $\mathbf{x} \in \mathbb{R}^n$:

$$\boldsymbol{\gamma}_\theta(\mathbf{x}) = \mathbf{W}\mathbf{x} + \mathbf{b} \quad (12)$$

where $\theta = \{\mathbf{W}, \mathbf{b}\}$ are the trainable parameters with $\mathbf{W} \in \mathbb{R}^{m \times n}$ being the weight matrix, and $\mathbf{b} \in \mathbb{R}^m$ is the bias term.

Softmax layer. Given a context input c_t, the final layer outputs a score for each word $w_t \in \mathcal{W}$, $\boldsymbol{\phi}_\theta(c_t) \in \mathbb{R}^{|\mathcal{W}|}$. The probability distribution is obtained by applying the softmax activation function:

$$P(w_t = w|c_t) = \frac{\exp(\boldsymbol{\phi}_\theta(c_t, w))}{\sum_{i=1}^{|\mathcal{W}|} \exp(\boldsymbol{\phi}_\theta(c_t, w_i))} \quad (13)$$

4.2 Embeddings as inputs

A key aspect of neural language models is the use of word embeddings. Similar words tend to have similar embeddings and thus share latent features. The probability estimates of those models are smooth functions of these embeddings, and a small change in the features results in a small change in the probability estimates (Bengio et al., 2003). Therefore, neural language models can achieve better generalization for unseen n-grams. Next, we show how we map fact tables to continuous space in similar spirit.

Word embeddings. Formally, the embedding layer maps each context word index to a continuous d-dimensional vector. It relies on a parameter matrix $\mathbf{E} \in \mathbb{R}^{|\mathcal{W}| \times d}$ to convert the input c_t into $n-1$ vectors of dimension d:

$$\boldsymbol{\psi}_{\mathbf{E}}(c_t) = \left[\boldsymbol{\psi}_{\mathbf{E}}(w_{t-(n-1)}); \ldots; \boldsymbol{\psi}_{\mathbf{E}}(w_{t-1})\right]. \quad (14)$$

$\mathbf{E}$ can be initialized randomly or with pre-trained word embeddings.

Table embeddings. As described in Section 3.2, the language model is conditioned on elements from the table. Embedding matrices are therefore defined to model both local and global conditioning information. For local conditioning, we denote the maximum length of a sequence of words as l. Each field $f_j \in \mathcal{F}$ is associated with $2 \times l$ vectors of d dimensions, the first l of those vectors embed all possible starting positions $1, \ldots, l$, and the remaining l vectors embed ending positions. This results in two parameter matrices $\mathbf{Z} = \{\mathbf{Z}^+, \mathbf{Z}^-\} \in \mathbb{R}^{|\mathcal{F}| \times l \times d}$. For a given triplet (f_j, p_i^+, p_i^-), $\boldsymbol{\psi}_{\mathbf{Z}^+}(f_j, p_i^+)$ and $\boldsymbol{\psi}_{\mathbf{Z}^-}(f_j, p_i^-)$ refer to the embedding vectors of the start and end position for field f_j, respectively.

Finally, global conditioning uses two parameter matrices $\mathbf{G}^f \in \mathbb{R}^{|\mathcal{F}| \times g}$ and $\mathbf{G}^w \in \mathbb{R}^{|\mathcal{W}| \times g}$. $\boldsymbol{\psi}_{\mathbf{G}^f}(f_j)$ maps a table field f_j into a vector of dimension g, while $\boldsymbol{\psi}_{\mathbf{G}^w}(w_t)$ maps a word w_t into a vector of the same dimension. In general, $\mathbf{G}^w$ shares its parameters with $\mathbf{E}$, provided $d = g$.

Aggregating embeddings. We represent each occurence of a word w as a triplet (field, start, end) where we have embeddings for the start and end position as described above. Often times a particular word w occurs multiple times in a table, e.g., 'linguistics' has two instances in Figure 1. In this case, we perform a component-wise max over the start embeddings of all instances of w to obtain the best features across all occurrences of w. We do the same for end position embeddings:

$$\boldsymbol{\psi}_{\mathbf{Z}}(z_{w_t}) = \Big[\max\left\{\boldsymbol{\psi}_{\mathbf{Z}^+}(f_j, p_i^+), \forall (f_j, p_i^+, p_i^-) \in z_{w_t}\right\}; \max\left\{\boldsymbol{\psi}_{\mathbf{Z}^-}(f_j, p_i^-), \forall (f_j, p_i^+, p_i^-) \in z_{w_t}\right\}\Big] \quad (15)$$

A special no-field embedding is assigned to w_t when the word is not associated to any fields. An embedding $\boldsymbol{\psi}_{\mathbf{Z}}(z_{c_t})$ for encoding the local conditioning of the input c_t is obtained by concatenation.

For global conditioning, we define $\mathcal{F}^q \subset \mathcal{F}$ as the set of all the fields in a given table q, and $\mathcal{Q}$ as the set of all words in q. We also perform max aggregation. This yields the vectors

$$\boldsymbol{\psi}_{\mathbf{G}^f}(g_f) = \max\left\{\boldsymbol{\psi}_{\mathbf{G}^f}(f_j), \forall f_j \in \mathcal{F}^q\right\}, \quad (16)$$

and

$$\boldsymbol{\psi}_{\mathbf{G}^w}(g_w) = \max\left\{\boldsymbol{\psi}_{\mathbf{G}^w}(w_t), \forall w_t \in \mathcal{Q}\right\}. \quad (17)$$

The final embedding which encodes the context input with conditioning is then the concatenation of these vectors:

$$\boldsymbol{\psi}_{\alpha_1}(c_t, z_{c_t}, g_f, g_w) = \left[\boldsymbol{\psi}_{\mathbf{E}}(c_t);\, \boldsymbol{\psi}_{\mathbf{Z}}(z_{c_t});\, \boldsymbol{\psi}_{\mathbf{G}^f}(g_f);\, \boldsymbol{\psi}_{\mathbf{G}^w}(g_w)\right] \in \mathbb{R}^{d^1}, \quad (18)$$

with $\alpha_1 = \{\mathbf{E}, \mathbf{Z}^+, \mathbf{Z}^-, \mathbf{G}^f, \mathbf{G}^w\}$ and $d^1 = (n-1) \times (3 \times d) + (2 \times g)$. For simplification purpose, we define the context input $x = \{c_t, z_{c_t}, g_f, g_w\}$ in the following equations. This context embedding is mapped to a latent context representation using a linear operation followed by a hyperbolic tangent:

$$\mathbf{h}(x) = \tanh\Big(\boldsymbol{\gamma}_{\alpha_2}\big(\boldsymbol{\psi}_{\alpha_1}(x)\big)\Big) \in \mathbb{R}^{\text{nhu}}, \quad (19)$$

where $\alpha_2 = \{\mathbf{W}_2, \mathbf{b}_2\}$, with $\mathbf{W}_2 \in \mathbb{R}^{\text{nhu} \times d^1}$ and $\mathbf{b}_2 \in \mathbb{R}^{\text{nhu}}$.

4.3 In-vocabulary outputs

The hidden representation of the context then goes to another linear layer to produce a real value score for each word in the vocabulary:

$$\boldsymbol{\phi}_{\alpha}^{\mathcal{W}}(x) = \boldsymbol{\gamma}_{\alpha_3}\Big(\mathbf{h}(x)\Big) \in \mathbb{R}^{|\mathcal{W}|}, \quad (20)$$

where $\alpha_3 = \{\mathbf{W}_3, \mathbf{b}_3\}$, with $\mathbf{W}_3 \in \mathbb{R}^{|\mathcal{W}| \times \text{nhu}}$ and $\mathbf{b}_3 \in \mathbb{R}^{|\mathcal{W}|}$, and $\alpha = \{\alpha_1, \alpha_2, \alpha_3\}$.

4.4 Mixing outputs for better copying

Section 3.3 explains that each word w from the table is also associated with z_w, the set of fields in which it occurs, along with the position in that field. Similar to local conditioning, we represent each field and position pair (f_j, p_i) with an embedding $\boldsymbol{\psi}_{\mathbf{F}}(f_j, p_i)$, where $\mathbf{F} \in \mathbb{R}^{|\mathcal{F}| \times l \times d}$. These embeddings are then projected into the same space as the latent representation of context input $\mathbf{h}(x) \in \mathbb{R}^{\text{nhu}}$. Using the max operation over the embedding dimension, each word is finally embedded into a unique vector:

$$\mathbf{q}(w) = \max \Big\{ \tanh\Big(\boldsymbol{\gamma}_\beta\big(\boldsymbol{\psi}_{\mathbf{F}}(f_j, p_i)\big)\Big), \forall (f_j, p_i) \in z_w \Big\}, \quad (21)$$

where $\beta = \{\mathbf{W}_4, \mathbf{b}_4\}$ with $\mathbf{W}_4 \in \mathbb{R}^{\text{nhu} \times d}$, and $\mathbf{b}_4 \in \mathbb{R}^{\text{nhu}}$. A dot product with the context vector produces a score for each word w in the table,

$$\phi_\beta^{\mathcal{Q}}(x, w) = \mathbf{h}(x) \cdot \mathbf{q}(w)\,. \quad (22)$$

Each word $w \in \mathcal{W} \cup \mathcal{Q}$ receives a final score by summing the vocabulary score and the field score:

$$\phi_\theta(x, w) = \phi_\alpha^{\mathcal{W}}(x, w) + \phi_\beta^{\mathcal{Q}}(x, w)\,, \quad (23)$$

with $\theta = \{\alpha, \beta\}$, and where $\phi_\beta^{\mathcal{Q}}(x, w) = 0$ when $w \notin \mathcal{Q}$. The softmax function then maps the scores to a distribution over $\mathcal{W} \cup \mathcal{Q}$,

$$\log P(w|x) = \phi_\theta(x, w) - \log \sum_{w' \in \mathcal{W} \cup \mathcal{Q}} \exp \phi_\theta(x, w')\,.$$

4.5 Training

The neural language model is trained to minimize the negative log-likelihood of a training sentence s with stochastic gradient descent (SGD; LeCun et al. 2012) :

$$L_\theta(s) = -\sum_{t=1}^{T} \log P(w_t | c_t, z_{c_t}, g_f, g_w)\,. \quad (24)$$

5 Experiments

Our neural network model (Section 4) is designed to generate sentences from tables for large-scale problems, where a diverse set of sentence types need to be generated. Biographies are therefore a good framework to evaluate our model, with Wikipedia offering a large and diverse dataset.

5.1 Biography dataset

We introduce a new dataset for text generation, WIKIBIO, a corpus of 728,321 articles from English Wikipedia (Sep 2015). It comprises all biography articles listed by WikiProject Biography[1] which also have a table (infobox). We extract and tokenize the first sentence of each article with Stanford CoreNLP (Manning et al., 2014). All numbers are mapped to a special token, except for years which are mapped to different special token. Field values from tables are similarly tokenized. All tokens are lower-cased. Table 2 summarizes the dataset statistics: on average, the first sentence is twice as short as the table (26.1 vs 53.1 tokens), about a third of the sentence tokens (9.5) also occur in the table. The final corpus has been divided into three sub-parts to provide training (80%), validation (10%) and test sets (10%). The dataset is available for download[2].

5.2 Baseline

Our baseline is an interpolated Kneser-Ney (KN) language model and we use the KenLM toolkit to train 5-gram models without pruning (Heafield et al., 2013). We also learn a KN language model over templates. For that purpose, we replace the words occurring in both the table and the training sentences with a special token reflecting its table descriptor z_w (Equation 3). The introduction section of the table in Figure 1 looks as follows under this scheme: "`name_1 name_2` (`birthdate_1 birthdate_2 birthdate_3` – `deathdate_1 deathdate_2 deathdate_3`) was an english linguist , `fields_3` pathologist , `fields_10` scientist , mathematician , mystic and mycologist ." During inference, the decoder is constrained to emit words from the regular vocabulary or special tokens occurring in the input table. When picking a special token we copy the corresponding word from the table.

5.3 Training setup

For our neural models, we train 11-gram language models ($n = 11$) with a learning rate set to 0.0025.

Table 1: BLEU, ROUGE, NIST and perplexity without copy actions (first three rows) and with copy actions (last five rows). For neural models we report "mean $\pm$ standard deviation" for five training runs with different initialization. Decoding beam width is 5. Perplexities marked with * and † are not directly comparable as the output vocabularies differ slightly.

	Mean	Percentile 5%	Percentile 95%
# tokens per sentence	26.1	13	46
# tokens per table	53.1	20	108
# table tokens per sent.	9.5	3	19
# fields per table	19.7	9	36

Table 2: Dataset statistics

Parameter	Value		
# word types	$\lvert\mathcal{W}\rvert$	=	$20,000$
# field types	$\lvert\mathcal{F}\rvert$	=	$1,740$
Max. # tokens in a field	l	=	10
word/field embedding size	d	=	64
global embedding size	g	=	128
# hidden units	nhu	=	256

Table 3: Model Hyperparameters

Table 3 describes the other hyper-parameters. We include all fields occurring at least 100 times in the training data in $\mathcal{F}$, the set of fields. We include the $20,000$ most frequent words in the vocabulary. The other hyperparameters are set through validation, maximizing BLEU over a validation subset of $1,000$ sentences. Similarly, early stopping is applied: training ends when BLEU stops improving on the same validation subset. One should note that the maximum number of tokens in a field $l = 10$ means that we encode only 10 positions: for longer field values the final tokens are not dropped but their position is capped to 10. We initialize the word embeddings W from Hellinger PCA computed over the set of training biographies. This representation has shown to be helpful for various applications (Lebret and Collobert, 2014).

5.4 Evaluation metrics

We use different metrics to evaluate our models. Performance is first evaluated in terms of perplexity which is the standard metric for language modeling. Generation quality is assessed automatically with BLEU-4, ROUGE-4 (F-measure) and NIST-4[3] (Belz and Reiter, 2006).

6 Results

This section describes our results and discusses the impact of the different conditioning variables.

6.1 The more, the better

The results (Table 1) show that more conditioning information helps to improve the performance of our models. The generation metrics BLEU, ROUGE and NIST all gives the same performance ordering over models. We first discuss models without copy actions (the first three results) and then discuss models with copy actions (the remaining results). Note that the factorization of our models results in three different output domains which makes perplexity comparisons less straightforward: models without copy actions operate over a fixed vocabulary. Template KN adds a fixed set of field/position pairs to this vocabulary while Table NLM models a variable set $\mathcal{Q}$ depending on the input table, see Section 3.3.

Without copy actions. In terms of perplexity the (i) neural language model (NLM) is slightly better

[3]We rely on standard software, NIST mteval-v13a.pl (for NIST, BLEU), and MSR rouge-1.5.5 (for ROUGE).

than an interpolated KN language model, and (ii) adding local conditioning on the field start and end position further improves accuracy. Generation metrics are generally very low but there is a clear improvement when using local conditioning since it allows to learn transitions between fields by linking previous predictions to the table unlike KN or plain NLM.

With copy actions. For experiments with copy actions we use the full local conditioning (Equation 4) in the neural language models. BLEU, ROUGE and NIST all improves when moving from Template KN to Table NLM and more features successively improve accuracy. Global conditioning on the fields improves the model by over 7 BLEU and adding words gives an additional 1.3 BLEU. This is a total improvement of nearly 15 BLEU over the Template Kneser-Ney baseline. Similar observations are made for ROUGE +15 and NIST +2.8.

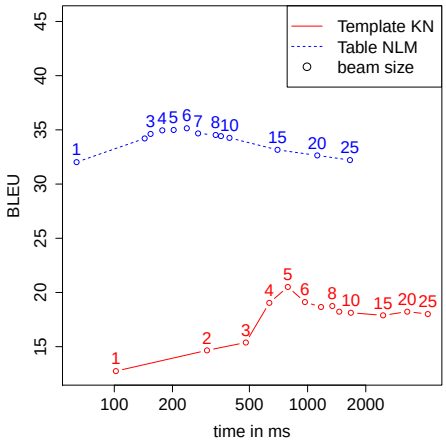

Figure 3: Comparison between our best model (Table NLM) and the baseline (Template KN) for different beam sizes. The x-axis is the average timing (in milliseconds) for generating one sentence. The y-axis is the BLEU score. All results are measured on a subset of 1,000 samples of the validation set.

6.2 Attention mechanism

Our model implements attention over input table fields. For each word w in the table, Equation (23) takes the language model score $\phi_{c_t}^{\mathcal{W}}$ and adds a bias $\phi_{c_t}^{\mathcal{Q}}$. The bias is the dot-product between a representation of the table field in which w occurs and a representation of the context, Equation (22) that summarizes the previously generated fields and words.

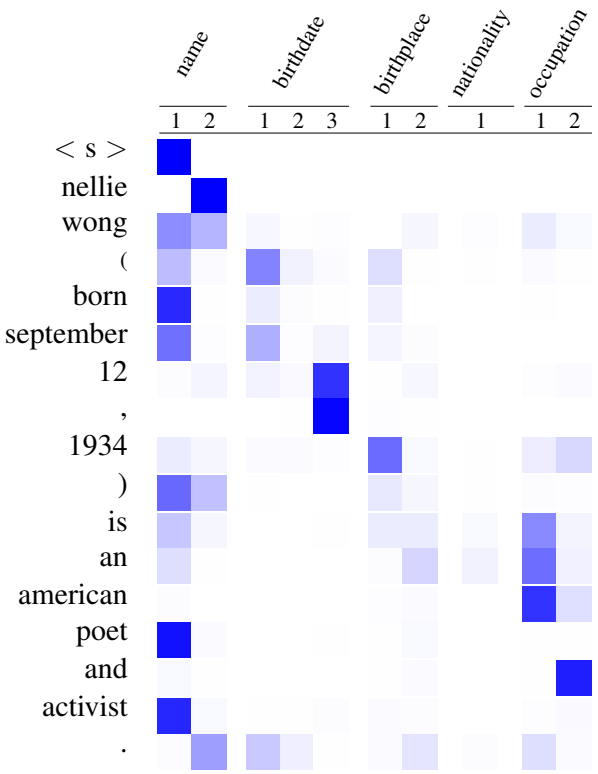

Figure 4: Visualization of attention scores for Nellie Wong's Wikipedia infobox. Each row represents the probability distribution over (field, position) pairs given the previous words (i.e. the words heading the preceding rows as well as the current row). Darker colors depict higher probabilities.

Figure 4 shows that this mechanism adds a large bias to continue a field if it has not generated all tokens from the table, e.g., it emits the word occurring in `name_2` after generating `name_1`. It also nicely handles transitions between field types, e.g., the model adds a large bias to the words occurring in the *occupation* field after emitting the *birthdate*.

6.3 Sentence decoding

We use a standard beam search to explore a larger set of sentences compared to simple greedy search. This allows us to explore K times more paths which comes at a linear increase in the number of forward computation steps for our language model. We compare various beam settings for the baseline Template KN and our Table NLM (Figure 3). The best validation BLEU can be obtained with a beam size of $K = 5$. Our model is also several times faster than the baseline, requiring only about 200 ms per sentence with $K = 5$. Beam search generates many n-gram lookups for Kneser-Ney which requires many

random memory accesses; while neural models perform scoring through matrix-matrix products, an operation which is more local and can be performed in a block parallel manner where modern graphic processors shine (Kindratenko, 2014).

6.4 Qualitative analysis

Table 4 shows generations for different variants of our model based on the Wikipedia table in Figure 1. First of all, comparing the reference to the fact table reveals that our training data is not perfect. The birth month mentioned in the fact table and the first sentence of the Wikipedia article are different; this may have been introduced by one contributor editing the article and not keeping the information consistent.

All three versions of our model correctly generate the beginning of the sentence by copying the name, the birth date and the death date from the table. The model correctly uses the past tense since the death date in the table indicates that the person has passed away. Frederick Parker-Rhodes was a scientist, but this occupation is not directly mentioned in the table. The model without global conditioning can therefore not predict the right occupation, and it continues the generation with the most common occupation (in Wikipedia) for a person who has died. In contrast, the global conditioning over the fields helps the model to understand that this person was indeed a scientist. However, it is only with the global conditioning on the words that the model can infer the correct occupation, i.e., *computer scientist*.

7 Conclusions

We have shown that our model can generate fluent descriptions of arbitrary people based on structured data. Local and global conditioning improves our model by a large margin and we outperform a Kneser-Ney language model by nearly 15 BLEU. Our task uses an order of magnitude more data than previous work and has a vocabulary that is three orders of magnitude larger.

In this paper, we have only focused on generating the first sentence and we will tackle the generation of longer biographies in future work. Also, the encoding of field values can be improved. Currently, we only attach the field type and token position to each word type and perform a max-pooling for local conditioning. One could leverage a richer representation by learning an encoder conditioned on the field type, e.g. a recurrent encoder or a convolutional encoder with different pooling strategies.

Furthermore, the current training loss function does not explicitly penalize the model for generating incorrect facts, e.g. predicting an incorrect nationality or occupation is currently not considered worse than choosing an incorrect determiner. A loss function that could assess factual accuracy would certainly improve sentence generation by avoiding such mistakes. Also it will be important to define a strategy for evaluating the factual accuracy of a generation, beyond BLEU, ROUGE or NIST.

Abstract

This article tackles a new challenging task in computational argumentation. Given a pair of two arguments to a certain controversial topic, we aim to directly assess qualitative properties of the arguments in order to explain why one argument is more convincing than the other one. We approach this task in a fully empirical manner by annotating 26k explanations written in natural language. These explanations describe convincingness of arguments in the given argument pair, such as their strengths or flaws. We create a new crowd-sourced corpus containing 9,111 argument pairs, multi-labeled with 17 classes, which was cleaned and curated by employing several strict quality measures. We propose two tasks on this data set, namely (1) predicting the full label distribution and (2) classifying types of flaws in less convincing arguments. Our experiments with feature-rich SVM learners and Bidirectional LSTM neural networks with convolution and attention mechanism reveal that such a novel fine-grained analysis of Web argument convincingness is a very challenging task. We release the new corpus *UKPConvArg2* and the accompanying software under permissive licenses to the research community.

1 Introduction

People engage in argumentation in various contexts, both online and in the real life. Existing definitions of argumentation do not solely focus on giving reasons and laying out a logical framework of premises and conclusions, but also highlight its social purpose which is to convince or to persuade (O'Keefe, 2011; van Eemeren et al., 2014; Blair, 2011). Assessing the quality and strength of perceived arguments therefore plays an inherent role in argumentative discourse. Despite strong theoretical foundations and plethora of normative theories, such as Walton's schemes and their critical questions (Walton, 1989), an ideal model of critical discussion in the pragma-dialectic view (Van Eemeren and Grootendorst, 1987), or research into fallacies (Boudry et al., 2015), assessing qualitative criteria of everyday argumentation represents a challenge for argumentation scholars and practitioners (Weltzer-Ward et al., 2009; Swanson et al., 2015; Rosenfeld and Kraus, 2015).

Addressing qualitative aspects of arguments has recently started gaining attention in the field of computational argumentation. Scoring strength of persuasive essays (Farra et al., 2015; Persing and Ng, 2015), exploring interaction in persuasive dialogues on Reddit (Tan et al., 2016), or detecting convincing arguments (Habernal and Gurevych, 2016) are among recent attempts to tackle the quality of argumentation. However, these approaches are holistic and do not necessarily explain why a given argument is strong or convincing.

We asked the following research questions. First, can we assess what makes an argument convincing in a purely empirical fashion as opposite to theoretical normative approaches? Second, to what extent can the problem be tackled by computational models? To address these questions, we exploit our recently introduced *UKPConvArg1* corpus (Habernal and Gurevych, 2016). This data set consists of 11,650 *argument pairs* – two arguments with the

Prompt: Should physical education be mandatory in schools? **Stance:** Yes!

Argument 1	Argument 2
PE should be compulsory because it keeps us constantly fit and healthy. If you really dislike sports, then you can quit it when you're an adult. But when you're a kid, the best thing for you to do is study, play and exercise. If you prefer to be lazy and lie on the couch all day then you are most likely to get sick and unfit. Besides, PE helps kids be better at teamwork.	physical education should be mandatory cuhz 112,000 people have died in the year 2011 so far and it's because of the lack of physical activity and people are becoming obese!!!!

A1 is more convincing than A2, because:

- "A1 is more intelligently written and makes some good points (teamwork, for example). A2 used 'cuhz' and I was done reading because that sounds stupid."
- "A1 gives more reasons and goes into detail, A2 only has one fact"
- "A1 makes several compelling points. A2 uses poor spelling and grammar."

Figure 1: An annotated argument pair from the *UKPConvArg* corpus with three *reasons* explaining the decision about convincingness (ID `arg54258_arg202285`).

same standpoint to the given topic, annotated with a binary relation describing which argument from the pair is more convincing. Each pair also contains several *reasons* written in natural language explaining which properties of the arguments influence their convincingness. An example of such an argument pair is shown in Figure 1.

We use these natural language reasons as a proxy to assess qualitative properties of the arguments in each argument pair. Our main contributions are: (1) We propose empirically inspired labels of quality properties of Web arguments and design a hierarchical annotation scheme. (2) We create a new large crowd-sourced benchmark data set containing 9,111 argument pairs multi-labeled with 17 categories which is improved by local and global filtering techniques. (3) We experiment with several computational models, both traditional and neural network-based, and evaluate their performance quantitatively and qualitatively.

The newly created data set *UKPConvArg2* is available under CC-BY-SA license along with the experimental software for full reproducibility at GitHub.[1]

2 Related Work

The growing field of computational argumentation has been traditionally devoted to structural tasks, such as argument component detection and classification (Habernal and Gurevych, 2017; Habernal and Gurevych, 2015), argument structure parsing (Peldszus and Stede, 2015; Stab and Gurevych, 2014), or argument schema classification (Lawrence and Reed, 2015), leaving the issues of argument evaluation or quality assessment as an open future work.

There are only few attempts to tackle the qualitative aspects of arguments, especially in the Web discourse. Park and Cardie (2014) classified propositions in Web arguments into four classes with respect to their level of verifiability. Focusing on convincingness of Web arguments, Habernal and Gurevych (2016) annotated 16k pairs of arguments with a binary relation "is more convincing" and also elicited explanation for the annotators' decisions.

Recently, research in persuasive essay scoring has started combining holistic approaches based on rubrics for several dimensions typical to this genre with explicit argument detection. Persing and Ng (2015) manually labeled 1,000 student persuasive essays with a single score on the 1–4 scale and trained a regression predictor with a rich feature set using LIBSVM. Among traditional features (such as POS or semantic frames), an argument structure parser by Stab and Gurevych (2014) was employed. Farra et al. (2015) also deal with essay scoring but rather then tackling the argument structure, they focus on methods for detecting opinion expressions. Persuasive essays however represent a genre with a rather strict qualitative and formal requirements (as taught in curricula) and substantially differ from online argumentation.

Argument evaluation belongs to the central research topics among argumentation scholars (Toul-

[1] `https://github.com/UKPLab/emnlp2016-empirical-convincingness`

min, 2003; Walton et al., 2008; Van Eemeren and Grootendorst, 1987). Yet treatment of assessing argumentation quality, persuasiveness, or convincingness is traditionally based on evaluating relevance, sufficiency or acceptability of premises (Govier, 2010; Johnson and Blair, 2006) or categorizing fallacies (Hamblin, 1970; Tindale, 2007). However, the nature of these normative approaches causes a gap between the 'ideal' models and empirically encountered real-world arguments, such as those on the Web (van Eemeren et al., 2014; Walton, 2012).

Regarding the methodology utilized later in this paper, deep (recursive) neural networks have gained extreme popularity in NLP in recent years. Long Short-Term Memory networks (LSTM) with Attention mechanism have been applied on textual entailment (Rocktäschel et al., 2016), Question-Answering (Golub and He, 2016), or source-code summarization (Allamanis et al., 2016).

3 Data

As our source data set, we took the publicly available *UKPConvArg1* corpus.[2] It is based on arguments originated from 16 debates from Web debate platforms `createdebate.com` and `convinceme.net`, each debate has two sides (usually pro and con). Arguments from each of the 32 debate sides are connected into a set of argument pairs, and each argument pair is annotated with a binary relation (argument A is more/less convincing than argument B), resulting in total into 11,650 argument pairs. Annotations performed by Habernal and Gurevych (2016) also contain several *reasons* written by crowd-workers that explain why a particular argument is more or less convincing; see an example in Figure 1.

As these *reasons* were written in an uncontrolled setting, they naturally reflect the main properties of argument quality in a downstream task, which is to decide which argument from a pair is more convincing. It differs from scoring arguments in isolation, which is inherently harder not only due to subjectivity in argument "strength" decision but also because of possible annotator's prior bias (Habernal and Gurevych, 2016). Assessing an argument in context helps to emphasize its main flaws or strengths. This approach is also known as *knowledge elicitation* – acquiring appropriate information from experts by asking "why?" (Reed and Rowe, 2004).

We therefore used the *reasons* as a proxy for developing a scheme for labeling argument quality attributes. This was done in a purely bottom-up empirical manner, as opposed to using 'standard' evaluation criteria known from argumentation literature (Johnson and Blair, 2006; Schiappa and Nordin, 2013). In particular, we split all *reasons* into several *reason units* by simple preprocessing (splitting using Stanford CoreNLP (Manning et al., 2014), segmentation into Elementary Discourse Units by RST tools (Surdeanu et al., 2015)) and identified the referenced arguments (A1 or A2) by pattern matching and dependency parsing. For example, each *reason* from Figure 1 would be transformed into two *reason units*.[3] Overall, we obtained about 70k *reason units* from the entire *UKPConvArg1* corpus.

3.1 Annotation scheme

In order to develop a code book for assigning a label to each *reason unit*, we ran several pilot expert annotation studies (each with 200-300 *reason units*). Having a set of $\approx$ 25 distinct labels, we ran two larger studies on Amazon Mechanical Turk (AMT), each with 500 reason units and 10 workers. The workers were split into two groups; we then estimated gold labels for each group using MACE (Hovy et al., 2013) and compared both groups' results in order to find systematic discrepancies. Finally, we ended up with a set of 19 distinct labels (classes). As the number of classes is too big for non-expert crowd workers, we developed a hierarchical annotation process guided by questions that narrow down the final class decision. The scheme is depicted in Figure 2.[4] Workers were shown only the *reason units* without seeing the original arguments.

[2] `https://github.com/UKPLab/acl2016-convincing-arguments`

[3] We picked this example for its simplicity, in reality the texts are much more fuzzy.

[4] It might seem that some labels are missing, such as C8-2 and C8-3; these belong to those removed during the pilot studies.

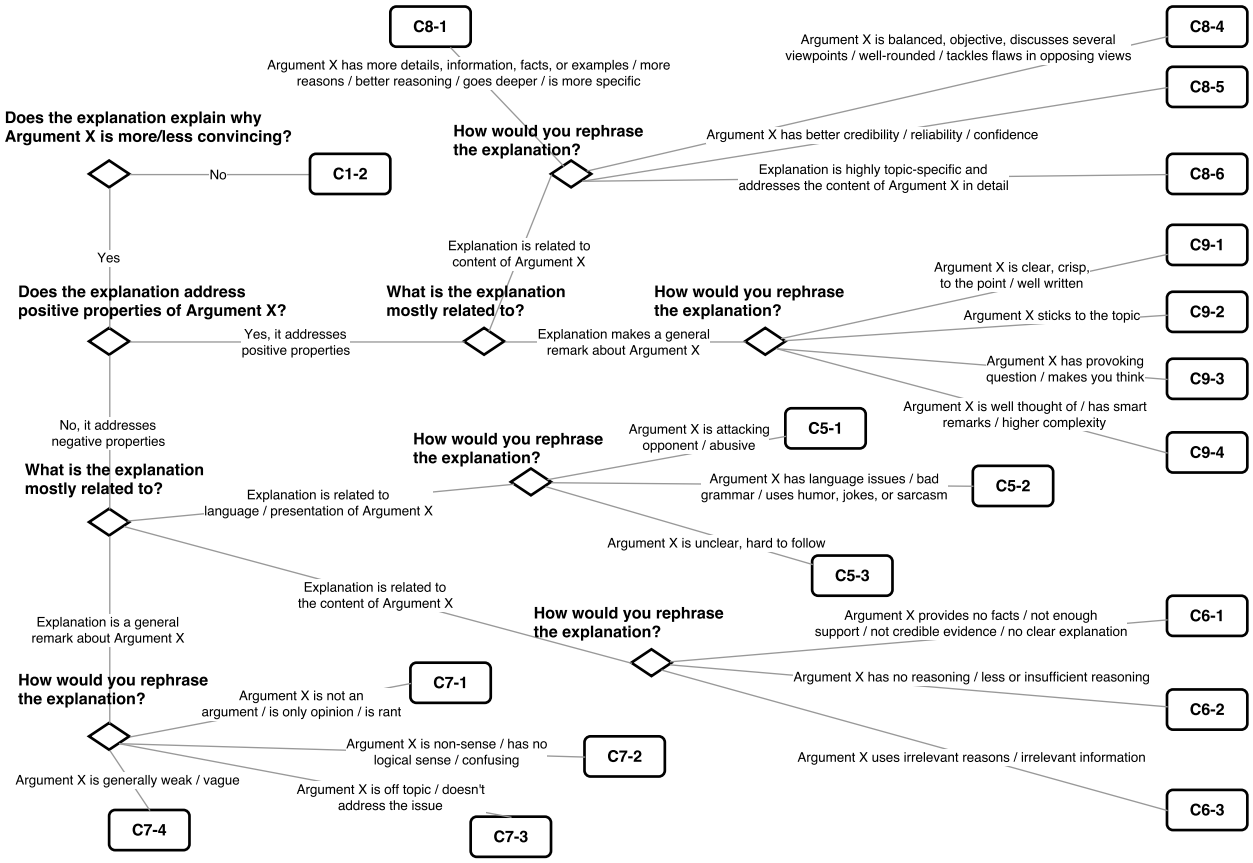

Figure 2: Decision tree-based annotation schema for labeling reason units using Mechanical Turk. *CX-Y* represent the final labels.

3.2 Annotation

We sampled 26,000 unique reason units ordered by the original author competence provided as part of the *UKPConvArg* corpus. We expected that workers with higher competence tend to write better reasons for their explanations. Using the previously introduced scheme, 776 AMT workers annotated the batch during two weeks; we required assignments from 5 workers for a single item. We employed MACE (Hovy et al., 2013) for gold label and worker competence estimation with 95% threshold to ignore the less confident labels. Several workers were rejected based on their low computed competence and other criteria, such as too short submission times.

3.3 Data cleaning

We performed several cleaning procedures to increase quality and consistency of the annotated data (apart from initial MACE filtering already explained above).

Local cleaning First, we removed 3,859 *reason units* annotated either with C1-2 (”not an explanation”) and C8-6 (”too topic-specific”, which usually paraphrases some details from the related argument and is not general enough). In the next step, we removed *reason units* with wrong polarity. In particular, all *reason units* labeled with C8-* or C9-* should refer to the more convincing argument in the argument pair (as they describe positive properties), whereas all reasons with labels C5-*, C6-*, and C7-* should refer to the less convincing argument. The target arguments for *reason units* were known from the heuristic preprocessing (see above); in this step 2,455 units were removed.

Global cleaning Since the argument pairs from one debate can be projected into an argument graph (Habernal and Gurevych, 2016), we utilized this ‘global’ context for further consistency cleaning.

Suppose we have two argument pairs, $P_1(A \rightarrow B)$ and $P_2(B \rightarrow C)$ (where $\rightarrow$ means “is more convincing than”). Let $P_1(R_B)$ be reason unit targeting

B in argument pair P_1 and similarly $P_2(R_B)$ reason unit targeting B in argument pair P_2. In other words, two reason units target the same argument in two different argument pairs (in one of them the argument is more convincing while in the other pair it is less convincing). There might then exist contradicting combination of classes for $P_1(R_B)$ and $P_2(R_B)$. For example classes C9-2 and C7-3 are contradicting, as the same argument cannot be both "on the topic" and "off-topic" at the same time.

When such a conflict between two reason units occurred, we selected the reason with a higher score using the following formula:

$$w_W * \sigma \left(\sum_{A=G} w_A - \lambda \sum_{A \neq G} w_A \right) \quad (1)$$

where w_W is the competence of the original author of the reason unit (originated from the *UKP-ConvArg* corpus), $A = G$ are crowdsourced assignments for a single reason unit that match the final predicted gold label, $A \neq G$ are assignments that differ from the final predicted gold label, w_A is the competence of worker for assignment A, λ is a penalty for non-gold labels, and σ is the sigmoid function to squeeze the score between 0 and 1.

We found 25 types of global contradictions between labels for reason units and used them for cleaning the data; in total 3,790 *reason units* were removed in this step. After all cleaning procedures, annotations from *reason units* were mapped back to *argument pairs*, resulting into a multi-label annotation of one or both arguments from the given pair. In total 9,111 pairs from the *UKPConvArg* corpus were annotated.

For example, the final annotations of argument pair shown in Figure 1 contain four labels – C8-1 (as the more convincing argument *"has more details, information, facts, or examples / more reasons / better reasoning / goes deeper / is more specific"*), C9-3 (as the more convincing argument *"has provoking question / makes you think"*), C5-2 (as the less convincing argument *"has language issues / bad grammar /..."*), and C6-1 (as the less convincing argument *"provides not enough support / ..."*). Only four of six *reason units* for this argument pair were annotated because of the competence score of their authors.

# of labels/pair	# of pairs
1	4,584
2	2,959
3	1,162
4	330
5	68
6	8
Total	9,111

Table 1: Number of annotated labels per argument pairs.

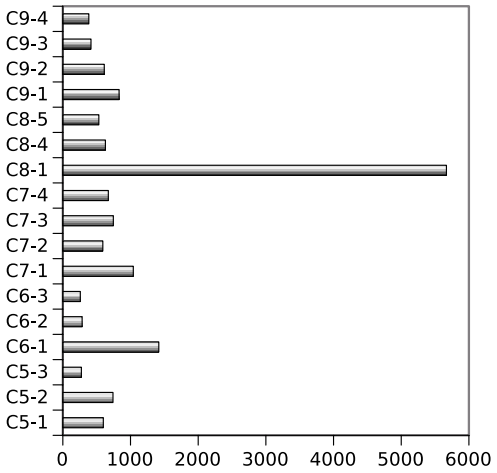

Figure 3: Distribution of labels in the annotated argument pairs. Consult Figure 2 for label descriptions.

Table 1 shows number of labels per argument pairs; about a half of the argument pairs have only one label. Figure 3 shows distribution of label in the entire data set which is heavily skewed towards C8-1 label. This is not surprising, as this label was used for reason units pointing out that the more convincing argument provided more reasons, details, information or better reasoning – a feature inherent to argumentation seen as *giving reasons* (Freeley and Steinberg, 2008).

3.4 Data validation

Since the qualitative attributes of arguments were annotated indirectly by labeling their corresponding reason units without seeing the original arguments, we wanted to validate correctness of this approach. We designed a validation study, in which workers were shown the original argument pair and two sets of labels. The first set contained the true labels as annotated previously, while we randomly replaced few labels in the second set. The goal was then to decide which set of labels better explains that argument A is

more convincing than argument B. For example, for the argument pair from Figure 1, one set of shown labels would be {C8-1, C9-3, C5-2, C6-1} (the correct set) while the other 'distracting' set would be {C8-1, C9-3, C5-1, C7-3} .

We randomly sampled 500 argument pairs and collected 9 assignments per pair on AMT; we again used MACE with 95% threshold. Accuracy of workers on 235 argument pairs achieved 82%. We can thus conclude that workers tend to prefer explanations based on labels from the *reason units* and using the annotation process presented in this section is reliable. Total costs of the annotations including pilot studies, bonuses, and data validation were USD 3,300.

4 Experiments

We propose two experiments, both performed in 16-fold cross-domain validation. In each fold, argument pairs from 15 debates are used and the remaining one is used for testing. In both experiments, it is assumed that the more convincing argument in a pair is known and we concatenate (using a particular delimiter) both arguments such that the more convincing argument comes first.

4.1 Predicting full multi-label distribution

This experiment is a multi-label classification. Given an argument pair annotated with several labels, the goal is to predict all these labels.

We use two deep learning models. Our first model, Bidirectional Long Short-Term Memory (BLSTM) network contains two LSTM blocks (forward and backward), each with 64 hidden units on the output. The output is concatenated into a single vector and pushed through sigmoid layer with 17 output units (corresponding to 17 labels). We use cross entropy loss function in order to minimize distance of label distributions in training and test data (Nam et al., 2014). In the input layer, we rely on pre-trained word embeddings from Glove (Pennington et al., 2014) whose weights are updated during training the network.

The second models is BLSTM extended with an attention mechanism (Rocktäschel et al., 2016; Golub and He, 2016) combined with convolution layers over the input. In particular, the input embedding layer is convoluted using 4 different convolution sizes (2, 3, 5, 7), each with 1,000 randomly initialized weight vectors. Then we perform max-over-time pooling and concatenate the output into a single vector. This vector is used as the attention module in BLSTM.

Table 2: Results of multi-label classification from Experiment 1. Hamming-loss and One-Error are shown for two systems – Bidirectional LSTM and Bidirectional LSTM with Convolution and Attention.

We evaluate the system using two widely used metrics in multi-label classification. First, Hamming loss is the average per-item per-class total error; the smaller the better (Zhang and Zhou, 2007). Second, we report One-error (Sokolova and Lapalme, 2009) which corresponds to the error of the predicted label with highest probability; the smaller the better. We do not report other metrics (such as Area Under PRC-curves, MAP, or cover) as they require tuning a threshold parameter, see a survey by Zhang and Zhou (2014).

Results from Table 2 do not show significant differences between the two models. Putting the one-error numbers into human performance context can be done only indirectly, as the data validation pre-

sented in Section 3.4 had a different set-up. Here we can see that the error rate of the most confident predicted label is about 30%, while human performed similarly by choosing from a two different label sets in a binary settings, so their task was inherently harder.

Error analysis and discussion We examined outputs from the label distribution prediction for BLSTM/ATT/CNN. It turns out that the output layer leans toward predicting the dominant label *C8-1*, while prediction of other labels is seldom. We suspect two causes, first, the highly skewed distribution of labels (see Figure 3) and, second, insufficient training data sizes where 13 classes have less than 1k training examples (while Goodfellow et al. (2016) recommend at least 5k instances per class).

Although multi-label classification may be viewed as a set of binary classification tasks that decides for each label independently (and thus allows for employing other 'standard' classifiers such as SVM), this so-called binary relevance approach ignores dependencies between the labels. That is why we focused directly on deep-learning methods, as they are capable of learning and predicting a full label distribution (Nam et al., 2014).

4.2 Predicting flaws in less convincing arguments

In the second experiment, we focus on predicting flaws in arguments using coarse-grained labels. While this task makes several simplifications in the labeling, it still provides meaningful insights into argument quality assessment. For this purpose, we use only argument pairs where the less convincing argument is labeled with a single label (no multi-label classification). Second, we merged all labels from categories *C5-* C6-* C7-** into three classes corresponding to their parent nodes in the annotation decision schema from Figure 2. Table 3 shows distribution of the gold data for this task with explanation of the labels. It is worth noting that predicting flaws in the less convincing argument is still context-dependent and requires the entire argument pair because some of the quality labels are relative to the more convincing argument (such as "less reasoning" or "not enough support").

For this experiment, we modified the output layer of the neural models from the previous experiment. The non-linear output function is *softmax* and we train the networks using categorical cross-entropy loss. We also add another baseline model that employs SVM with RBF kernel[5] and a rich set of linguistically motivated features, similarly to (Habernal and Gurevych, 2016). The feature set includes *uni- and bi-gram presence*, ratio of *adjective and adverb endings* that may signalize neuroticism (Corney et al., 2002), *contextuality measure* (Heylighen and Dewaele, 2002), *dependency tree depth*, ratio of *exclamation* or *quotation* marks, ratio of *modal verbs*, counts of several *named entity types*, ratio of *past* vs. *future* tense verbs, *POS* n-grams, presence of dependency tree *production rules*, seven different *readability measures* (e.g., *Ari* (Senter and Smith, 1967), *Coleman-Liau* (Coleman and Liau, 1975), *Flesch* (Flesch, 1948), and others), five *sentiment scores* (from very negative to very positive) (Socher et al., 2013), *spell-checking* using standard Unix `words`, ratio of *superlatives*, and some *surface* features such as sentence lengths, longer words count, etc.[6] It results into a sparse 60k-dimensional feature vector space.

Label	Instances	Description
C5	856	Language and presentation issues
C6	1,203	Reasoning and factuality issues
C7	1,651	Off-topic, non-argument, nonsense
Total	3,710	

Table 3: Gold data distribution for the second experiment. Argument pairs with a single label for the less convincing argument.

Results in Table 4 suggest that the SVM-RBF baseline system performs poorly and its results are on par with a majority class baseline (not reported in detail). Both deep learning models significantly outperform the baseline, yielding Macro-F_1 score about 0.35. The attention-based model performs better than simple BLSTM in two classes (C5 and C6), but the overall Macro-F_1 score is not significantly better.

[5] We used LISBVM (Chang and Lin, 2011) with the default hyper-parameters. As Fernández-Delgado et al. (2014) show, SVM with gaussian kernels is a reasonable best choice on average.

[6] Detailed explanation of the features can be found directly in the attached source codes.

	Class C5			Class C6			Class C7				
Model	P	R	F_1	P	R	F_1	P	R	F_1	**M-F_1**	**C.I.**

BLSTM	0.265	0.600	0.368	0.376	0.229	0.285	0.479	0.301	0.370	0.341	0.015
BLSTM/ATT/CNN	0.270	0.625	0.378	0.421	0.247	0.311	0.484	0.301	0.371	**0.353**	0.015

Table 4: Results for experiment 2. P = precision, R = recall, M-F_1 = macro F_1, C.I. = confidence interval at 0.95. Both *BLSTM* and *BLSTM/ATT/CNN* are significantly better than *SVM-RBF* ($p < 0.05$, exact Liddell's test).

Error analysis We manually examined several dozens of predictions where the BLSTM model failed but the BLSTM/ATT/CNN model was correct in order to reveal some phenomena that the system is capable to cope with. First, the BLSTM/ATT/CNN model started catching some purely abusive, sarcastic, and attacking arguments. Also, the language/grammar issues were revealed in many cases, as well as using slang in arguments.

Examining predictions in which both systems failed reveal some fundamental limitations of the current purely data-driven computational approach. While the problem of not catching off-topic arguments can be probably modeled by incorporating the debate description or some sort of debate topic model into the attention vector, the more common issue of non-sense arguments or fallacious arguments (which seem like actual arguments on the first view) needs much deeper understanding of real-world knowledge, logic, and reasoning.

5 Conclusion

This paper presented a novel task in the field of computational argumentation, namely empirical assessment of reasons for argument convincingness. We created a new large benchmark data set by utilizing a new annotation scheme and several filtering strategies for crowdsourced data. Then we tackled two challenging tasks, namely multi-label classification of argument pairs in order to reveal qualitative properties of the arguments, and predicting flaws in the less convincing argument from the given argument pair. We performed all evaluations in a cross-domain scenario and experimented with feature-rich SVM and two state-of-the-art neural network models. The results are promising but show that the task is inherently complex as it requires deep reasoning about the presented arguments that goes beyond capabilities of the current computational models. By releasing the *UKPConvArg2* data and code to the community, we believe more progress can be made in this direction in the near future.

Recognizing Implicit Discourse Relations via Repeated Reading: Neural Networks with Multi-Level Attention

Yang Liu[1,2], **Sujian Li**[1]
[1] Key Laboratory of Computational Linguistics, Peking University, MOE, China

Abstract

Recognizing implicit discourse relations is a challenging but important task in the field of Natural Language Processing. For such a complex text processing task, different from previous studies, we argue that it is necessary to repeatedly read the arguments and dynamically exploit the efficient features useful for recognizing discourse relations. To mimic the repeated reading strategy, we propose the neural networks with multi-level attention (NNMA), combining the attention mechanism and external memories to gradually fix the attention on some specific words helpful to judging the discourse relations. Experiments on the PDTB dataset show that our proposed method achieves the state-of-art results. The visualization of the attention weights also illustrates the progress that our model observes the arguments on each level and progressively locates the important words.

1 Introduction

Discourse relations (e.g., contrast and causality) support a set of sentences to form a coherent text. Automatically recognizing discourse relations can help many downstream tasks such as question answering and automatic summarization. Despite great progress in classifying explicit discourse relations where the discourse connectives (e.g., "because", "but") explicitly exist in the text, implicit discourse relation recognition remains a challenge due to the absence of discourse connectives. Previous research mainly focus on exploring various kinds of efficient features and machine learning models to classify the implicit discourse relations (Soricut and Marcu, 2003; Baldridge and Lascarides, 2005; Subba and Di Eugenio, 2009; Hernault et al., 2010; Pitler et al., 2009; Joty et al., 2012). To some extent, these methods simulate the single-pass reading process that a person quickly skim the text through one-pass reading and directly collect important clues for understanding the text. Although single-pass reading plays a crucial role when we just want the general meaning and do not necessarily need to understand every single point of the text, it is not enough for tackling tasks that need a deep analysis of the text. In contrast with single-pass reading, repeated reading involves the process where learners repeatedly read the text in detail with specific learning aims, and has the potential to improve readers' reading fluency and comprehension of the text (National Institute of Child Health and Human Development, 2000; LaBerge and Samuels, 1974). Therefore, for the task of discourse parsing, repeated reading is necessary, as it is difficult to generalize which words are really useful on the first try and efficient features should be dynamically exploited through several passes of reading .

Now, let us check one real example to elaborate the necessity of using repeated reading in discourse parsing.

Arg-1 : the use of 900 toll numbers has been *expanding rapidly* in recent years

Arg-2 : for a while, high-cost pornography lines and services that tempt children to dial (and redial) movie or music information *earned the service a somewhat sleazy image*

(Comparison - wsj_2100)

To identify the "**Comparison**" relation between

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1224–1233,
Austin, Texas, November 1-5, 2016.

the two arguments *Arg-1* and *Arg-2*, the most crucial clues mainly lie in some content, like *"expanding rapidly"* in *Arg-1* and *"earned the service a somewhat sleazy image"* in *Arg-2*, since there exists a contrast between the semantic meanings of these two text spans. However, it is difficult to obtain sufficient information for pinpointing these words through scanning the argument pair left to right in one pass. In such case, we follow the repeated reading strategy, where we obtain the general meaning through reading the arguments for the first time, re-read them later and gradually pay close attention to the key content.

Recently, some approaches simulating repeated reading have witnessed their success in different tasks. These models mostly combine the attention mechanism that has been originally designed to solve the alignment problem in machine translation (Bahdanau et al., 2014) and the external memory which can be read and written when processing the objects (Sukhbaatar et al., 2015). For example, Kumar et al. (2015) drew attention to specific facts of the input sequence and processed the sequence via multiple hops to generate an answer. In computation vision, Yang et al. (2015) pointed out that repeatedly giving attention to different regions of an image could gradually lead to more precise image representations.

Inspired by these recent work, for discourse parsing, we propose a model that aims to repeatedly read an argument pair and gradually focus on more fine-grained parts after grasping the global information. Specifically, we design the Neural Networks with Multi-Level Attention (NNMA) consisting of one general level and several attention levels. In the general level, we capture the general representations of each argument based on two bidirectional long short-term memory (LSTM) models. For each attention level, NNMA generates a weight vector over the argument pair to locate the important parts related to the discourse relation. And an external short-term memory is designed to store the information exploited in previous levels and help update the argument representations. We stack this structure in a recurrent manner, mimicking the process of reading the arguments multiple times. Finally, we use the representation output from the highest attention level to identify the discourse relation. Experiments on the PDTB dataset show that our proposed model achieves the state-of-art results.

2 Repeated Reading Neural Network with Multi-Level Attention

In this section, we describe how we use the neural networks with multi-level attention to repeatedly read the argument pairs and recognize implicit discourse relations.

First, we get the general understanding of the arguments through skimming them. To implement this, we adopt the bidirectional Long-Short Term Memory Neural Network (bi-LSTM) to model each argument, as bi-LSTM is good at modeling over a sequence of words and can represent each word with consideration of more contextual information. Then, several attention levels are designed to simulate the subsequent multiple passes of reading. On each attention level, an external short-term memory is used to store what has been learned from previous passes and guide which words should be focused on. To pinpoint the useful parts of the arguments, the attention mechanism is used to predict a probability distribution over each word, indicating to what degree each word should be concerned. The overall architecture of our model is shown in Figure 1. For clarity, we only illustrate two attention levels in the figure. It is noted that we can easily extend our model to more attention levels.

2.1 Representing Arguments with LSTM

The Long-Short Term Memory (LSTM) Neural Network is a variant of the Recurrent Neural Network which is usually used for modeling a sequence. In our model, we adopt two LSTM neural networks to respectively model the two arguments: the left argument *Arg-1* and the right argument *Arg-2*.

First of all, we associate each word w in our vocabulary with a vector representation $\boldsymbol{x}_w \in \mathbb{R}^{D_e}$. Here we adopt the pre-trained vectors provided by GloVe (Pennington et al., 2014). Since an argument can be viewed as a sequence of word vectors, let $\boldsymbol{x}_i^1$ ($\boldsymbol{x}_i^2$) be the i-th word vector in argument *Arg-1* (*Arg-*

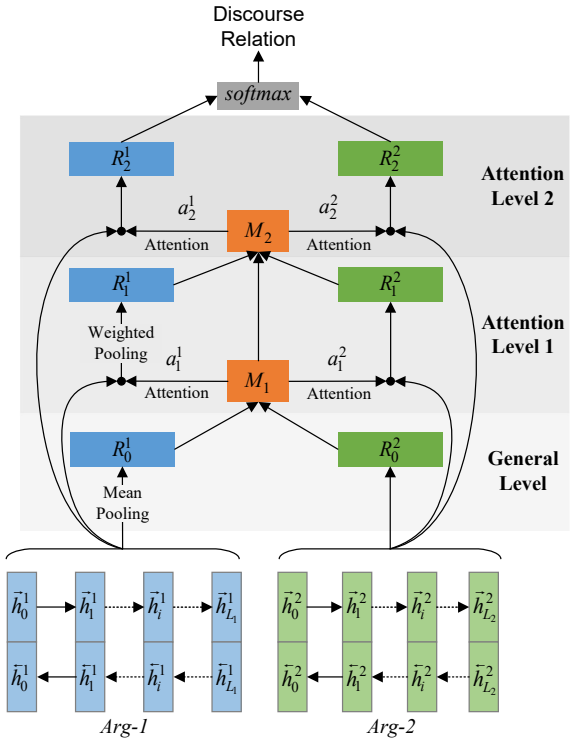

Figure 1: Neural Network with Multi-Level Attention. (Two attention levels are given here.)

2) and the two arguments can be represented as,

$$Arg\text{-}1 : [\boldsymbol{x}_1^1, \boldsymbol{x}_2^1, \cdots, \boldsymbol{x}_{L_1}^1]$$
$$Arg\text{-}2 : [\boldsymbol{x}_1^2, \boldsymbol{x}_2^2, \cdots, \boldsymbol{x}_{L_2}^2]$$

where *Arg-1* has L_1 words and *Arg-2* has L_2 words.

To model the two arguments, we briefly introduce the working process how the LSTM neural networks model a sequence of words. For the i-th time step, the model reads the i-th word $\boldsymbol{x}_i$ as the input and updates the output vector $\boldsymbol{h}_i$ as follows (Zaremba and Sutskever, 2014).

$$\boldsymbol{i}_i = sigmoid(\boldsymbol{W}_i[\boldsymbol{x}_i, \boldsymbol{h}_{i-1}] + \boldsymbol{b}_i) \quad (1)$$
$$\boldsymbol{f}_i = sigmoid(\boldsymbol{W}_f[\boldsymbol{x}_i, \boldsymbol{h}_{i-1}] + \boldsymbol{b}_f) \quad (2)$$
$$\boldsymbol{o}_i = sigmoid(\boldsymbol{W}_o[\boldsymbol{x}_i, \boldsymbol{h}_{i-1}] + \boldsymbol{b}_o) \quad (3)$$
$$\tilde{\boldsymbol{c}}_i = tanh(\boldsymbol{W}_c[\boldsymbol{x}_i, \boldsymbol{h}_{i-1}] + \boldsymbol{b}_c) \quad (4)$$
$$\boldsymbol{c}_i = \boldsymbol{i}_i * \tilde{\boldsymbol{c}}_i + \boldsymbol{f}_i * \boldsymbol{c}_{i-1} \quad (5)$$
$$\boldsymbol{h}_i = \boldsymbol{o}_i * tanh(\boldsymbol{c}_i) \quad (6)$$

where $[\ ]$ means the concatenation operation of several vectors. $\boldsymbol{i}, \boldsymbol{f}, \boldsymbol{o}$ and $\boldsymbol{c}$ denote the input gate, forget gate, output gate and memory cell respectively in the LSTM architecture. The input gate $\boldsymbol{i}$ determines how much the input $\boldsymbol{x}_i$ updates the memory cell. The output gate $\boldsymbol{o}$ controls how much the memory cell influences the output. The forget gate $\boldsymbol{f}$ controls how the past memory $\boldsymbol{c}_{i-1}$ affects the current state. $\boldsymbol{W}_i, \boldsymbol{W}_f, \boldsymbol{W}_o, \boldsymbol{W}_c, \boldsymbol{b}_i, \boldsymbol{b}_f, \boldsymbol{b}_o, \boldsymbol{b}_c$ are the network parameters.

Referring to the work of Wang and Nyberg (2015), we implement the bidirectional version of LSTM neural network to model the argument sequence. Besides processing the sequence in the forward direction, the bidirectional LSTM (bi-LSTM) neural network also processes it in the reverse direction. As shown in Figure 1, using two bi-LSTM neural networks, we can obtain $\boldsymbol{h}_i^1 = [\overrightarrow{\boldsymbol{h}}_i^1, \overleftarrow{\boldsymbol{h}}_i^1]$ for the i-th word in *Arg-1* and $\boldsymbol{h}_i^2 = [\overrightarrow{\boldsymbol{h}}_i^2, \overleftarrow{\boldsymbol{h}}_i^2]$ for the i-th word in *Arg-2*, where $\overrightarrow{\boldsymbol{h}}_i^1, \overrightarrow{\boldsymbol{h}}_i^2 \in \mathbb{R}^d$ and $\overleftarrow{\boldsymbol{h}}_i^1, \overleftarrow{\boldsymbol{h}}_i^2 \in \mathbb{R}^d$ are the output vectors from two directions.

Next, to get the general-level representations of the arguments, we apply a mean pooling operation over the bi-LSTM outputs, and obtain two vectors $\boldsymbol{R}_0^1$ and $\boldsymbol{R}_0^2$, which can reflect the global information of the argument pair.

$$\boldsymbol{R}_0^1 = \frac{1}{L_1}\sum_{i=0}^{L_1} \boldsymbol{h}_i^1 \quad (7)$$
$$\boldsymbol{R}_0^2 = \frac{1}{L_2}\sum_{i=0}^{L_2} \boldsymbol{h}_i^2 \quad (8)$$

2.2 Tuning Attention via Repeated Reading

After obtaining the general-level representations by treating each word equally, we simulate the repeated reading and design multiple attention levels to gradually pinpoint those words particularly useful for discourse relation recognition. In each attention level, we adopt the attention mechanism to determine which words should be focused on. An external short-term memory is designed to remember what has seen in the prior levels and guide the attention tuning process in current level.

Specifically, in the first attention level, we concatenate $\boldsymbol{R}_0^1$, $\boldsymbol{R}_0^2$ and $\boldsymbol{R}_0^1$–$\boldsymbol{R}_0^2$ and apply a non-linear transformation over the concatenation to catch the general understanding of the argument pair. The use of $\boldsymbol{R}_0^1$–$\boldsymbol{R}_0^2$ takes a cue from the difference between two vector representations which

has been found explainable and meaningful in many applications (Mikolov et al., 2013). Then, we get the memory vector $\boldsymbol{M}_1 \in \mathbb{R}^{d_m}$ of the first attention level as

$$\boldsymbol{M}_1 = tanh(\boldsymbol{W}_{m,1}[\boldsymbol{R}_0^1, \boldsymbol{R}_0^2, \boldsymbol{R}_0^1 - \boldsymbol{R}_0^2]) \quad (9)$$

where $\boldsymbol{W}_{m,1} \in \mathbb{R}^{d_m \times 6d}$ is the weight matrix.

With $\boldsymbol{M}_1$ recording the general meaning of the argument pair, our model re-calculates the importance of each word. We assign each word a weight measuring to what degree our model should pay attention to it. The weights are so-called "attention" in our paper. This process is designed to simulate the process that we re-read the arguments and pay more attention to some specific words with an overall understanding derived from the first-pass reading. Formally, for *Arg-1*, we use the memory vector $\boldsymbol{M}_1$ to update the representation of each word with a non-linear transformation. According to the updated word representations $\boldsymbol{o}_1^1$, we get the attention vector $\boldsymbol{a}_1^1$.

$$\boldsymbol{h}^1 = [\boldsymbol{h}_0^1, \boldsymbol{h}_1^1, \cdots, \boldsymbol{h}_{L_1}^1] \quad (10)$$

$$\boldsymbol{o}_1^1 = tanh(\boldsymbol{W}_{a,1}^1 \boldsymbol{h}^1 + \boldsymbol{W}_{b,1}^1 (\boldsymbol{M}_1 \otimes \boldsymbol{e})) \quad (11)$$

$$\boldsymbol{a}_1^1 = softmax(\boldsymbol{W}_{s,1}^1 \boldsymbol{o}_1^1) \quad (12)$$

where $\boldsymbol{h}^1 \in \mathbb{R}^{2d \times L_1}$ is the concatenation of all LSTM output vectors of *Arg-1*. $\boldsymbol{e} \in \mathbb{R}^{L_1}$ is a vector of 1s and the $M_1 \otimes \boldsymbol{e}$ operation denotes that we repeat the vector M_1 L_1 times and generate a $d_m \times L_1$ matrix. The attention vector $\boldsymbol{a}_1^1 \in \mathbb{R}^{L_1}$ is obtained through applying a $softmax$ operation over $\boldsymbol{o}_1^1$. ${\boldsymbol{W}_{a,1}}^1 \in \mathbb{R}^{2d \times 2d}$, ${\boldsymbol{W}_{b,1}}^1 \in \mathbb{R}^{2d \times d_m}$ and ${\boldsymbol{W}_{s,1}}^1 \in \mathbb{R}^{1 \times 2d}$ are the transformation weights. It is noted that the subscripts denote the current attention level and the superscripts denote the corresponding argument. In the same way, we can get the attention vector $\boldsymbol{a}_1^2$ for *Arg-2*.

Then, according to $\boldsymbol{a}_1^1$ and $\boldsymbol{a}_1^2$, our model re-reads the arguments and get the new representations $\boldsymbol{R}_1^1$ and $\boldsymbol{R}_1^2$ for the first attention level.

$$\boldsymbol{R}_1^1 = \boldsymbol{h}^1 (\boldsymbol{a}_1^1)^T \quad (13)$$

$$\boldsymbol{R}_1^2 = \boldsymbol{h}^2 (\boldsymbol{a}_1^2)^T \quad (14)$$

Next, we iterate the "memory-attention-representation" process and design more attention levels, giving NNMA the ability to gradually infer more precise attention vectors. The processing of the second or above attention levels is slightly different from that of the first level, as we update the memory vector in a recurrent way. To formalize, for the k-th attention level ($k \geq 2$), we use the following formulae for *Arg-1*.

$$\boldsymbol{M}_k = tanh(\boldsymbol{W}_{m,k}[\boldsymbol{R}_{k-1}^1, \boldsymbol{R}_{k-1}^2, \boldsymbol{R}_{k-1}^1 - \boldsymbol{R}_{k-1}^2, \boldsymbol{M}_{k-1}]) \quad (15)$$

$$\boldsymbol{o}_k^1 = tanh(\boldsymbol{W}_{a,k}^1 \boldsymbol{h}^1 + \boldsymbol{W}_{b,k}^1 (\boldsymbol{M}_k \otimes \boldsymbol{e})) \quad (16)$$

$$\boldsymbol{a}_k^1 = softmax(\boldsymbol{W}_{s,k}^1 \boldsymbol{o}_k^1) \quad (17)$$

$$\boldsymbol{R}_k^1 = \boldsymbol{h}^1 (\boldsymbol{a}_k^1)^T \quad (18)$$

In the same way, we can computer $\boldsymbol{o}_k^2, \boldsymbol{a}_k^2$ and $\boldsymbol{R}_k^2$ for *Arg-2*.

Finally, we use the newest representation derived from the top attention level to recognize the discourse relations. Suppose there are totally K attention levels and n relation types, the predicted discourse relation distribution $\boldsymbol{P} \in \mathbb{R}^n$ is calculated as

$$\boldsymbol{P} = softmax(\boldsymbol{W}_p[\boldsymbol{R}_K^1, \boldsymbol{R}_K^2, \boldsymbol{R}_K^1 - \boldsymbol{R}_K^2] + \boldsymbol{b}_p) \quad (19)$$

where $\boldsymbol{W}_p \in \mathbb{R}^{n \times 6d}$ and $\boldsymbol{b}_p \in \mathbb{R}^n$ are the transformation weights.

2.3 Model Training

To train our model, the training objective is defined as the cross-entropy loss between the outputs of the softmax layer and the ground-truth class labels. We use stochastic gradient descent (SGD) with momentum to train the neural networks.

To avoid over-fitting, dropout operation is applied on the top feature vector before the softmax layer. Also, we use different learning rates λ and λ_e to train the neural network parameters Θ and the word embeddings Θ_e referring to (Ji and Eisenstein, 2015). λ_e is set to a small value for preventing over-fitting on this task. In the experimental part, we will introduce the setting of the hyper-parameters.

3 Experiments

3.1 Preparation

We evaluate our model on the Penn Discourse Treebank (PDTB) (Prasad et al., 2008). In our work,

we experiment on the four top-level classes in this corpus as in previous work (Rutherford and Xue, 2015). We extract all the implicit relations of PDTB, and follow the setup of (Rutherford and Xue, 2015). We split the data into a training set (Sections 2-20), development set (Sections 0-1), and test set (Section 21-22). Table 1 summarizes the statistics of the four PDTB discourse relations, i.e., Comparison, Contingency, Expansion and Temporal.

Relation	Train	Dev	Test
Comparison	1855	189	145
Contingency	3235	281	273
Expansion	6673	638	538
Temporal	582	48	55
Total	12345	1156	1011

Table 1: Statistics of Implicit Discourse Relations in PDTB.

We first convert the tokens in PDTB to lowercase. The word embeddings used for initializing the word representations are provided by GloVe (Pennington et al., 2014), and the dimension of the embeddings D_e is 50. The hyper-parameters, including the momentum δ, the two learning rates λ and λ_e, the dropout rate q, the dimension of LSTM output vector d, the dimension of memory vector d_m are all set according to the performance on the development set Due to space limitation, we do not present the details of tuning the hyper-parameters and only give their final settings as shown in Table 2.

δ	λ	λ_e	q	d	d_m
0.9	0.01	0.002	0.1	50	200

Table 2: Hyper-parameters for Neural Network with Multi-Level Attention.

To evaluate our model, we adopt two kinds of experiment settings. The first one is the four-way classification task, and the second one is the binary classification task, where we build a one-vs-other classifier for each class. For the second setting, to solve the problem of unbalanced classes in the training data, we follow the reweighting method of (Rutherford and Xue, 2015) to reweigh the training instances according to the size of each relation class. We also use visualization methods to analyze how multi-level attention helps our model.

3.2 Results

First, we design experiments to evaluate the effectiveness of attention levels and how many attention levels are appropriate. To this end, we implement a baseline model (LSTM with no attention) which directly applies the mean pooling operation over LSTM output vectors of two arguments without any attention mechanism. Then we consider different attention levels including one-level, two-level and three-level. The detailed results are shown in Table 3. For four-way classification, macro-averaged $F1$ and Accuracy are used as evaluation metrics. For binary classification, $F1$ is adopted to evaluate the performance on each class.

System	Four-way		Binary			
	$F1$	Acc.	Comp.	Cont.	Expa.	Temp.
LSTM	39.40	54.50	33.72	44.79	68.74	33.14
NNMA (one-level)	43.48	55.59	34.72	49.47	68.52	36.70
NNMA (two-level)	**46.29**	57.17	36.70	**54.48**	**70.43**	**38.84**
NNMA (three-level)	44.95	**57.57**	**39.86**	53.69	69.71	37.61

Table 3: Performances of NNMA with Different Attention Levels.

From Table 3, we can see that the basic LSTM model performs the worst. With attention levels added, our NNMA model performs much better. This confirms the observation above that one-pass reading is not enough for identifying the discourse relations. With respect to the four-way F_1 measure, using NNMA with one-level attention produces a 4% improvement over the baseline system with no attention. Adding the second attention level gives another 2.8% improvement. We perform significance test for these two improvements, and they are both significant under one-tailed t-test ($p < 0.05$). However, when adding the third attention level, the performance does not promote much and almost reaches its plateau. We can see that three-level NNMA experiences a decease in F_1 and a slight increase in Accuracy compared to two-level NNMA. The results imply that with more attention levels considered, our model may perform slightly better, but it may incur the over-fitting problem due to adding more parameters. With respect to the binary classification F_1 measures, we can see

System	Four-way		Binary				
	F_1	Acc.	Comp.	Cont.	Expa.	Expa.+EntRel	Temp.
P&C2012	-	-	31.32	49.82	-	79.22	26.57
J&E2015	-	-	35.93	52.78	-	80.02	27.63
Zhang2015	38.80	55.39	32.03	47.08	68.96	80.22	20.29
R&X2014	38.40	55.50	39.70	54.40	70.20	80.44	28.70
R&X2015	40.50	57.10	**41.00**	53.80	69.40	-	33.30
B&D2015	-	-	36.36	55.76	61.76	-	27.30
Liu2016	44.98	57.27	37.91	**55.88**	69.97	-	37.17
Ji2016	42.30	**59.50**	-	-	-	-	-
NNMA(two-level)	**46.29**	57.17	36.70	54.48	**70.43**	80.73	**38.84**

Table 4: Comparison with the State-of-the-art Approaches.

that the "Comparison" relation needs more passes of reading compared to the other three relations. The reason may be that the identification of the "Comparison" depends more on some deep analysis such as semantic parsing, according to (Zhou et al., 2010).

Next, we compare our models with six state-of-the-art baseline approaches, as shown in Table 4. The six baselines are introduced as follows.

- **P&C2012**: Park and Cardie (2012) designed a feature-based method and promoted the performance through optimizing the feature set.
- **J&E2015**: Ji and Eisenstein (2015) used two recursive neural networks on the syntactic parse tree to induce the representation of the arguments and the entity spans.
- **Zhang2015**: Zhang et al. (2015) proposed to use shallow convolutional neural networks to model two arguments respectively. We replicated their model since they used a different setting in preprocessing PDTB.
- **R&X2014, R&X2015**: Rutherford and Xue (2014) selected lexical features, production rules, and Brown cluster pairs, and fed them into a maximum entropy classifier. Rutherford and Xue (2015) further proposed to gather extra weakly labeled data based on the discourse connectives for the classifier.
- **B&D2015**: Braud and Denis (2015) combined several hand-crafted lexical features and word embeddings to train a max-entropy classifier.
- **Liu2016**: Liu et al. (2016) proposed to better classify the discourse relations by learning from other discourse-related tasks with a multi-task neural network.
- **Ji2016**: Ji et al. (2016) proposed a neural language model over sequences of words and used the discourse relations as latent variables to connect the adjacent sequences.

It is noted that P&C2012 and J&E2015 merged the "EntRel" relation into the "Expansion" relation[1]. For a comprehensive comparison, we also experiment our model by adding a *Expa.+EntRel vs Other* classification. Our NNMA model with two attention levels exhibits obvious advantages over the six baseline methods on the whole. It is worth noting that NNMA is even better than the R&X2015 approach which employs extra data.

As for the performance on each discourse relation, with respect to the F_1 measure, we can see that our NNMA model can achieve the best results on the "Expansion", "Expansion+EntRel" and "Temporal" relations and competitive results on the "Contingency" relation . The performance of recognizing the "Comparison" relation is only worse than R&X2014 and R&X2015. As (Rutherford and Xue, 2014) stated, the "Comparison" relation is closely related to the constituent parse feature of the text, like production rules. How to represent and

[1]EntRel is the entity-based coherence relation which is independent of implicit and explicit relations in PDTB. However some research merges it into the implicit Expansion relation.

exploit these information in our model will be our next research focus.

3.3 Analysis of Attention Levels

The multiple attention levels in our model greatly boost the performance of classifying implicit discourse relations. In this subsection, we perform both qualitative and quantitative analysis on the attention levels.

First, we take a three-level NNMA model for example and analyze its attention distributions on different attention levels by calculating the mean Kullback-Leibler (KL) Divergence between any two levels on the training set. In Figure 3, we use kl_{ij} to denote the KL Divergence between the i^{th} and the j^{th}attention level and use kl_{ui} to denote the KL Divergence between the uniform distribution and the i^{th} attention level. We can see that each attention level forms different attention distributions and the difference increases in the higher levels. It can be inferred that the 2^{nd} and 3^{rd} levels in NNMA gradually neglect some words and pay more attention to some other words in the arguments. One point worth mentioning is that *Arg-2* tends to have more non-uniform attention weights, since kl_{u2} and kl_{u3} of *Arg-2* are much larger than those of *Arg-1*. And also, the changes between attention levels are more obvious for *Arg-2* through observing the values of kl_{12}, kl_{13} and kl_{23}. The reason may be that *Arg-2* contains more information related with discourse relation and some words in it tend to require focused attention, as *Arg-2* is syntactically bound to the implicit connective.

At the same time, we visualize the attention levels of some example argument pairs which are analyzed by the three-level NNMA. To illustrate the k^{th} attention level, we get its attention weights $\boldsymbol{a}_k^1$ and $\boldsymbol{a}_k^2$ which reflect the contribution of each word and then depict them by a row of color-shaded grids in Figure 2.

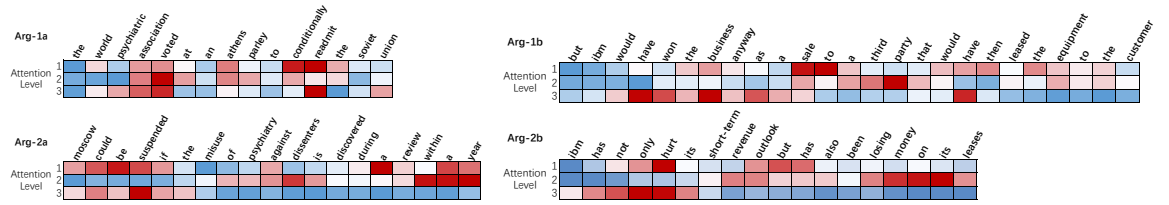
We can see that the NNMA model focuses on different words on different attention levels. Interestingly, from Figure 2, we find that the 1^{st} and 3^{rd} attention levels focus on some similar words, while the 2^{nd} level is relatively different from them. It seems that NNMA tries to find some clues (e.g. "moscow could be suspended" in *Arg-2a*; "won the business" in *Arg-1b*; "with great aplomb he considers not only" in *Arg-2c*) for recognizing the discourse relation on the 1^{st} level, looking closely at other words (e.g. "misuse of psychiatry against dissenters" in *Arg-2a*; "a third party that" in *Arg-1b*; "and support of hitler" in *Arg-2c*) on the 2^{nd} level, and then reconsider the arguments, focus on some specific words (e.g. "moscow could be suspended" in *Arg-2a*; "has not only hurt" in *Arg-2b*) and make the final decision on the last level.

4 Related Work

4.1 Implicit Discourse Relation Classification

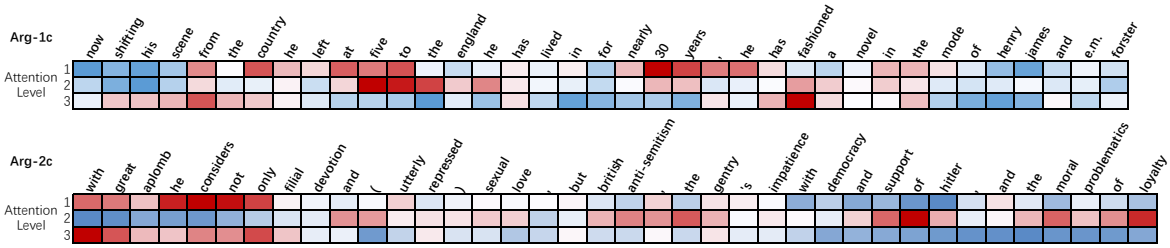
The Penn Discourse Treebank (PDTB) (Prasad et al., 2008), known as the largest discourse corpus, is composed of 2159 Wall Street Journal articles. Each document is annotated with the predicate-argument structure, where the predicate is the discourse connective (e.g. while) and the arguments are two text spans around the connective. The discourse connective can be either explicit or implicit. In PDTB, a hierarchy of relation tags is provided for annotation. In our study, we use the four top-level tags, including Temporal, Contingency, Comparison and Expansion. These four core relations allow us to be theory-neutral, since they are almost included in all discourse theories, sometimes with different names (Wang et al., 2012).

Implicit discourse relation recognition is often treated as a classification problem. The first work to tackle this task on PDTB is (Pitler et al., 2009). They selected several surface features to train four binary classifiers, each for one of the top-level PDTB relation classes. Extending from this work, Lin et al. (2009) further identified four different feature types representing the context, the constituent parse trees, the dependency parse trees and the raw text respectively. Rutherford and Xue (2014) used brown cluster to replace the word pair features for solving the sparsity problem. Ji and Eisenstein (2015) adopted two recursive neural networks to exploit the representation of arguments and entity spans. Very recently, Liu et al. (2016) proposed a two-dimensional convolutional neural network (CNN) to model the argument pairs and employed a multi-task learning framework to boost the performance by learning from other discourse-related tasks. Ji et al. (2016) considered discourse relations as



(a) Example with *Comparison* relation

(b) Example with *Contingency* relation



(c) Example with *Expansion* relation

latent variables connecting two token sequences and trained a discourse informed language model.

4.2 Neural Networks and Attention Mechanism

Recently, neural network-based methods have gained prominence in the field of natural language processing (Kim, 2014). Such methods are primarily based on learning a distributed representation for each word, which is also called a word embedding (Collobert et al., 2011).

Attention mechanism was first introduced into neural models to solve the alignment problem between different modalities. Graves (2013) designed a neural network to generate handwriting based on a text. It assigned a window on the input text at each step and generate characters based on the content within the window. Bahdanau et al. (2014) introduced this idea into machine translation, where their model computed a probabilistic distribution over the input sequence when generating each target word. Tan et al. (2015) proposed an attention-based neural network to model both questions and sentences for selecting the appropriate non-factoid answers.

In parallel, the idea of equipping the neural model with an external memory has gained increasing attention recently. A memory can remember what the model has learned and guide its subsequent actions. Weston et al. (2015) presented a neural network to read and update the external memory in a recurrent manner with the guidance of a question embedding. Kumar et al. (2015) proposed a similar model where a memory was designed to change the gate of the gated recurrent unit for each iteration.

5 Conclusion

As a complex text processing task, implicit discourse relation recognition needs a deep analysis

of the arguments. To this end, we for the first time propose to imitate the repeated reading strategy and dynamically exploit efficient features through several passes of reading. Following this idea, we design neural networks with multiple levels of attention (NNMA), where the general level and the attention levels represent the first and subsequent passes of reading. With the help of external short-term memories, NNMA can gradually update the arguments representations on each attention level and fix attention on some specific words which provide effective clues to discourse relation recognition. We conducted experiments on PDTB and the evaluation results show that our model can achieve the state-of-the-art performance on recognizing the implicit discourse relations.

Antecedent Selection for Sluicing: Structure and Content

Pranav Anand

Abstract

Sluicing is an elliptical process where the majority of a question can go unpronounced as long as there is a salient antecedent in previous discourse. This paper considers the task of antecedent selection: finding the correct antecedent for a given case of sluicing. We argue that both syntactic and discourse relationships are important in antecedent selection, and we construct linguistically sophisticated features that describe the relevant relationships. We also define features that describe the relation of the content of the antecedent and the sluice type. We develop a linear model which achieves accuracy of 72.4%, a substantial improvement over a strong manually constructed baseline. Feature analysis confirms that both syntactic and discourse features are important in antecedent selection.

1 Introduction

Ellipsis involves sentences with missing subparts, where those subparts must be interpretatively filled in by the hearer. How this is possible has been a major topic in linguistic theory for decades (Sag, 1976; Chung et al., 1995; Merchant, 2001). One widely studied example is *verb phrase ellipsis* (VPE), exemplified by (1).

(1) Harry traveled to southern Denmark to study botany . Tom did too .

In the second sentence (*Tom did too*) the verb phrase is entirely missing, yet the hearer effortlessly 'resolves' (understands) its content to be *traveled to southern Denmark to study botany*.

Another widely studied case of ellipsis is *sluicing*, in which the majority of a question is unpronounced, as in (2).

(2) Harry traveled to southern Denmark to study botany . I want to know **why** .

Here the content of the question, introduced by the WH-phrase *why*, is missing, yet it is understood by the hearer to be *why did Harry travel to southern Denmark to study botany?*. In both of these cases, ellipsis resolution is made possible by the presence of an *antecedent*, material in prior discourse that, informally speaking, is equivalent to what is missing.

Ellipsis poses an important challenge for many applications in language technology, as various forms of ellipsis are known to be frequent in a variety of languages and text types. This is perhaps most evident in the case of question-answering systems, since elliptical questions and elliptical answers are both very common in discourse. A computational system that can effectively deal with ellipsis involves three subtasks (Nielsen, 2005): *ellipsis detection*, in which a case of ellipsis is identified, *antecedent selection*, in which the antecedent for a case of ellipsis is found, and *ellipsis resolution*, where the content of the ellipsis is filled in with reference to the antecedent and the context of the ellipsis. Here, we focus on antecedent selection for sluicing. In addressing this problem of antecedent selection, we make use of a newly available annotated corpus of sluice occurrences (Anand and McCloskey, 2015). This corpus consists of 4100 automatically parsed and annotated examples from the New York Times subset of the Gigaword Corpus, of which 2185 are

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1234–1243,
Austin, Texas, November 1-5, 2016.

publicly available.

Sluicing antecedent selection might appear simple – after all, it typically involves a sentential expression in the nearby context. However, analysis of the annotated corpus data reveals surprising ambiguity in the identification of the antecedent for sluicing.

In what follows, we describe a series of algorithms and models for antecedent selection in sluicing. Following section 2 on background, we describe our dataset in section 3. Then in section 4, we describe the structural factors that we have identified as relevant for antecedent selection. In section 5, we look at ways in which the content of the sluice and the content of the antecedent tend to be related to each other: we address lexical overlap, as well as the probabilistic relation of head verbs to WH-phrase types, and the relation of correlate expressions to sluice types. In section 6 we present two manually constructed baseline classifiers, and then we describe an approach to automatically tuning weights for the complete set of features. In section 7 we present the results of these algorithms and models, including results involving various subsets of features, to better understand their contributions to the overall results. Finally in section 8 we discuss the results in light of plans for future work.

2 Background

2.1 Sluicing and ellipsis

Sluicing is formally defined in theoretical linguistics as ellipsis of a question, leaving only a WH-phrase *remnant*. While VPE is licensed only by a small series of auxiliaries (e.g., modals, *do*, see Lobeck (1995)), sluicing can occur wherever questions can, both in unembedded 'root' environments (e.g., *Why?*) or governed by the range of expressions that embed questions, like *know* in (2). Sluicing is argued to be possible principally in contexts where there is uncertainty or vagueness about an issue (Ginzburg and Sag, 2000). In some cases, this manifests as a *correlate*, an overt indefinite expression whose value is not further specified, like *one of the candidates* in (3). But in many others, like that in (2) or (4), there is no correlate, and the uncertainty is implicit.

(3) They 've made an offer to [$_{cor}$ one of the candidates] , but I 'm not sure **which one**

(4) They were firing , but **at what** was unclear

The existence of correlate-sluices suggests an obvious potential feature type for antecedent detection. However, the annotated sluices in (Anand and McCloskey, 2015) have correlates only 22% of the time, making this process considerably harder. We return to the question of correlates in section 5.1.

2.2 Related Work

The first large-scale study of ellipsis is due to Hardt (1997), which addresses VPE. Examining 644 cases of VPE in the Penn Treebank, Hardt presents a manually constructed algorithm for locating the antecedent for VPE, and reports accuracy of 75% to 94.8%, depending on whether the metric used requires exact match or more liberal overlap or containment. Several preference factors for choosing VPE antecedents are identified (Recency, Clausal Relations, Parallelism, and Quotation). One of the central components of the analysis is the identification of structural constraints which rule out antecedents that improperly contain the ellipsis site, an issue we also address here for sluicing. Drawing on 1510 instances of VPE in both the British National Corpus (BNC) and the Penn Treebank, Nielsen (2005) shows that a maxent classifier using refinements of Hardt's features can achieve roughly similar results to Hardt's, but that additional lexical features do not help appreciably.

Nielsen chooses to optimize for Hardt's Head Overlap metric, which assigns success to any candidate containing/contained in the correct antecedent. There are thus many "correct" antecedents for a given instance of VPE, which mitigates the class imbalance problem. However, the approach does not provide a way to discriminate between these containing candidates, an important step in the eventual goal of resolving the ellipsis.

There is no similar work on antecedent selection for sluicing, though there have been small-scale corpora gathered for sluices (Nykiel, 2010; Beecher, 2008). In addition, Fernandez et al. (2005) build rule-based and memory-based classifiers for the pragmatic import of root (unembedded) sluices in the BNC, based on the typology of Ginzburg and Sag (2000). Using features for the type of WH-

phrase, markers of mood (declarative/interrogative) and polarity (positive/negative) as well as the presence of correlate-like material (e.g., quantifiers, definites, etc.), they can diagnose the purpose of a sluice in a dataset of 300 root sluices with 79% average F-score, a 5% improvement over the MLE. Fernandez et al. (2007) address the problem of identifying sluices and other non-sentential utterances. We don't address that problem in the current work. Furthermore, Fernandez et al. (2007) and Fernandez et al. (2008) address the general problem of non-sentential utterances or fragments in dialogue, including sluices. Sluicing in dialogue differs from sluicing in written text in various ways: there is a high proportion of root sluices, and antecedent selection is likely mitigated by the length of utterances and the order of conversation. As we discuss, many of our newswire sluices evince difficult patterns of containment inside the antecedent (particularly what we call interpolated and cataphoric sluices), and it does not appear from inspection that root sluices ever participate in such processes.

Looking more generally, there is an obvious potential connection between antecedent selection for ellipsis and the problem of coreference resolution (see Hardt (1999) for an explicit theoretical link between the two). However, entity coreference resolution is a problem with two major differences from ellipsis antecedent detection: a) the antecedent and anaphor often share a variety of syntactic, semantic, and morphological characteristics that can be featurally exploited; b) entity expressions in a text are often densely coreferent, which can help provide proxies for discourse salience of an entity.

In contrast, abstract anaphora, particularly discourse anaphora (*this/that* anaphora to something sentential), may offer a more parallel case to ours. Here, Kolhatkar et al. (2013) use a combination of syntactic type, syntactic/word context, length, and lexical features to identify the antecedents of anaphoric shell nouns (*this fact*) with precision from 0.35-0.72. Because of the sparsity of these cases, Kolhatkar et al. use Denis and Baldridge's (2008) candidate ranking model (versus a standard mention-pair model (Soon et al., 2001)), in which all potential candidates for an anaphor receive a relative rank in the overall candidate pool. In this paper, we will pursue a hillclimbing approach to antecedent selection, inspired by the candidate ranking scheme.

3 Data

3.1 The Annotated Dataset

Our dataset, described in Anand and McCloskey (2015), consists of 4100 sluicing examples from the New York Times subset of the Gigaword Corpus, 2nd edition. This dataset is the first systematic, exhaustive corpus of sluicing.[1] Each example is annotated with four main tags, given in terms of token sequence offsets: the *sluice remnant*, the *antecedent*, and then inside the antecedent the main *predicate* and the *correlate*, if any. The annotations also provide a free-text resolution. Of the 4100 annotated, 2185 sluices have been made publicly available; we use that smaller dataset here. We make use of the annotation of the antecedent and remnant tags. See Anand and McCloskey (2015) for additional information on the dataset and the annotation scheme. For the feature extraction in section 4, we rely on the the token, parsetree, and dependency parse information in Annotated Gigaword (extracted from Stanford CoreNLP).

3.2 Defining the Correct Antecedent

Because of disagreements with the automatic parses of their data, Anand and McCloskey (2015) had annotators tag token sequences, not parsetree constituents. As a result, 10% of the annotations are not sentence-level (i.e., S, SBAR, SBARQ) constituents, such as the VP antecedent in (5), and 15% are not constituents at all, such as the case of (6), where the parse lacks an S node excluding the initial temporal clause. We describe two different ways to define what will count as the correct antecedent in building and assessing our models.

3.2.1 Constituent-Based Accuracy

Linguists generally agree that the antecedent for sluicing is a sentential constituent (see Merchant (2001) and references therein). Thus, it is straightforward to define the antecedent as the minimal

[1] 4100 sluices works out to roughly 0.14% of WH-phrases in the NYT portion of Gigaword. However, note that this includes all uses of WH-phrases (e.g., clefts and relative clauses), whereas sluicing is only possible for WH-questions. It's not clear how many questions there are in the dataset (distinguishing questions and other WH-phrases is non-trivial).

sentence-level constituent containing the token sequence marked as the antecedent. Then we define CONACCURACY as the percentage of cases in which the system selects the correct antecedent, as defined here.

While it is linguistically appealing to uniformly define candidates as sentential constituents, the annotator choices are sometimes not parsed that way, as in the following examples:

(5) " I do n't know how , " said Mrs. Kitayeva , " but [$_S$ we want [$_{VP}$ **to bring Lydia home**] , in any condition] . "

(6) [$_S$ [$_S$$BAR$ When Brown , an all-America tight end , was selected in the first round in 1992] **he was one of the highest rated players on the Giants ' draft board**]

In such cases, there is a risk that we will not accurately assess the performance of our systems, since the system choice and annotator choice will only partially overlap.

3.2.2 Token-Based Precision and Recall

Here we define a metric which calculates the precision and recall of individual token occurrences, following Bos and Spenader (2011) (see also Kolhatkar and Hirst (2012)). This will accurately reflect the discrepancy in examples like (5) – according to ConAccuracy, a system choice of *we want to bring Lydia home in any condition* is simply considered correct, as it is the smallest sentential consituent containing the annotator choice. According to the Token-Based metric, we see that the system achieves recall of 1; however, since the system includes six extraneous tokens, precision is .4. We define TOKF as the harmonic mean of Token-Based Precision and Recall; for (5), TokF is .57.

3.3 Development and Test Data

The dataset consists of 2185 sluices extracted from the New York Times between July 1994 and December 2000. For feature development, we segmented the data into a development set (DS) of the 453 sluices from July 1994 to December 1995. The experiments in section 6 were carried out on a test set (TS) of the 1732 sluices in the remainder of the dataset, January 1996 to December 2000.

4 Structure

Under our assumptions, the candidate antecedent set for a given sluice is the set of all sentence-level parsetree constituents within a n-sentence radius around the sluice sentence (based on DS, we set $n = 2$). Because sentence-level constituents embed, in DS there are on average 6.4 candidate antecedents per sluice. However, because ellipsis resolution involves identification of an antecedent, we assume that it, like anaphora resolution, should be sensitive to the overall salience of the antecedent. This means that there should be, in principle, proxies for salience that we can exploit to diagnose the plausibility of a candidate for sluicing in general. We consider four principle kinds of proxies: measures of candidate-sluice distance, measures of candidate-sluice containment, measures of candidate 'main point', and candidate-sluice discourse relation markers.

4.1 Distance

Within DS, 63% of antecedents are within the same sentence as the sluice site, and 33% are in the immediately preceding sentence. In terms of candidates, the antecedent is on average the 5th candidate from the end of the n-sentence window. The positive integer-valued feature DISTANCE tracks these notions of recency, where DISTANCE is 1 if the candidate is the candidate immediately preceding or following the sluice site (DISTANCE is defined to be 0 only for infinitival Ss like S0 in (7) below). The feature FOLLOWS marks whether a candidate follows the sluice.

4.2 Containment

As two-thirds of the antecedents are in the same sentence as the sluice, we need measures to distinguish the candidates internal to the sentence containing the sluice. In general, we want to exclude any candidate that 'contains' (i.e., dominates) the sluice, such as S0 and S-1 in (7). One might have thought that we want to always exclude the entire sentence (here, S-4) as well, but there are several cases where the smallest sentence-level constituent containing the annotated antecedent dominates the sluice, including: parenthetical sluices inside the antecedent (8), sluices in subordinating clauses (9), or

sluice VPs coordinated with the antecedent VP (10). We thus need features to mark when such candidates are 'non-containers'.

(7) [$_{S-4}$ [$_{S-3}$ I have concluded that [$_{S-2}$ I can not support the nomination] , and [$_{S-1}$ I need [$_{S0}$ to explain **why**]].]

(8) [$_{S-2}$ A major part of the increase in coverage , [$_{S-1}$ though Mitchell 's aides could not say just **how much** ,] would come from a provision providing insurance for children and pregnant women .]

(9) [$_{S-3}$ Weltlich still plans [$_{S-2}$ to go , [$_{S-1}$ although he does n't know **where**]]]

(10) [$_{S-2}$ State regulators have ordered 20th Century Industries Inc. [$_{S-1}$ to begin paying $ 119 million in Proposition 103 rebates or explain **why not** by Nov. 14 .]]

Conceptually, what renders S-3 in (9), S-2 in (8), and S-1 in (10) non-containers is that in all three cases the sluice is semantically dissociable from the rest of the sentence. We provide three features to mark this. First, the boolean feature SLUICEINPARENTHETICAL marks when the sluice is dominated by a parenthetical (a PRN node in the parse or an *(al)though* SBAR delimited by punctuation). Second, SLUICEINCOORDVP marks the configuration exemplified (10).

We also compute a less structure-specific measure of whether the candidate is meaningful once the sluice (and material dependent on it) is removed. This means determining, for example, that S-4 in (7) is meaningful once *to explain why* . is removed but S-1 is not. But the latter result follows from the fact that the main predicate of S-1, *need* takes the sluice govering verb *explain* as an argument, and hence removing that argument renders it semantically incomplete. We operationalize this in terms of complement dependency relations. We first locate the largest subgraph containing the sluice in a chain of *ccomp* and *xcomp* relations. This gives us gov_{max}, the highest such governor (i.e., *explain*) in Fig. 1. The subgraph dependent on gov_{max} is then removed, as indicated by the grayed boxes in Fig 1. If the resulting subgraph contains a verbal governor, the candidate is meaningful and CONTAINSSLUICE is false. By this logic, S-4 in (7) is meaningful because it contains *concluded*, but S-1 is not, because there is no verbal material remaining.

4.3 Discourse Structure

It has often been suggested (Asher, 1993; Hardt, 1997; Hardt and Romero, 2004) that the antecedent selection process is very closely tied to discourse relations, in the sense that there is a strong preference or even a requirement for a discourse relation between the antecedent and ellipsis.

Here we define several features that indicate either that a discourse relation is present or is not present.

We begin with features indicating that a discourse relation is not present: the theoretical linguistics literature on sluicing has noted that antecedents not in the 'main point' of an assertion (e.g., ones in appositives (AnderBois, 2014) or relative clauses (Cantor, 2013)) are very poor antecedents for sluices, presumably because their content is not very salient. The boolean features CANDINPARENTHETICAL (determined as for the sluice above) and CANDINRELCLAUSE mark these patterns.[2]

We also define features that would tend to indicate the presence of a discourse relation. These have to do with antecedents that occur after the sluice. Although antecedents overwhelmingly occur prior to sluices, we observe one prominent cataphoric pattern in DS, where the sentence containing the sluice is coordinated with a contrastive discourse relation; this is exemplified in (11).

(11) " I do n't know **why** , but I like Jimmy Carter . "

Three features are designed to capture this pattern: COORDWITHSLUICE indicates whether the sluice and candidate are connected by a coordination dependency, AFTERINITIALSLUICE marks the conjunctive condition where the candidate follows a sluice initial in its sentence, and IMMEDAFTERINITIALSLUICE marks a candidate that is the closest following candidate to an initial sluice.

[2]This feature might be seen as an analog to the apposition features used in nominal coreference resolution (Bengtson and Roth, 2008), but there it is used to link appositives, whereas here it is to exclude candidates.

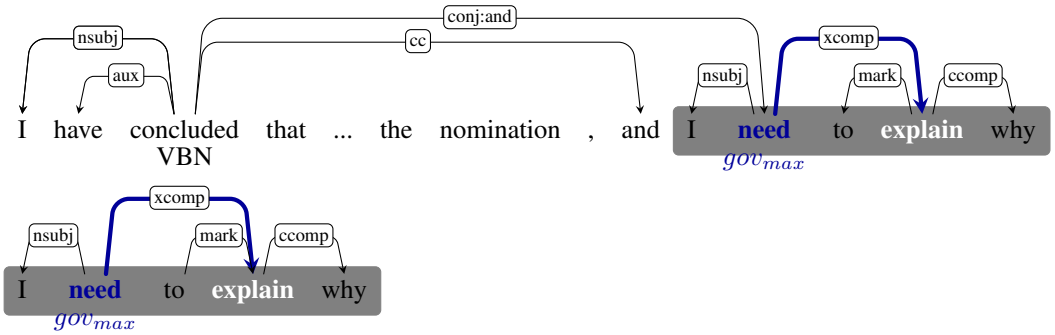

Figure 1: Sluice containment for S-4 and S-1 in (7). Starting at the governor of the sluice, *explain*, find gov_{max} *need* and delete its transitive dependents. The candidate does not contain the sluice if the remaining graph contains verbal governors.

5 Content

In addition to the structural features above, we also compute several features relating the content of the sluice site and the antecedent. The intuition behind these relational features is the following: each sluice type (*why*, *who*, *how much*, etc.) represents a certain type of question, and each candidate represents a particular type of predication. For a given a sluice type, some predications might fit more naturally than others. More generally, it is a common view that an elliptical expression and its antecedent contain matching "parallel elements".[3]

Below we describe three approaches to this: one simply looks for lexical overlap – words that occur both in the sluice expression and in the candidate. The second involves a more general notion of how a predication fits with a sluice type. To capture this, we gather co-occurrence counts of main verb and sluice types. The third approach compares potential correlates in candidates with the type of sluice.

5.1 Overlap

One potential candidate for overlap information is the presence of a correlate in the antecedent. However, 75% of of sluices involve WH-phrases that typically involve no correlate (e.g., *how, when, why*). The pertinent exception to this are extent sluices (ones where the remnant is *how (much|many|JJ)*), which have been argued to heavily favor a correlate (Merchant, 2001), such as (12) below (though see (13) for a counterexample).

[3]This term is from Dalrymple et al. (1991); a similar general view about parallelism in ellipsis arises in many different theories, such as Prüst et al. (1994) and Asher (1993).

(12) The 49ers are [$_{corr}$ very good] .
It 's hard to know **how good** because the Cowboys were the only team in the league who could test them .

We thus compute the number of tokens of OVERLAP between the content terms in the WH-phrase sluice (non-WH, non prepositional) and the entire antecedent.

5.2 Wh-Predicate

Even for correlate-less sluices, the WH-phrase must semantically cohere with the main predicate of the antecedent. Thus, in (13), S-3 is a more likely antecedent than S-2 because *increase* is more likely to take an implicit extent than *predict*. Although we could have consulted a lexically rich resource (e.g, VerbNet, FrameNet), our hope was that this general approach could carry over to less argument-specific combinations such as *how* with *complete* and *raise* in (14).

(13) [$_{S-3}$ Deliveries would increase as a result of the acquisition] , [$_{S-2}$ he predicted] , but [$_{S-1}$ he would not say by how much]

(14) [$_{S-4}$ [$_{S-3}$ Once the city and team complete a contract] , the Firebirds will begin to raise $ 9 million] , [$_{S-2}$ team president Yount said] , [$_{S-1}$ but he would not say how] .

Our assumption is that some main predicates are more likely than others for a given sluice type, and we wish to gather data that reveals these probabilities. This is somewhat similar to the approach of Hindle and Rooth (1993), who gather probabilities

that reflect the association of verbal and nominal heads with prepositions to disambiguiate prepositional phrase attachment.

One way to collect these would be to use our sluicing data, which consists of a total of 2185 annotated examples. However, the probabilities of interest are not about sluicing *per se*. Rather, they are about how well a given predication fits with a given type of question. Thus instead of using our comparatively small set of annotated sluicing examples, we used overt WH-constructions in Gigaword to observe cooccurrences between question types and main predicates. To find overt WH-constructions, we extracted all instances where a WH-phrase is: a) a dependent (to exclude cases like *Who?*) and b) not at the right edge of a VP (to exclude sluices like *know who*, per Anand and McCloskey (2015)). To further ensure that we were not overlapping with our dataset, we did this only for the non=NYT subsets of Gigaword (i.e., AFP, APW, CNA, and LTW). This procedure generated 687,000 WH-phrase instances, and 79,753 WH-phrase-governor bigram types. From these bigrams, we calculated WH-PREDICATE, the normalized pmi of WH-phrase type and governor lemma in Annotated Gigaword.

5.3 Correlate Overlap

Twenty-two percent of our data has correlates, and these correlates should be discriminative for particular sluice types. For example, temporal (*when*) sluices have timespan correlates (e.g., *tomorrow*, *later*), while entity (*who/what*) sluices have individuals as correlates (e.g., *someone*, *a book*). We extracted four potential integer-valued correlate features from each candidate: LOCATIVECORR is the number of primarily locative prepositions (those with a locative MLE in The Preposition Project (Litowski and Hargraves, 2005)). ENTITYCORR is the number of nominals in the candidate that are indefinite (bare nominals or ones with a determiner relation to *a, an* and weak quantifiers (*some*, *many*, *much*, *few*, *several*).TEMPORALCORR is the number of lexical patterns in the candidate for TIMEX3 annotations in Timebank 1.2 (Pustejovesky et al., 2016). WHICHCORR is the pattern for entities plus *or*.

distance	DISTANCE, FOLLOWS
containment	CONTAINSSLUICE ISDOMINATED-BYSLUICE

content	OVERLAP, WH-PREDICATE
correlate	LOCATIVECORR, ENTITYCORR, TEMPORALCORR, WHICHCORR

Table 1: Summary of features used in experiments.

6 Algorithms

Mention-pair coreference models reduce coreference resolution to two steps: a local binary classification, and a global resolution of coreference chains. We may see antecedent selection as a similar two-stage process: classification on the probability a given candidate is an antecedent, and then selection of the most likely candidate for a given sluice. As Denis and Baldridge (2008) note, one limitation of this approach is that the overall rank of the candidates is never directly learned. They instead propose to learn the *rank* of a candidate c for antecedent a, modeled as the log-linear score of a candidate across a set of coreference models m, $(exp \sum_j w_j m_j(c, a))$, normalized by the sum of candidate scores. We apply the same approach to our problem, viewing each feature in Table 1 as a model, and estimating weights for the features by hill-climbing. We begin by defining constructed baselines which are implemented by manually assigning weights. We then consider the results of a maxent classifier over the features. Finally, we determine the weights directly by hill-climbing with random restarts.

6.1 Manual Baselines

Random simply selects candidates at random. Clst chooses the closest candidate that starts before the sluice. This is done by assigning a weight of -1 to DISTANCE and -10 to FOLLOWING (to exclude

the following candidate), and 0 to all other features. ClstBef chooses the closest candidate that entirely precedes the sluice (i.e., starts before and does not contain the sluice site). To construct ClstBef, we change the weight of CONTAINSSLUICE to -10, which means that candidates containing the sluice will never be chosen.

6.2 A maxent model

We trained a maxent classifier on the features in Table 1 for the binary antecedent-not antecedent task. With 10-fold cross-validation on the test set, the maxent model achieved an average accuracy on the binary antecedent task of 87.1 and an F-score of 53.8 (P=63.9, R=46.5). We then constructed an antecedent selector that chose the candidate with the highest classifier score.

6.3 Hill-Climbing

We define a procedure to hill-climb over weights in order to maximize ConAccuracy over the entire training set (maximizing TokF yielded similar results, and is not reported here). Weights are initialized with random values in the interval [-10,10]. At iteration i, the current weight vector is compared to alternatives differing from it by the current step size on one weight, and the best new vector is selected. For the results reported here, we performed 13 random restarts and exponential step size $10 * i^{.5}$ (values that maximized performance on the DS).

7 Results

We performed 10-fold cross-validation over TS on the hill-climbed and maxent models above, producing average ConAccuracy and TokF as shown in Table 2, which also gives results of the three baselines on the entire dataset. The hill-climbed approach with all features substantially outperformed the baselines, achieving a ConAccuracy of 72.4%.

We investigated the performance of our hill-climbing procedure with ablation of several feature subsets. We ablated features by group, as in Table 1. Table 2 shows the results for using four groups and only one group, as well as the top two three group and two group combinations.

Features fall in three tiers. Distance features are the most predictive: all the top systems use them, and they alone perform reasonably well (like Clst).

	A:Tr	F:Tr	A:Tes	F:Tes
HC-DCSNR	73.8	72.4	72.4	71.5
HC-CSNR	41.8	51.8	40.3	51.6

Table 2: Average (Con)A(ccuracy) and (Tok)F(-Score) for Tr(ain) and Tes(t) splits on 10-fold cross-validation of data. Feature groups: **D**istance, **C**ontainment, Discourse **S**tructure, co**N**tent, co**R**relate. (Red marks results not significantly different (via paired t-test) from HC-DCSNR.)

Containment and then Discourse Structure features are the next most helpful. The full system has a ConAccuracy of 72.4 on the TS, not reliably different from several systems without Content and/or Correlate features. At the same time, the scores for these feature types on their own show that they are predictive of the antecedent: The Correlate feature **R** has a score of 22.2, which is a rather modest, but statistically significant, improvement over Random. The Content feature **N** improves quite substantially, up to 30.7. This suggests that there is some redundancy with the other features, so that the contributions of Content and Correlate are not observed in combination with them. (HC-N and HC-R's lower than Random TokF is a result of precision: Random more often selects very small candidates inside the correct antecedent, leading to a higher precision.)

The Content and Correlate features concern relations between the type of sluice and the content of the antecedent; since other features do not capture this, it is puzzling that these provide no further improvement. To better understand why this is, we investigated the performance of our feature

sets by sluice type. For the top performing systems, we found that antecedent selection for sluices over extents (e.g, *how much*, *how tall*) performed 11% better than average and those over reasons (*why*) and manner (*how*) performed 13% worse than average; no other WH-phrase types differed significantly from average. Importantly, this finding was consistent even for the systems without Content or Correlate features, which we extracted in large part to help highlight possible correlate material for extent sluices as well as entity (*who/what*) and temporal (*when*) sluices.

We also examined systems knocking out our best performing features, Distance, Containment, and Discourse Structure. When Distance features were omitted, we saw a bimodal distribution: reason and manner sluice antecedent selection was 31% better than expected (based on the full system differences discussed above), and the other sluices performed 22% worse. When Containment features were omitted, reason sluices performed 10% better than expected, while extent ones were 10% worse. Finally, when Discourse Structure features were removed, entity and temporal sluices had half the error rate we would expect. While it is hard to provide a clear takeaway from these differences, they do point to the relative difficulty in locating sluice antecedents based on WH-phrase type, and they also suggest that different sluice types present quite different challenges. This suggests that one promising line might be to learn different featural weights for each sluice type.

8 Conclusion

We have addressed the problem of sluicing antecedent selection by defining linguistically sophisticated features describing the structure and content of candidates. We described a hill-climbed model which achieves accuracy of 72.4%, a substantial improvement over a strong manually constructed baseline. We have shown that both syntactic and discourse relationships are important in antecedent selection. In future work, we hope to improve the performance of several of our features. Notable among these are the discourse structural proxies we found to make a contribution to the model. These features constitute a quite limited view of discourse structure, and we suspect that a better representation of discourse structure might well lead to further improvements. One potential path would be to leverage data where discourse relations are explicitly annotated, such as that in the Penn Discourse Treebank (Prasad et al., 2008). In addition, although our Content and Correlate features were not useful alongside the others, we hope that more refined versions of those could provide some assistance. We also noted that our performance was impacted by WH-types, and therefore it might be helpful to learn different featural weights per type.

In closing, we would like to return to the larger question of effectively handling ellipsis. The solution to antecedent selection that we have presented here provides a starting point for addressing the problem of *resolution*, in which the content of the sluice is filled in. However, even if the correct antecedent is selected, the missing content is not always an exact copy of the antecedent – often substantial modifications will be required – and an effective resolution system will have to negotiate such mismatches. As it turns out, many incorrect antecedents differ from the correct antecedent in ways highly reminiscent of these mismatches. Thus, some of the errors of our selection algorithm may be most naturally addressed by the resolution system, and it may be that the relative priority of the specific challenges we identified here will become clearer as we address the next step down in the overall pipeline.

Acknowledgments

We gratefully acknowledge the work of Jim McCloskey in helping to create the dataset investigated here, as well as the principal annotators on the project. We thank Jordan Boyd-Graber, Ellen Riloff, and three incisive reviewers for helpful comments. This research has been sponsored by NSF grant number 1451819.

Abstract

This paper proposes a method for intra-sentential subject zero anaphora resolution in Japanese. Our proposed method utilizes a Multi-column Convolutional Neural Network (MCNN) for predicting zero anaphoric relations. Motivated by Centering Theory and other previous works, we exploit as clues both the surface word sequence and the dependency tree of a target sentence in our MCNN. Even though the F-score of our method was lower than that of the state-of-the-art method, which achieved relatively high recall and low precision, our method achieved much higher precision (>0.8) in a wide range of recall levels. We believe such high precision is crucial for real-world NLP applications and thus our method is preferable to the state-of-the-art method.

1 Introduction

In such pro-drop languages as Japanese, Chinese and Italian, pronouns are frequently omitted in text. For example, the subject of *uketa* (suffered) is unrealized in the following Japanese example (1):

(1) *sono-houkokusho-wa* *seifu$_i$-ga*
the report-TOP government$_i$-SUBJ
jouyaku-o *teiketsushi* *(ϕ_i-ga)* *keizaitekini*
treaty-OBJ make it$_i$-SUBJ economically
higai-o *uke-ta* *koto-o* *shitekishi-ta*
damage-OBJ suffer-PAST COMP point out-PAST
The report pointed out that the government$_i$ agreed to a treaty and (it$_i$) suffered economically.

The omitted argument is called a *zero anaphor*, which is represented using ϕ. In example (1), zero anaphor ϕ_i refers to its antecedent, *seifu$_i$* (government). Such a reference phenomenon is called *zero anaphora*. Identifying zero anaphoric relations is an essential task in developing such accurate NLP applications as information extraction and machine translation for pro-drop languages. For example, in Japanese, 60% of subjects in newspaper articles are unrealized as zero anaphors (Iida et al., 2007).

This paper proposes a method for *intra-sentential subject zero anaphora resolution*, in which a zero anaphor and its antecedent appear in the same sentence and the zero anaphor must be a *subject* of a predicate, for Japanese. We target *subject* zero anaphors because they represent 85% of the intra-sentential zero anaphora in our data set (example (1) is such a case). Furthermore, this work focuses on intra-sentential zero anaphora because inter-sentential cases, in which a zero anaphor and its antecedent do not appear in the same sentence, are extremely difficult. The accuracy of the state-of-the-art method for resolving inter-sentential anaphora is low (Sasano and Kurohashi, 2011), and we believe the current technologies are not mature enough to deal with inter-sentential cases.

Our method *locally* predicts the likelihood of a zero anaphoric relation between every possible combination of potential zero anaphor and potential antecedent without considering the other (potential) zero anaphoric relations in the same sentence. The final determination of zero anaphoric relations for each zero anaphor in a given sentence is done in a *greedy way*; only the most likely candidate antecedent for each zero anaphor is selected as its antecedent as far as the likelihood score exceeds a

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1244–1254,
Austin, Texas, November 1-5, 2016.

given threshold. This approach contrasts with *global* optimization methods (Yoshikawa et al., 2011; Iida and Poesio, 2011; Ouchi et al., 2015), which have recently become popular. These methods use the constraints among possible zero anaphoric relations, such as "if a candidate antecedent is identified as the antecedent of a subject zero anaphor of a predicate, the candidate cannot be referred to by the object zero anaphor of the same predicate", and determine an optimal set of zero anaphoric relations in an entire sentence while satisfying such constraints, using such optimization techniques as sentence-wise global learning (Ouchi et al., 2015) and integer linear programming (Iida and Poesio, 2011).

Although the global optimization methods have outperformed the previous greedy-style methods, our contention is that greedy-style methods can still, in a certain sense, outperform the state-of-the-art global optimization methods. Ouchi et al. (2015)'s global optimization method achieved the state-of-the-art F-score for Japanese intra-sentential subject zero anaphora resolution, but its performance has not yet reached a level of practical use. In our setting, for example, it actually obtained a precision of only 0.61, and even after attempting to obtain more reliable zero anaphoric relations by several modifications, we could only achieve 0.80 precision at extremely low recall levels ($<$0.01). On the other hand, while our proposed greedy-style method obtained a lower F-score than Ouchi et al.'s method, it achieved much higher precision in a wide range of recall levels (e.g., around 0.8 precision at 0.25 in recall and around 0.7 precision at 0.4 in recall). We believe such high precision is crucial to real-world applications, even though the recall remains low, and thus our method is preferable to Ouchi et al.'s method in that sense.

In our proposed method, we use a Multi-column Convolutional Neural Network (MCNN) (Cireşan et al., 2012), which is a variant of a Convolutional Neural Network (CNN) (LeCun et al., 1998). An MCNN has several independent columns, each of which has its own convolutional and pooling layers. The outputs of all the columns are combined in the final layer to provide a final prediction. In this work, motivated by Centering Theory (Grosz et al., 1995) and other previous works, we exploit as distinct columns the word sequences obtained from the surface word sequence and the dependency tree of a target sentence in our MCNN. Although the existing works also exploited such word sequences, they used only particular types of information from them as features based on the researchers' linguistic insights. In contrast, we minimized such feature engineering due to using an MCNN.

The rest of this paper is organized as follows. In Section 2, we briefly overview previous work on zero anaphora resolution. In Section 3, we present the procedure of our zero anaphora resolution method and explain the column sets used in our MCNN architecture. We evaluate how effectively our method recognizes intra-sentential subject zero anaphora in Section 4 and summarize this work and discuss future directions in Section 5.

2 Related work

The typical zero anaphora resolution algorithms proposed so far have exploited the information of a predicate that potentially has a zero anaphor and its candidate antecedent in a supervised manner (Seki et al., 2002; Iida et al., 2003; Isozaki and Hirao, 2003; Iida et al., 2006; Taira et al., 2008; Sasano et al., 2008; Imamura et al., 2009; Hayashibe et al., 2011; Iida and Poesio, 2011; Sasano and Kurohashi, 2011; Yoshikawa et al., 2011). In addition, existing works have exploited the dependency path between a predicate and a candidate antecedent either by encoding such paths to the set of binary features of the words that appear in the path (Iida and Poesio, 2011) or by mining from the paths the sub-trees that effectively discriminate zero anaphoric relations (Iida et al., 2006). However, both methods just focus on the dependency paths between a predicate and a candidate antecedent without exploiting other structural fragments in the dependency tree representing a target sentence, whereas our method uses the text fragments that cover the entire dependency tree.

Another important clue was derived from discourse theories, such as Centering Theory (Grosz et al., 1995). In this theory, (zero) anaphoric phenomenon is explained based on the rules and principles regarding the recency and saliency of candidate antecedents. Okumura and Tamura (1996) developed a rule-based method based on the idea of Centering Theory. Iida et al. (2003) and Imamura et

al. (2009) used as features for machine learning the results of rule-based antecedent identification based on a variant of Centering Theory (Nariyama, 2002). However, we observed that actual anaphoric phenomena often do not obey Centering Theory. To robustly resolve zero anaphora, we need to explore additional clues that are represented in a target sentence (or text).

Recent work by Iida et al. (2015) newly introduced a sub-problem of zero anaphora resolution, *subject sharing recognition*, which is the task that judges whether two predicates have the same subject. In their method, a network of subject sharing predicates is created by their subject sharing recognizer, and then zero anaphora resolution is performed by propagating a subject to the unrealized subject positions through the path in the network. Even though the accuracy of subject sharing recognition exceeds that of zero anaphora resolution, the zero anaphoric relations identified using the results of subject sharing recognition are limited to those that can be reached by subject sharing relations. The recall of this method is not high.

Although most zero anaphora resolution methods independently identify a zero anaphoric relation for each predicate, some previous works optimized the global assignment of zero anaphoric relations in an entire sentence (or an entire text) while satisfying several constraints among zero anaphoric relations. For example, Iida and Poesio (2011) found the best assignment of subject zero anaphoric relations using integer linear programming. As mentioned in the Introduction, Ouchi et al. (2015) estimated the global score of all of the predicate-argument assignments in a sentence, which include the assignments of intra-sentential zero anaphoric relations, to find the best assignment using a hill-climbing technique. Their method has an advantage: it can exploit complicated relations (e.g., the combination of two potential zero anaphoric relations) as features to directly decide more than one predicate-argument relation simultaneously. We adopted Ouchi et al. (2015)'s method as a baseline in Section 4 because it achieved the state-of-the-art performance for intra-sentential zero anaphora resolution.

Collobert et al. (2011) proposed CNN architecture that can be applied to various NLP tasks, such as PoS tagging, chunking, named entity recognition and semantic role labeling. Following this work, CNNs have been utilized in such NLP tasks as document classification (Kalchbrenner et al., 2014; Kim, 2014; Johnson and Zhang, 2015), paraphrase (Hu et al., 2014; Yin and Schütze, 2015) and relation extraction (Liu et al., 2013; Zeng et al., 2014; dos Santos et al., 2015; Nguyen and Grishman, 2015). MCNNs were first introduced for image classification (Cireşan et al., 2012). In NLP tasks, they have been utilized for question-answering (Dong et al., 2015) and relation extraction (Zeng et al., 2015). Our MCNN architecture was inspired by a Siamese architecture (Chopra et al., 2005), which we extend to a multi-column network and replace its similarity measure with a softmax function at its top.

3 Proposed method

Our proposed method consists of the following four steps:

Step 1 Extract every pair of a predicate and a candidate antecedent, $\langle pred_i, cand_i \rangle$, that appears in a target sentence.

Step 2 Predict the probability of each pair using our MCNN.

Step 3 Rank in descending order all the pairs by their probabilities obtained in Step 2.

Step 4 Choose the top pair $\langle pred_i, cand_i \rangle$ in the ranked list and fill the zero anaphor position of predicate $pred_i$ by $cand_i$ if the position has not already been filled by another candidate. Remove $\langle pred_i, cand_i \rangle$ from the list and repeat this step as long as the score of the chosen pair exceeds a given threshold.

In Step 1, we extract set of pairs $\langle pred_i, cand_i \rangle$ in which candidate antecedent $cand_i$ is paired with predicate $pred_i$. Note that we extracted predicate $pred_i$, instead of a zero anaphor that is an unrealized subject of $pred_i$, because the (potential) zero anaphor of $pred_i$ is omitted in the text and cannot be extracted directly.

In Step 2, our MCNN gives a probability that indicates the likelihood of a zero anaphoric relation to judge for each pair whether $cand_i$ fills the blank subject position of $pred_i$ through zero anaphora and ranks all of the pairs by the probabilities in Step 3.

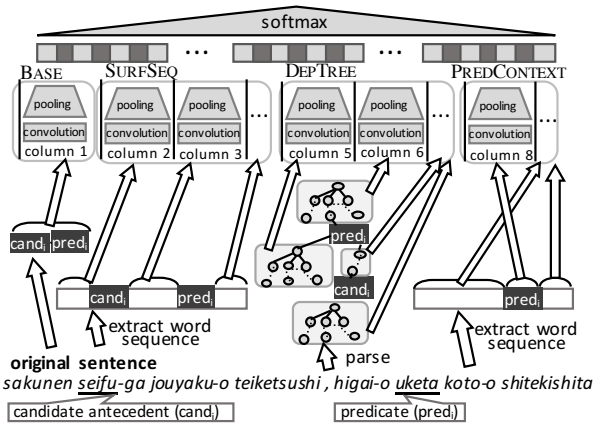

Figure 1: Our multi-column CNN architecture

Finally, in Step 4 we actually fill $cand_i$ in the blank subject positions of $pred_i$ in a greedy style in the order of the ranked list in Step 3, i.e., the zero anaphora resolution with a higher probability is done before that with a lower probability. If the subject position is already occupied by another candidate antecedent, candidate antecedents are no longer filled at that position.

3.1 Design of columns used in MCNN

In Step 2 of our method, we use a Multi-column Convolutional Neural Network (MCNN). Note that zero anaphoric phenomena can be divided into two different referential phenomena: *anaphoric* (i.e., an antecedent precedes its zero anaphor) and *cataphoric* (i.e., a zero anaphor precedes its antecedent) cases. To capture this difference, we divided the set of training instances into two subsets by the relative occurrence positions of a predicate and a candidate antecedent and respectively trained two independent MCNNs using each set.

Our MCNN simultaneously uses four column sets, as illustrated in Figure 1. In the following explanation for each column set, we assume that candidate antecedent $cand_i$ precedes predicate $pred_i$ in the surface order (for the opposite case, i.e., the cataphoric case, the positions of $cand_i$ and $pred_i$ are switched).

BASE The first column set consists of one column, which stores the word vectors of the *bunsetsu* phrases[1] including either $cand_i$ or $pred_i$. We call this column set the BASE column set.

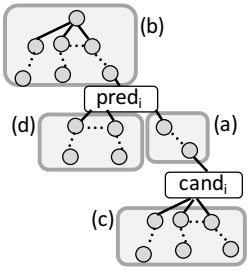

Figure 2: Columns (a, b, c, d) in DEPTREE column set

SURFSEQ The second column set consists of three columns, which store the word vectors of (a) the surface word sequence spanning from the beginning of the sentence to $cand_i$, (b) the sequence between $cand_i$ and $pred_i$, and (c) the remainder, i.e., from $pred_i$ to the end of the sentence. Note that $cand_i$ and $pred_i$ are not included in any column of this column set. We call this column set the SURFSEQ column set.

DEPTREE The third set consists of four columns. We extracted four partial dependency trees from the entire dependency tree of a target sentence: (a) the dependency path between $pred_i$ and $cand_i$, (b) the sub-trees that depend on $pred_i$, (c) the sub-trees on which $cand_i$ depends and (d) the remaining sub-trees, which are illustrated in Figure 2. Note that $cand_i$ and $pred_i$ are not included in the partial trees. Each column stores the word vectors of the word sequence in which the words in (the set of) the partial trees are ordered by their surface order. We call this set the DEPTREE column set.

PREDCONTEXT The fourth set consists of three columns, which store the word vectors of (a) the bunsetsu phrase including $pred_i$, (b) the surface word sequence that appears before (a) (from the beginning of the sentence) and (c) the sequence that appears after (a) (until the end of the sentence). We call this column set the PREDCONTEXT column set.

Among the four column sets, the SURFSEQ column set was designed to introduce the clues based

[1] A bunsetsu phrase is a Japanese base phrase that consists of at least one content word optionally followed by function words.

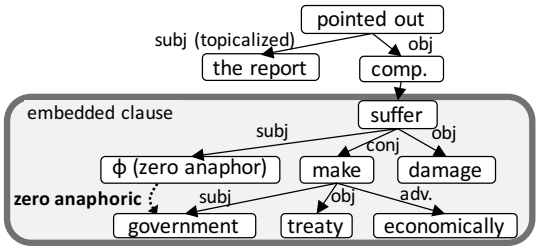

Figure 3: Dependency tree of example (1)

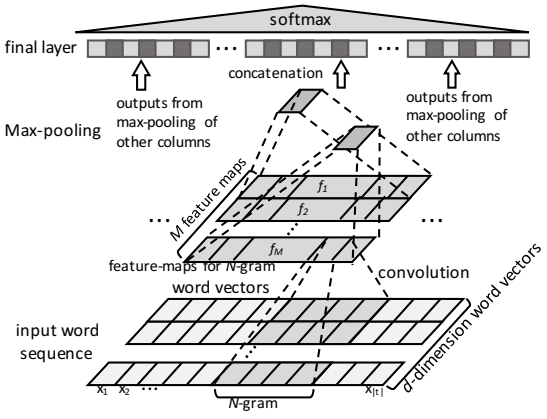

Figure 4: Column of our MCNN

on Centering Theory, in which the antecedent for a given zero anaphor can basically be identified by the *recency* and *saliency* properties of a candidate antecedent. More precisely, in the set of the most salient candidate antecedents, the most recent one is preferred. For example, suppose example (2) in which the predicate *increase* has a subject zero anaphor and its antecedent is *France*:

(2) *nihon-wa* *shoshikataisaku-ni*
Japan-TOP countermeasures to falling birth rate-IOBJ
shippaishi-taga, *furansu-wa* *sore-ni* *seikoushi*
fail-PAST/BUT France-TOP it-IOBJ succeed
(ϕ_i-ga) *shusseiritsu-o* *fuyashiteiru*
(it$_i$-SUBJ) birth rate-OBJ increase
Japan failed to develop countermeasures to its falling birth rate, but France$_i$ succeeded and (ϕ_i) increased its birth rate.

In this situation, there are two most salient candidate antecedents, *Japan* and *France*, because they are marked with topic marker *wa*, which basically indicates the highest degree of candidate saliency. In this case, *France* is selected as the antecedent because it appears more recently than *Japan*, and such recency can be estimated by consulting the surface word sequence between *France* and *increase*: no other salient candidates are included in the word sequence. Also, the other two types of word sequences (i.e., the sequence that spans from the beginning of the sentence to $cand_i$ and that spans from $pred_i$ to its end) are important for confirming whether a more salient candidate than $cand_i$ appears in each word sequence. If such a more salient candidate is found, it should be a stronger candidate of the antecedent.

The DEPTREE column set is introduced for capturing a different aspect of intra-sentential zero anaphora. In the explanation based on Centering Theory, the most salient candidate (e.g., the candidate marked with *wa* (topic marker)) is selected as an antecedent, but example (1) in Section 1 cannot be interpreted based on saliency and recency. In example (1), the *report* is the most salient candidate in the sentence because it is marked with topic marker *wa*, but the less salient candidate *government* becomes the antecedent of zero anaphor ϕ. Such a problem is often solved by introducing the dependency tree of a sentence. Figure 3 represents the dependency tree of example (1) in which the antecedent of ϕ_i appears in the embedded clause. In such a case, an antecedent probably exists among the most salient candidates in the embedded clause. To introduce such structural clues, we used the partial dependency trees as columns in the DEPTREE column set.

Anaphoricity determination, which is the task of judging whether a candidate anaphor has an antecedent, was established as a subtask of coreference resolution. This problem was basically solved by exploring the possible candidate antecedents for a given anaphor candidate in its search space, and the results were used for improving the overall performance of coreference resolution, especially in English (Ng, 2004; Wiseman et al., 2015). Inspired by such previous works, we designed the PRED-CONTEXT set to determine the anaphoricity of zero anaphors, i.e., to judge whether a zero anaphor candidate has its antecedent in a sentence, by consulting the surface word sequences before and after $pred_i$.

3.2 MCNN architecture

In our MCNN (Figure 4), we represent each word in text fragment t by d-dimensional embedding vec-

tor x_i and t by matrix $\mathbf{T} = [\mathrm{x}_1, \ldots, \mathrm{x}_{|t|}]$.[2] $\mathbf{T}$ is then wired to a set of M feature maps where each feature map is a vector. Each element O in the feature map is computed by a filter denoted by f_j ($1 \leq j \leq M$) from the N-gram word sequences in t for a fixed integer N, as $O = \mathrm{ReLU}(\mathbf{W}_{f_j} \bullet \mathrm{x}_{i:i+N-1} + b_{f_j})$, where $\bullet$ denotes element-wise multiplication followed by the summation of the resulting elements (i.e., a Frobenious inner product of $\mathbf{W}_{f_j}$ and $\mathrm{x}_{i:i+N-1}$) and $\mathrm{ReLU}(x) = \max(0, x)$. In other words, we construct a feature map by convolving a text fragment with a filter, which is parameterized by weight $\mathbf{W}_{f_j} \in \mathbb{R}^{d \times N}$ and bias $b_{f_j} \in \mathbb{R}$. Note that there can be several sets of feature maps where each set covers N-grams for different N. Note that the weight of the feature maps for each N-gram in each column set is shared.

As a whole, these feature maps are referred to as a *convolution layer*. The next layer is called a *pooling layer*. Here we use max-pooling (Scherer et al., 2010; Collobert et al., 2011), which simply selects the maximum value among the elements in the same feature map. Our assumption is that the maximum value indicates the existence of a strong clue, i.e., N-gram, for our final judgment. The selected maximum values from all the M feature maps are simply concatenated, and the resulting M-dimensional vector is given to our final layer.

The final layer has vectors coming from multiple feature maps in multiple columns. They are again simply concatenated and constitute a high dimensional feature vector. The final layer applies a linear softmax function to produce the class probabilities of the zero anaphoric labels: *true* and *false*. We use a mini-batch stochastic gradient descent (SGD) with the Adadelta update rule (Zeiler, 2012), apply random initialization within (-0.01, 0.01) for $\mathbf{W}_{f_j}$, and initialize the remaining parameters at zero.

4 Experiments

4.1 Revising annotation results

In our preliminary investigation of the intra-sentential zero anaphoric relations in the NAIST Text Corpus (Iida et al., 2007), since we found more annotation errors than we expected, we decided to revise the annotation results. In this revision, we additionally annotated the subject sharing relations, where two predicates have the same subject regardless whether the subject is realized or omitted, between pairs of predicates in our data set. Note that two predicates can have a subject sharing relation even if neither has a realized subject as far as a subject exists that can naturally fill the subject position of the two predicates. We used the annotated results of subject sharing relations to efficiently detect the annotation errors of intra-sentential zero anaphoric relations, as shown below.

Twenty-six human annotators directly annotated the subject sharing relations for pairs of predicates in a sentence. For this annotation, we automatically extracted from the NAIST Text Corpus all the pairs of predicates that appear in the same sentence and obtained 227,517 predicate pairs. For making the annotation results more reliable, each subject sharing relation was individually judged by three annotators, and the final label was decided by a majority vote. After that, further revisions of the subject sharing relations and the zero anaphoric relations were performed by focusing on the inconsistent annotations between the newly annotated subject sharing relations and the original predicate-argument relations in the NAIST Text Corpus. More precisely, we scrutinized the suspicious annotations such that a subject, which was determined through the annotated subject sharing relations, is not the same as a subject that was directly annotated in the NAIST Text Corpus. In this revision phase, both the subject sharing and zero anaphora relations for such suspicious instances were independently re-annotated by three annotators, and their final labels of both relations were determined by a majority of the their decisions.[3] As a result, 2,120 zero anaphoric instances were newly added to the corpus and 1,184 instances were removed from it for a total of 19,049 instances of intra-sentential subject zero anaphoric relations.[4]

[2] We use zero padding for dealing with text fragments of variable length (Kim, 2014).

[3] We are planning to release the annotated results and information on the data separation used in our evaluation from https://alaginrc.nict.go.jp/.

[4] After this revision, a small number of inconsistent annotated results have both a syntactically dependent subject and a subject zero anaphor because the revision was performed locally. There were 30 inconsistent instances in the testing set and 100 in the training and development sets. We only removed such instances from the testing set without changing the other

Table 1: Statistics of our data set

4.2 Experimental settings

The documents in the corpus were divided into five subsets, three of which were used as a training data set, one as a development data set, and one as a testing data set. The statistics of our data set are summarized in Table 1. We evaluated the performance of our intra-sentential subject zero anaphora resolution method and three baseline methods described below using the revised annotated results in our data set.

We implemented our MCNN using Theano (Bastien et al., 2012). We pre-trained 300-dimensional word embedding vectors for 1,658,487 words[5] using Skip-gram with a negative-sampling algorithm (Mikolov et al., 2013)[6] on a set of all the sentences extracted from Wikipedia articles[7] (35,975,219 sentences). We removed from the training data all the words that only appeared once before training. In training, we treated them as unknown words and assigned them a random vector. To avoid overfitting, we applied early-stopping and dropout (Hinton et al., 2012) of 0.5 to the final layer. We used an SGD with mini-batches of 100 and a learning rate decay of 0.95. We ran ten epochs through all of the training data, where each epoch consisted of many mini-batch updates. We utilized 3-, 4- and 5-grams with 100 filters each and used the F-score of positive instances as our evaluation metric. The total number of the nodes in the final layers of our MCNN was 3,300: 11 columns $\times$ 3 N-gram $\times$ 100 filters.

Word segmentation, PoS tagging and dependency parsing of the sentences in the NAIST Text Corpus were performed by a Japanese morphological analyzer, MeCab[8] (Kudo et al., 2004), and a dependency parser, J.DepP[9] (Yoshinaga and Kitsuregawa, 2009).

4.3 Baselines

We compared our method with three baseline methods. The first baseline is a single-column convolutional neural network in which the column includes the entire surface word sequence of a sentence. To give the positions of $pred_i$ and $cand_i$ to the network, we concatenated to each word vector an additional 2-dimensional vector, where the first element is set to one if the corresponding word is $pred_i$, the second element is set to 1 if the corresponding word is $cand_i$, and otherwise they are set to 0. This baseline was adopted for estimating the impact of a multi-column network compared to a single-column one.

The remaining two baselines are Ouchi et al. (2015)'s global optimization method and Iida et al. (2015)'s method based on subject sharing recognition. Note that Ouchi's method outputs predicate-argument relations for three grammatical roles (subj, obj, iobj), but for this evaluation we used only the outputs related to intra-sentential subject zero anaphora resolution. As done in Ouchi et al. (2015), we averaged their performances across ten independent runs because the initial random assignment of the predicate-argument relations that was employed in their method changes the performance. Ouchi's method does not require any development data set, so we used both the development and training data sets for training their joint model. For training the subject sharing recognizer used in Iida's method, we used the annotated subject sharing relations in the training and development data sets. In these two baselines, we used the same morphological analyzer and dependency analyzer as for our method.

4.4 Results

Table 2 shows the results for each method. Their performances were evaluated by measuring recall, precision, F-score and average precision (Avg.P). To assess the effectiveness of each column set introduced in Section 3.1, we evaluated the performance of our method using every possible combination of column sets that includes at least the BASE column set. We also gave the precision-recall (PR)

two sets.

[5]Words occurring less than five times in all the sentences were ignored to train the word embedding vectors.

[6]We set the skip distance to 5 and the number of negative samples to 10.

curves of our method using the four column sets (BASE+SURFSEQ+DEPTREE+PREDCONTEXT), the single column baseline, and Ouchi's method in Figure 5 to investigate the behavior of each method at a high precision level.[10] The PR-curves of our method and the single-column baseline were plotted just by altering the threshold parameters in Step 4 of our method (See Section 3). In contrast, the PR-curve of Ouchi's method cannot be easily plotted because it gives a score to each sentence, not to each zero anaphoric relation. For plotting the PR-curve, we used the normalized global score of a sentence as the score of any zero anaphoric relations in the sentence.[11] Note that the recall of their PR-curve reached just 0.539, shown in Table 2, because we could not estimate the scores of the zero anaphoric relations that were not outputted by their method. The PR-curves of the other methods also fail to reach 1.0 in recall. This is because the zero anaphoric relations are exclusive; a zero anaphor does not refer to more than one antecedent. If a method provides an incorrect zero anaphoric relation, a correct relation for the same zero anaphor will never be provided in its output. Also, note that the average precision of each method was calculated by averaging the precisions at the available recall levels for each method.

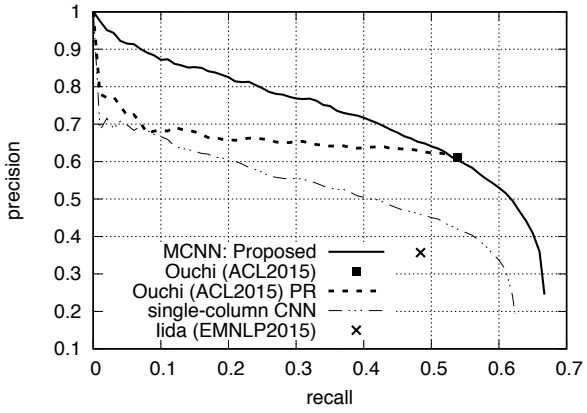

Figure 5: PR-curves of each method

The results in Table 2 show that our method using all the column sets achieved the best average precision among the combination of column sets that include at least the BASE column set. This suggests that all of the clues introduced by our four column sets are effective for performance improvement. Table 2 also demonstrates that our method using all the column sets obtained better average precision than the strongest baseline, Ouchi's method, in spite of an unfavorable condition for it.[12] The results also show that our method with all of the column sets achieved a better F-score than Iida's method and the single-column baseline. However, it achieved a lower F-score than Ouchi's method. This was caused by the choice of different recall levels for computing the F-score. In contrast, the PR-

[10] The PR-curve of Iida et al. (2015)'s method was not plotted because it does not provide the score of each zero anaphoric relation.

[11] The global score provided by Ouchi's method becomes greater based on the number of predicate-argument pairs in a sentence. To control this, we normalized the original global score by the sum of the frequencies of the single or double predicate-argument pairs because the feature functions were applied to such pairs in their method. This achieved the best performance among the normalization schemes we have tried so far.

[12] When calculating the average precision of each method, the relatively low values in precision at high recall levels (i.e., from 0.54 to 0.67) were used in our method but not in Ouchi's method, as seen in Figure 5.

Set	Method	Recall	Precision	F-score	Avg.P

Table 3: Results of instance-wise evaluation for anaphoric and cataphoric sets

curves for these two methods in Figure 5 show that our method obtained higher precision than Ouchi's method at all recall levels. Particularly, it got high precision in a wide range of recall levels (e.g., around 0.8 in precision at 0.25 in recall and around 0.7 in precision at 0.4 in recall), while the precision obtained by Ouchi's method at 0.25 in recall was just around 0.65. We believe this difference becomes crucial when using the outputs of each method for developing accurate real-world NLP applications.

In addition to an evaluation that used all of the test instances, we also investigated how our method performed differently for anaphoric and cataphoric cases. In this evaluation, we first divided our data set into anaphoric and cataphoric sets by the relative position of the candidate antecedent and evaluated the performance by measuring the recall, precision, F-score and average precision for each set. This evaluation was done instance-wise, where we took into account each pair of a predicate and its candidate antecedent as a classification target, while in the previous evaluation the performance was measured for the set of zero anaphors in the test set. Thus, the figures in Table 2 and Table 3 are not comparable. Note that we only compared our method with the baseline using a single-column convolutional neural network because the other baselines are not able to output the score of each instance for measuring their average precision.

The results in Table 3 show that our MCNN-based method achieved better average precision than the single-column CNN baseline except the method that uses only the BASE column set for the cataphoric case. The results also demonstrate that each column set consistently contributes to improving the average precision for both the anaphoric and cataphoric cases. However, Table 3 shows that the average precision for the cataphoric set remains low. As one future direction for further improvement, we need to explore clues for identifying cataphoric relations more accurately.

5 Conclusion

This paper proposed an accurate method for intra-sentential subject zero anaphora resolution using a Multi-column Convolutional Neural Network (MCNN). As clues, our MCNN exploits both the surface word sequence and the dependency tree of a target sentence. Our experimental results show that the proposed method achieved better precision than the strong baselines in a wide range of recall levels.

As future work, we plan to use our MCNN architecture for inter-sentential zero anaphora resolution and develop highly accurate NLP applications using our intra-sentential subject zero anaphora resolution method.

An Unsupervised Probability Model for Speech-to-Translation Alignment of Low-Resource Languages

Antonios Anastasopoulos and David Chiang

University of Melbourne
lduong@student.unimelb.edu.au

Abstract

For many low-resource languages, spoken language resources are more likely to be annotated with translations than with transcriptions. Translated speech data is potentially valuable for documenting endangered languages or for training speech translation systems. A first step towards making use of such data would be to automatically align spoken words with their translations. We present a model that combines Dyer et al.'s reparameterization of IBM Model 2 (`fast_align`) and k-means clustering using Dynamic Time Warping as a distance measure. The two components are trained jointly using expectation-maximization. In an extremely low-resource scenario, our model performs significantly better than both a neural model and a strong baseline.

1 Introduction

For many low-resource languages, speech data is easier to obtain than textual data. And because speech transcription is a costly and slow process, speech is more likely to be annotated with translations than with transcriptions. This translated speech is a potentially valuable source of information – for example, for documenting endangered languages or for training speech translation systems.

In language documentation, data is usable only if it is interpretable. To make a collection of speech data usable for future studies of the language, something resembling interlinear glossed text (transcription, morphological analysis, word glosses, free translation) would be needed at minimum. New technologies are being developed to facilitate collection of translations (Bird et al., 2014), and there already exist recent examples of parallel speech collection efforts focused on endangered languages (Blachon et al., 2016; Adda et al., 2016). As for the other annotation layers, one might hope that a first pass could be done automatically. A first step towards this goal would be to automatically align spoken words with their translations, capturing information similar to that captured by word glosses.

In machine translation, statistical models have traditionally required alignments between the source and target languages as the first step of training. Therefore, producing alignments between speech and text would be a natural first step towards MT systems operating directly on speech.

We present a model that, in order to learn such alignments, adapts and combines two components: Dyer et al.'s reparameterization of IBM Model 2 (Dyer et al., 2013), more commonly known as `fast_align`, and k-means clustering using Dynamic Time Warping (Berndt and Clifford, 1994) as a distance measure. The two components are trained jointly using expectation-maximization.

We experiment on two language pairs. One is Spanish-English, using the CALLHOME and Fisher corpora. The other is Griko-Italian; Griko is an endangered language for which we created (and make freely available)[1] gold-standard translations and word alignments (Lekakou et al., 2013). In all cases, our model outperforms both a naive but strong baseline and a neural model (Duong et al., 2016).

2 Background

In this section, we briefly describe the existing models that the two components of our model are based on. In the next section, we will describe how we adapt and combine them to the present task.

2.1 IBM Model 2 and `fast_align`

The IBM translation models (Brown et al., 1993) aim to model the distribution $p(\mathbf{e} \mid \mathbf{f})$ for an English sentence $\mathbf{e} = e_1 \cdots e_l$, given a French sentence $\mathbf{f} = f_1 \cdots e_m$. They all introduce a hidden variable $\mathbf{a} = a_1 \cdots a_l$ that gives the position of the French word to which each English word is aligned.

The general form of IBM Models 1, 2 and `fast_align` is

$$p(\mathbf{e}, \mathbf{a} \mid \mathbf{f}) = p(l) \prod_{i=1}^{l} t(e_i \mid f_{a_i})\, \delta(a_i \mid i, l, m)$$

where $t(e \mid f)$ is the probability of translating French word f to English word e, and $\delta(a_i = j \mid i, l, m)$ is the probability of aligning the i-th English word with the j-th French word.

In Model 1, δ is uniform; in Model 2, it is a categorical distribution. Dyer et al. (2013) propose a reparameterization of Model 2, known as `fast_align`:

$$h(i, j, l, m) = -\left|\frac{i}{l} - \frac{j}{m}\right|$$

$$\delta(a_i \mid i, l, m) = \begin{cases} p_0 & a_i = 0 \\ (1 - p_0)\frac{\exp \lambda h(i, a_i, l, m)}{Z_\lambda(i, l, m)} & a_i > 0 \end{cases}$$

where the null alignment probability p_0 and precision $\lambda \geq 0$ are hyperparameters optimized by grid search. As $\lambda \to 0$, the distribution gets closer to the distribution of IBM Model 1, and as λ gets larger, the model prefers monotone word alignments more strongly.

2.2 DTW and DBA

Dynamic Time Warping (DTW) (Berndt and Clifford, 1994) is a dynamic programming method for measuring distance between two temporal sequences of variable length, as well as computing an alignment based on this distance. Given two sequences ϕ, ϕ' of length m and m' respectively, DTW constructs an $m \times m'$ matrix w. The warping path can be found by evaluating the following recurrence:

$$w_{i,j} = d(\phi_i, \phi'_j) + \min\{w_{i-1,j}, w_{i-1,j-1}, w_{i,j-1}\}$$

where d is a distance measure. In this paper, we normalize the cost of the warping path:

$$\mathrm{DTW}(\phi, \phi') = \frac{w_{m,m'}}{m + m'}$$

which lies between zero and one.

DTW Barycenter Averaging (DBA) (Petitjean et al., 2011) is an iterative approximate method that attempts to find a centroid of a set of sequences, minimizing the sum of squared DTW distances.

In the original definition, given a set of sequences, DBA chooses one sequence randomly to be a "skeleton." Then, at each iteration, DBA computes the DTW between the skeleton and every sequence in the set, aligning each of the skeleton's points with points in all the sequences. The skeleton is then refined using the found alignments, by updating each frame in the skeleton to the mean of all the frames aligned to it. In our implementation, in order to avoid picking a skeleton that is too short or too long, we randomly choose one of the sequences with median length.

3 Model

We use a generative model from a source-language speech segment consisting of feature frames $\boldsymbol{\phi} = \phi_1 \cdots \phi_m$ to a target-language segment consisting of words $\mathbf{e} = e_1 \ldots e_l$. We chose to model $p(\mathbf{e} \mid \boldsymbol{\phi})$ rather than $p(\boldsymbol{\phi} \mid \mathbf{e})$ because it makes it easier to incorporate DTW. The other direction is also possible, and we plan to explore it in future work.

In addition to the target-language sentence $\mathbf{e}$, our model hypothesizes a sequence $\mathbf{f} = f_1 \cdots f_l$ of source-language clusters (intuitively, source-language words), and spans (a_i, b_i) of the source signal that each target word e_i is aligned to. Thus, the clusters $\mathbf{f} = f_1 \cdots f_l$ and the spans $\mathbf{a} = a_1, \ldots, a_l$ and $\mathbf{b} = b_1, \ldots, b_l$ are the hidden variables of the model:

$$p(\mathbf{e} \mid \boldsymbol{\phi}) = \sum_{\mathbf{a},\mathbf{b},\mathbf{f}} p(\mathbf{e}, \mathbf{a}, \mathbf{b}, \mathbf{f} \mid \boldsymbol{\phi}).$$

The model generates $\mathbf{e}, \mathbf{a}, \mathbf{b}$, and $\mathbf{f}$ from $\boldsymbol{\phi}$ as follows.

1. Choose l, the number of target words, with uniform probability. (Technically, this assumes a maximum target sentence length, which we can just set to be very high.)

2. For each target word position $i = 1, \ldots, l$:
   (a) Choose a cluster f_i.
   (b) Choose a span of source frames (a_i, b_i) for e_i to be aligned to.
   (c) Generate a target word e_i from f_i.

Accordingly, we decompose $p(\mathbf{e}, \mathbf{a}, \mathbf{b}, \mathbf{f} \mid \boldsymbol{\phi})$ into several submodels:

$$p(\mathbf{e}, \mathbf{a}, \mathbf{b}, \mathbf{f} \mid \boldsymbol{\phi}) = p(l) \prod_{i=1}^{l} u(f_i) \times s(a_i, b_i \mid f_i, \boldsymbol{\phi}) \times \delta(a_i, b_i \mid i, l, |\boldsymbol{\phi}|) \times t(e_i \mid f_i).$$

Note that submodels δ and s both generate spans (corresponding to step 2b), making the model deficient. We could make the model sum to one by replacing $u(f_i)s(a_i, b_i \mid f_i, \boldsymbol{\phi})$ with $s(f_i \mid a_i, b_i, \boldsymbol{\phi})$, and this was in fact our original idea, but the model as defined above works much better, as discussed in Section 7.4. We describe both δ and s in detail below.

Clustering model The probability over clusters, $u(f)$, is just a categorical distribution. The submodel s assumes that, for each cluster f, there is a "prototype" signal $\boldsymbol{\phi}^f$ (cf. Ristad and Yianilos, 1998). Technically, the $\boldsymbol{\phi}^f$ are parameters of the model, and will be recomputed during the M step. Then we can define:

$$s(a, b \mid f, \boldsymbol{\phi}) = \frac{\exp(-\mathrm{DTW}(\boldsymbol{\phi}^f, \phi_a \cdots \phi_b)^2)}{\sum_{a,b=1}^{m} \exp(-\mathrm{DTW}(\boldsymbol{\phi}^f, \phi_a \cdots \phi_b)^2)}$$

where DTW is the distance between the prototype and the segment computed using Dynamic Time Warping. Thus s assigns highest probability to spans of $\boldsymbol{\phi}$ that are most similar to the prototype $\boldsymbol{\phi}^f$.

Distortion model The submodel δ controls the reordering of the target words relative to the source frames. It is an adaptation of `fast_align` to our setting, where there is not a single source word position a_i, but a span (a_i, b_i). We want the model to prefer the middle of the word to be close to the diagonal, so we need the variable a to be somewhat to the left and b to be somewhat to the right. Therefore, we introduce an additional hyperparameter μ which is intuitively the number of frames in a word. Then we define

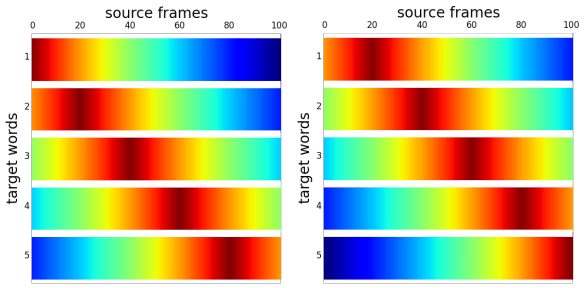

Figure 1: Sample distributions for the alignment variables a and b for $m = 100$, $l = 5$, $p_0 = 0$, $\lambda = 0.5$, and $\mu = 20$.

$$h_a(i, j, l, m, \mu) = -\left|\frac{i}{l} - \frac{j}{m - \mu}\right|$$

$$h_b(i, j, l, m, \mu) = -\left|\frac{i}{l} - \frac{j - \mu}{m - \mu}\right|$$

$$\delta_a(a_i \mid i, l, m) = \begin{cases} p_0 & a_i = 0 \\ (1 - p_0)\frac{\exp \lambda h_a(i, a_i, l, m)}{Z_\lambda(i, l, m)} & a_i > 0 \end{cases}$$

$$\delta_b(b_i \mid i, l, m) = \begin{cases} p_0 & b_i = 0 \\ (1 - p_0)\frac{\exp \lambda h_b(i, b_i, l, m)}{Z_\lambda(i, l, m)} & b_i > 0 \end{cases}$$

$$\delta(a_i, b_i \mid i, l, m) = \delta_a(a_i \mid i, l, m)\, \delta_b(b_i \mid i, l, m)$$

where the $Z_\lambda(i, l, m)$ are set so that all distributions sum to one. Figure 1 shows an example visualisation of the the resulting distributions for the two variables of our model.

We set μ differently for each word. For each i, we set μ_i to be proportional to the number of *characters* in e_i, such that $\sum_i \mu_i = m$.

Translation model The translation model $t(e \mid f)$ is just a categorical distribution, in principle allowing a many-to-many relation between source clusters and target words. To speed up training (with nearly no change in accuracy, in our experiments), we restrict this relation so that there are k source clusters for each target word, and a source cluster uniquely determines its target word. Thus, $t(e \mid f)$ is fixed to

either zero or one, and does not need to be reestimated. In our experiments, we set $k = 2$, allowing each target word to have up to two source-language translations/pronunciations. (If a source word has more than one target translation, they are treated as distinct clusters with distinct prototypes.)

4 Training

We use the hard (Viterbi) version of the Expectation-Maximization (EM) algorithm to estimate the parameters of our model, because calculating expected counts in full EM would be prohibitively expensive, requiring summations over all possible alignments.

Recall that the hidden variables of the model are the alignments (a_i, b_i) and the source words (f_i). The parameters are the translation probabilities $t(e_i \mid f)$ and the prototypes $(\boldsymbol{\phi}^f)$. The (hard) E step uses the current model and prototypes to find, for each target word, the best source segment to align it to and the best source word. The M step reestimates the probabilities $t(e \mid f)$ and the prototypes $\boldsymbol{\phi}^f$. We describe each of these steps in more detail below.

Initialization Initialization is especially important since we are using hard EM.

To initialize the parameters, we initialize the hidden variables and then perform an M step. We associate each target word type e with $k = 2$ source clusters, and for each occurrence of e, we randomly assign it one of the k source clusters.

The alignment variables a_i, b_i are initialized to

$$a_i, b_i = \arg\max_{a,b} \delta(a, b \mid i, l, m).$$

M step The M step reestimates the probabilities $t(e \mid f)$ using relative-frequency estimation.

The prototypes $\boldsymbol{\phi}^f$ are more complicated. Theoretically, the M step should recompute each $\boldsymbol{\phi}^f$ so as to maximize that part of the log-likelihood that depends on $\boldsymbol{\phi}^f$:

$$\begin{aligned} L_{\boldsymbol{\phi}^f} &= \sum_{\boldsymbol{\phi}} \sum_{i|f_i=f} \log s(a_i, b_i \mid f, \boldsymbol{\phi}) \\ &= \sum_{\boldsymbol{\phi}} \sum_{i|f_i=f} \log \frac{\exp(-\mathrm{DTW}(\phi^f, \phi_{a_i} \cdots \phi_{b_i})^2)}{Z(f, \boldsymbol{\phi})} \\ &= \sum_{\boldsymbol{\phi}} \sum_{i|f_i=f} -\mathrm{DTW}(\phi^f, \phi_{a_i} \cdots \phi_{b_i})^2 - \log Z(f, \boldsymbol{\phi}) \end{aligned}$$

where the summation over $\boldsymbol{\phi}$ is over all source signals in the training data. This is a hard problem, but note that the first term is just the sum-of-squares of the DTW distance between $\boldsymbol{\phi}^f$ and all source segments that are classified as f. This is what DBA is supposed to approximately minimize, so we simply set $\boldsymbol{\phi}^f$ using DBA, ignoring the denominator.

E step The (hard) E step uses the current model and prototypes to find, for each target word, the best source segment to align it to and the best source cluster.

In order to reduce the search space for **a** and **b**, we use the unsupervised phonetic boundary detection method of Khanagha et al. (2014). This method operates directly on the speech signal and provides us with candidate phone boundaries, on which we restrict the possible values for **a** and **b**, creating a list of candidate utterance spans.

Furthermore, we use a simple silence detection method. We pass the envelope of the signal through a low-pass filter, and then mark as "silence" time spans of 50ms or longer in which the magnitude is below a threshold of 5% relative to the maximum of the whole signal. This method is able to detect about 80% of the total pauses, with a 90% precision in a 50ms window around the correct silence boundary. We can then remove from the candidate list the utterance spans that include silence, on the assumption that a word should not include silences. Finally, in case one of the span's boundaries happens to be within a silence span, we also move it so as to not include the silence.

Hyperparameter tuning The hyperparameters p_0, λ, and μ are not learned. We simply set p_0 to zero (disallowing unaligned target words) and set μ as described above.

For λ we perform a grid search over candidate values to maximize the alignment F-score on the development set. We obtain the best scores with $\lambda = 0.5$.

5 Related Work

A first step towards modelling parallel speech can be performed by modelling phone-to-word alignment, instead of directly working on continuous speech. For example, Stahlberg et al. (2012) extend IBM Model 3 to align phones to words in order to build

cross-lingual pronunciation lexicons. Pialign (Neubig et al., 2012) aligns characters and can be applied equally well to phones. Duong et al. (2016) use an extension of the neural attentional model of Bahdanau et al. (2015) for aligning phones to words and speech to words; we discuss this model below in Section 6.2.

There exist several supervised approaches that attempt to integrate speech recognition and machine translation. However, they rely heavily on the abundance of training data, pronunciation lexicons, or language models, and therefore cannot be applied in a low- or zero-resource setting.

A task somewhat similar to ours, which operates at a monolingual level, is the task of zero-resource spoken term discovery, which aims to discover repeated words or phrases in continuous speech. Various approaches (Ten Bosch and Cranen, 2007; Park and Glass, 2008; Muscariello et al., 2009; Zhang and Glass, 2010; Jansen et al., 2010) have been tried, in order to spot keywords, using segmental DTW to identify repeated trajectories in the speech signal.

Kamper et al. (2016) try to discover word segmentation and a pronunciation lexicon in a zero-resource setting, combining DTW with acoustic embeddings; their methods operate in a very low-vocabulary setting. Bansal (2015) attempts to build a speech translation system in a low-resource setting, by using as source input the simulated output of an unsupervised term discovery system.

6 Experiments

We evaluate our method on two language pairs, Spanish-English and Griko-Italian, against two baseline methods, a naive baseline, and the model of Duong et al. (2016).

6.1 Data

For each language pair, we require a sentence-aligned parallel corpus of source-language speech and target-language text. A subset of these sentences should be annotated with span-to-word alignments for use as a gold standard.

6.1.1 Spanish-English

For Spanish-English, we use the Spanish CALLHOME corpus (LDC96S35) and the Fisher corpus (LDC2010T04), which consist of telephone conversations between Spanish native speakers based in the US and their relatives abroad, together with English translations produced by Post et al. (2013). Spanish is obviously not a low-resource language, but we pretend that it is low-resource by not making use of any Spanish ASR or resources like transcribed speech or pronunciation lexicons.

Since there do not exist gold standard alignments between the Spanish speech and English words, we use the "silver" standard alignments produced by Duong et al. (2016) for the CALLHOME corpus, and followed the same procedure for the Fisher corpus as well. In order to obtain them, they first used a forced aligner to align the speech to its transcription, and GIZA++ with the `gdfa` symmetrization heuristic to align the Spanish transcription to the English translation. They then combined the two alignments to produce "silver" standard alignments between the Spanish speech and the English words.

The CALLHOME dataset consists of 17532 Spanish utterances, based on the dialogue turns. We first use a sample of 2000 sentences, out of which we use 200 as a development set and the rest as a test set. We also run our experiments on the whole dataset, selecting 500 utterances for a development set, using the rest as a test set. The Fisher dataset consists of 143355 Spanish utterances. We use 1000 of them as a development set and the rest as a test set.

6.1.2 Griko-Italian

We also run our model on a corpus that consists of about 20 minutes of speech in Griko, an endangered minority dialect of Greek spoken in south Italy, along with text translations into Italian (Lekakou et al., 2013).[2] The corpus consists of 330 mostly prompted utterances by nine native speakers. Although the corpus is very small, we use it to showcase the effectiveness of our method in a hard setting with extremely low resources.

All utterances were manually annotated and transcribed by a trained linguist and bilingual speaker of both languages, who produced the Griko transcriptions and Italian glosses. We created full translations into Italian and manually aligned the translations with the Griko transcriptions. We then com-

[2] http://griko.project.uoi.gr

bined the two alignments (speech-to-transcription and transcription-to-translation) to produce speech-to-translation alignments. Therefore, our comparison is done against an accurate "gold" standard alignment. We split the data into a development set of just 30 instances, and a test set of the remaining 300 instances.

6.1.3 Preprocessing

In both data settings, we treat the speech data as a sequence of 39-dimensional Perceptual Linear Prediction (PLP) vectors encoding the power spectrum of the speech signal (Hermansky, 1990), computed at 10ms intervals. We also normalize the features at the utterance level, shifting and scaling them to have zero mean and unit variance.

6.2 Baselines

Our naive baseline assumes that there is no reordering between the source and target language, and aligns each target word e_i to a source span whose length in frames is proportional to the length of e_i in characters. This actually performs very well on language pairs that show minimal or no reordering, and language pairs that have shared or related vocabularies.

The other baseline that we compare against is the neural network attentional model of Duong et al. (2016), which extends the attentional model of Bahdanau et al. (2015) to be used for aligning and translating speech, and, along with several modifications, achieve good results on the phone-to-word alignment task, and almost match the baseline performance on the speech-to-word alignment task.

7 Results

To evaluate an automatic alignment between the speech and its translation against the gold/silver standard alignment, we compute alignment precision, recall, and F-score as usual, but on links between source-language frames and target-language words.

7.1 Overview

Table 1 shows the precision, recall, and balanced F-score of the three models on the Spanish-English CALLHOME corpus (both the 2000-sentence subset and the full set), the Spanish-English Fisher corpus, and the Griko-Italian corpus.

		method	precision	recall	F-score
CALLHOME spa-eng	2k sents	ours	**38.8**	38.9	**38.8**
		naive	31.9	**40.8**	35.8
		neural	23.8	29.8	26.4
	17k sents	ours	**38.4**	38.8	**38.6**
		naive	31.8	**40.7**	35.7
		neural	26.1	32.9	29.1
Fisher spa-eng	143k sents	ours	**33.3**	28.7	**30.8**
		naive	24.0	**33.2**	27.8
gri-ita	300 sents	ours	**56.6**	51.2	**53.8**
		naive	42.2	**52.2**	46.7
		neural	24.6	30.0	27.0

Table 1: Our model achieves higher precision and F-score than both the naive baseline and the neural model on all datasets.

In all cases, our model outperforms both the naive baseline and the neural attentional model. Our model, when compared to the baselines, improves greatly on precision, while slightly underperforming the naive baseline on recall. In certain applications, higher precision may be desirable: for example, in language documentation, it's probably better to err on the side of precision; in phrase-based translation, higher-precision alignments lead to more extracted phrases.

The rest of the section provides a further analysis of the results, focusing on the extremely low-resource Griko-Italian dataset.

7.2 Speaker robustness

Figure 2 shows the alignments produced by our model for three utterances of the same sentence from the Griko-Italian dataset by three different speakers. Our model's performance is roughly consistent across these utterances. In general, the model does not seem significantly affected by speaker-specific variations, as shown in Table 2.

We do find, however, that the performance on male speakers is slightly higher compared to the female speakers. This might be because the female speakers' utterances are, on average, longer by about 2 words than the ones uttered by males.

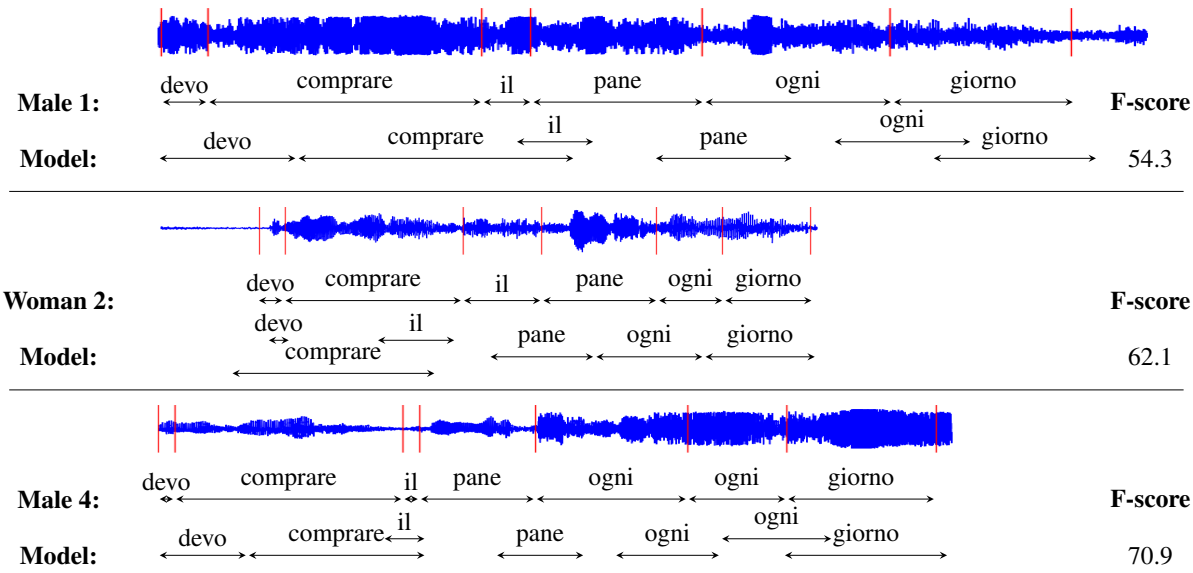

Figure 2: Alignments produced for the Italian sentence `devo comprare il pane ogni giorno` as uttered by three different Griko speakers.

speaker	utt	len	F-score
female 1	55	9.0	49.4
female 2	61	8.1	55.0
female 3	41	9.6	51.0
female 4	23	7.3	54.4
female 5	21	6.1	56.6
male 1	35	5.9	59.5
male 2	32	6.0	61.9
male 3	34	6.7	60.2
male 4	23	6.4	64.0

Table 2: Model performance (F-score) is generally consistent across speakers. The second column (utt) shows the number of utterances per speaker; the third (len), their average length in words.

7.3 Word level analysis

We also compute F-scores for each Italian word type. As shown in Figure 3, the longer the word's utterance, the easier it is for our model to correctly align it. Longer utterances seem to carry enough information for our DTW-based measure to function properly. On the other hand, shorter utterances are harder to align. The vast majority of Griko utterances that have less than 20 frames and are less accurately aligned correspond to monosyllabic determiners (`o`, `i`,`a`, `to`, `ta`) or conjunctions and prepositions (`ka`, `ce`, `en`, `na`, `an`). For such short utterances, there could be several parts of the signal that possibly match the prototype, leading the clustering component to prefer to align to wrong spans.

Furthermore, we note that rare word types tend to be correctly aligned. The average F-score for hapax legomena (on the Italian side) is 63.2, with 53% of them being aligned with an F-score higher than 70.0.

7.4 Comparison with proper model

As mentioned in Section 3, our model is deficient, but it performs much better than the model that sums to one (henceforth, the "proper" model): In the Spanish-English dataset (2000 sentences sample) the proper model yields an F-score of 32.1, performing worse than the naive baseline; in the Griko-

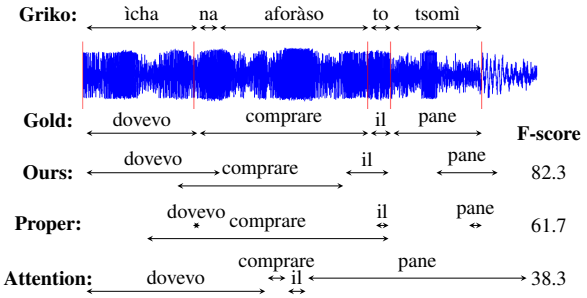

Figure 4: The deficient model performs very well, whereas the proper and the attentional model prefer extreme alignment spans. For example, the proper model's alignment for the words `dovevo` and `pane` are much too short.

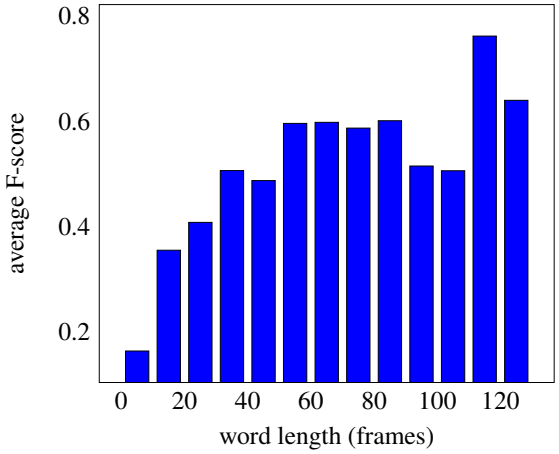

Figure 3: There is a positive correlation between average word-level F-score and average word utterance length (in frames).

Italian dataset, it achieves an F-score of 44.3, which is better than the baselines, but still worse than our model.

In order to further examine why this happens, we performed three EM iterations on the Griko-Italian dataset with our model (in our experience, three iterations are usually enough for convergence), and then computed one more E step with both our model and the proper model, so as to ensure that the two models would align the dataset using the exact same prototypes and that their outputs will be comparable.

In this case, the proper model achieved an overall F-score of 44.0, whereas our model achieved an F-score of 53.6. Figures 4 and 5 show the resulting alignments for two sentences. In both of these examples, it is clear that the proper model prefers extreme spans: the selected spans are either much too short or

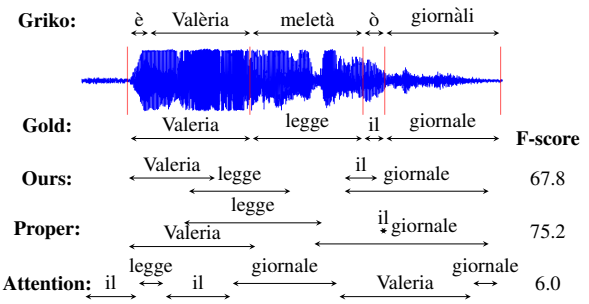

Figure 5: One of the rare examples where the proper model performs better than the deficient one. The hapax legomena `Valeria` and `giornali` are not properly handled by the attentional model.

(less frequently) much too long. This is further verified by examining the statistics of the alignments: the average span selected by the proper model has a length of about 30 ± 39 frames whereas the average span of the alignments produced by our deficient model is 37 ± 24 frames. This means that the alignments of the deficient model are much closer to the gold ones, whose average span is 42 ± 26 frames.

We think that this is analogous to the "garbage collection" problem in word alignment. In the IBM word alignment models, if a source word f occurs in only one sentence, then EM can align many target words to f and learn a very peaked distribution $t(e \mid f)$. This can happen in our model and the proper model as well, of course, since IBM Model 2 is embedded in them. But in the proper model, something similar can also happen with $s(f \mid a, b)$: EM can make the span (a, b) large or small, and evidently making the span small allows it to learn a very peaked distribution $s(f \mid a, b)$. By contrast, our model has $s(a, b \mid f)$, which seems less susceptible to this kind of effect.

8 Conclusion

Alignment of speech to text translations is a relatively new task, one with particular relevance for low-resource or endangered languages. The model we propose here, which combines `fast_align` and k-means clustering using DTW and DBA, outperforms both a very strong naive baseline and a neural attentional model, on three tasks of various sizes.

The language pairs used here do not have very much word reordering, and more divergent language

pairs should prove more challenging. In that case, the naive baseline should be much less competitive. Similarly, the `fast_align`-based distortion model may become less appopriate; we plan to try incorporating IBM Model 3 or the HMM alignment model (Vogel et al., 1996) instead. Finally, we will investigate downstream applications of our alignment methods, in the areas of both language documentation and speech translation.

Abstract

Human evaluation of machine translation normally uses sentence-level measures such as relative ranking or adequacy scales. However, these provide no insight into possible errors, and do not scale well with sentence length. We argue for a semantics-based evaluation, which captures what meaning components are retained in the MT output, thus providing a more fine-grained analysis of translation quality, and enabling the construction and tuning of semantics-based MT. We present a novel human semantic evaluation measure, Human UCCA-based MT Evaluation (HUME), building on the UCCA semantic representation scheme. HUME covers a wider range of semantic phenomena than previous methods and does not rely on semantic annotation of the potentially garbled MT output. We experiment with four language pairs, demonstrating HUME's broad applicability, and report good inter-annotator agreement rates and correlation with human adequacy scores.

1 Introduction

Human judgement should be the ultimate test of the quality of an MT system. Nevertheless, common measures for human MT evaluation, such as adequacy and fluency judgements or the relative ranking of possible translations, are problematic in two ways. First, as the quality of translation is multi-faceted, it is difficult to quantify the quality of the entire sentence in a single number. This is indeed reflected in the diminishing inter-annotator agreement (IAA) rates of human ranking measures with the sentence length (Bojar et al., 2011). Second, a sentence-level quality score does not indicate what parts of the sentence are badly translated, and so cannot inform developers in repairing these errors.

These problems are partially addressed by measures that decompose over parts of the evaluated translation, often words or n-grams (see §2 for a brief survey of previous work). A promising line of research decomposes metrics over semantically defined units, quantifying the similarity of the output and the reference in terms of their verb argument structure; the most notable of these measures is HMEANT (Lo and Wu, 2011).

We propose the HUME metric, a human evaluation measure that decomposes over UCCA semantic units. UCCA (Abend and Rappoport, 2013) is an appealing candidate for semantic analysis, due to its cross-linguistic applicability, support for rapid annotation, and coverage of many fundamental semantic phenomena, such as verbal, nominal and adjectival argument structures and their inter-relations.

HUME operates by aggregating human assessments of the translation quality of individual semantic units in the source sentence. We are thus avoiding the semantic annotation of machine-generated text, which is often garbled or semantically unclear. This also allows the re-use of the source semantic annotation for measuring the quality of different translations of the same source sentence and avoids relying on reference translations, which have been shown to bias annotators (Fomicheva and Specia, 2016).

After a brief review (§2), we describe HUME in

* All authors contributed equally to this work.

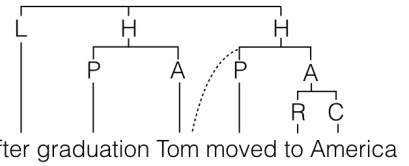
Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1264–1274,
Austin, Texas, November 1-5, 2016.

detail (§3). Our experiments with four language pairs: English to Czech, German, Polish and Romanian (§4) document HUME's inter-annotator agreement and efficiency (time of annotation). We further empirically compare HUME with direct assessment of human adequacy ratings (§5), and conclude by discussing the differences with HMEANT (§6).

2 Background

MT Evaluation. Human evaluation is generally done by ranking the outputs of multiple systems e.g., in the WMT tasks (Bojar et al., 2015), or by assigning adequacy/fluency scores to each translation, a procedure recently improved by Graham et al. (2015b) under the title Direct Assessment. We use this latter method to compare and contrast with HUME later in the paper. HTER (Snover et al., 2006) is another widely used human evaluation metric which uses edit distance metrics to compare a translation and its human post-edition. HTER suffers from the problem that small edits in the translation could in fact be serious flaws in accuracy, e.g., deleting a negation. Some manual measures ask annotators to explicitly mark errors, but this has been found to have even lower agreement than ranking (Lommel et al., 2014).

However, while providing the gold standard for MT evaluation, human evaluation is not a scalable solution. Scalability is addressed by employing automatic and semi-automatic approximations of human judgements. Commonly, such scores decompose over the sub-parts of the translation, and quantify how many of these sub-parts appear in a manually created reference translation. This decomposition allows system developers to localize the errors. The most commonly used measures decompose over n-grams or individual words, e.g., BLEU (Papineni et al., 2002), NIST (Doddington, 2002) and METEOR (Banerjee and Lavie, 2005). Another common approach is to determine the similarity between the reference and translation in terms of string edits (Snover et al., 2006). While these measures stimulated much progress in MT research by allowing the evaluation of massive-scale experiments, the focus on words and n-grams does not provide a good estimate of semantic correctness, and may favour shallow string-based MT models.



L	Linker	A	Participant
H	Parallel Scene	R	Relater
P	Process	C	Centre

Figure 1: Sample UCCA annotation. Leaves correspond to words and nodes to units. The dashed edge indicates that "Tom" is also a participant in the "moved to America" Scene. Edge labels mark UCCA categories.

In order to address this shortcoming, more recent work quantified the similarity of the reference and translation in terms of their structure. Liu and Gildea (2005) took a syntactic approach, using dependency grammar, and Owczarzak et al. (2007) took a similar approach using Lexical Functional Grammar structures. Giménez and Màrquez (2007) proposed to combine multiple types of information, capturing the overlap between the translation and reference in terms of their semantic (predicate-argument structures), lexical and morphosyntactic features. Macháček and Bojar (2015) divided the source sentences into shorter segments, defined using a phrase structure parse, and applied human ranking to the resulting segments.

Perhaps the most notable attempt at semantic MT evaluation is MEANT and its human variant HMEANT (Lo and Wu, 2011), which quantifies the similarity between the reference and translation in terms of the overlap in their verbal argument structures and associated semantic roles. We discuss the differences between HMEANT and HUME in §6.

Semantic Representation. UCCA (Universal Conceptual Cognitive Annotation) (Abend and Rappoport, 2013) is a cross-linguistically applicable scheme for semantic annotation. Formally, an UCCA structure is a directed acyclic graph (DAG), whose leaves correspond to the words of the text. The graph's nodes, called *units*, are either terminals or several elements jointly viewed as a single entity according to some semantic or cognitive consideration. Edges bear a category, indicating the role of the sub-unit in the structure the unit represents.

UCCA's basic inventory of distinctions (its *foundational layer*) focuses on argument structures (ad-

jectival, nominal, verbal and others) and relations between them. The most basic notion is the *Scene*, which describes a movement, an action or a state which persists in time. Each Scene contains one main relation and zero or more participants. For example, the sentence "After graduation, Tom moved to America" contains two Scenes, whose main relations are "graduation" and "moved". The participant "Tom" is a part of both Scenes, while "America" only of the latter (Figure 1). Further categories account for inter-scene relations and the sub-structures of participants and relations.

The use of UCCA for semantic MT evaluation has several motivations. First, UCCA's foundational layer can be annotated by non-experts after a short training (Abend and Rappoport, 2013; Marinotti, 2014). Second, UCCA is cross-linguistically applicable, seeking to represent what is shared between languages by building on linguistic typological theory (Dixon, 2010b; Dixon, 2010a; Dixon, 2012). Its cross-linguistic applicability has so far been tested in annotations of English, French, German and Czech. Third, the scheme has been shown to be stable across translations: UCCA annotations of translated text usually contain the same set of relations (Sulem et al., 2015), indicating that UCCA reflects a layer of representation that in a correct translation is mostly shared between the translation and the source.

The Abstract Meaning Representation (AMR) (Banarescu et al., 2013) shares UCCA's motivation for defining a more complete semantic annotation. However, using AMR is not optimal for defining a decomposition of a sentence into semantic units as it does not anchor its semantic symbols in the text, and thus does not provide clear decomposition of the sentence into sub-spans. Also, AMR is more fine-grained than UCCA and consequently harder to annotate. Other approaches represent semantic structures as bi-lexical dependencies (Sgall et al., 1986; Hajič et al., 2012; Oepen and Lønning, 2006), which are indeed anchored in the text, but are less suitable for MT evaluation as they require linguistic expertise for their annotation.

3 The HUME Measure

3.1 Annotation Procedure

This section summarises the manual annotation procedure used to compute the HUME measure. We denote the source sentence as s and the translation as t. The procedure involves two manual steps: (1) UCCA-annotating s, (2) HUME-annotation: human judgements as to the translation quality of each semantic unit of s relative to t, where units are defined according to the UCCA annotation. UCCA annotation is performed once for every source sentence, irrespective of the number of its translations we wish to evaluate, and requires proficiency in the source language only. HUME annotation requires the employment of bilingual annotators.[1]

UCCA Annotation. We begin by creating UCCA annotations for the source sentence, following the UCCA guidelines.[2] A UCCA annotation for a sentence s is a labeled DAG G, whose leaves are the words of s. For every node in G, we define its *yield* to be its leaf descendants. The semantic units for s according to G are the yields of nodes in G.

Translation Evaluation. HUME annotation is done by traversing the semantic units of the source sentence, which correspond to the arguments and relations expressed in the text, and marking the extent to which they have been correctly translated. HUME aggregates the judgements of the users into a composite score, which reflects the overall extent to which the semantic content of s is preserved in t.

Annotation of the semantic units requires first deciding whether a unit is *structural*, i.e., has meaning-bearing sub-units in the target language, or *atomic*. In most cases, atomic units correspond to individual words, but they may also correspond to multi-word expressions that translate as one unit. For instance, the expression "took a shower" is translated into the German "duschte", while its individual words do not correspond to any sub-part of the German translation, motivating the labeling the entire expression as an atomic node. When a multi-word unit is labeled

[1] Where bilingual annotators are not available, the evaluation could be based on the UCCA structure for the *reference* translation. See discussion in §6.

[2] All UCCA-related resources can be found here: `http://www.cs.huji.ac.il/~oabend/ucca.html`

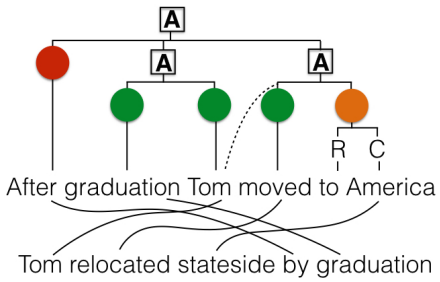


Figure 2: HUME annotation of an UCCA tree with a word-aligned example translation shown below. Atomic units are labelled using traffic lights (Red, Orange, Green) and structural units are marked A or B.

as atomic, its sub-units' annotations are ignored in the evaluation.

Atomic units can be labelled as "Green" (G, correct), "Orange" (O, partially correct) and "Red" (R, incorrect). Green means that the meaning of the word or phrase has been largely preserved. Orange means that the essential meaning of the unit has been preserved, but some part of the translation is wrong. This is often be due to the translated word having the wrong inflection, in a way that impacts little on the understandability of the sentence. Red means that the essential meaning of the unit has not been captured.

Structural units have sub-units (children in the UCCA graph), which are themselves atomic or structural. Structural units are labeled as "Adequate" (A) or "Bad" (B), meaning that the relation between the sub-units went wrong[3]. We will use the example "man bites dog" to illustrate typical examples of why a structural node should be labelled as "Bad": incorrect ordering ("dog bites man"), deletion ("man bites") and insertion ("man bites biscuit dog").

HUME labels reflect adequacy, rather than fluency judgements. Specifically, annotators are instructed to label a unit as Adequate if its translation is understandable and preserves the meaning of the source unit, even if its fluency is impaired.

Figure 2 presents an example of a HUME annotation, where the translation is in English for ease of comprehension. When evaluating "to America" the annotator looks at the translation and sees the word "stateside". This word captures the whole phrase and so we mark this non-leaf node with an atomic label. Here we choose Orange since it approximately captures the meaning in this context. The ability to mark non-leaves with atomic labels allows the annotator to account for translations which only correspond at the phrase level. Another feature highlighted in this example is that by separating structural and atomic units, we are able to define where an error occurs, and localise the error to its point of origin. The linker "After" is translated incorrectly as "by" which changes the meaning of the entire sentence. This error is captured at the atomic level, and it is labelled Red. The sentence still contains two Scenes and a Linker and therefore we mark the root node as structurally correct, Adequate.

3.2 Composite Score

We proceed to detailing how judgements on the semantic units of the source are aggregated into a composite score. We start by taking a very simple approach and compute an accuracy score. Let $\mathit{Green}(s,t)$, $\mathit{Adequate}(s,t)$ and $\mathit{Orange}(s,t)$ be the number of Green, Adequate and Orange units, respectively. Let $\mathit{Units}(s)$ be the number of units marked with any of the labels. Then HUME's composite score is:

$$\mathit{HUME}(s,t) = \frac{\mathit{Green}(s,t) + \mathit{Adequate}(s,t) + 0.5 \cdot \mathit{Orange}(s,t)}{\mathit{Units}(s)}$$

3.3 Annotation Interface

Figure 3 shows the HUME annotation interface[4]. One source sentence and one translation are presented at a time. The user is asked to select a label for each source semantic unit, by clicking the "A", "B", Green, Orange, or Red buttons to the right of the unit's box. Units with multiple parents (as with "Tom" in Figure 2) are displayed twice, once under each of their parents, but are only annotatable in one of their instances, to avoid double counting.

The interface presents, for each unit, the translation segment aligned with it. This allows the user, especially in long sentences, to focus her attention on the parts that are most likely to be relevant for her judgement. As the alignments are automatically derived, and therefore noisy, the annotator is instructed to treat the aligned text is a cue, but to ignore the alignment if it is misleading, and instead make a

[3]Three labels are used with atomic units, as opposed to two labels with structural units, as atomic units are more susceptible to slight errors.

[4]A demo of HUME can be found in `www.cs.huji.ac.il/~oabend/hume_demo.html`

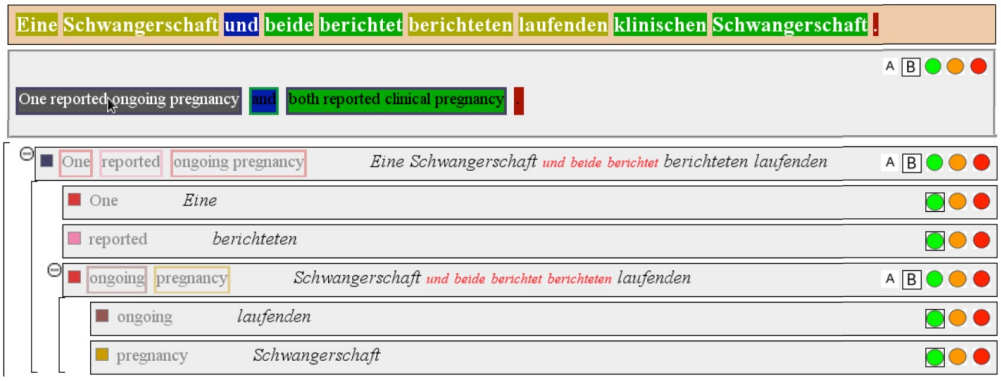

Figure 3: The HUME annotation tool. The top orange box contains the translation. The source sentence is directly below it, followed by the tree of the source semantic units. Alignments between the source and translation are in italics and unaligned intervening words are in red (see text).

judgement according to the full translation. Concretely, let s be a source sentence, t a translation, and $A \subset 2^s \times 2^t$ a many-to-many word alignment. If u is a semantic unit in s, whose yield is $yld(u)$, we define the aligned text in t to be $\bigcup_{(x_s,x_t)\in A \wedge x_s \cap yld(u) \neq \emptyset} x_t$.

Where the aligned text is discontinuous in t, words between the left and right boundaries which are not contained in it (intervening words) are presented in a smaller red font. Intervening words are likely to change the meaning of the translation of u, and thus should be attended to when considering whether the translation is correct or not.

For example, in Figure 3, "ongoing pregnancy" is translated to "Schwangerschaft ... laufenden" (lit. "pregnancy ... ongoing"). This alone seems acceptable but the interleaving words in red notify the annotator to check the whole translation, in which the meaning of the expression is not preserved[5]. The annotator should thus mark this structural node as Bad.

4 Experiments

In order to validate the HUME metric, we ran an annotation experiment with one source language (English), and four target languages (Czech, German, Polish and Romanian), using text from the public health domain. Semantically accurate translation is paramount in this domain, which makes it particularly suitable for semantic MT evaluation. HUME is evaluated in terms of its consistency (inter-annotator agreement), efficiency (time of annotation) and validity (by comparing it with crowd-sourced adequacy judgements).

4.1 Datasets and Translation Systems

For each of the four language pairs under consideration we built phrase-based MT systems using Moses (Koehn et al., 2007). These were trained on large parallel data sets extracted from OPUS (Tiedemann, 2009), and the data sets released for the WMT14 medical translation task (Bojar et al., 2014), giving between 45 and 85 million sentences of training data, depending on the language pair. These translation systems were used to translate texts derived from both NHS 24[6] and Cochrane[7] into the four languages. NHS 24 is a public body providing healthcare and health-service related information in Scotland; Cochrane is an international NGO which provides independent systematic reviews on health-related research. NHS 24 texts come from the "Health A-Z" section in the NHS Inform website, and Cochrane texts come from their plain language summaries and abstracts.

4.2 HUME Annotation Statistics

The source sentences are all in English, and their UCCA annotation was performed by four computational linguists and one linguist. For the annotation of the MT output, we recruited two annotators for each of German, Romanian and Polish and one main annotator for Czech. For computing Czech IAA, several further annotators worked on a small number of sentences each. We treat these further annotators

[5]The interleaving words are "... und beide berichtet berichteten ..." (lit. "... and both report reported ..."), which doesn't form any coherent relation with the rest of the sentence.

Table 2: Median annotation times per sentence, in seconds. *: no timing information is available, as this was a collection of annotators, working in parallel.

as one annotator, resulting in two annotators for each language pair. The annotators were all native speakers of the respective target languages and fluent in English. They completed a three hour on-line training session which included a description of UCCA and the HUME task, followed by walking through a few examples.

Table 1 shows the total number of sentences and units annotated by each annotator. Not all units in all sentences were annotated, often due to the annotator accidentally missing a node.

Efficiency. We estimate the annotation time using the timestamps provided by the annotation tool, which are recorded whenever an annotated sentence is submitted. Annotators are not able to re-open a sentence once submitted. To estimate the annotation time, we compute the time difference between successive sentences, and discard outlying times, assuming annotation was not continuous in these cases. From inspection of histograms of annotation times, we set the upper threshold at 500 seconds. Median annotation times are presented in Table 2, indicating that the annotation of a sentence takes around 2–4 minutes, with some variation between annotators.

Inter-Annotator Agreement. In order to assess the consistency of the annotation, we measure the Inter-Annotator Agreement (IAA) using Cohen's Kappa on the multiply-annotated units. Table 3 reports the number of units which have two annotations from different annotators and the corresponding Kappas. We report the overall Kappa, as well as separate Kappas on atomic units (annotated as Red, Orange or Green) and structural units (annotated as

	cs	de	pl	ro
Sentences	181	102	334	217
All units	4686	2793	8384	5604
Kappa	0.64	0.61	0.58	0.69
Atomic units	2982	1724	5386	3570
Kappa	0.54	0.29	0.54	0.50
Structural units	1602	1040	2655	1989
Kappa	0.31	0.44	0.33	0.58

Table 3: IAA for the multiply-annotated units, measured by Cohen's Kappa.

(c) English-Polish (d) English-Romanian

Figure 4: Confusion matrices for each language pair.

Adequate or Bad). As expected and confirmed by confusion matrices in Figure 4, there is generally little confusion between the two types of units. This results in the Kappa for all units being considerably higher than the Kappa over the atomic units or structural units, where there is more internal confusion.

To assess HUME reliability for long sentences, we binned the sentences according to length and measured Kappa on each bin (Figure 5). We see no discernible reduction of IAA with sentence length. Table 3 also shows that the overall IAA is similar for all languages, presenting good agreement (0.6–0.7). However, there are differences observed when we break down by node type. Specifically, we see a contrast between Czech and Polish, where the IAA is higher for atomic than for structural units, and German and Romanian, where the reverse is true. We also observe low IAA (around 0.3) in the cases of German atomic units, and Polish and Czech structural units.

Looking more closely at the areas of disagree-

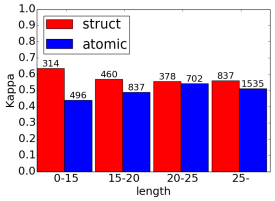
(c) English-Polish



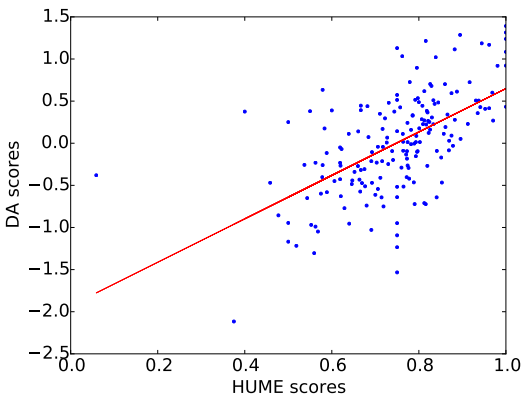
(d) English-Romanian

Figure 5: Kappa versus sentence length for structural and atomic units. (Node counts in bins on top of each bar.)

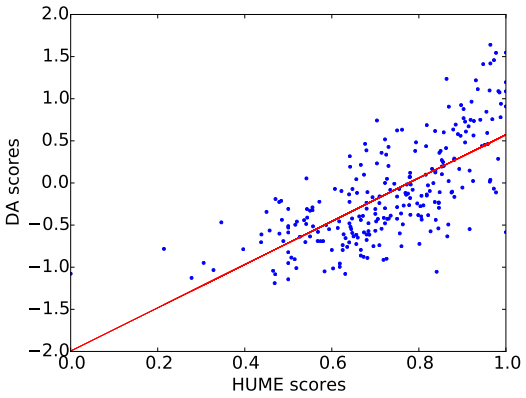
ment, we see that for the Polish structural units, the proportion of As was quite different between the two annotators (53% vs. 71%), whereas for other languages the annotators agree in the proportions. We believe that this was because one of the Polish annotators did not fully understand the guidelines for structural units, and percolated errors up the tree, creating more Bs. For German atomic and Czech structural units, where Kappa is also around 0.3, the proportion of such units being marked as "correct" is relatively high, meaning that the class distribution is more skewed, so the expected agreement used in the Kappa calculation is high, lowering Kappa. Finally we note some evidence of domain-specific disagreements, for instance the German MT system normally translated "review" (as in "systematic review" – a frequent term in the Cochrane texts) as "Überprüfung", which one annotator marked correct, and the other (a Cochrane employee) as incorrect.

5 Comparison with Direct Assessment

Recent research (Graham et al., 2015b; Graham et al., 2015a; Graham, 2015) has proposed a new approach for collecting accuracy ratings, direct assessment (DA). Statistical interpretation of a large number of crowd-sourced adequacy judgements for each candidate translation on a fine-grained scale of 0 to 100 results in reliable aggregate scores, that correlate very strongly with one another.



(a) English-German



(b) English-Romanian

Figure 6: HUME vs DA scores. DA score have been standardised for each crowdsourcing annotator and averaged across exactly 10 annotators. HUME scores are averaged where there were two annotations.

We attempted to follow Graham et al. (2015b) but struggled to get enough crowd-sourced judgements for our target languages. We ended up with 10 adequacy judgements on most of the HUME annotated translations for German and Romanian but insufficient data for Czech and Polish. We see this as a severe practical limitation of DA.

Figure 6 plots the HUME score for each sentence against its DA score. HUME and Direct Assessment scores correlate reasonably well. The Pearson correlation for en-ro (en-de) is 0.70 (0.58), or 0.78 (0.74) if only doubly HUME-annotated points are considered. This confirms that HUME is consistent with an accepted human evaluation method, despite their conceptual differences. While DA is a valuable tool, HUME has two advantages: it returns fine-grained

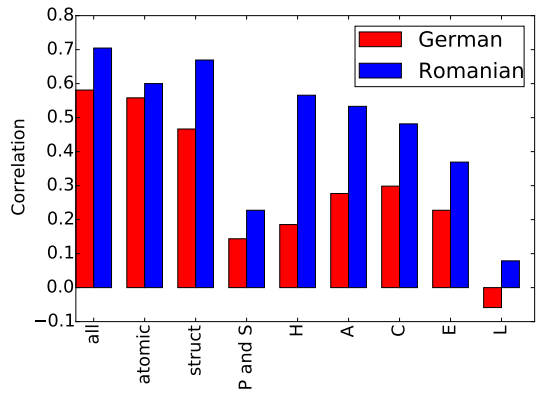


Figure 7: Pearson correlation of HUME vs. DA scores for en-ro and en-de. Each bar represents a correlation between DA and an aggregate HUME score based on a sub-set of the units (#nodes for the en-de/en-ro setting in brackets): all units ("all", 8624/10885), atomic ("atomic", 5417/6888) and structural units ("struct", 3207/3997), and units by UCCA categories: Scene main relations (i.e, Process and State units; "P and S", 954/1178), Parallel Scenes ("H", 656/784), Participants ("A", 1348/1746), Centres ("C", 1904/2474), elaborators ("E", 1608/2031) and linkers ("L", 261/315).

semantic information about the quality of translations and it only requires very few annotators. Direct assessment returns a single opaque score, and (as also noted by Graham et al.) requires a large crowd which may not be available or reliable.

Figure 7 presents an analysis of HUME's correlations with DA by HUME unit type, an analysis enabled by HUME's semantic decomposition. For both target languages, correlation is highest in the 'all' case, supporting our claim for the value of aggregating over a wide range of semantic phenomena. Some types of nodes predict the DA scores better than others. HUME scores on As correlate more strongly with DA than scores on Scene Main Relations (P+S). Center nodes (C) are also more correlated than elaborator nodes (E), which is expected given that Centers are defined to be more semantically dominant. Future work will construct an aggregate HUME score which weights the different node types according to their semantic prominence.

HUME and DA are conceptually very different metrics: while DA standardises and averages scores across annotators to denoise the crowd-sourced raw data, thus obtaining a single aggregate score, HUME decomposes over a combinatorial structure, thus allowing to localize the translation errors. We now turn to comparing HUME to a more conceptually-related measure, namely HMEANT.

6 Comparison with HMEANT

HMEANT is a human MT evaluation metric that measures the overlap between the translation a reference in terms of their SRL annotations. In this section we present a qualitative comparison between HUME and HMEANT, using examples from our experimental data.

Verbal Structures Only? HMEANT focuses on verbal argument structures, ignoring other pervasive phenomena such as non-verbal predicates and interclausal relations. Consider the following example:

Source	a coronary angioplasty may not be technically possible
Transl.	eine koronare Angioplastie kann nicht technisch möglich
Gloss	a coronary angioplasty can not technically possible

The German translation is largely correct, except that the main verb "sein" ("be") is omitted. While this may be interpreted as a minor error, HMEANT will assign the sentence a very low score, as it failed to translate the main verb.

It is also relatively common that verbal constructions are translated as non-verbal ones or vice versa. Consider the following example:

Source	... tend to be higher in saturated fats
Transl.	... in der Regel höher in gesättigte Fette
Gloss	... as a rule higher in saturated fats

The German translation is largely correct, despite the grammatical divergence, namely that the English verb "tend" is translated into the German prepositional phrase "in der Regel" ("as a rule"). HMEANT will consider the translation to be of poor quality as there is no German verb to align with the English one.

We conducted an analysis of the English UCCA Wikipedia corpus (5324 sentences) in order to assess the pervasiveness of three phenomena that are not well supported by HMEANT.[8] First, copula clauses

[8] Argument structures and linkers are explicitly marked in UCCA. Non-auxiliary instances of "be" and nouns are identi-

are treated in HMEANT simply as instances of the main verb "be", which generally does not convey the meaning of these clauses. They appear in 21.7% of the sentences, according to conservative estimates that only consider non-auxiliary instances of "be". Second, nominal argument structures, ignored by HMEANT, are in fact highly pervasive, appearing in 48.7% of the sentences. Third, linkers that express inter-relations between clauses (mainly discourse markers and conjunctions) appear in 56% of the sentences, but are again ignored by HMEANT. For instance, linkers are sometimes omitted in translation, but these omissions are not penalized by HMEANT. The following is such an example from our experimental dataset:

Source	However, this review was restricted to ...
Transl.	Diese Überprüfung bescränkte sich auf ...
Gloss	This review was restricted to ...

We note that some of these issues were already observed in previous applications of HMEANT to languages other than English. See Birch et al. (2013) for German, Bojar and Wu (2012) for Czech and Chuchunkov et al. (2014) for Russian.

One Structure or Two. HUME only annotates the source, while HMEANT relies on two independently constructed structural annotations, one for the reference and one for the translation. Not annotating the translation is appealing as it is often impossible to assign a semantic structure to a low quality translation. On the other hand, HUME may be artificially boosting the perceived understandability of the translation by allowing access to the source.

Alignment. In HMEANT, the alignment between the reference and translation structures is a key part of the manual annotation. If the alignment cannot be created, the translation is heavily penalized. Bojar and Wu (2012) and Chuchunkov et al. (2014) argue that the structures of the reference and of an accurate translation may still diverge, for instance due to a different interpretation of a PP-attachment, or the verb having an additional modifier in one of the structures. It would be desirable to allow modifications to the SRL annotations at the alignment stage, to avoid unduly penalizing such spurious divergences.

The same issue is noted by Lo and Wu (2014): the IAA on SRL dropped from 90% to 61% when the two aligned structures were from two different annotators. HUME uses automatic (word-level) alignment, which only serves as a cue for directing the attention of the annotators. The user is expected to mentally correct the alignment as needed, thus circumventing this difficulty.

Monolingual vs. Bilingual Evaluation. HUME diverges from HMEANT and from shallower measures like BLEU, in not requiring a reference. Instead, it directly compares the source and the translation. This requires the employment of bilingual annotators, but has the benefit of avoiding using a reference, which is never uniquely defined, and may thus lead to unjustly low scores where the translation is a paraphrase of the reference. If only monolingual annotators are available, the HUME evaluation could be performed with a reference sentence instead of with the source. This, however, would risk inaccurate judgements due to the naturally occurring differences between the source and its reference translations.

7 Conclusion

We have introduced HUME, a human semantic MT evaluation measure which addresses a wide range of semantic phenomena. We have shown that it can be reliably and efficiently annotated in multiple languages, and that annotation quality is robust to sentence length. Comparison to direct assessments further support HUME's validity. We believe that HUME, and a future automated version of HUME, allows for a finer-grained analysis of translation quality, and will be useful in informing the development of a more semantically aware approach to MT.

All annotation data gathered in this project, together with analysis scripts, is available online[9].

Improving Multilingual Named Entity Recognition with Wikipedia Entity Type Mapping

Abstract

The state-of-the-art named entity recognition (NER) systems are statistical machine learning models that have strong generalization capability (i.e., can recognize unseen entities that do not appear in training data) based on lexical and contextual information. However, such a model could still make mistakes if its features favor a wrong entity type. In this paper, we utilize Wikipedia as an open knowledge base to improve multilingual NER systems. Central to our approach is the construction of high-accuracy, high-coverage multilingual Wikipedia entity type mappings. These mappings are built from weakly annotated data and can be extended to new languages with no human annotation or language-dependent knowledge involved. Based on these mappings, we develop several approaches to improve an NER system. We evaluate the performance of the approaches via experiments on NER systems trained for 6 languages. Experimental results show that the proposed approaches are effective in improving the accuracy of such systems on unseen entities, especially when a system is applied to a new domain or it is trained with little training data (up to 18.3 F_1 score improvement).

1 Introduction

Named entity recognition (NER) is an important NLP task that automatically detects entities in text and classifies them into pre-defined entity types such as persons, organizations, geopolitical entities, locations, events, etc. NER is a fundamental component of many information extraction and knowledge discovery applications, including relation extraction, entity linking, question answering and data mining.

The state-of-the-art NER systems are usually statistical machine learning models that are trained with human-annotated data. Popular models include maximum entropy Markov models (MEMM) (McCallum et al., 2000), conditional random fields (CRF) (Lafferty et al., 2001) and neural networks (Collobert et al., 2011; Lample et al., 2016). Such models have strong generalization capability to recognize *unseen entities*[1] based on lexical and contextual information (features). However, a model could still make mistakes if its features favor a wrong entity type, which happens more frequently for unseen entities as we have observed in our experiments.

Wikipedia is an open-access, free-content Internet encyclopedia, which has become the de facto on-line source for general reference. A Wikipedia page about an entity normally includes both structured information and unstructured text information, and such information can be used to help determine the entity type of the referred entity.

So far there are two classes of approaches that exploit Wikipedia to improve NER. The first class of approaches use Wikipedia to generate features for NER systems, e.g., (Kazama and Torisawa, 2007; Ratinov and Roth, 2009; Radford et al., 2015). Kazama and Torisawa (2007) try to find the Wikipedia entity for each candidate word sequence and then extract a category label from the first sentence of the Wikipedia entity page. A part-of-speech (POS) tagger is used to extract the category label

[1] An entity is an *unseen entity* if it does not appear in the training data used to train the NER model.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1275–1284,
Austin, Texas, November 1-5, 2016.

features in the training and decoding phase. Ratinov and Roth (2009) aggregate several Wikipedia categories into higher-level concept and build a gazetteer on top of it. The two approaches were shown to be able to improve an English NER system. Both approaches, however, are language-dependent because (Kazama and Torisawa, 2007) requires a POS tagger and (Ratinov and Roth, 2009) requires manual category aggregation by inspection of the annotation guidelines and the training set. Radford et al. (2015) assume that document-specific knowledge base (e.g., Wikipedia) tags for each document are provided, and they use those tags to build gazetteer type features for improving an English NER system.

The second class of approaches use Wikipedia to generate weakly annotated data for training multilingual NER systems, e.g., (Richman and Schone, 2008; Nothman et al., 2013). The motivation is that annotating multilingual NER data by human is both expensive and time-consuming. Richman and Schone (2008) utilize the category information of Wikipedia to determine the entity type of an entity based on manually constructed rules (e.g., category phrase "Living People" is mapped to entity type PERSON). Such a rule-based entity type mapping is limited both in accuracy and coverage, e.g., (Toral and Muoz, 2006). Nothman et al. (2013) train a Wikipedia entity type classifier using human-annotated Wikipedia pages. Such a supervised-learning based approach has better accuracy and coverage, e.g., (Dakka and Cucerzan, 2008). A number of heuristic rules are developed in both works to label the Wikipedia text to create weakly annotated NER training data. The NER systems trained with the weakly annotated data may achieve similar accuracy compared with systems trained with little human-annotated data (e.g., up to 40K tokens as in (Richman and Schone, 2008)), but they are still significantly worse than well-trained systems (e.g., a drop of 23.9 F_1 score on the CoNLL data and a drop of 19.6 F_1 score on the BBN data as in (Nothman et al., 2013)).

In this paper, we propose a new class of approaches that utilize Wikipedia to improve multilingual NER systems. Central to our approaches is the construction of high-accuracy, high-coverage multilingual Wikipedia entity type mappings. We use weakly annotated data to train an English Wikipedia entity type classifier, as opposed to using human-annotated data as in (Dakka and Cucerzan, 2008; Nothman et al., 2013). The accuracy of the classifier is further improved via self-training. We apply the classifier on all the English Wikipedia pages and construct an English Wikipedia entity type mapping that includes entities with high classification confidence scores. To build multilingual Wikipedia entity type mappings, we generate weakly annotated classifier training data for another language via projection using the inter-language links of Wikipedia. This approach requires no human annotation or language-dependent knowledge, and thus can be easily applied to new languages.

Our goal is to utilize the Wikipedia entity type mappings to improve NER systems. A natural approach is to use a mapping to create dictionary type features for training an NER system. In addition, we develop several other approaches. The first approach applies an entity type mapping as a *decoding constraint* for an NER system. The second approach uses a mapping to *post-process* the output of an NER system. We also design a robust *joint* approach that combines the decoding constraint approach and the post-processing approach in a smart way. We evaluate the performance of the Wikipedia-based approaches on NER systems trained for 6 languages. We find that when a system is well trained (e.g., with 200K to 300K tokens of human-annotated data), the dictionary feature approach achieves the best improvement over the baseline system; while when a system is trained with little human-annotated training data (e.g., 20K to 30K tokens), a more aggressive decoding constraint approach achieves the best improvement. In both scenarios, the Wikipedia-based approaches are effective in improving the accuracy on unseen entities, especially when a system is applied to a new domain (3.6 F_1 score improvement on political party articles/English NER) or it is trained with little training data (18.3 F_1 score improvement on Japanese NER).

We organize the paper as follows. We describe how to build English Wikipedia entity type mapping in Section 2 and extend it to multilingual mappings in Section 3. We present several Wikipedia-based approaches for improving NER systems in Section 4 and evaluate their performance in Section 5. We conclude the paper in Section 6.

2 English Wikipedia Entity Type Mapping

In this section, we focus on English Wikipedia. We divide Wikipedia pages into two types:

- Entity pages that describe an entity or object, either a named entity such as "Michael Jordan" or a common entity such as "Basketball."
- Non-entity pages that do not describe a certain entity, including disambiguation pages, redirection pages, list pages, etc.

We have developed an in-house English NER system (Florian et al., 2004). The system has 51 entity types, and the main motivation of deploying such a fine-grained entity type set is to build cognitive question answering applications on top of the NER system. An important check for a question answering system is the capability to detect whether a particular answer matches the expected type derived from the question. The entity type system used in this paper has been engineered to cover many of the frequent types that are targeted by naturally-phrased questions (such as PERSON, ORGANIZATION, GPE, TITLEWORK, FACILITY, EVENT, DATE, TIME, LOCATION, etc), and it was created over a long period of time, being updated as more types were found to be useful for question answering, and to improve inter-annotator consistency.

We want to classify Wikipedia pages into one of the entity types used in the NER system. For non-entity pages and entity pages describing common entities, we assign them with a new type OTHER.

2.1 Wikipedia Entity Type Classification

2.1.1 Features

We build maximum entropy classifiers (Nigam et al., 1999) for Wikipedia entity type classification. We use both structured information and unstructured information of a Wikipedia page as features.

Each Wikipedia page has a unique *title*. The title of an entity page is usually the name of the entity, and may include auxiliary information in a bracket to distinguish entities with the same name. We use both the entity name and auxiliary information in a bracket (if any) of a Wikipedia title as features because each could provide useful information for entity type classification. For example, based on the word "Prize" in the title "Nobel Prize" or the word "Awards" in the title "Academy Awards", one can infer that the entity type is AWARD. Likewise, the auxiliary information "company" in the title "Jordan (company)" indicates that the entity is an ORGANIZATION, and the auxiliary information "film" in the title "Alien (film)" indicates that the entity is a TITLEWORK.

The *text* in a Wikipedia page of an entity provides rich information about the entity. A person can usually correctly infer the entity type by reading the first few sentences of the text in a Wikipedia page. Using more sentences provides additional information about the entity which might be helpful, but it is also more likely to introduce noisy information which could affect the classification accuracy adversely. Therefore, we use the first 200 tokens of the text in a Wikipedia page and create n-gram word features out of them. We have also found that including additional n-gram word features of the *first sentence* in a Wikipedia page results in a better classification accuracy.

Most Wikipedia pages also have a structured table called *infobox*, which is placed on the right top of a page. An infobox contains attribute-value pairs, often providing summary information about an entity. The attributes in an infobox could be particularly useful for entity type classification. For example, the attribute "Born" in an infobox provides strong evidence that the corresponding entity is a PERSON; and the attribute "Headquarters" implies that the corresponding entity is an ORGANIZATION. We include the infobox attributes as classifier features.

2.1.2 Training and Test Data

Entity linking (EL) or entity disambiguation is the task of determining the identities of entities mentioned in text, by linking each entity to an entry (if exists) in an open knowledge base such as Wikipedia (Han et al., 2011; Hoffart et al., 2011). We apply an EL system (Sil and Florian, 2014) to generate training data for Wikipedia entity type classification as follows: if a named entity in our NER training data with entity type T is linked to a Wikipedia page, that page will be labeled with entity type T. Similarly, we apply the EL system to generate a set of test data by linking named entities in our NER test data to Wikipedia pages. The English Wikipedia snapshot

Features	ALL	PER	ORG	GPE	TITL	FAC
Title	62.4	73.4	67.2	59.0	57.1	47.1
Infobox	77.3	92.6	87.8	92.0	95.4	50.0
Text	87.2	97.5	87.3	95.1	88.5	40.0
All	90.1	96.1	92.5	95.1	96.9	75.0

Table 1: F_1 score of English Wikipedia entity type classifiers.

Classifier	Train Size	$\mathbf{F_1}$
Original Classifier	4,699	90.1
Self-Training (Standard)	+2,352,836	91.1
Self-Training (Sampling)	+26,518	91.8

Table 2: Improving classifier accuracy via self-training.

was dumped in April 2014 which contains around 4.6M pages. Using this method we generate a training data set with 4,699 English Wikipedia pages and a test set of 415 English Wikipedia pages.

Notice that the automatically generated classifier training and test data are *weakly labeled* since the EL system may link an entity to a wrong Wikipedia page and thus the entity type assigned to that page could be wrong. Since the test data is crucial for evaluating the classification accuracy, we manually corrected the output.

2.1.3 Classifier Performance

To evaluate the prediction power of different types of features, we train a number of classifiers using only title features, only infobox features, only text features, and all features respectively. We show the F_1 score of the classifiers on different entity types in Table 1. ALL is the overall performance, and PER (PERSON), ORG (ORGANIZATION), GPE, TITL (TITLEWORK), FAC (FACILITY) are the top five most frequently entity types in the test data.

From Table 1, we can see that text features are the most important features for classifying Wikipedia pages, since the classifier trained with only text features achieves an overall F_1 score of 87.2, which is better than the classifier trained with either title or infobox features alone. Nevertheless, both infobox and title features provide additional useful information for entity type classification, and the classifier trained with all the features achieves an overall F_1 score of 90.1.

2.1.4 Improvement via Self-Training

Self-training is a *semi-supervised* learning technique that can be used in applications where there is only a small number of labeled training examples but a large number of unlabeled examples. Since our weakly annotated classifier training data only covers around 1% of all the Wikipedia pages, we are motivated to use self-training to further improve the classification accuracy.

We first apply a standard self-training approach. The classifier trained with the initial training data is used to decode (i.e., classify) all the unlabeled Wikipedia pages to predict their entity types with confidence scores. We add the self-decoded Wikipedia pages with high confidence scores to the training data and train a new classifier. Via experiments a threshold of 0.9 is used to sort out high-confident self-decoded examples. The F_1 score of the new classifier is improved to 91.1, as shown in Table 2.

Under the standard approach, about 2.3M self-decoded examples are added, the size of which is about 500 times of the size of the original training data. The errors of the original classifier could be amplified with such a big increase of the training size with so many self-decoded examples.

To address this issue, we have developed a *sampling-based* self-training approach. Instead of adding all the self-decoded examples with confidence scores greater than or equal to 0.9, we do a random sampling of those high-confident examples. We use a sampling probability $p(e) = q \cdot c(e)$, where q is a sampling ratio parameter and $c(e)$ is the confidence score of example e. Under this approach, examples with higher confidence scores are more likely to be selected, while the total number of selected examples is controlled by the sampling ratio q. Via experiments we found that a small sampling ratio like $q = 0.01$ yields good improvement (although the improvement is not sensitive to q). As shown in Table 2, the classification accuracy under the sampling-based approach is further improved to 91.8 F_1 score (the improvement is calculated by averaging over 5 random samples with $q = 0.01$).

2.2 Wikipedia Entity Type Mapping

We construct an English Wikipedia entity type mapping by applying the English Wikipedia entity type classifier on all the English Wikipedia pages

(∼4.6M). Each entry of the mapping includes an *entity name* (which is extracted from the title of a Wikipedia page) and the associated *entity type* with *confidence score* (which is determined by the classifier). We denote the English Wikipedia entity type mapping that includes all the pages by *English-Wiki-Mapping*.

To build a high-accuracy mapping, one may want to include only entities with confidence scores greater than or equal to a threshold t in the mapping, and we denote such a mapping by *English-Wiki-Mapping*(t). Notice that a mapping with a higher t will have more accurate entity types for its entities, but it will include fewer entities. Therefore, there is a trade-off between *accuracy* and *coverage* of the mapping, which can be tuned by the confidence threshold t. There are about 2.9M entities in *English-Wiki-Mapping*(0.9), which covers about 63% of all the English Wikipedia pages.

We have also found that the *length* of an entity name (i.e., number of words in an entity name) also plays an important role for determining which entities should be included in the mapping for improving an NER system. Therefore, we use *English-Wiki-Mapping*(t, i) to denote the English Wikipedia entity type mapping that includes all the entities with confidence scores greater than or equal to t and at least i words in their names. *English-Wiki-Mapping*(0.9,2) covers about 55% of all the English Wikipedia pages, and *English-Wiki-Mapping*(0.9,3) covers about 25% of all the English Wikipedia pages.

3 Multilingual Wikipedia Entity Type Mapping

Based on the English Wikipedia entity type mapping, we want to build high-accuracy, high-coverage Wikipedia entity type mappings for other languages with minimum human annotation and language-dependent knowledge involved. We utilize the *inter-language links* of Wikipedia, which are the links between one entity's pages in different languages. The inter-language links between English Wikipedia pages and Wikipedia pages of another language provide useful information for this task.

Suppose we want to build a Wikipedia entity type mapping for a new language, and we use Portuguese as an example. A direct approach is *projection* using the inter-language links between English and Portuguese Wikipedia pages: for each Portuguese Wikipedia page that has an inter-language link to an English Wikipedia page, we project the entity type of the English Wikipedia page (determined by the English entity type mapping) to the Portuguese Wikipedia page. The rationale is that both the English and Portuguese pages are describing the same entity, even probably with different spelling (e.g., **United States** in English vs. **Estados Unidos** in Portuguese), the entity type of that entity does not change from one language to another.

However, the main limitation of the direct projection approach is coverage. Only a fraction of all the Portuguese Wikipedia pages have inter-language links to English Wikipedia pages, and among those pages only a subset of them have classified entity types with confidence scores high enough (e.g., at least 0.9). For example, projecting *English-Wiki-Mapping*(0.9) to Portuguese Wikipedia returns 143K pages, which covers only 15% of all the Portuguese Wikipedia pages (around 920K in total).

We apply an alternative approach, which uses the 143K Portuguese Wikipedia pages (acquired by projection from *English-Wiki-Mapping*(0.9)) as weakly annotated training data to train a Portuguese Wikipedia entity type classifier. For feature engineering purpose, we also project the English Wikipedia entity type classifier training and test data (as described in Section 2.1.2) to Portuguese Wikipedia pages via inter-language links, and this produces 1,190 Portuguese Wikipedia pages which are used as the test data. Pages in the test data set are excluded from the 143K training data set.

We use similar features (title, infobox and text) as for the English classifiers to train the Portuguese classifiers. Again we find that the classifier trained with all the features achieves the best accuracy of 86.3 F_1 score. Notice that this is an approximated evaluation because the pages in the test data set are labeled via projection and not by human.

We build Portuguese Wikipedia entity type mappings by applying the Portuguese Wikipedia entity type classifier on all the Portuguese Wikipedia pages. We use *Portuguese-Wiki-Mapping*(t) to denote the mapping that includes entities with confidence scores greater than or equal to a thresh-

old t. There are 525K entities in *Portuguese-Wiki-Mapping*(0.9), which covers about 57% of all the Portuguese Wikipedia pages, a significant improvement of coverage compared to the direct projection approach (15%).

The main advantage of our approach is that no human annotation or language-dependent knowledge is required, so it can be easily applied to a new language. We have applied this approach to build high-accuracy, high-coverage Wikipedia entity type mappings for several new languages including Portuguese, Japanese, Spanish, Dutch and German.

4 Improving NER Systems

We have developed several approaches that utilize the Wikipedia entity type mappings to improve NER systems. Let $\mathcal{M}$ be a Wikipedia entity type mapping. For an entity name x, let $\mathcal{M}(x)$ denote the set of possible entity types for x determined by the mapping. If an entity name x is in the mapping, then $\mathcal{M}(x)$ includes at least one entity type, i.e., $|\mathcal{M}(x)| \geq 1$, where $|\mathcal{M}(x)|$ is the cardinality of $\mathcal{M}(x)$. Otherwise if an entity name x is not in the mapping, then $\mathcal{M}(x) = \emptyset$ is the empty set and $|\mathcal{M}(x)| = 0$.

The first approach is to use a Wikipedia entity type mapping $\mathcal{M}$ as a *decoding constraint* for an NER system. Under this approach, the mapping is applied as a constraint during the decoding procedure: if a sequence of words in the text form an entity name x that is included in the mapping, i.e., $|\mathcal{M}(x)| \geq 1$, then the sequence of words will be identified as an entity, and its entity type is determined by the decoding algorithm while being constrained to one of the entity types in $\mathcal{M}(x)$.

The second approach is to use a Wikipedia entity type mapping $\mathcal{M}$ to *post-process* the output of an NER system. Under this approach, the mapping is applied after the decoding procedure: if the name of a system entity x is in the mapping and the entity type for that entity name is unique based on the mapping, i.e., $|\mathcal{M}(x)| = 1$, then its entity type will be determined by the unique entity type in $\mathcal{M}(x)$.

The decoding constraint approach is more aggressive than the post-processing approach, because it may create new entities and change entity boundaries. This approach is more reliable for entities with longer names. Via experiments we find that using *Wiki-Mapping*(0.9,2) or *Wiki-Mapping*(0.9,3) achieves the best improvement under the decoding constraint approach. Remember *Wiki-Mapping*(t, i) includes all the entities with confidence scores at least t and at least i words in their names.

In contrast, the post-processing approach is a more conservative approach since it relies on the system entity boundaries and only changes their entity types if determined by the mapping, so it will not create new entities. Via experiments we find that using *Wiki-Mapping*(0.9,2) achieves the best improvement under the post-processing approach.

Based on the observation that the decoding constraint approach is more reliable for longer entities while the post-processing approach can better handle short entities, we have designed a *joint* approach that combines the two approaches as follows: it first applies *Wiki-Mapping*(0.9,3) as a decoding constraint for an NER system to produce system entities, and then applies *Wiki-Mapping*(0.9,2) to post-process the system output. The joint approach combines the advantages of both approaches and achieves robust performance in our experiments.

Finally, we can use a Wikipedia entity type mapping to create *dictionary features* for training an NER system. The idea of using Wikipedia to create training features was explored before, e.g., (Kazama and Torisawa, 2007; Ratinov and Roth, 2009; Radford et al., 2015). The difference between our approach and the previous approaches is how the features are created: we first build high-accuracy, high-coverage multilingual Wikipedia entity type mappings and then use the mappings to generate dictionary features. Via experiments we find that using *Wiki-Mapping*(0.9,1) or *Wiki-Mapping*(0.9,2) achieves the best improvement under the dictionary feature approach.

5 Experiments

In this section, we evaluate the effectiveness of the proposed Wikipedia-based approaches via experiments on NER systems trained for 6 languages: English, Portuguese, Japanese, Spanish, Dutch and German. For each language, we compare the baseline NER system with the following approaches:

- DC(i): the decoding constraint approach with

mapping *Language-Wiki-Mapping*(0.9,i).

- PP(i): the post-processing approach with mapping *Language-Wiki-Mapping*(0.9,i).
- Joint: the joint approach that combines DC(3) and PP(2).
- DF(i): the dictionary feature approach with mapping *Language-Wiki-Mapping*(0.9,i).

To evaluate the generalization capability of an NER system, we compute the F_1 score on the unseen entities (*Unseen*) as well as on all the entities (*All*) in a test data set.

5.1 English

The baseline English NER system is a CRF model trained with 328K tokens of human-annotated news articles. It uses standard NER features in the literature including n-gram word features, word type features, prefix and suffix features, Brown cluster type features, gazetteer features, document-level cache features, etc.

We have two human-annotated test data sets: the first set, Test (News), consists of 40K tokens of human-annotated news articles; and the second set, Test (Political), consists of 77K tokens of human-annotated political party articles from Wikipedia. The results are shown in Table 3.

For Test (News) which is in the same domain as the training data, the baseline system achieves 88.2 F_1 score on all the entities, and a relatively low F_1 score of 78.7 on the unseen entities (38% of all the entities are unseen entities). The dictionary feature approach DF(2) achieves the highest F_1 scores among the Wikipedia-based approaches. It improves the baseline system by 1.2 F_1 score on all the entities and by 3.1 F_1 score on the unseen entities. The joint approach achieves the second highest F_1 scores. It improves the baseline by 0.7 F_1 score on all the entities and by 2.0 F_1 score on the unseen entities.

For Test (Political) which is in a different domain from the training data, the fraction of unseen entities increases to 84%. In this case, the F_1 score of the baseline system drops to 64.1, and the Wikipedia-based approaches demonstrate larger improvements. For example, DF(2) improves the baseline system by 2.7 F_1 score on all the entities and by 3.6 F_1 score on the unseen entities.

NER System	**Test (News)**		**Test (Political)**	
	All 100%	*Unseen* 38%	*All* 100%	*Unseen* 84%
Baseline	88.2	78.7	64.1	60.9
DC(2)	88.1	79.4	66.3	63.5
DC(3)	88.7	80.2	65.8	62.9
PP(2)	88.6	79.8	64.7	61.7
Joint	88.9	80.7	66.3	63.6
DF(1)	88.5	80.0	66.3	64.2
DF(2)	**89.4**	**81.8**	**66.8**	**64.5**

Table 3: Experimental results for English NER (the highest F_1 score among all approaches in a column is shown in bold).

5.2 Portuguese

For Portuguese, we have applied a semi-supervised learning approach to build the baseline NER system. The training data set includes 31K tokens of human-annotated news articles, and 2M tokens of weakly annotated data. The weakly annotated data is generated as follows. We have a large number of parallel sentences between English and Portuguese news articles. We apply the English NER system on the English sentences and project the entity type tags to the Portuguese sentences via alignments between the English and Portuguese sentences.

The baseline NER system is an MEMM model (CRF cannot handle such a big size of training data, since our NER system has 51 entity types, and the number of features and training time of CRF grow at least quadratically in the number of entity types). The test data set consists of 34K tokens of human-annotated Portuguese news articles.

The results are shown in Table 4. Because the system is trained with little human-annotated training data, the performance of the baseline system achieves only 60.1 F_1 score on all the entities and 50.2 F_1 score on the unseen entities (80% of all the entities). In this case, the more aggressive decoding constraint approach DC(2) achieves the best improvement among the Wikipedia-based approaches, which improves the baseline by 5.9 F_1 score on all the entities and by 8.6 F_1 score on the unseen entities. The joint approach improves the baseline by 3.0 F_1 score on all the entities and by 4.3 F_1 score on the unseen entities.

NER System	Test (News)	
	All 100%	*Unseen* 80%
Baseline	60.1	50.2
DC(2)	**66.0**	**58.8**
DC(3)	62.2	53.4
PP(2)	60.9	51.4
Joint	63.1	54.5
DF(1)	62.4	52.7
DF(2)	61.3	51.9

Table 4: Experimental results for Portuguese NER.

NER System	Test (News)	
	All 100%	*Unseen* 59%
Baseline	50.8	27.3
DC(2)	**59.8**	**45.6**
DC(3)	55.6	36.9
PP(2)	50.8	27.3
Joint	55.6	36.9
DF(1)	52.9	29.0
DF(2)	51.8	28.0

Table 5: Experimental results for Japanese NER.

5.3 Japanese

For Japanese, the baseline NER system is an MEMM model trained with 20K tokens of human-annotated news articles and 2.1M tokens of weakly annotated data. The weakly annotated data was generated using similar steps as for the Portuguese NER system. The test data set consists of 22K tokens of human-annotated Japanese news articles.

The results are shown in Table 5. Again, in this low-resource case, DC(2) achieves the best improvement among the Wikipedia-based approaches. It improves the baseline by 9.0 F_1 score on all the entities and by 18.3 F_1 score on the unseen entities (59% of all the entities). The joint approach improves the baseline by 4.8 F_1 score on all the entities and by 9.6 F_1 score on the unseen entities.

5.4 Spanish, Dutch and German

We also evaluate the Wikipedia-based approaches on Spanish, Dutch and German NER systems trained with the CoNLL data sets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003). There are only 4 entity types in the CoNLL data: PER (person), ORG (organization), LOC (location), MISC (miscellaneous names). Accordingly, we have trained a CoNLL-style Wikipedia entity type classifier that produces the CoNLL entity types. The training data for the classifier is generated by using the CoNLL English training data set and the AIDA-YAGO2 data set that provides the Wikipedia titles for the named entities in the CoNLL English data set (Hoffart et al., 2011). Applying the classifier on all the English Wikipedia pages, we construct a CoNLL-style English Wikipedia entity type mapping. We then build CoNLL-style Wikipedia entity type mappings for Spanish, Dutch and German using steps as described in Section 3.

For each of the three languages, the baseline NER system is a CRF model trained with human-annotated news data ($\sim$200K tokens), and there are two test data sets, TestA and TestB, that are also human-annotated news data (ranging from 40K to 70K tokens). The results are shown in Table 6. For Dutch and German, DF(1) achieves the best improvement among the Wikipedia-based approaches. For Spanish, the joint approach achieves the best improvement among the Wikipedia-based approaches. Again, in all cases, the Wikipedia-based approaches demonstrate larger improvements (ranging from 1.0 to 3.4 F_1 score) on the unseen entities.

5.5 Discussion

From the experimental results, we have the following observations:

- NER systems are more likely to make mistakes on unseen entities. In all cases, the F_1 score of an NER system on all the entities is always higher than the F_1 score on the unseen entities.
- The Wikipedia-based approaches are effective in improving the generalization capability of NER systems (i.e., improving the accuracy on unseen entities), especially when a system is applied to a new domain (3.6 F_1 score improvement on political party articles/English NER) or it is trained with little human-annotated training data (18.3 F_1 score improvement on Japanese NER).
- In the low-resource scenario where an NER

NER System	TestA		TestB	
	All	*Unseen*	*All*	*Unseen*
Spanish	100%	47%	100%	38%
Baseline	77.9	69.4	81.5	71.0
DC(2)	77.9	69.7	81.4	71.0
DC(3)	78.4	70.1	81.6	71.2
PP(2)	78.2	70.1	**82.0**	**72.1**
Joint	**78.5**	**70.4**	**82.0**	**72.1**

DC(3)	69.9	63.5	70.4	63.1
PP(2)	70.5	64.4	70.6	63.4
Joint	70.8	64.8	70.6	63.4
DF(1)	**71.8**	**65.8**	**71.8**	**65.3**
DF(2)	71.2	65.4	70.5	63.6

Table 6: Experimental results for Spanish, Dutch, and German NER.

system is trained with little human-annotated data (e.g., 20K-30K tokens of training data for the Portuguese and Japanese systems), the decoding constraint approach, which uses a high-accuracy, high-coverage Wikipedia entity type mapping to create constraints during the decoding phase, achieves the best improvement.

- In the rich-resource scenario where an NER system is well trained (e.g., 200K-300K tokens of training data for the English, Dutch and German systems), the dictionary feature approach, which uses a Wikipedia entity type mapping to create dictionary type features, achieves the best improvement.

- In both scenarios, the joint approach, which combines the decoding constraint approach and the post-processing approach in a smart way, achieves relatively robust performance among the Wikipedia-based approaches.

6 Conclusion

In this paper, we proposed and evaluated several approaches that utilize high-accuracy, high-coverage Wikipedia entity type mappings to improve multilingual NER systems. These mappings are built from weakly annotated data, and can be easily extended to new languages with no human annotation or language-dependent knowledge involved.

Experimental results show that the Wikipedia-based approaches are effective in improving the generalization capability of NER systems. When a system is well trained, the dictionary feature approach achieves the best improvement over the baseline system; while when a system is trained with little human-annotated training data, a more aggressive decoding constraint approach achieves the best improvement. The improvements are larger on unseen entities, and the approaches are especially useful when a system is applied to a new domain or it is trained with little training data.

Abstract

Crosslingual word embeddings represent lexical items from different languages in the same vector space, enabling transfer of NLP tools. However, previous attempts had expensive resource requirements, difficulty incorporating monolingual data or were unable to handle polysemy. We address these drawbacks in our method which takes advantage of a high coverage dictionary in an EM style training algorithm over monolingual corpora in two languages. Our model achieves state-of-the-art performance on bilingual lexicon induction task exceeding models using large bilingual corpora, and competitive results on the monolingual word similarity and cross-lingual document classification task.

1 Introduction

Monolingual word embeddings have had widespread success in many NLP tasks including sentiment analysis (Socher et al., 2013), dependency parsing (Dyer et al., 2015), machine translation (Bahdanau et al., 2014). Crosslingual word embeddings are a natural extension facilitating various crosslingual tasks, e.g. through transfer learning. A model built in a source resource-rich language can then applied to the target resource poor languages (Yarowsky and Ngai, 2001; Das and Petrov, 2011; Täckström et al., 2012; Duong et al., 2015). A key barrier for crosslingual transfer is lexical matching between the source and the target language. Crosslingual word embeddings are a natural remedy where both source and target language lexicon are presented as dense vectors in the same vector space (Klementiev et al., 2012).

Most previous work has focused on down-stream crosslingual applications such as document classification and dependency parsing. We argue that good crosslingual embeddings should preserve both monolingual and crosslingual quality which we will use as the main evaluation criterion through monolingual word similarity and bilingual lexicon induction tasks. Moreover, many prior work (Chandar A P et al., 2014; Kočiský et al., 2014) used bilingual or comparable corpus which is also expensive for many low-resource languages. Søgaard et al. (2015) impose a less onerous data condition in the form of linked Wikipedia entries across several languages, however this approach tends to underperform other methods. To capture the monolingual distributional properties of words it is crucial to train on large monolingual corpora (Luong et al., 2015). However, many previous approaches are not capable of scaling up either because of the complicated objective functions or the nature of the algorithm. Other methods use a dictionary as the bridge between languages (Mikolov et al., 2013a; Xiao and Guo, 2014), however they do not adequately handle translation ambiguity.

Our model uses a bilingual dictionary from Panlex (Kamholz et al., 2014) as the source of bilingual signal. Panlex covers more than a thousand languages and therefore our approach applies to many languages, including low-resource languages. Our method selects the translation based on the context in an Expectation-Maximization style training algorithm which explicitly handles polysemy through incorporating multiple dictionary translations (word sense and translation are closely linked (Resnik and Yarowsky, 1999)). In addition to the dictionary,

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1285–1295,
Austin, Texas, November 1-5, 2016.

our method only requires monolingual data. Our approach is an extension of the continuous bag-of-words (CBOW) model (Mikolov et al., 2013b) to inject multilingual training signal based on dictionary translations. We experiment with several variations of our model, whereby we predict only the translation or both word and its translation and consider different ways of using the different learned center-word versus context embeddings in application tasks. We also propose a regularisation method to combine the two embedding matrices during training. Together, these modifications substantially improve the performance across several tasks. Our final model achieves state-of-the-art performance on bilingual lexicon induction task, large improvement over word similarity task compared with previous published crosslingual word embeddings, and competitive result on cross-lingual document classification task. Notably, our embedding combining techniques are general, yielding improvements also for monolingual word embedding.

This paper makes the following contributions:

- Proposing a new crosslingual training method for learning vector embeddings, based only on monolingual corpora and a bilingual dictionary;
- Evaluating several methods for combining embeddings, which are shown to help in both crosslingual and monolingual evaluations; and
- Achieving consistent results which are competitive in monolingual, bilingual and crosslingual transfer settings.

2 Related work

There is a wealth of prior work on crosslingual word embeddings, which all exploit some kind of bilingual resource. This is often in the form of a parallel bilingual text, using word alignments as a bridge between tokens in the source and target languages, such that translations are assigned similar embedding vectors (Luong et al., 2015; Klementiev et al., 2012). These approaches are affected by errors from automatic word alignments, motivating other approaches which operate at the sentence level (Chandar A P et al., 2014; Hermann and Blunsom, 2014; Gouws et al., 2015) through learning compositional vector representations of sentences, in order that sentences and their translations representations closely match. The word embeddings learned this way capture translational equivalence, despite not using explicit word alignments. Nevertheless, these approaches demand large parallel corpora, which are not available for many language pairs.

Vulić and Moens (2015) use bilingual comparable text, sourced from Wikipedia. Their approach creates a psuedo-document by forming a bag-of-words from the lemmatized nouns in each comparable document concatenated over both languages. These pseudo-documents are then used for learning vector representations using `Word2Vec`. Their system, despite its simplicity, performed surprisingly well on a bilingual lexicon induction task (we compare our method with theirs on this task.) Their approach is compelling due to its lesser resource requirements, although comparable bilingual data is scarce for many languages. Related, Søgaard et al. (2015) exploit the comparable part of Wikipedia. They represent word using Wikipedia entries which are shared for many languages.

A bilingual dictionary is an alternative source of bilingual information. Gouws and Søgaard (2015) randomly replace the text in a monolingual corpus with a random translation, using this corpus for learning word embeddings. Their approach doesn't handle polysemy, as very few of the translations for each word will be valid in context. For this reason a high coverage or noisy dictionary with many translations might lead to poor outcomes. Mikolov et al. (2013a), Xiao and Guo (2014) and Faruqui and Dyer (2014) filter a bilingual dictionary for one-to-one translations, thus side-stepping the problem, however discarding much of the information in the dictionary. Our approach also uses a dictionary, however we use all the translations and explicitly disambiguate translations during training.

Another distinguishing feature on the above-cited research is the method for training embeddings. Mikolov et al. (2013a) and Faruqui and Dyer (2014) use a cascade style of training where the word embeddings in both source and target language are trained separately and then combined later using the dictionary. Most of the other works train multlingual models jointly, which appears to have better performance over cascade training (Gouws et al., 2015).

For this reason we also use a form of joint training in our work.

3 Word2Vec

Our model is an extension of the contextual bag of words (CBOW) model of Mikolov et al. (2013b), a method for learning vector representations of words based on their distributional contexts. Specifically, their model describes the probability of a token w_i at position i using logistic regression with a factored parameterisation,

$$p(w_i|w_{i\pm k\setminus i}) = \frac{\exp(\mathbf{u}_{w_i}^\top \mathbf{h}_i)}{\sum_{w\in W}\exp(\mathbf{u}_w^\top \mathbf{h}_i)}\,, \qquad (1)$$

where $\mathbf{h}_i = \frac{1}{2k}\sum_{j=-k;j\neq 0}^{k}\mathbf{v}_{w_{i+j}}$ is a vector encoding the context over a window of size k centred around position i, W is the vocabulary and the parameters $\mathbf{V}$ and $\mathbf{U} \in \mathbb{R}^{|W|\times d}$ are matrices referred to as the context and word embeddings. The model is trained to maximise the log-pseudo likelihood of a training corpus, however due to the high complexity of computing the denominator of equation (1), Mikolov et al. (2013b) propose negative sampling as an approximation, by instead learning to differentiate data from noise (negative examples). This gives rise to the following optimisation objective

$$\sum_{i\in D}\left(\log\sigma(\mathbf{u}_{w_i}^\top \mathbf{h}_i) + \sum_{j=1}^{p}\mathbb{E}_{w_j\sim P_n(w)}\log\sigma(-\mathbf{u}_{w_j}^\top \mathbf{h}_i)\right), \qquad (2)$$

where D is the training data and p is the number of negative examples randomly drawn from a noise distribution $P_n(w)$.

4 Our Approach

Our approach extends CBOW to model bilingual text, using two monolingual corpora and a bilingual dictionary. We believe this data condition to be less stringent than requiring parallel or comparable texts as the source of the bilingual signal. It is common for field linguists to construct a bilingual dictionary when studying a new language, as one of the first steps in the language documentation process. Translation dictionaries are a rich information source, capturing much of the lexical ambiguity in a language through translation. For example, the word *bank* in English might mean the *river bank* or *financial bank* which corresponds to two different translations *sponda* and *banca* in Italian. If we are able to learn to select good translations, then this implicitly resolves much of the semantic ambiguity in the language, and accordingly we seek to use this idea to learn better semantic vector representations of words.

Algorithm 1 EM algorithm for selecting translation during training, where $\theta = (\mathbf{U}, \mathbf{V})$ are the model parameters and η is the learning rate.

randomly initialize $\mathbf{V}$, $\mathbf{U}$

4.1 Dictionary replacement

To learn bilingual relations, we use the context in one language to predict the translation of the centre word in another language. This is motivated by the fact that the context is an excellent means of disambiguating the translation for a word. Our method is closely related to Gouws and Søgaard (2015), however we only replace the middle word w_i with a translation $\bar{w}_i$ while keeping the context fixed. We replace each centre word with a translation on the fly during training, predicting instead $p(\bar{w}_i|w_{i\pm k\setminus i})$ but using the same formulation as equation (1) albeit with an augmented $\mathbf{U}$ matrix to cover word types in both languages.

The translation $\bar{w}_i$ is selected from the possible translations of w_i listed in the dictionary. The problem of selecting the correct translation from the many options is reminiscent of the problem faced in expectation maximisation (EM), in that cross-lingual word embeddings will allow for accurate translation, however to learn these embeddings we need to know the translations. We propose an EM-inspired algorithm, as shown in Algorithm 1, which operates over both monolingual corpora, D_e and D_f. The vector $\mathbf{s}$ is the semantic representation combining both the centre word, w_i, and the con-

text,[1] which is used to choose the best translation into the other language from the bilingual dictionary $dict(w_i)$.[2] After selecting the translation, we use $\bar{w}_i$ together with the context vector $\mathbf{h}$ to make a stochastic gradient update of the CBOW log-likelihood.

4.2 Joint Training

Words and their translations should appear in very similar contexts. One way to enforce this is to jointly learn to predict both the word and its translation from its monolingual context. This gives rise to the following joint objective function,

$$\mathcal{O} = \sum_{i \in D_e \cup D_f} \Big(\alpha \log \sigma(\mathbf{u}_{w_i}^\top \mathbf{h}_i) + (1-\alpha) \log \sigma(\mathbf{u}_{\bar{w}_i}^\top \mathbf{h}_i) + \sum_{j=1}^{p} \mathbb{E}_{w_j \sim P_n(w)} \log \sigma(-\mathbf{u}_{w_j}^\top \mathbf{h}_i) \Big), \quad (3)$$

where α controls the contribution of the two terms. For our experiments, we set $\alpha = 0.5$. The negative examples are drawn from combined vocabulary unigram distribution calculated from combined data $D_e \cup D_f$.

4.3 Combining Embeddings

Many vector learning methods learn two embedding spaces $\mathbf{V}$ and $\mathbf{U}$. Usually only $\mathbf{V}$ is used in application. The use of $\mathbf{U}$, on the other hand, is understudied (Levy and Goldberg, 2014) with the exception of Pennington et al. (2014) who use a linear combination $\mathbf{U} + \mathbf{V}$, with minor improvement over $\mathbf{V}$ alone.

We argue that with our model, $\mathbf{V}$ is better at capturing the monolingual regularities and $\mathbf{U}$ is better at capturing bilingual signal. The intuition for this is as follows. Assuming that we are predicting the word *finance* and its Italian translation *finanze* from the context (*money, loan, bank, debt, credit*) as shown in figure 1. In $\mathbf{V}$ only the context word representations are updated and in $\mathbf{U}$ only the representations of *finance, finanze* and negative samples such as *tree* and *dog* are updated. CBOW learns good embeddings because each time it updates the parameters, the words in the contexts are pushed closer to each other in the $\mathbf{V}$ space. Similarly, the target word w_i and the translation $\bar{w}_i$ are also pushed closer in the $\mathbf{U}$ space. This is directly related to poitwise mutual information values of each pair of word and context explained in Levy and Goldberg (2014). Thus, $\mathbf{U}$ is bound to better at bilingual lexicon induction task and $\mathbf{V}$ is better at monolingual word similarity task.

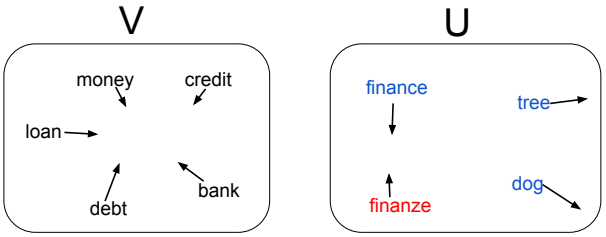

Figure 1: Example of $\mathbf{V}$ and $\mathbf{U}$ space during training.

The simple question is, how to combine both $\mathbf{V}$ and $\mathbf{U}$ to produce a better representation. We experiment with several ways to combine $\mathbf{V}$ and $\mathbf{U}$. First, we can follow Pennington et al. (2014) to *interpolate* $\mathbf{V}$ and $\mathbf{U}$ in the post-processing step. i.e.

$$\gamma \mathbf{V} + (1-\gamma)\mathbf{U} \quad (4)$$

where γ controls the contribution of each embedding space. Second, we can also *concatenate* $\mathbf{V}$ and $\mathbf{U}$ instead of interpolation such that $\mathbf{C} = [\mathbf{V} : \mathbf{U}]$ where $\mathbf{C} \in \mathbb{R}^{|W| \times 2d}$ and W is the combined vocabulary from $D_e \cup D_f$.

Moreover, we can also fuse $\mathbf{V}$ and $\mathbf{U}$ during training. For each word in the combined dictionary $V_e \cup V_f$, we encourage the model to learn similar representation in both $\mathbf{V}$ and $\mathbf{U}$ by adding a *regularization* term to the objective function in equation (3) during training.

$$\mathcal{O}' = \mathcal{O} + \delta \sum_{w \in V_e \cup V_f} \|\mathbf{u}_w - \mathbf{v}_w\|_2^2 \quad (5)$$

where δ controls to what degree we should bind two spaces together.[3]

5 Experimental Setup

Our experimental evaluation seeks to determine how well lexical distances in the learned embedding

[1] Using both embeddings gives a small improvement compared to just using context vector $\mathbf{h}$ alone.

[2] We also experimented with using expectations over translations, as per standard EM, with slight degredation in results.

[3] In the stochastic gradient update for a given word in context, we only compute the gradient of the regularisation term in (5) with respect to the words in the set of positive and negative examples.

spaces match with known lexical similarity judgements from bilingual and monolingual lexical resources. To this end, in §6 we test crosslingual distances using a bilingual lexicon induction task in which we evaluate the embeddings in terms of how well nearby pairs of words from two languages in the embedding space match with human judgements. Next, to evaluate the monolingual embeddings we evaluate word similarities in a single language against standard similarity datasets (§7). Lastly, to demonstrate the usefulness of our embeddings in a task-based setting, we evaluate on crosslingual document classification (§9).

Monolingual Data The monolingual data is taken from the pre-processed Wikipedia dump from Al-Rfou et al. (2013). The data is already cleaned and tokenized. We additionally lower-case all words. Normally monolingual word embeddings are trained on billions of words. However, obtaining that much monolingual data for a low-resource language is infeasible. Therefore, we only select the first 5 million sentences (around 100 million words) for each language.

Dictionary A bilingual dictionary is the only source of bilingual correspondence in our technique. We prefer a dictionary that covers many languages, such that our approach can be applied widely to many low-resource languages. We use Panlex, a dictionary which currently covers around 1300 language varieties with about 12 million expressions. The translations in PanLex come from various sources such as glossaries, dictionaries, automatic inference from other languages, etc. Accordingly, Panlex has high language coverage but often noisy translations.[4] Table 1 summarizes the sizes of monolingual corpora and dictionaries for each pair of language in our experiments.

[4]We also experimented with a crowd-sourced dictionary from Wiktionary. Our initial observation was that the translation quality was better but with a lower-coverage. For example, for `en-it` dictionary, Panlex and Wiktionary have a coverage of 42.1% and 16.8% respectively for the top 100k most frequent English words from Wikipedia. The average number of translations are 5.2 and 1.9 respectively. We observed similar trend using Panlex and Wiktionary dictionary in our model. However, using Panlex results in much better performance. We can run the model on the combined dictionary from both Panlex and Wiktionary but we leave it for future work.

	Source (M)	Target (M)	Dict (k)
`en-es`	120.1 (73.9%)	126.8 (74.4%)	712.0
`en-it`	120.1 (74.7%)	114.6 (67.4%)	560.1
`en-nl`	120.1 (69.1%)	80.2 (63.4%)	406.6
`en-de`	120.1 (77.8%)	90.8 (68.3%)	964.4
`en-sr`	120.1 (28.0%)	7.5 (17.5%)	35.1

Table 1: Number of tokens in millions for the source and target languages in each language pair. Also shown is the number of entries in the bilingual dictionary in thousands. The number in the parenthesis shows the token coverage in the dictionary on each monolingual corpus.

6 Bilingual Lexicon Induction

Given a word in a source language, the bilingual lexicon induction (BLI) task is to predict its translation in the target language. Vulić and Moens (2015) proposed this task to test crosslingual word embeddings. The difficulty of this is that it is evaluated using the recall of the top ranked word. The model must be very discriminative in order to score well.

We build the CLWE for 3 language pairs: `it-en`, `es-en` and `nl-en`, using similar parameters setting with Vulić and Moens (2015).[5] The remaining tunable parameters in our system are δ from Equation (5), and the choice of algorithm for combining embeddings. We use the regularization technique from §4.3 for combining context and word embeddings with $\delta = 0.01$, and word embeddings $\mathbf{U}$ are used as the output for all experiments (but see comparative experiments in §8.)

Qualitative evaluation We jointly train the model to predict both w_i and the translation $\bar{w_i}$, combine $\mathbf{V}$ and $\mathbf{U}$ during training for each language pair. Table 2 shows the top 10 closest words in both source and target languages according to cosine similarity. Note that the model correctly identifies the translation in `en` as the top candidate, and the top 10 words in both source and target languages are highly related. This qualitative evaluation initially demonstrates the ability of our CLWE to capture both the bilingual and monolingual relationship.

Quantitative evaluation Table 3 shows our results compared with prior work. We reimple-

[5]Default learning rate of 0.025, negative sampling with 25 samples, subsampling rate of value $1e^{-4}$, embedding dimension $d = 200$, window size $cs = 48$ and run for 15 epochs.

gravedad$_{es}$		*tassazione*$_{it}$

msugra	free-falling	l'imposta	revenue
centrífuga	gravitational	tonnage	levy
curvatura	free-fall	tax	annates
masa	newton	accise	evasion

Table 2: Top 10 closest words in both source and target language corresponding to es word *gravedad* (left) and it word *tassazione* (right). They have 15 and 4 dictionary translations respectively. The en words in the dictionary translations are marked with $(^*)$. The correct translation is in bold.

ment Gouws and Søgaard (2015) using Panlex and Wiktionary dictionaries. The result with Panlex is substantially worse than with Wiktionary. This confirms our hypothesis in §2. That is the context might be corrupted if we just randomly replace the training data with the translation from noisy dictionary such as Panlex.

Our model when randomly picking the translation is similar to Gouws and Søgaard (2015), using the Panlex dictionary. The biggest difference is that they replace the training data (both context and middle word) while we fix the context and only replace the middle word. For a high coverage yet noisy dictionary such as Panlex, our approach gives better average score. Comparing our two most basic models (EM selection and random selection), it is clear that the model using EM to select the translation outperforms random selection by a significant margin.

Our joint model, as described in equation (3) which predicts both target word and the translation, further improves the performance, especially for nl-en. We use equation (5) to combine both context embeddings $\mathbf{V}$ and word embeddings $\mathbf{U}$ for all three language pairs. This modification during training substantially improves the performance. More importantly, all our improvements are consistent for all three language pairs and both evaluation metrics, showing the robustness of our models.

Our combined model out-performed previous approaches by a large margin. Vulić and Moens (2015) used bilingual comparable data, but this might be hard to obtain for some language pairs. Their performance on nl-en is poor because their comparable data between en and nl is small. Besides, they also use POS tagger and lemmatizer to filter only *Noun* and reduce the morphology complexity during training. These tools might not be available for many languages. For a fairer comparison to their work, we also use the same Treetagger (Schmid, 1995) to lemmatize the output of our combined model before evaluation. Table 3 (+lemmatization) shows some improvements but minor. It demonstrates that our model is already good at disambiguating morphology. For example, the top 2 translations for es word *lenguas* in en are *languages* and *language* which correctly prefer the plural translation.

7 Monolingual Word Similarity

Now we consider the efficacy of our CLWE on monolingual word similarity. We evaluate on English monolingual similarity on WordSim353 (WS-en), RareWord (RW-en) and German version of WordSim353 (WS-de) (Finkelstein et al., 2001; Luong et al., 2013; Luong et al., 2015). Each of those datasets contain many tuples (w_1, w_2, s) where s is a scalar denoting the semantic similarity between w_1 and w_2 given by human annotators. Good system should produce the score correlated with human judgement.

We train the model as described in §4, which is the *combine embeddings* setting from Table 3. Since the evaluation involves de and en word similarity, we train the CLWE for en-de pair. Table 4 shows the performance of our combined model compared with several baselines. Our combined model out-performed both Luong et al. (2015) and Gouws and Søgaard (2015)[6] which represent the best published crosslingual embeddings trained on bitext and monolingual data respectively.

We also compare our system with the monolingual CBOW model trained on the monolingual data for each language, using the same parameter settings from earlier (§6). Surprisingly, our combined model performs better than the monolingual CBOW baseline which makes our result close to the monolingual state-of-the-art on each different dataset. However, the best monolingual methods use much larger

[6]trained using the Panlex dictionary

Table 4: Spearman's rank correlation for monolingual similarity measurement on 3 datasets WS-de (353 pairs), WS-en (353 pairs) and RW-en (2034 pairs). We compare against 5 baseline crosslingual word embeddings. The best CLWE performance is bold. For reference, we add the monolingual CBOW with and without embeddings combination, Yih and Qazvinian (2012) and Shazeer et al. (2016) which represents the monolingual state-of-the-art results for WS-en and RW-en.

monolingual corpora (Shazeer et al., 2016), WordNet or the output of commercial search engines (Yih and Qazvinian, 2012).

Next we explain the gain of our combined model compared with the monolingual CBOW model. First, we compare the combined model with the joint-model with respect to monolingual CBOW model (Table 4). It shows that the improvement seems mostly come from combining $\mathbf{V}$ and $\mathbf{U}$. If we apply the combining algorithm to the monolingual CBOW model (CBOW + combine), we also observe an improvement. Clearly most of the improvement is from combining $\mathbf{V}$ and $\mathbf{U}$, however our $\mathbf{V}$ and $\mathbf{U}$ are more complementary as the gain is more marked. Other improvements can be explained by the observation that a dictionary can improve monolingual accuracy through linking synonyms (Faruqui and Dyer, 2014). For example, since *plane*, *airplane* and *aircraft* have the same Italian translation *aereo*, the model will encourage those words to be closer in the embedding space.

8 Model selection

Combining context embeddings and word embeddings results in an improvement in both monolingual similarity and bilingual lexicon induction. In §4.3, we introduce several combination methods including post-processing (interpolation and concatenation) and during training (regularization). In this section, we justify our parameter and model choices.

We use en-it pair for tuning purposes, considering the value of γ in equation 4. Figure 2 shows the performances using different values of γ. The two extremes where $\gamma = 0$ and $\gamma = 1$ corresponds to no interpolation where we just use $\mathbf{U}$ or $\mathbf{V}$ respectively. As γ increases, the performance on WS-en increases yet BLI decreases. These results confirm our hypothesis in §4.3 that $\mathbf{U}$ is better at capturing bilingual relations and $\mathbf{V}$ is better at capturing monolingual relations. As a compromise, we choose $\gamma = 0.5$ in our experiments. Similarly, we tune the regularization sensitivity δ in equation (5) which combines embeddings space during training. We test $\delta = 10^{-n}$ with $n = \{0, 1, 2, 3, 4\}$ and us-

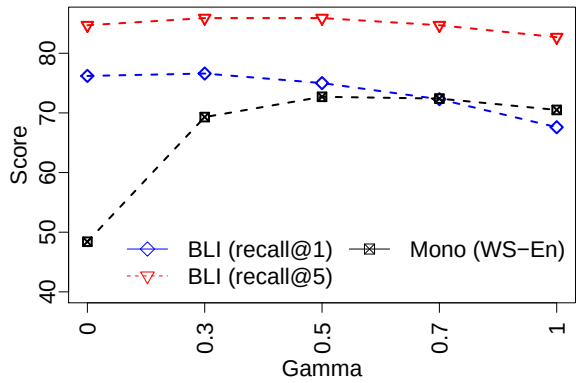

Figure 2: Performance of word embeddings interpolated using different values of γ evaluated using BLI (Recall@1, Recall@5) and English monolingual WordSim353 (WS-en).

	Model	BLI rec_1	BLI rec_5	Mono WS-en
Alone	Joint-model + **V**	67.6	82.8	70.5
	Joint-model + **U**	76.2	84.7	48.4
Combine	Interpolation $\left[\frac{\mathbf{V}+\mathbf{U}}{2}\right]$	75.0	85.9	72.7
	Concatenation	72.7	85.2	71.2
	Regularization + **V**	80.3	89.8	45.9
	Regularization + **U**	80.8	90.4	**74.8**
	Regularization + $\frac{\mathbf{V}+\mathbf{U}}{2}$	**80.9**	**91.1**	72.3

Table 5: Performance on en−it BLI and en monolingual similarity WordSim353 (WS-en) for various combining algorithms mentioned in §4.3 w.r.t just using **U** or **V** alone (after joint-training). We use $\gamma = 0.5$ for interpolation and $\delta = 0.01$ for regularization with the choice of **V**, **U** or interpolation of both $\frac{\mathbf{V}+\mathbf{U}}{2}$ for the output. The best scores are bold.

ing **V**, **U** or the interpolation of both $\frac{\mathbf{V}+\mathbf{U}}{2}$ as the learned embeddings, evaluated on the same BLI and WS-en. We select $\delta = 0.01$.

Table 5 shows the performance with and without using combining algorithms mentioned in §4.3. As the compromise between both monolingual and crosslingual tasks, we choose regularization + **U** as the combination algorithm. All in all, we apply the regularization algorithm for combining **V** and **U** with $\delta = 0.01$ and **U** as the output for all language pairs without further tuning.

9 Crosslingual Document Classification

In this section, we evaluate our CLWE on a downstream crosslingual document classification (CLDC) task. In this task, the document classifier is trained on a source language and then applied directly to classify a document in the target language. This is convenient for a target low-resource language where we do not have document annotations. The experimental setup is the same as Klementiev et al. (2012)[7] with the training and testing data sourced from Reuter RCV1/RCV2 corpus (Lewis et al., 2004).

Model	en → de	de → en
MT baseline	68.1	67.4
Klementiev et al. (2012)	77.6	71.1
Gouws et al. (2015)	86.5	75.0
Kočiský et al. (2014)	83.1	75.4
Chandar A P et al. (2014)	**91.8**	74.2
Hermann and Blunsom (2014)	86.4	74.7
Luong et al. (2015)	88.4	**80.3**
Our model	86.3	76.8

Table 6: CLDC performance for both en → de and de → en direction for many CLWE. The MT baseline uses phrase-based statistical machine translation to translate the source language to target language (Klementiev et al., 2012). The best scores are bold.

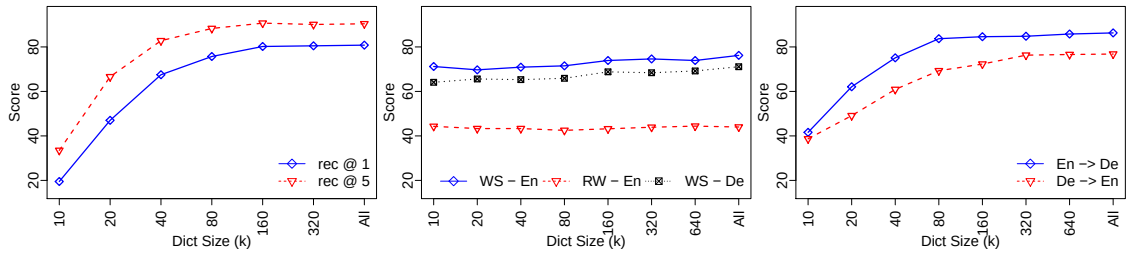
The documents are represented as the bag of word embeddings weighted by tf.idf. A multi-class classifier is trained using the average perceptron algorithm on 1000 documents in the source language and tested on 5000 documents in the target language. We use the CLWE, such that the document representation in the target language embeddings is in the same space with the source language.

We build the en-de CLWE using combined models as described in section §4. Following prior work, we also use monolingual data[8] from the RCV1/RCV2 corpus (Klementiev et al., 2012; Gouws et al., 2015; Chandar A P et al., 2014).

Table 6 shows the CLDC results for various CLWE. Despite its simplicity, our model achieves competitive performance. Note that aside from our model, all other models in Table 6 use a large bitext (Europarl) which may not exist for many low-resource languages, limiting their applicability.

[7]The data split and code are kindly provided by the authors.

[8]We randomly sample documents in RCV1 and RCV2 corpora and selected around 85k documents to form 400k monolingual sentences for both en and de. For each document, we perform basic pre-processing including: lower-casing, remove html tags and tokenization. These monolingual data are then concatenated with the monolingual data from Wikipedia to form the final training data.



(a) BLI (b) Mono Similarity (c) CLDC

Figure 3: Learning curve showing how task scores increase with increasing dictionary size; showing bilingual lexicon induction (BLI) task (left), monolingual similarity (center) and crosslingual document classification (right). BLI is trained on `en-it`, and monolingual similarity and CLDC are trained on `en-de`.

10 Low-resource languages

Our model exploits dictionaries, which are more widely available than parallel corpora. However the question remains as to how well this performs of a real low-resource language, rather than a simulated condition like above, whereupon the quality of the dictionary is likely to be worse. To test this, we evaluation on Serbian, a language with few annotated language resources. Table 1 shows the relative size of monolingual data and dictionary for `en-sr` compared with other language pairs. Both the Serbian monolingual data and the dictionary size is more than 10 times smaller than other language pairs. We build the `en-sr` CLWE using our best model (joint + combine) and evaluate on the bilingual word induction task using 939 gold translation pairs.[9] We achieved recall score of 35.8% and 45.5% at 1 and 5 respectively. Although worse than the earlier results, these numbers are still well above chance.

We can also simulate low-resource setting using our earlier datasets. For estimating the performance loss on all three tasks, we down sample the dictionary for `en-it` and `en-de` based on `en` word frequency. Figure 3 shows the performance with different dictionary sizes for all three tasks. The monolingual similarity performance is very similar across various sizes. For BLI and CLDC, dictionary size is more important, although performance levels off at around 80k dictionary pairs. We conclude that this size is sufficient for decent performance.

[9]The `sr`→`en` translations are sourced from Google Translate by translating one word at a time, followed by manually verification, after which 61 translation pairs were ruled out as being bad or questionable.

11 Conclusion

Previous CLWE methods often impose high resource requirements yet have low accuracy. We introduce a simple framework based on a large noisy dictionary. We model polysemy using EM translation selection during training to learn bilingual correspondences from monolingual corpora. Our algorithm allows to train on massive amount of monolingual data efficiently, representing monolingual and bilingual properties of language. This allows us to achieve state-of-the-art performance on bilingual lexicon induction task, competitive result on monolingual word similarity and crosslingual document classification task. Our combination techniques during training, especially using regularization, are highly effective and could be used to improve monolingual word embeddings.

Acknowledgments

This work was conducted during Duong's internship at IBM Research – Tokyo and partially supported by the University of Melbourne and National ICT Australia (NICTA). Sequence-to-Sequence Learning as Beam-Search Optimization

Sam Wiseman and **Alexander M. Rush**

{swiseman,srush}@seas.harvard.edu

Abstract

Sequence-to-Sequence (seq2seq) modeling has rapidly become an important general-purpose NLP tool that has proven effective for many text-generation and sequence-labeling tasks. Seq2seq builds on deep neural language modeling and inherits its remarkable accuracy in estimating local, next-word distributions. In this work, we introduce a model and beam-search training scheme, based on the work of Daumé III and Marcu (2005), that extends seq2seq to learn global sequence scores. This structured approach avoids classical biases associated with local training and unifies the training loss with the test-time usage, while preserving the proven model architecture of seq2seq and its efficient training approach. We show that our system outperforms a highly-optimized attention-based seq2seq system and other baselines on three different sequence to sequence tasks: word ordering, parsing, and machine translation.

1 Introduction

Sequence-to-Sequence learning with deep neural networks (herein, seq2seq) (Sutskever et al., 2011; Sutskever et al., 2014) has rapidly become a very useful and surprisingly general-purpose tool for natural language processing. In addition to demonstrating impressive results for machine translation (Bahdanau et al., 2015), roughly the same model and training have also proven to be useful for sentence compression (Filippova et al., 2015), parsing (Vinyals et al., 2015), and dialogue systems (Serban et al., 2016), and they additionally underlie other text generation applications, such as image or video captioning (Venugopalan et al., 2015; Xu et al., 2015).

The dominant approach to training a seq2seq system is as a conditional language model, with training maximizing the likelihood of each successive target word conditioned on the input sequence and the *gold* history of target words. Thus, training uses a strictly word-level loss, usually cross-entropy over the target vocabulary. This approach has proven to be very effective and efficient for training neural language models, and seq2seq models similarly obtain impressive perplexities for word-generation tasks.

Notably, however, seq2seq models are not used as conditional language models at test-time; they must instead generate fully-formed word sequences. In practice, generation is accomplished by searching over output sequences greedily or with beam search. In this context, Ranzato et al. (2016) note that the combination of the training and generation scheme just described leads to at least two major issues:

1. *Exposure Bias*: the model is never exposed to its own errors during training, and so the inferred histories at test-time do not resemble the gold training histories.

2. *Loss-Evaluation Mismatch*: training uses a word-level loss, while at test-time we target improving sequence-level evaluation metrics, such as BLEU (Papineni et al., 2002).

We might additionally add the concern of *label bias* (Lafferty et al., 2001) to the list, since word-probabilities at each time-step are locally normalized, guaranteeing that successors of incorrect his-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1296–1306,
Austin, Texas, November 1-5, 2016.

tories receive the same mass as do the successors of the true history.

In this work we develop a non-probabilistic variant of the seq2seq model that can assign a score to any possible target *sequence*, and we propose a training procedure, inspired by the learning as search optimization (LaSO) framework of Daumé III and Marcu (2005), that defines a loss function in terms of errors made during beam search. Furthermore, we provide an efficient algorithm to back-propagate through the beam-search procedure during seq2seq training.

This approach offers a possible solution to each of the three aforementioned issues, while largely maintaining the model architecture and training efficiency of standard seq2seq learning. Moreover, by scoring sequences rather than words, our approach also allows for enforcing hard-constraints on sequence generation *at training time*. To test out the effectiveness of the proposed approach, we develop a general-purpose seq2seq system with beam search optimization. We run experiments on three very different problems: word ordering, syntactic parsing, and machine translation, and compare to a highly-tuned seq2seq system with attention (Luong et al., 2015). The version with beam search optimization shows significant improvements on all three tasks, and particular improvements on tasks that require difficult search.

2 Related Work

The issues of exposure bias and label bias have received much attention from authors in the structured prediction community, and we briefly review some of this work here. One prominent approach to combating exposure bias is that of SEARN (Daumé III et al., 2009), a meta-training algorithm that learns a search policy in the form of a cost-sensitive classifier trained on examples generated from an interpolation of an oracle policy and the model's current (learned) policy. Thus, SEARN explicitly targets the mismatch between oracular training and non-oracular (often greedy) test-time inference by training on the output of the model's own policy. DAgger (Ross et al., 2011) is a similar approach, which differs in terms of how training examples are generated and aggregated, and there have additionally been important refinements to this style of training over the past several years (Chang et al., 2015). When it comes to training RNNs, SEARN/DAgger has been applied under the name "scheduled sampling" (Bengio et al., 2015), which involves training an RNN to generate the $t+1$'st token in a target sequence after consuming either the true t'th token, or, with probability that increases throughout training, the predicted t'th token.

Though technically possible, it is uncommon to use beam search when training with SEARN/DAgger. The early-update (Collins and Roark, 2004) and LaSO (Daumé III and Marcu, 2005) training strategies, however, explicitly account for beam search, and describe strategies for updating parameters when the gold structure becomes unreachable during search. Early update and LaSO differ primarily in that the former discards a training example after the first search error, whereas LaSO resumes searching after an error from a state that includes the gold partial structure. In the context of feed-forward neural network training, early update training has been recently explored in a feed-forward setting by Zhou et al. (2015) and Andor et al. (2016). Our work differs in that we adopt a LaSO-like paradigm (with some minor modifications), and apply it to the training of seq2seq RNNs (rather than feed-forward networks). We also note that Watanabe and Sumita (2015) apply maximum-violation training (Huang et al., 2012), which is similar to early-update, to a parsing model with recurrent components, and that Yazdani and Henderson (2015) use beam-search in training a discriminative, locally normalized dependency parser with recurrent components.

Recently authors have also proposed alleviating exposure bias using techniques from reinforcement learning. Ranzato et al. (2016) follow this approach to train RNN decoders in a seq2seq model, and they obtain consistent improvements in performance, even over models trained with scheduled sampling. As Daumé III and Marcu (2005) note, LaSO is similar to reinforcement learning, except it does not require "exploration" in the same way. Such exploration may be unnecessary in supervised text-generation, since we typically know the gold partial sequences at each time-step. Shen et al. (2016) use minimum risk training (approximated by

sampling) to address the issues of exposure bias and loss-evaluation mismatch for seq2seq MT, and show impressive performance gains.

Whereas exposure bias results from training in a certain way, label bias results from properties of the model itself. In particular, label bias is likely to affect structured models that make sub-structure predictions using locally-normalized scores. Because the neural and non-neural literature on this point has recently been reviewed by Andor et al. (2016), we simply note here that RNN models are typically locally normalized, and we are unaware of any specifically seq2seq work with RNNs that does *not* use locally-normalized scores. The model we introduce here, however, is not locally normalized, and so should not suffer from label bias. We also note that there are some (non-seq2seq) exceptions to the trend of locally normalized RNNs, such as the work of Sak et al. (2014) and Voigtlaender et al. (2015), who train LSTMs in the context of HMMs for speech recognition using sequence-level objectives; their work does not consider search, however.

3 Background and Notation

In the simplest seq2seq scenario, we are given a collection of source-target sequence pairs and tasked with learning to generate target sequences from source sequences. For instance, we might view machine translation in this way, where in particular we attempt to generate English sentences from (corresponding) French sentences. Seq2seq models are part of the broader class of "encoder-decoder" models (Cho et al., 2014), which first use an encoding model to transform a source object into an encoded representation $\boldsymbol{x}$. Many different sequential (and non-sequential) encoders have proven to be effective for different source domains. In this work we are agnostic to the form of the encoding model, and simply assume an abstract source representation $\boldsymbol{x}$.

Once the input sequence is encoded, seq2seq models generate a target sequence using a *decoder*. The decoder is tasked with generating a target sequence of words from a target vocabulary $\mathcal{V}$. In particular, words are generated sequentially by conditioning on the input representation $\boldsymbol{x}$ and on the previously generated words or *history*. We use the notation $w_{1:T}$ to refer to an arbitrary word sequence of length T, and the notation $y_{1:T}$ to refer to the *gold* (i.e., correct) target word sequence for an input $\boldsymbol{x}$.

Most seq2seq systems utilize a recurrent neural network (RNN) for the decoder model. Formally, a recurrent neural network is a parameterized nonlinear function $\mathbf{RNN}$ that recursively maps a sequence of vectors to a sequence of hidden states. Let $\boldsymbol{m}_1, \ldots, \boldsymbol{m}_T$ be a sequence of T vectors, and let $\boldsymbol{h}_0$ be some initial state vector. Applying an RNN to any such sequence yields hidden states $\boldsymbol{h}_t$ at each time-step t, as follows:

$$\boldsymbol{h}_t \leftarrow \mathbf{RNN}(\boldsymbol{m}_t, \boldsymbol{h}_{t-1}; \boldsymbol{\theta}),$$

where $\boldsymbol{\theta}$ is the set of model parameters, which are shared over time. In this work, the vectors $\boldsymbol{m}_t$ will always correspond to the embeddings of a target word sequence $w_{1:T}$, and so we will also write $\boldsymbol{h}_t \leftarrow \mathbf{RNN}(w_t, \boldsymbol{h}_{t-1}; \boldsymbol{\theta})$, with w_t standing in for its embedding.

RNN decoders are typically trained to act as conditional language models. That is, one attempts to model the probability of the t'th target word conditioned on $\boldsymbol{x}$ and the target history by stipulating that $p(w_t|w_{1:t-1}, \boldsymbol{x}) = g(w_t, \boldsymbol{h}_{t-1}, \boldsymbol{x})$, for some parameterized function g typically computed with an affine layer followed by a softmax. In computing these probabilities, the state $\boldsymbol{h}_{t-1}$ represents the target history, and $\boldsymbol{h}_0$ is typically set to be some function of $\boldsymbol{x}$. The complete model (including encoder) is trained, analogously to a neural language model, to minimize the cross-entropy loss at each time-step while conditioning on the gold history in the training data. That is, the model is trained to minimize $-\ln \prod_{t=1}^{T} p(y_t|y_{1:t-1}, \boldsymbol{x})$.

Once the decoder is trained, discrete sequence generation can be performed by approximately maximizing the probability of the target sequence under the conditional distribution, $\hat{y}_{1:T} = \mathrm{argbeam}_{w_{1:T}} \prod_{t=1}^{T} p(w_t|w_{1:t-1}, \boldsymbol{x})$, where we use the notation $\mathrm{argbeam}$ to emphasize that the decoding process requires heuristic search, since the RNN model is non-Markovian. In practice, a simple beam search procedure that explores K prospective histories at each time-step has proven to be an effective decoding approach. However, as noted above, decoding in this manner after conditional language-model style training *potentially* suffers from the is-

sues of exposure bias and label bias, which motivates the work of this paper.

4 Beam Search Optimization

We begin by making one small change to the seq2seq modeling framework. Instead of predicting the probability of the next word, we instead learn to produce (non-probabilistic) scores for ranking sequences. Define the score of a sequence consisting of *history* $w_{1:t-1}$ followed by a single word w_t as $f(w_t, \boldsymbol{h}_{t-1}, \boldsymbol{x})$, where f is a parameterized function examining the current hidden-state of the relevant RNN at time $t-1$ as well as the input representation $\boldsymbol{x}$. In experiments, our f will have an identical form to g but *without* the final softmax transformation (which transforms unnormalized scores into probabilities), thereby allowing the model to avoid issues associated with the label bias problem.

More importantly, we also modify how this model is trained. Ideally we would train by comparing the gold sequence to the highest-scoring complete sequence. However, because finding the argmax sequence according to this model is intractable, we propose to adopt a LaSO-like (Daumé III and Marcu, 2005) scheme to train, which we will refer to as beam search optimization (BSO). In particular, we define a loss that penalizes the gold sequence falling off the beam during training.[1] The proposed training approach is a simple way to expose the model to incorrect histories and to match the training procedure to test generation. Furthermore we show that it can be implemented efficiently without changing the asymptotic run-time of training, beyond a factor of the beam size K.

4.1 Search-Based Loss

We now formalize this notion of a search-based loss for RNN training. Assume we have a set S_t of K candidate sequences of length t. We can calculate a score for each sequence in S_t using a scoring function f parameterized with an RNN, as above, and we define the sequence $\hat{y}^{(K)}_{1:t} \in S_t$ to be the K'th ranked sequence in S_t according to f. That is, assuming distinct scores,

$$|\{\hat{y}^{(k)}_{1:t} \in S_t \mid f(\hat{y}^{(k)}_t, \hat{\boldsymbol{h}}^{(k)}_{t-1}) > f(\hat{y}^{(K)}_t, \hat{\boldsymbol{h}}^{(K)}_{t-1})\}| = K - 1,$$

where $\hat{y}^{(k)}_t$ is the t'th token in $\hat{y}^{(k)}_{1:t}$, $\hat{\boldsymbol{h}}^{(k)}_{t-1}$ is the RNN state corresponding to its $t-1$'st step, and where we have omitted the $\boldsymbol{x}$ argument to f for brevity.

We now define a loss function that gives loss each time the score of the gold prefix $y_{1:t}$ does not exceed that of $\hat{y}^{(K)}_{1:t}$ by a margin:

$$\mathcal{L}(f) = \sum_{t=1}^{T} \Delta(\hat{y}^{(K)}_{1:t}) \left[1 - f(y_t, \boldsymbol{h}_{t-1}) + f(\hat{y}^{(K)}_t, \hat{\boldsymbol{h}}^{(K)}_{t-1})\right].$$

Above, the $\Delta(\hat{y}^{(K)}_{1:t})$ term denotes a mistake-specific cost-function, which allows us to scale the loss depending on the severity of erroneously predicting $\hat{y}^{(K)}_{1:t}$; it is assumed to return 0 when the margin requirement is satisfied, and a positive number otherwise. It is this term that allows us to use sequence- rather than word-level costs in training (addressing the 2nd issue in the introduction). For instance, when training a seq2seq model for machine translation, it may be desirable to have $\Delta(\hat{y}^{(K)}_{1:t})$ be inversely related to the partial sentence-level BLEU score of $\hat{y}^{(K)}_{1:t}$ with $y_{1:t}$; we experiment along these lines in Section 5.3.

Finally, because we want the full gold sequence to be at the top of the beam at the end of search, when $t = T$ we modify the loss to require the score of $y_{1:T}$ to exceed the score of the *highest* ranked incorrect prediction by a margin.

We can optimize the loss $\mathcal{L}$ using a two-step process: (1) in a forward pass, we compute candidate sets S_t and record margin violations (sequences with non-zero loss); (2) in a backward pass, we back-propagate the errors through the seq2seq RNNs. Unlike standard seq2seq training, the first-step requires running search (in our case beam search) to find margin violations. The second step can be done by adapting back-propagation through time (BPTT). We next discuss the details of this process.

4.2 Forward: Find Violations

In order to minimize this loss, we need to specify a procedure for constructing candidate sequences $\hat{y}^{(k)}_{1:t}$

[1] Using a non-probabilistic model further allows us to incur no loss (and thus require no update to parameters) when the gold sequence *is* on the beam; this contrasts with models based on a CRF loss, such as those of Andor et al. (2016) and Zhou et al. (2015), though in training those models are simply not updated when the gold sequence remains on the beam.

at each time step t so that we find margin violations. We follow LaSO (rather than early-update [2]; see Section 2) and build candidates in a recursive manner. If there was no margin violation at $t-1$, then S_t is constructed using a standard beam search update. If there was a margin violation, S_t is constructed as the K best sequences assuming the gold history $y_{1:t-1}$ through time-step $t-1$.

Formally, assume the function succ maps a sequence $w_{1:t-1} \in \mathcal{V}^{t-1}$ to the set of all valid sequences of length t that can be formed by appending to it a valid word $w \in \mathcal{V}$. In the simplest, unconstrained case, we will have

$$\text{succ}(w_{1:t-1}) = \{w_{1:t-1}, w \mid w \in \mathcal{V}\}.$$

As an important aside, note that for some problems it may be preferable to define a succ function which imposes hard constraints on successor sequences. For instance, if we would like to use seq2seq models for parsing (by emitting a constituency or dependency structure encoded into a sequence in some way), we will have hard constraints on the sequences the model can output, namely, that they represent valid parses. While hard constraints such as these would be difficult to add to standard seq2seq at training time, in our framework they can naturally be added to the succ function, allowing us to *train* with hard constraints; we experiment along these lines in Section 5.3, where we refer to a model trained with constrained beam search as ConBSO.

Having defined an appropriate succ function, we specify the candidate set as:

$$S_t = \text{topK} \begin{cases} \text{succ}(y_{1:t-1}) & \text{violation at } t-1 \\ \bigcup_{k=1}^{K} \text{succ}(\hat{y}_{1:t-1}^{(k)}) & \text{otherwise,} \end{cases}$$

where we have a margin violation at $t-1$ iff $f(y_{t-1}, \boldsymbol{h}_{t-2}) < f(\hat{y}_{t-1}^{(K)}, \hat{\boldsymbol{h}}_{t-2}^{(K)}) + 1$, and where topK considers the scores given by f. This search procedure is illustrated in the top portion of Figure 1.

In the forward pass of our training algorithm, shown as the first part of Algorithm 1, we run this version of beam search and collect all sequences and their hidden states that lead to losses.

[2] We found that training with early-update rather than (delayed) LaSO did not work well, even after pre-training. Given the success of early-update in many NLP tasks this was somewhat surprising. We leave this question to future work.

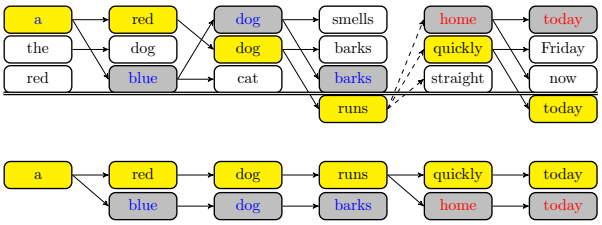

Figure 1: Top: possible $\hat{y}_{1:t}^{(k)}$ formed in training with a beam of size $K=3$ and with gold sequence $y_{1:6}$ = "a red dog runs quickly today". The gold sequence is highlighted in yellow, and the predicted prefixes involved in margin violations (at $t=4$ and $t=6$) are in gray. Note that time-step $T=6$ uses a different loss criterion. Bottom: prefixes that actually participate in the loss, arranged to illustrate the back-propagation process.

4.3 Backward: Merge Sequences

Once we have collected margin violations we can run backpropagation to compute parameter updates. Assume a margin violation occurs at time-step t between the predicted history $\hat{y}_{1:t}^{(K)}$ and the gold history $y_{1:t}$. As in standard seq2seq training we must back-propagate this error through the gold history; however, unlike seq2seq we also have a gradient for the wrongly predicted history.

Recall that to back-propagate errors through an RNN we run a recursive backward procedure — denoted below by **BRNN** — at each time-step t, which accumulates the gradients of next-step and future losses with respect to $\boldsymbol{h}_t$. We have:

$$\nabla_{\boldsymbol{h}_t}\mathcal{L} \leftarrow \mathbf{BRNN}(\nabla_{\boldsymbol{h}_t}\mathcal{L}_{t+1}, \nabla_{\boldsymbol{h}_{t+1}}\mathcal{L}),$$

where $\mathcal{L}_{t+1}$ is the loss at step $t+1$, deriving, for instance, from the score $f(y_{t+1}, \boldsymbol{h}_t)$. Running this **BRNN** procedure from $t=T-1$ to $t=0$ is known as back-propagation through time (BPTT).

In determining the total computational cost of back-propagation here, first note that in the worst case there is one violation at each time-step, which leads to T independent, incorrect sequences. Since we need to call **BRNN** $O(T)$ times for each sequence, a naive strategy of running BPTT for each incorrect sequence would lead to an $O(T^2)$ backward pass, rather than the $O(T)$ time required for the standard seq2seq approach.

Fortunately, our combination of search-strategy and loss make it possible to efficiently share **BRNN** operations. This shared structure comes

naturally from the LaSO update, which resets the beam in a convenient way.

We informally illustrate the process in Figure 1. The top of the diagram shows a possible sequence of $\hat{y}^{(k)}_{1:t}$ formed during search with a beam of size 3 for the target sequence $y =$ "a red dog runs quickly today." When the gold sequence falls off the beam at $t = 4$, search resumes with $S_5 = \text{succ}(y_{1:4})$, and so all subsequent predicted sequences have $y_{1:4}$ as a prefix and are thus functions of $\boldsymbol{h}_4$. Moreover, because our loss function only involves the scores of the gold prefix and the violating prefix, we end up with the relatively simple computation tree shown at the bottom of Figure 1. It is evident that we can backpropagate in a single pass, accumulating gradients from sequences that diverge from the gold at the time-step that precedes their divergence. The second half of Algorithm 1 shows this explicitly for a single sequence, though it is straightforward to extend the algorithm to operate in batch.[3]

      $grad\_\widehat{\boldsymbol{h}}_t \leftarrow \mathbf{0}$

5 Data and Methods

We run experiments on three different tasks, comparing our approach to the seq2seq baseline, and to other relevant baselines.

5.1 Model

While the method we describe applies to seq2seq RNNs in general, for all experiments we use the global attention model of Luong et al. (2015) — which consists of an LSTM (Hochreiter and Schmidhuber, 1997) encoder and an LSTM decoder with a global attention model — as both the baseline seq2seq model (i.e., as the model that computes the g in Section 3) and as the model that computes our sequence-scores $f(w_t, \boldsymbol{h}_{t-1}, \boldsymbol{x})$. As in Luong et al. (2015), we also use "input feeding," which involves feeding the attention distribution from the previous time-step into the decoder at the current step. This model architecture has been found to be highly performant for neural machine translation and other seq2seq tasks.

To distinguish the models we refer to our system as BSO (beam search optimization) and to the baseline as seq2seq. When we apply constrained training (as discussed in Section 4.2), we refer to the model as ConBSO. In providing results we also distinguish between the beam size K_{tr} with which the model is trained, and the beam size K_{te} which is used at test-time. In general, if we plan on evaluating with a beam of size K_{te} it makes sense to train with a beam of size $K_{tr} = K_{te} + 1$, since our objective requires the gold sequence to be scored higher than the *last* sequence on the beam.

5.2 Methodology

Here we detail additional techniques we found necessary to ensure the model learned effectively. First, we found that the model failed to learn when trained from a random initialization.[4] We therefore found it necessary to pre-train the model using a standard, word-level cross-entropy loss as described in Sec-

[3] We also note that because we do not update the parameters until after the T'th search step, our training procedure differs slightly from LaSO (which is online), and in this aspect is essentially equivalent to the "delayed LaSO update" of Björkelund and Kuhn (2014).

[4] This may be because there is relatively little signal in the sparse, sequence-level gradient, but this point requires further investigation.

tion 3. The necessity of pre-training in this instance is consistent with the findings of other authors who train non-local neural models (Kingsbury, 2009; Sak et al., 2014; Andor et al., 2016; Ranzato et al., 2016).[5]

Similarly, it is clear that the smaller the beam used in training is, the less room the model has to make erroneous predictions without running afoul of the margin loss. Accordingly, we also found it useful to use a "curriculum beam" strategy in training, whereby the size of the beam is increased gradually during training. In particular, given a desired training beam size K_{tr}, we began training with a beam of size 2, and increased it by 1 every 2 epochs until reaching K_{tr}.

Finally, it has been established that *dropout* (Srivastava et al., 2014) regularization improves the performance of LSTMs (Pham et al., 2014; Zaremba et al., 2014), and in our experiments we run beam search under dropout.[6]

For all experiments, we trained both seq2seq and BSO models with mini-batch Adagrad (Duchi et al., 2011) (using batches of size 64), and we renormalized all gradients so they did not exceed 5 before updating parameters. We did not extensively tune learning-rates, but we found initial rates of 0.02 for the encoder and decoder LSTMs, and a rate of 0.1 or 0.2 for the final linear layer (i.e., the layer tasked with making word-predictions at each time-step) to work well across all the tasks we considered. Code implementing the experiments described below can be found at `https://github.com/harvardnlp/BSO`.[7]

5.3 Tasks and Results

Our experiments are primarily intended to evaluate the effectiveness of beam search optimization over standard seq2seq training. As such, we run experiments with the same model across three very different problems: word ordering, dependency parsing, and machine translation. While we do not include all the features and extensions necessary to reach state-of-the-art performance, even the baseline seq2seq model is generally quite performant.

Word Ordering The task of correctly ordering the words in a shuffled sentence has recently gained some attention as a way to test the (syntactic) capabilities of text-generation systems (Zhang and Clark, 2011; Zhang and Clark, 2015; Liu et al., 2015; Schmaltz et al., 2016). We cast this task as seq2seq problem by viewing a shuffled sentence as a source sentence, and the correctly ordered sentence as the target. While word ordering is a somewhat synthetic task, it has two interesting properties for our purposes. First, it is a task which plausibly requires search (due to the exponentially many possible orderings), and, second, there is a clear hard constraint on output sequences, namely, that they be a permutation of the source sequence. For both the baseline and BSO models we enforce this constraint at test-time. However, we also experiment with constraining the BSO model during training, as described in Section 4.2, by defining the succ function to only allow successor sequences containing un-used words in the source sentence.

For experiments, we use the same PTB dataset (with the standard training, development, and test splits) and evaluation procedure as in Zhang and Clark (2015) and later work, with performance reported in terms of BLEU score with the correctly ordered sentences. For all word-ordering experiments we use 2-layer encoder and decoder LSTMs, each with 256 hidden units, and dropout with a rate of 0.2 between LSTM layers. We use simple 0/1 costs in defining the Δ function.

We show our test-set results in Table 1. We see that on this task there is a large improvement at each beam size from switching to BSO, and a further improvement from using the constrained model.

Inspired by a similar analysis in Daumé III and Marcu (2005), we further examine the relationship between K_{tr} and K_{te} when training with ConBSO in Table 2. We see that larger K_{tr} hurt greedy inference, but that results continue to improve, at least initially, when using a K_{te} that is (somewhat) bigger than $K_{tr} - 1$.

[5] Andor et al. (2016) found, however, that pre-training only increased convergence-speed, but was not necessary for obtaining good results.

[6] However, it is important to ensure that the same mask applied at each time-step of the forward search is also applied at the corresponding step of the backward pass. We accomplish this by pre-computing masks for each time-step, and sharing them between the partial sequence LSTMs.

[7] Our code is based on Yoon Kim's seq2seq code, `https://github.com/harvardnlp/seq2seq-attn`.

	Word Ordering (BLEU)		
	K_{te} = 1	K_{te} = 5	K_{te} = 10
seq2seq	25.2	29.8	31.0
BSO	28.0	33.2	34.3
ConBSO	**28.6**	**34.3**	**34.5**
LSTM-LM	15.4	-	26.8

	Word Ordering Beam Size (BLEU)		
	K_{te} = 1	K_{te} = 5	K_{te} = 10
K_{tr} = 2	30.59	31.23	30.26
K_{tr} = 6	28.20	34.22	34.67
K_{tr} = 11	26.88	34.42	34.88
seq2seq	26.11	30.20	31.04

Table 2: Beam-size experiments on word ordering development set. All numbers reflect training with constraints (ConBSO).

Dependency Parsing We next apply our model to dependency parsing, which also has hard constraints and plausibly benefits from search. We treat dependency parsing with arc-standard transitions as a seq2seq task by attempting to map from a source sentence to a target sequence of source sentence words interleaved with the arc-standard, reduce-actions in its parse. For example, we attempt to map the source sentence

> But it was the Quotron problems that ...

to the target sequence

> But it was @L_SBJ @L_DEP the Quotron problems @L_NMOD @L_NMOD that ...

We use the standard Penn Treebank dataset splits with Stanford dependency labels, and the standard UAS/LAS evaluation metric (excluding punctuation) following Chen and Manning (2014). All models thus see only the words in the source and, when decoding, the actions it has emitted so far; no other features are used. We use 2-layer encoder and decoder LSTMs with 300 hidden units per layer and dropout with a rate of 0.3 between LSTM layers. We replace singleton words in the training set with an UNK token, normalize digits to a single symbol, and initialize word embeddings for both source and target words from the publicly available `word2vec` (Mikolov et al., 2013) embeddings. We use simple 0/1 costs in defining the Δ function.

	Dependency Parsing (UAS/LAS)		
	K_{te} = 1	K_{te} = 5	K_{te} = 10
seq2seq	**87.33/82.26**	88.53/84.16	88.66/84.33
BSO	86.91/82.11	91.00/**87.18**	91.17/**87.41**
ConBSO	85.11/79.32	**91.25**/86.92	**91.57**/87.26
Andor	93.17/91.18	-	-

Table 3: Dependency parsing. UAS/LAS of seq2seq, BSO, ConBSO and baselines on PTB test set. Andor is the current state-of-the-art model for this data set (Andor et al. 2016), and we note that with a beam of size 32 they obtain 94.41/92.55. All experiments above have $K_{tr} = 6$.

As in the word-ordering case, we also experiment with modifying the succ function in order to train under hard constraints, namely, that the emitted target sequence be a valid parse. In particular, we constrain the output at each time-step to obey the stack constraint, and we ensure words in the source are emitted in order.

We show results on the test-set in Table 3. BSO and ConBSO both show significant improvements over seq2seq, with ConBSO improving most on UAS, and BSO improving most on LAS. We achieve a reasonable final score of 91.57 UAS, which lags behind the state-of-the-art, but is promising for a general-purpose, word-only model.

Translation We finally evaluate our model on a small machine translation dataset, which allows us to experiment with a cost function that is not 0/1, and to consider other baselines that attempt to mitigate exposure bias in the seq2seq setting. We use the dataset from the work of Ranzato et al. (2016), which uses data from the German-to-English portion of the IWSLT 2014 machine translation evaluation campaign (Cettolo et al., 2014). The data comes from translated TED talks, and the dataset contains roughly 153K training sentences, 7K development sentences, and 7K test sentences. We use the same preprocessing and dataset splits as Ranzato et

	Machine Translation (BLEU)		
	K_{te} = 1	K_{te} = 5	K_{te} = 10
seq2seq	22.53	24.03	23.87

XENT	17.74	20.10	20.28
DAD	20.12	22.25	22.40
MIXER	20.73	21.81	21.83

Table 4: Machine translation experiments on test set; results below middle line are from MIXER model of Ranzato et al. (2016). SB-Δ indicates sentence BLEU costs are used in defining Δ. XENT is similar to our seq2seq model but with a convolutional encoder and simpler attention. DAD trains seq2seq with scheduled sampling (Bengio et al., 2015). BSO, SB-Δ experiments above have $K_{tr} = 6$.

al. (2016), and like them we also use a single-layer LSTM decoder with 256 units. We also use dropout with a rate of 0.2 between each LSTM layer. We emphasize, however, that while our decoder LSTM is of the same size as that of Ranzato et al. (2016), our results are not directly comparable, because we use an LSTM encoder (rather than a convolutional encoder as they do), a slightly different attention mechanism, and input feeding (Luong et al., 2015).

For our main MT results, we set $\Delta(\hat{y}^{(k)}_{1:t})$ to $1 - \mathrm{SB}(\hat{y}^{(K)}_{r+1:t}, y_{r+1:t})$, where r is the last margin violation and SB denotes smoothed, sentence-level BLEU (Chen and Cherry, 2014). This setting of Δ should act to penalize erroneous predictions with a relatively low sentence-level BLEU score more than those with a relatively high sentence-level BLEU score. In Table 4 we show our final results and those from Ranzato et al. (2016).[8] While we start with an improved baseline, we see similarly large increases in accuracy as those obtained by DAD and MIXER, in particular when $K_{te} > 1$.

We further investigate the utility of these sequence-level costs in Table 5, which compares using sentence-level BLEU costs in defining Δ with using 0/1 costs. We see that the more sophisticated sequence-level costs have a moderate effect on BLEU score.

[8] Some results from personal communication.

	Machine Translation (BLEU)		
	K_{te} = 1	K_{te} = 5	K_{te} = 10
0/1-Δ	25.73	28.21	27.43
SB-Δ	25.99	28.45	27.58

Table 5: BLEU scores obtained on the machine translation development data when training with $\Delta(\hat{y}^{(k)}_{1:t}) = 1$ (top) and $\Delta(\hat{y}^{(k)}_{1:t}) = 1 - \mathrm{SB}(\hat{y}^{(K)}_{r+1:t}, y_{r+1:t})$ (bottom), and K_{tr} = 6.

Timing Given Algorithm 1, we would expect training time to increase linearly with the size of the beam. On the above MT task, our highly tuned seq2seq baseline processes an average of 13,038 tokens/second (including both source and target tokens) on a GTX 970 GPU. For beams of size K_{tr} = 2, 3, 4, 5, and 6, our implementation processes on average 1,985, 1,768, 1,709, 1,521, and 1,458 tokens/second, respectively. Thus, we appear to pay an initial constant factor of ≈ 3.3 due to the more complicated forward and backward passes, and then training scales with the size of the beam. Because we batch beam predictions on a GPU, however, we find that in practice training time scales sub-linearly with the beam-size.

6 Conclusion

We have introduced a variant of seq2seq and an associated beam search training scheme, which addresses exposure bias as well as label bias, and moreover allows for both training with sequence-level cost functions as well as with hard constraints. Future work will examine scaling this approach to much larger datasets.

Acknowledgments

We thank Yoon Kim for helpful discussions and for providing the initial seq2seq code on which our implementations are based. We thank Allen Schmaltz for help with the word ordering experiments. We also gratefully acknowledge the support of a Google Research Award.

Abstract

We introduce an online neural sequence to sequence model that learns to alternate between encoding and decoding segments of the input as it is read. By independently tracking the encoding and decoding representations our algorithm permits exact polynomial marginalization of the latent segmentation during training, and during decoding beam search is employed to find the best alignment path together with the predicted output sequence. Our model tackles the bottleneck of vanilla encoder-decoders that have to read and memorize the entire input sequence in their fixed-length hidden states before producing any output. It is different from previous attentive models in that, instead of treating the attention weights as output of a deterministic function, our model assigns attention weights to a sequential latent variable which can be marginalized out and permits online generation. Experiments on abstractive sentence summarization and morphological inflection show significant performance gains over the baseline encoder-decoders.

1 Introduction

The problem of mapping from one sequence to another is an importance challenge of natural language processing. Common applications include machine translation and abstractive sentence summarisation. Traditionally this type of problem has been tackled by a combination of hand-crafted features, alignment models, segmentation heuristics, and language models, all of which are tuned separately.

The recently introduced encoder-decoder paradigm has proved very successful for machine translation, where an input sequence is encoded into a fixed-length vector and an output sequence is then decoded from said vector (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014). This architecture is appealing, as it makes it possible to tackle the problem of sequence-to-sequence mapping by training a large neural network in an end-to-end fashion. However it is difficult for a fixed-length vector to memorize all the necessary information of an input sequence, especially for long sequences. Often a very large encoding needs to be employed in order to capture the longest sequences, which invariably wastes capacity and computation for short sequences. While the attention mechanism of Bahdanau et al. (2015) goes some way to address this issue, it still requires the full input to be seen before any output can be produced.

In this paper we propose an architecture to tackle the limitations of the vanilla encoder-decoder model, a segment to segment neural transduction model (SSNT) that learns to generate and align simultaneously. Our model is inspired by the HMM word alignment model proposed for statistical machine translation (Vogel et al., 1996; Tillmann et al., 1997); we impose a monotone restriction on the alignments but incorporate recurrent dependencies on the input which enable rich locally non-monotone alignments to be captured. This is similar to the sequence transduction model of Graves (2012), but we propose alignment distributions which are parameterised separately, making the model more flexible

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1307–1316,
Austin, Texas, November 1-5, 2016.

and allowing online inference.

Our model introduces a latent segmentation which determines correspondences between tokens of the input sequence and those of the output sequence. The aligned hidden states of the encoder and decoder are used to predict the next output token and to calculate the transition probability of the alignment. We carefully design the input and output RNNs such that they independently update their respective hidden states. This enables us to derive an exact dynamic programme to marginalize out the hidden segmentation during training and an efficient beam search to generate online the best alignment path together with the output sequence during decoding. Unlike previous recurrent segmentation models that only capture dependencies in the input (Graves et al., 2006; Kong et al., 2016), our segmentation model is able to capture unbounded dependencies in both the input and output sequences while still permitting polynomial inference.

While attentive models treat the attention weights as output of a deterministic function, our model assigns attention weights to a sequential latent variable which can be marginalized out. Our model is general and could be incorporated into any RNN-based encoder-decoder architecture, such as Neural Turing Machines (Graves et al., 2014), memory networks (Weston et al., 2015; Kumar et al., 2016) or stack-based networks (Grefenstette et al., 2015), enabling such models to process data online.

We conduct experiments on two different transduction tasks, abstractive sentence summarisation (sequence to sequence mapping at word level) and morphological inflection generation (sequence to sequence mapping at character level). We evaluate our proposed algorithms in both the online setting, where the input is encoded with a unidirectional LSTM, and where the whole input is available such that it can be encoded with a bidirectional network. The experimental results demonstrate the effectiveness of SSNT — it consistently output performs the baseline encoder-decoder approach while requiring significantly smaller hidden layers, thus showing that the segmentation model is able to learn to break one large transduction task into a series of smaller encodings and decodings. When bidirectional encodings are used the segmentation model outperforms an attention-based benchmark. Qualitative analysis shows that the alignments found by our model are highly intuitive and demonstrates that the model learns to read ahead the required number of tokens before producing output.

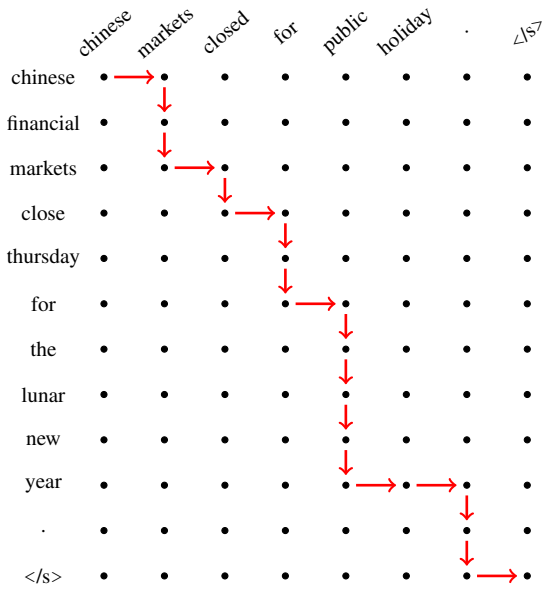

Figure 1: Example output of our recurrent segmentation model on the task of abstractive sentence summarisation. The path highlighted is the alignment found by the model during decoding.

2 Model

Let $\boldsymbol{x}_1^I$ be the input sequence of length I and $\boldsymbol{y}_1^J$ the output sequence of length J. Let y_j denote the j-th token of $\boldsymbol{y}$. Our goal is to model the conditional distribution

$$p(\boldsymbol{y}|\boldsymbol{x}) = \prod_{j=1}^{J} p(y_j|\boldsymbol{y}_1^{j-1}, \boldsymbol{x}). \quad (1)$$

We introduce a hidden alignment sequence $\boldsymbol{a}_1^J$ where each $a_j = i$ corresponds to an input position $i \in \{1, \ldots, I\}$ that we want to focus on when generating y_j. Then $p(\boldsymbol{y}|\boldsymbol{x})$ is calculated by marginalizing over all the hidden alignments,

$$
\begin{aligned}
& p(\boldsymbol{y}|\boldsymbol{x}) = \textstyle\sum_{\boldsymbol{a}} p(\boldsymbol{y}, \boldsymbol{a}|\boldsymbol{x}) \qquad (2)\\
\approx \quad & \textstyle\sum_{\boldsymbol{a}} \prod_{j=1}^{J} \underbrace{p(a_j|a_{j-1}, \boldsymbol{y}_1^{j-1}, \boldsymbol{x})}_{\text{transition probability}} \cdot \\
& \qquad \underbrace{p(y_j|\boldsymbol{y}_1^{j-1}, a_j, \boldsymbol{x})}_{\text{word prediction}}.
\end{aligned}
$$

Figure 1 illustrates the model graphically. Each path from the top left node to the right-most column in the graph corresponds to an alignment. We constrain the alignments to be monotone, i.e. only forward and downward transitions are permitted at each point in the grid. This constraint enables the model to learn to perform online generation. Additionally, the model learns to align input and output segments, which means that it can learn local reorderings by memorizing phrases. Another possible constraint on the alignments would be to ensure that the entire input sequence is consumed before last output word is emitted, i.e. all valid alignment paths have to end in the bottom right corner of the grid. However, we do not enforce this constraint in our setup.

The probability contributed by an alignment is obtained by accumulating the probability of word predictions at each point on the path and the transition probability between points. The transition probabilities and the word output probabilities are modeled by neural networks, which are described in detail in the following sub-sections.

2.1 Probabilities of Output Word Predictions

The input sentence $\boldsymbol{x}$ is encoded with a Recurrent Neural Network (RNN), in particular an LSTM (Hochreiter and Schmidhuber, 1997). The encoder can either be a unidirectional or bidirectional LSTM. If a unidirectional encoder is used the model is able to read input and generate output symbols online. The hidden state vectors are computed as

$$\mathbf{h}_i^{\rightarrow} = \text{RNN}(\mathbf{h}_{i-1}^{\rightarrow}, v^{(e)}(x_i)), \qquad (3)$$

$$\mathbf{h}_i^{\leftarrow} = \text{RNN}(\mathbf{h}_{i+1}^{\leftarrow}, v^{(e)}(x_i)), \qquad (4)$$

where $v^{(e)}(x_i)$ denotes the vector representation of the token x, and $\mathbf{h}_i^{\rightarrow}$ and $\mathbf{h}_i^{\leftarrow}$ are the forward and backward hidden states, respectively. For a bidirectional encoder, they are concatenated as $\mathbf{h}_i = [\mathbf{h}_i^{\rightarrow}; \mathbf{h}_i^{\leftarrow}]$; and for unidirectional encoder $\mathbf{h}_i = \mathbf{h}_i^{\rightarrow}$. The hidden state $\mathbf{s}_j$ of the RNN for the output sequence $\boldsymbol{y}$ is computed as

$$\mathbf{s}_j = \text{RNN}(\mathbf{s}_{j-1}, v^{(d)}(y_{j-1})), \qquad (5)$$

where $v^{(d)}(y_{j-1})$ is the encoded vector of the previously generated output word y_{j-1}. That is, $\mathbf{s}_j$ encodes $\boldsymbol{y}_1^{j-1}$.

To calculate the probability of the next word, we concatenate the aligned hidden state vectors $\mathbf{s}_j$ and $\mathbf{h}_{a_j}$ and feed the result into a softmax layer,

$$
\begin{aligned}
& p(y_j = l|\boldsymbol{y}_1^{j-1}, a_j, \boldsymbol{x}) \\
&= p(y_j = l|\mathbf{h}_{a_j}, \mathbf{s}_j) \qquad (6)\\
&= \text{softmax}(\mathbf{W}_w[\mathbf{h}_{a_j}; \mathbf{s}_j] + \mathbf{b}_w)_l.
\end{aligned}
$$

The word output distribution in Graves (2012) is parameterised in similar way.

Figure 2 illustrates the model structure. Note that the hidden states of the input and output decoders are kept independent to permit tractable inference, while the output distributions are conditionally dependent on both.

2.2 Transition Probabilities

As the alignments are constrained to be monotone, we can treat the transition from timestep j to $j+1$ as a sequence of `shift` and `emit` operations. Specifically, at each input position, a decision of `shift` or `emit` is made by the model; if the operation is `emit` then the next output word is generated; otherwise, the model will `shift` to the next input word. While the multinomial distribution is an alternative for parameterising alignments, the shift/emit parameterisation does not place an upper limit on the jump size, as a multinomial distribution would, and biases the model towards shorter jump sizes, which a multinomial model would have to learn.

We describe two methods for modelling the alignment transition probability. The first approach is independent of the input or output words. To parameterise the alignment distribution in terms of shift and emit operations we use a geometric distribution,

$$p(a_j|a_{j-1}) = (1-e)^{a_j - a_{j-1}} e, \qquad (7)$$

where e is the emission probability. This transition probability only has one parameter e, which can be

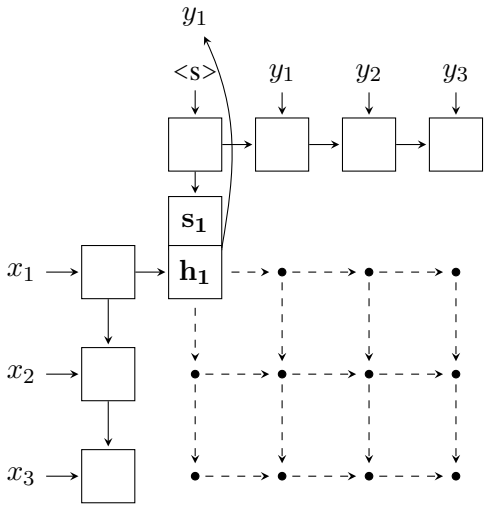

Figure 2: The structure of our model. (x_1, x_2, x_3) and (y_1, y_2, y_3) denote the input and output sequences, respectively. The points, e.g. (i, j), in the grid represent an alignment between x_i and y_j. For each column j, the concatenation of the hidden states $[\mathbf{h}_i, \mathbf{s}_j]$ is used to predict y_j.

estimated directly by maximum likelihood as

$$e = \frac{\sum_n J_n}{\sum_n I_n + \sum_n J_n}, \tag{8}$$

where I_n and J_n are the lengths of the input and output sequences of training example n, respectively.

For the second method we model the transition probability with a neural network,

$$\begin{aligned} p(a_1 = i) &= \prod_{d=1}^{i-1}(1 - p(e_{d,1}))p(e_{i,1}), \\ p(a_j = i | a_{j-1} = k) &= \prod_{d=k}^{i-1}(1 - p(e_{d,j}))p(e_{i,j}), \end{aligned} \tag{9}$$

where $p(e_{i,j})$ denotes the probability of `emit` for the alignment $a_j = i$. This probability is obtained by feeding $[\mathbf{h}_i; \boldsymbol{s}_j]$ into a feed forward neural network,

$$p(e_{i,j}) = \sigma(\text{MLP}(\mathbf{W}_t[\mathbf{h}_i; \mathbf{s}_j] + b_t)). \tag{10}$$

For simplicity, $p(a_j = i | a_{j-1} = k, \mathbf{s}_j, \mathbf{h}_k^i)$ is abbreviated as $p(a_j = i | a_{j-1} = k)$.

3 Training and Decoding

Since there are an exponential number of possible alignments, it is computationally intractable to explicitly calculate every $p(\boldsymbol{y}, \boldsymbol{a}|\boldsymbol{x})$ and then sum them to get the conditional probability $p(\boldsymbol{y}|\boldsymbol{x})$. We instead approach the problem using a dynamic-programming algorithm similar to the forward-backward algorithm for HMMs (Rabiner, 1989).

3.1 Training

For an input $\boldsymbol{x}$ and output $\boldsymbol{y}$, the forward variable $\alpha(i, j) = p(a_j = i, \boldsymbol{y}_1^j | \boldsymbol{x})$. The value of $\alpha(i, j)$ is computed by summing over the probabilities of every path that could lead to this cell. Formally, $\alpha(i, j)$ is defined as follows:

For $i \in [1, I]$:

$$\alpha(i, 1) = p(a_1 = i) p(y_1 | \mathbf{h}_i, \mathbf{s}_1). \tag{11}$$

For $j \in [2, J]$, $i \in [1, I]$:

$$\begin{aligned} \alpha(i, j) = p(y_j | \mathbf{h}_i, \mathbf{s}_j) \cdot \\ \sum_{k=1}^{i} \alpha(k, j-1) p(a_j = i | a_{j-1} = k). \end{aligned} \tag{12}$$

The backward variables, defined as $\beta(i, j) = p(\boldsymbol{y}_{j+1}^J | a_j = i, \boldsymbol{y}_1^j, \boldsymbol{x})$, are computed as:

For $i \in [1, I]$:

$$\beta(i, J) = 1. \tag{13}$$

For $j \in [1, J-1]$, $i \in [1, I]$:

$$\begin{aligned} \beta(i, j) = \sum_{k=i}^{I} p(a_{j+1} = k | a_j = i) \beta(k, j+1) \cdot \\ p(y_{j+1} | \mathbf{h}_k, \mathbf{s}_{j+1}). \end{aligned} \tag{14}$$

During training we estimate the parameters by minimizing the negative log likelihood of the training set S:

$$\begin{aligned} \mathcal{L}(\boldsymbol{\theta}) &= -\sum_{(\boldsymbol{x}, \boldsymbol{y}) \in S} \log p(\boldsymbol{y} | \boldsymbol{x}; \boldsymbol{\theta}) \\ &= -\sum_{(\boldsymbol{x}, \boldsymbol{y}) \in S} \log \sum_{i=1}^{I} \alpha(i, J). \end{aligned} \tag{15}$$

Let $\boldsymbol{\theta_j}$ be the neural network parameters w.r.t. the model output at position j. The gradient is computed as:

$$\frac{\partial \log p(\boldsymbol{y} | \boldsymbol{x}; \boldsymbol{\theta})}{\partial \boldsymbol{\theta}} = \sum_{j=1}^{J} \sum_{i=1}^{I} \frac{\partial \log p(\boldsymbol{y} | \boldsymbol{x}; \boldsymbol{\theta})}{\partial \alpha(i, j)} \frac{\partial \alpha(i, j)}{\partial \boldsymbol{\theta_j}}. \tag{16}$$

The derivative w.r.t. the forward weights is

$$\frac{\partial \log p(\boldsymbol{y}|\boldsymbol{x};\boldsymbol{\theta})}{\partial \alpha(i,j)} = \frac{\beta(i,j)}{p(\boldsymbol{y}|\boldsymbol{x};\boldsymbol{\theta})}. \quad (17)$$

The derivative of the forward weights w.r.t. the model parameters at position j is

$$\frac{\partial \alpha(i,j)}{\partial \boldsymbol{\theta_j}} = \frac{\partial p(y_j|\mathbf{h}_i,\mathbf{s}_j)}{\partial \boldsymbol{\theta_j}} \frac{\alpha(i,j)}{p(y_j|\mathbf{h}_i,\mathbf{s}_j)} + p(y_j|\mathbf{h}_i,\mathbf{s}_j) \sum_{k=1}^{i} \alpha(j-1,k) \frac{\partial}{\partial \boldsymbol{\theta_j}} p(a_j{=}i|a_{j-1}{=}k). \quad (18)$$

For the geometric distribution transition probability model $\frac{\partial}{\partial \boldsymbol{\theta_j}} p(a_j = i|a_{j-1} = k) = 0$.

3.2 Decoding

Algorithm 1 DP search algorithm

Input: source sentence $\boldsymbol{x}$
Output: best output sentence $\boldsymbol{y*}$
Initialization: $Q \in \mathbb{R}^{I \times J_{\text{max}}}$, bp $\in \mathbb{N}^{I \times J_{\text{max}}}$, $W \in \mathbb{N}^{I \times J_{\text{max}}}$, I_{end}, J_{end}.
for $i \in [1, I]$ **do**
  $Q[i,1] \leftarrow \max_{y \in \mathcal{V}} p(a_1 = i) p(y|\mathbf{h}_i, \mathbf{s}_1)$
  $bp[i,1] \leftarrow 0$
  $W[i,1] \leftarrow \arg\max_{y \in \mathcal{V}} p(a_1 = i) p(y|\mathbf{h}_i, \mathbf{s}_1)$
end for
for $j \in [2, J_{\text{max}}]$ **do**
  for $i \in [1, I]$ **do**
    $Q[i,j] \leftarrow \max_{y \in \mathcal{V}, k \in [1,i]} Q[k, j-1] \cdot p(a_j = i|a_{j-1} = k) p(y|\mathbf{h}_i, \mathbf{s}_j)$
    $bp[i,j], W[i,j] \leftarrow \arg\max_{y \in \mathcal{V}, k \in [1,i]} \cdot Q[k, j-1] p(a_j = i|a_{j-1} = k) p(y|\mathbf{h}_i, \mathbf{s}_j)$
  end for
  $I_{\text{end}} \leftarrow \arg\max_i Q[i,j]$
  if $W[I_{\text{end}}, j] = \text{EOS}$ **then**
    $J_{\text{end}} \leftarrow j$
    break
  end if
end for
return a sequence of words stored in W by following backpointers starting from $(I_{\text{end}}, J_{\text{end}})$.

For decoding, we aim to find the best output sequence $\boldsymbol{y}^*$ for a given input sequence $\boldsymbol{x}$:

$$\boldsymbol{y}^* = \arg\max_{\boldsymbol{y}} p(\boldsymbol{y}|\boldsymbol{x}) \quad (19)$$

The search algorithm is based on dynamic programming (Tillmann et al., 1997). The main idea is to create a path probability matrix Q, and fill each cell $Q[i,j]$ by recursively taking the most probable path that could lead to this cell. We present the greedy search algorithm in Algorithm 1. We also implemented a beam search that tracks the k best partial sequences at position (i,j). The notation bp refers to backpointers, W stores words to be predicted, $\mathcal{V}$ denotes the output vocabulary, J_{max} is the maximum length of the output sequences that the model is allowed to predict.

4 Experiments

We evaluate the effectiveness of our model on two representative natural language processing tasks, sentence compression and morphological inflection. The primary aim of this evaluation is to assess whether our proposed architecture is able to outperform the baseline encoder-decoder model by overcoming its encoding bottleneck. We further benchmark our results against an attention model in order to determine whether our alternative alignment strategy is able to provide similar benefits while processing the input online.

4.1 Abstractive Sentence Summarisation

Sentence summarisation is the task of generating a condensed version of a sentence while preserving its meaning. In abstractive sentence summarisation, summaries are generated from the given vocabulary without the constraint of copying words in the input sentence. Rush et al. (2015) compiled a data set for this task from the annotated Gigaword data set (Graff et al., 2003; Napoles et al., 2012), where sentence-summary pairs are obtained by pairing the headline of each article with its first sentence. Rush et al. (2015) use the splits of 3.8m/190k/381k for training, validation and testing. In previous work on this dataset, Rush et al. (2015) proposed an attention-based model with feed-forward neural networks, and Chopra et al. (2016) proposed an attention-based recurrent encoder-decoder, similar to one of our baselines.

Due to computational constraints we place the following restrictions on the training and validation set:

1. The maximum lengths for the input sentences

Model	ROUGE-1	ROUGE-2	ROUGE-L
Seq2seq	25.16	9.09	23.06
Attention	29.25	12.85	27.32
uniSSNT	26.96	10.54	24.59
biSSNT	27.05	10.62	24.64
uniSSNT+	30.15	13.59	27.88
biSSNT+	**30.27**	**13.68**	**27.91**

Table 1: ROUGE F1 scores on the sentence summarisation test set. Seq2seq refers to the vanilla encoder-decoder and attention denotes the attention-based model. SSNT denotes our model with alignment transition probability modelled as geometric distribution. SSNT+ refers to our model with transition probability modelled using neural networks. The prefixes uni- and bi- denote using unidirectional and bidirectional encoder LSTMs, respectively.

Model	Configuration	Perplexity
Seq2seq	$H = 128, L = 1$	48.5
	$H = 256, L = 1$	35.6
	$H = 256, L = 2$	32.1
	$H = 256, L = 3$	31.0
biSSNT+	$H = 128, L = 1$	26.7
	$H = 256, L = 1$	**22.6**

Table 2: Perplexity on the validation set with 172k sentence-summary pairs.

and summaries are 50 and 25, respectively.

2. For each sentence-summary pair, the product of the input and output lengths should be no greater than 500.

We use the filtered 172k pairs for validation and sample 1m pairs for training. While this training set is smaller than that used in previous work (and therefore our results cannot be compared directly against reported results), it serves our purpose for evaluating our algorithm against sequence to sequence and attention-based approaches under identical data conditions. Following from previous work (Rush et al., 2015; Chopra et al., 2016; Gülçehre et al., 2016), we report results on a randomly sampled test set of 2000 sentence-summary pairs. The quality of the generated summaries are evaluated by three versions of ROUGE for different match lengths, namely ROUGE-1 (unigrams), ROUGE-2 (bigrams), and ROUGE-L (longest-common substring).

For training, we use Adam (Kingma and Ba, 2015) for optimization, with an initial learning rate of 0.001. The mini-batch size is set to 32. The number of hidden units H is set to 256 for both our model and the baseline models, and dropout of 0.2 is applied to the input of LSTMs. All hyperparameters were optimised via grid search on the perplexity of the validation set. We use greedy decoding to generate summaries.

Table 1 displays the ROUGE-F1 scores of our models on the test set, together with baseline models, including the attention-based model. Our models achieve significantly better results than the vanilla encoder-decoder and outperform the attention-based model. The fact that SSNT+ performs better is in line with our expectations, as the neural network-parameterised alignment model is more expressive than that modelled by geometric distribution.

To make further comparison, we experimented with different sizes of hidden units and adding more layers to the baseline encoder-decoder. Table 2 lists the configurations of different models and their corresponding perplexities on the validation set. We can see that the vanilla encoder-decoder tends to get better results by adding more hidden units and stacking more layers. This is due to the limitation of compressing information into a fixed-size vector. It has to use larger vectors and deeper structure in order to memorize more information. By contrast, our model can do well with smaller networks. In fact, even with 1 layer and 128 hidden units, our model works much better than the vanilla encoder-decoder with 3 layers and 256 hidden units per layer.

4.2 Morphological Inflection

Morphological inflection generation is the task of predicting the inflected form of a given lexical item based on a morphological attribute. The transformation from a base form to an inflected form usually includes concatenating it with a prefix or a suffix and substituting some characters. For example, the inflected form of a German stem *abgang* is *abgängen* when the case is dative and the number is plural.

In our experiments, we use the same dataset as

Model	Avg. accuracy
Seq2Seq	79.08
Seq2Seq w/ Attention	95.64
Adapted-seq2seq (FTND16)	**96.20**
uniSSNT+	87.85
biSSNT+	95.32

Table 3: Average accuracy over all the morphological inflection datasets. The baseline results for Seq2Seq variants are taken from (Faruqui et al., 2016).

Dataset	DDN13	NCK15	FTND16	biSSNT+
de-N	88.31	**88.60**	88.12	87.50
de-V	94.76	97.50	**97.72**	92.11
es-V	99.61	99.80	**99.81**	99.52
fi-NA	92.14	93.00	95.44	**95.48**
fi-V	97.23	98.10	97.81	**98.10**
fr-V	98.80	**99.20**	98.82	98.65
nl-V	90.50	96.10	96.71	95.90
Avg.	94.47	96.04	**96.20**	95.32

Table 4: Comparison of the performance of our model (biSSNT+) against the previous state-of-the-art on each morphological inflection dataset.

Faruqui et al. (2016). This dataset was originally created by Durrett and DeNero (2013) from Wiktionary, containing inflections for German nouns (de-N), German verbs (de-V), Spanish verbs (es-V), Finnish noun and adjective (fi-NA), and Finnish verbs (fi-V). It was further expanded by Nicolai et al. (2015) by adding Dutch verbs (nl-V) and French verbs (fr-V). The number of inflection types for each language ranges from 8 to 57. The number of base forms, i.e. the number of instances in each dataset, ranges from 2000 to 11200. The predefined split is 200/200 for dev and test sets, and the rest of the data for training.

Our model is trained separately for each type of inflection, the same setting as the factored model described in Faruqui et al. (2016). The model is trained to predict the character sequence of the inflected form given that of the stem. The output is evaluated by accuracies of string matching. For all the experiments on this task we use 128 hidden units for the LSTMs and apply dropout of 0.5 on the input and output of the LSTMs. We use Adam (Kingma and Ba, 2015) for optimisation with initial learning rate of 0.001. During decoding, beam search is employed with beam size of 30.

Table 3 gives the average accuracy of the uniSSNT+, biSSNT+, vanilla encoder-decoder, and attention-based models. The model with the best previous average result — denoted as adapted-seq2seq (FTND16) (Faruqui et al., 2016) — is also included for comparison. Our biSSNT+ model outperforms the vanilla encoder-decoder by a large margin and almost matches the state-of-the-art result on this task. As mentioned earlier, a characteristic of these datasets is that the stems and their corresponding inflected forms mostly overlap. Compare to the vanilla encoder-decoder, our model is better at copying and finding correspondences between prefix, stem and suffix segments.

Table 4 compares the results of biSSNT+ and previous models on each individual dataset. DDN13 and NCK15 denote the models of Durrett and DeNero (2013) and Nicolai et al. (2015), respectively. Both models tackle the task by feature engineering. FTND16 (Faruqui et al., 2016) adapted the vanilla encoder-decoder by feeding the i-th character of the encoded string as an extra input into the i-th position of the decoder. It can be considered as a special case of our model by forcing a fixed diagonal alignment between input and output sequences. Our model achieves comparable results to these models on all the datasets. Notably it outperforms other models on the Finnish noun and adjective, and verbs datasets, whose stems and inflected forms are the longest.

5 Alignment Quality

Figure 3 presents visualisations of segment alignments generated by our model for sample instances from both tasks. We see that the model is able to learn the correct correspondences between segments of the input and output sequences. For instance, the alignment follows a nearly diagonal path for the example in Figure 3c, where the input and output sequences are identical. In Figure 3b, it learns to add the prefix 'ge' at the start of the sequence and replace 'en' with 't' after copying 'zock'. We observe that the model is robust on long phrasal mappings. As

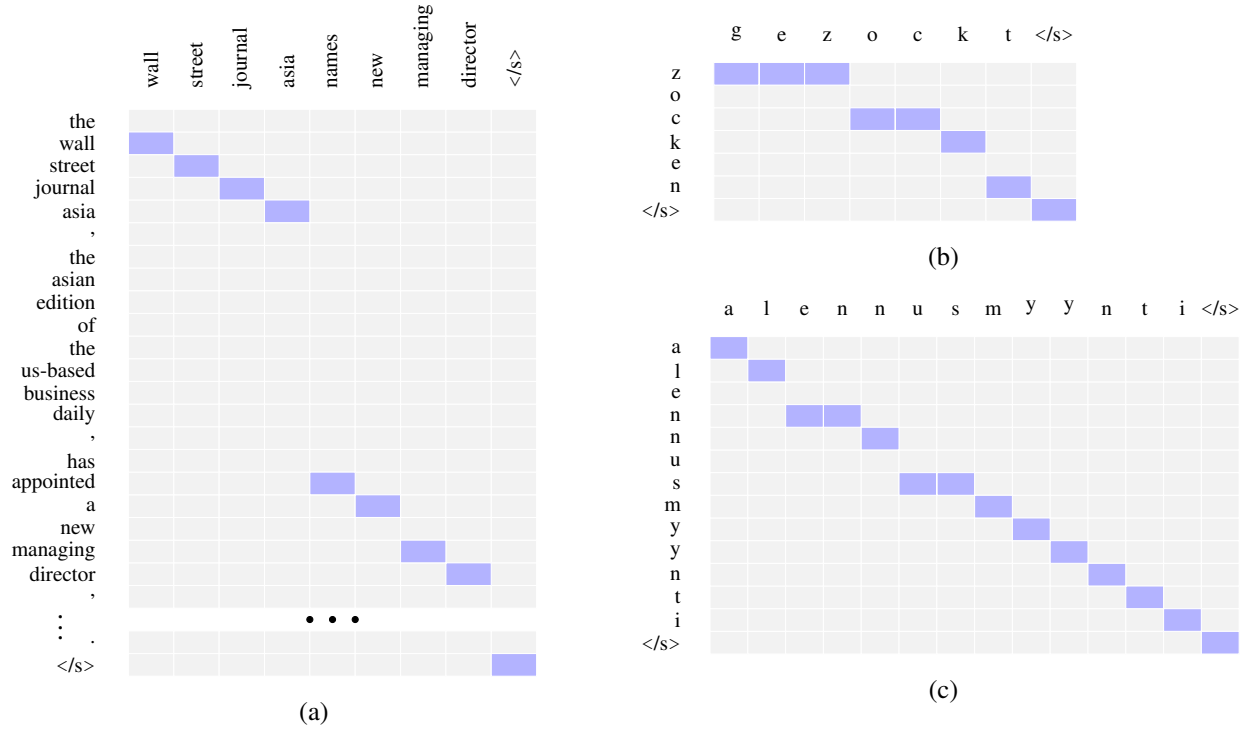

Figure 3: Example alignments found by BiSSNT+. Highlighted grid cells represent the correspondence between the input and output tokens.

shown in Figure 3a, the mapping between 'the wall street journal asia, the asian edition of the us-based business daily' and 'wall street journal asia' demonstrates that our model learns to ignore phrasal modifiers containing additional information. We also find some examples of word reordering, e.g., the phrase 'industrial production in france' is reordered as 'france industrial output' in the model's predicted output.

6 Related Work

Our work is inspired by the seminal HMM alignment model (Vogel et al., 1996; Tillmann et al., 1997) proposed for machine translation. In contrast to that work, when predicting a target word we additionally condition on all previously generated words, which is enabled by the recurrent neural models. This means that the model also functions as a conditional language model. It can therefore be applied directly, while traditional models have to be combined with a language model through a noisy channel in order to be effective. Additionally, instead of EM training on the most likely alignments at each iteration, our model is trained with direct gradient descent, marginalizing over all the alignments.

Latent variables have been employed in neural network-based models for sequence labelling tasks in the past. Examples include connectionist temporal classification (CTC) (Graves et al., 2006) for speech recognition and the more recent segmental recurrent neural networks (SRNNs) (Kong et al., 2016), with applications on handwriting recognition and part-of-speech tagging. Weighted finite-state transducers (WFSTs) have also been augmented to encode input sequences with bidirectional LSTMs (Rastogi et al., 2016), permitting exact inference over all possible output strings. While these models have been shown to achieve appealing performance on different applications, they have common limitations in terms of modelling dependencies between labels. It is not possible for CTCs to model explicit dependencies. SRNNs and neural WFSTs model fixed-length dependencies, making it is difficult to carry out effective inference as the dependencies become longer.

Our model shares the property of the sequence

transduction model of Graves (2012) in being able to model unbounded dependencies between output tokens via an output RNN. This property makes it possible to apply our model to tasks like summarisation and machine translation that require the tokens in the output sequence to be modelled highly dependently. Graves (2012) models the joint distribution over outputs and alignments by inserting null symbols (representing shift operations) into the output sequence. During training the model uses dynamic programming to marginalize over permutations of the null symbols, while beam search is employed during decoding. In contrast our model defines a separate latent alignment variable, which adds flexibility to the way the alignment distribution can be defined (as a geometric distribution or parameterised by a neural network) and how the alignments can be constrained, without redefining the dynamic program. In addition to marginalizing during training, our decoding algorithm also makes use of dynamic programming, allowing us to use either no beam or small beam sizes.

Our work is also related to the attention-based models first introduced for machine translation (Bahdanau et al., 2015). Luong et al. (2015) proposed two alternative attention mechanisms: a global method that attends all words in the input sentence, and a local one that points to parts of the input words. Another variation on this theme are pointer networks (Vinyals et al., 2015), where the outputs are pointers to elements of the variable-length input, predicted by the attention distribution. Jaitly et al. (2016) propose an online sequence to sequence model with attention that conditions on fixed-sized blocks of the input sequence and emits output tokens corresponding to each block. The model is trained with alignment information to generate supervised segmentations.

Although our model shares the same idea of joint training and aligning with the attention-based models, our design has fundamental differences and advantages. While attention-based models treat the attention weights as output of a deterministic function (soft-alignment), in our model the attention weights correspond to a hidden variable, that can be marginalized out using dynamic programming. Further, our model's inherent online nature permits it the flexibility to use its capacity to chose how much input to encode before decoding each segment.

7 Conclusion

We have proposed a novel segment to segment neural transduction model that tackles the limitations of vanilla encoder-decoders that have to read and memorize an entire input sequence in a fixed-length context vector before producing any output. By introducing a latent segmentation that determines correspondences between tokens of the input and output sequences, our model learns to generate and align jointly. During training, the hidden alignment is marginalized out using dynamic programming, and during decoding the best alignment path is generated alongside the predicted output sequence. By employing a unidirectional LSTM as encoder, our model is capable of doing online generation. Experiments on two representative natural language processing tasks, abstractive sentence summarisation and morphological inflection generation, showed that our model significantly outperforms encoder-decoder baselines while requiring much smaller hidden layers. For future work we would like to incorporate attention-based models to our framework to enable such models to process data online.

Abstract

Neural machine translation (NMT) offers a novel alternative formulation of translation that is potentially simpler than statistical approaches. However to reach competitive performance, NMT models need to be exceedingly large. In this paper we consider applying *knowledge distillation* approaches (Bucila et al., 2006; Hinton et al., 2015) that have proven successful for reducing the size of neural models in other domains to the problem of NMT. We demonstrate that standard knowledge distillation applied to word-level prediction can be effective for NMT, and also introduce two novel *sequence-level* versions of knowledge distillation that further improve performance, and somewhat surprisingly, seem to eliminate the need for beam search (even when applied on the original teacher model). Our best student model runs 10 times faster than its state-of-the-art teacher with little loss in performance. It is also significantly better than a baseline model trained without knowledge distillation: by $4.2/1.7$ BLEU with greedy decoding/beam search. Applying weight pruning on top of knowledge distillation results in a student model that has $13\times$ fewer parameters than the original teacher model, with a decrease of 0.4 BLEU.

1 Introduction

Neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015) is a deep learning-based method for translation that has recently shown promising results as an alternative to statistical approaches. NMT systems directly model the probability of the next word in the target sentence simply by conditioning a recurrent neural network on the source sentence and previously generated target words.

While both simple and surprisingly accurate, NMT systems typically need to have very high capacity in order to perform well: Sutskever et al. (2014) used a 4-layer LSTM with 1000 hidden units per layer (herein 4×1000) and Zhou et al. (2016) obtained state-of-the-art results on English $\rightarrow$ French with a 16-layer LSTM with 512 units per layer. The sheer size of the models requires cutting-edge hardware for training and makes using the models on standard setups very challenging.

This issue of excessively large networks has been observed in several other domains, with much focus on fully-connected and convolutional networks for multi-class classification. Researchers have particularly noted that large networks seem to be necessary for training, but learn redundant representations in the process (Denil et al., 2013). Therefore compressing deep models into smaller networks has been an active area of research. As deep learning systems obtain better results on NLP tasks, compression also becomes an important practical issue with applications such as running deep learning models for speech and translation locally on cell phones.

Existing compression methods generally fall into two categories: (1) *pruning* and (2) *knowledge distillation*. *Pruning* methods (LeCun et al., 1990; He et al., 2014; Han et al., 2016), zero-out weights or entire neurons based on an importance criterion: LeCun et al. (1990) use (a diagonal approximation to)

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1317–1327,
Austin, Texas, November 1-5, 2016.

the Hessian to identify weights whose removal minimally impacts the objective function, while Han et al. (2016) remove weights based on thresholding their absolute values. *Knowledge distillation* approaches (Bucila et al., 2006; Ba and Caruana, 2014; Hinton et al., 2015) learn a smaller *student* network to mimic the original *teacher* network by minimizing the loss (typically L_2 or cross-entropy) between the student and teacher output.

In this work, we investigate knowledge distillation in the context of neural machine translation. We note that NMT differs from previous work which has mainly explored non-recurrent models in the multi-class prediction setting. For NMT, while the model is trained on multi-class prediction at the word-level, it is tasked with predicting complete sequence outputs conditioned on previous decisions. With this difference in mind, we experiment with standard knowledge distillation for NMT and also propose two new versions of the approach that attempt to approximately match the sequence-level (as opposed to word-level) distribution of the teacher network. This sequence-level approximation leads to a simple training procedure wherein the student network is trained on a newly generated dataset that is the result of running beam search with the teacher network.

We run experiments to compress a large state-of-the-art 4×1000 LSTM model, and find that with sequence-level knowledge distillation we are able to learn a 2×500 LSTM that roughly matches the performance of the full system. We see similar results compressing a 2×500 model down to 2×100 on a smaller data set. Furthermore, we observe that our proposed approach has other benefits, such as not requiring any beam search at test-time. As a result we are able to perform greedy decoding on the 2×500 model 10 times faster than beam search on the 4×1000 model with comparable performance. Our student models can even be run efficiently on a standard smartphone.[1] Finally, we apply weight pruning on top of the student network to obtain a model that has $13\times$ fewer parameters than the original teacher model. We have released all the code for the models described in this paper.[2]

2 Background

2.1 Sequence-to-Sequence with Attention

Let $\mathbf{s} = [s_1, \ldots, s_I]$ and $\mathbf{t} = [t_1, \ldots, t_J]$ be (random variable sequences representing) the source/target sentence, with I and J respectively being the source/target lengths. Machine translation involves finding the most probable target sentence given the source:

$$\underset{\mathbf{t} \in \mathcal{T}}{\operatorname{argmax}}\, p(\mathbf{t} \mid \mathbf{s})$$

where $\mathcal{T}$ is the set of all possible sequences. NMT models parameterize $p(\mathbf{t} \mid \mathbf{s})$ with an *encoder* neural network which reads the source sentence and a *decoder* neural network which produces a distribution over the target sentence (one word at a time) given the source. We employ the attentional architecture from Luong et al. (2015), which achieved state-of-the-art results on English $\rightarrow$ German translation.[3]

2.2 Knowledge Distillation

Knowledge distillation describes a class of methods for training a smaller *student* network to perform better by learning from a larger *teacher* network (in addition to learning from the training data set). We generally assume that the teacher has previously been trained, and that we are estimating parameters for the student. Knowledge distillation suggests training by matching the student's predictions to the teacher's predictions. For classification this usually means matching the probabilities either via L_2 on the $\log$ scale (Ba and Caruana, 2014) or by cross-entropy (Li et al., 2014; Hinton et al., 2015).

Concretely, assume we are learning a multi-class classifier over a data set of examples of the form (x, y) with possible classes $\mathcal{V}$. The usual training criteria is to minimize NLL for each example from the training data,

$$\mathcal{L}_{\text{NLL}}(\theta) = -\sum_{k=1}^{|\mathcal{V}|} \mathbb{1}\{y = k\} \log p(y = k \mid x; \theta)$$

where $\mathbb{1}\{\cdot\}$ is the indicator function and p the distribution from our model (parameterized by θ).

[3] Specifically, we use the *global-general* attention model with the *input-feeding* approach. We refer the reader to the original paper for further details.

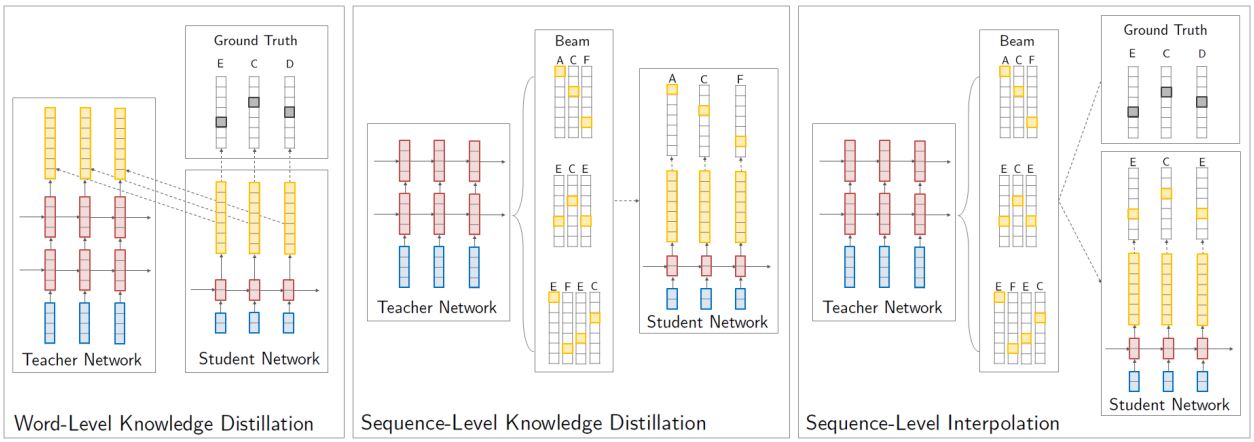

Figure 1: Overview of the different knowledge distillation approaches. In word-level knowledge distillation (left) cross-entropy is minimized between the student/teacher distributions (yellow) for each word in the actual target sequence (ECD), as well as between the student distribution and the degenerate data distribution, which has all of its probabilitiy mass on one word (black). In sequence-level knowledge distillation (center) the student network is trained on the output from beam search of the teacher network that had the highest score (ACF). In sequence-level interpolation (right) the student is trained on the output from beam search of the teacher network that had the highest sim with the target sequence (ECE).

This objective can be seen as minimizing the cross-entropy between the degenerate data distribution (which has all of its probability mass on one class) and the model distribution $p(y \mid x; \theta)$.

In knowledge distillation, we assume access to a learned teacher distribution $q(y \mid x; \theta_T)$, possibly trained over the same data set. Instead of minimizing cross-entropy with the observed data, we instead minimize the cross-entropy with the teacher's probability distribution,

$$\mathcal{L}_{\text{KD}}(\theta; \theta_T) = -\sum_{k=1}^{|\mathcal{V}|} q(y = k \mid x; \theta_T) \times \log p(y = k \mid x; \theta)$$

where θ_T parameterizes the teacher distribution and remains fixed. Note the cross-entropy setup is identical, but the target distribution is no longer a sparse distribution.[4] Training on $q(y \mid x; \theta_T)$ is attractive since it gives more information about other classes for a given data point (e.g. similarity between classes) and has less variance in gradients (Hinton et al., 2015).

[4] In some cases the entropy of the teacher/student distribution is increased by annealing it with a temperature term $\tau > 1$

$$\tilde{p}(y \mid x) \propto p(y \mid x)^{\frac{1}{\tau}}$$

After testing $\tau \in \{1, 1.5, 2\}$ we found that $\tau = 1$ worked best.

Since this new objective has no direct term for the training data, it is common practice to interpolate between the two losses,

$$\mathcal{L}(\theta; \theta_T) = (1 - \alpha)\mathcal{L}_{\text{NLL}}(\theta) + \alpha\mathcal{L}_{\text{KD}}(\theta; \theta_T)$$

where α is mixture parameter combining the one-hot distribution and the teacher distribution.

3 Knowledge Distillation for NMT

The large sizes of neural machine translation systems make them an ideal candidate for knowledge distillation approaches. In this section we explore three different ways this technique can be applied to NMT.

3.1 Word-Level Knowledge Distillation

NMT systems are trained directly to minimize word NLL, $\mathcal{L}_{\text{WORD-NLL}}$, at each position. Therefore if we have a teacher model, standard knowledge distillation for multi-class cross-entropy can be applied. We define this distillation for a sentence as,

$$\mathcal{L}_{\text{WORD-KD}} = -\sum_{j=1}^{J}\sum_{k=1}^{|\mathcal{V}|} q(t_j = k \mid \mathbf{s}, \mathbf{t}_{<j}) \times \log p(t_j = k \mid \mathbf{s}, \mathbf{t}_{<j})$$

where $\mathcal{V}$ is the target vocabulary set. The student can further be trained to optimize the mixture of

$\mathcal{L}_{\text{WORD-KD}}$ and $\mathcal{L}_{\text{WORD-NLL}}$. In the context of NMT, we refer to this approach as *word-level* knowledge distillation and illustrate this in Figure 1 (left).

3.2 Sequence-Level Knowledge Distillation

Word-level knowledge distillation allows transfer of these local word distributions. Ideally however, we would like the student model to mimic the teacher's actions at the *sequence-level*. The sequence distribution is particularly important for NMT, because wrong predictions can propagate forward at test-time.

First, consider the sequence-level distribution specified by the model over all possible sequences $\mathbf{t} \in \mathcal{T}$,

$$p(\mathbf{t} \mid \mathbf{s}) = \prod_{j=1}^{J} p(t_j \mid \mathbf{s}, \mathbf{t}_{<j})$$

for any length J. The sequence-level negative log-likelihood for NMT then involves matching the one-hot distribution over all complete sequences,

$$\begin{aligned}
\mathcal{L}_{\text{SEQ-NLL}} &= -\sum_{\mathbf{t} \in \mathcal{T}} \mathbb{1}\{\mathbf{t} = \mathbf{y}\} \log p(\mathbf{t} \mid \mathbf{s}) \\
&= -\sum_{j=1}^{J} \sum_{k=1}^{|\mathcal{V}|} \mathbb{1}\{y_j = k\} \log p(t_j = k \mid \mathbf{s}, \mathbf{t}_{<j}) \\
&= \mathcal{L}_{\text{WORD-NLL}}
\end{aligned}$$

where $\mathbf{y} = [y_1, \ldots, y_J]$ is the observed sequence. Of course, this just shows that from a negative log likelihood perspective, minimizing word-level NLL and sequence-level NLL are equivalent in this model.

But now consider the case of sequence-level knowledge distillation. As before, we can simply replace the distribution from the data with a probability distribution derived from our teacher model. However, instead of using a single word prediction, we use $q(\mathbf{t} \mid \mathbf{s})$ to represent the teacher's sequence distribution over the sample space of all possible sequences,

$$\mathcal{L}_{\text{SEQ-KD}} = -\sum_{\mathbf{t} \in \mathcal{T}} q(\mathbf{t} \mid \mathbf{s}) \log p(\mathbf{t} \mid \mathbf{s})$$

Note that $\mathcal{L}_{\text{SEQ-KD}}$ is inherently different from $\mathcal{L}_{\text{WORD-KD}}$, as the sum is over an exponential number of terms. Despite its intractability, we posit that this sequence-level objective is worthwhile. It gives the teacher the chance to assign probabilities to complete sequences and therefore transfer a broader range of knowledge. We thus consider an approximation of this objective.

Our simplest approximation is to replace the teacher distribution q with its mode,

$$q(\mathbf{t} \mid \mathbf{s}) \sim \mathbb{1}\{\mathbf{t} = \operatorname*{argmax}_{\mathbf{t} \in \mathcal{T}} q(\mathbf{t} \mid \mathbf{s})\}$$

Observing that finding the mode is itself intractable, we use beam search to find an approximation. The loss is then

$$\begin{aligned}
\mathcal{L}_{\text{SEQ-KD}} &\approx -\sum_{\mathbf{t} \in \mathcal{T}} \mathbb{1}\{\mathbf{t} = \hat{\mathbf{y}}\} \log p(\mathbf{t} \mid \mathbf{s}) \\
&= -\log p(\mathbf{t} = \hat{\mathbf{y}} \mid \mathbf{s})
\end{aligned}$$

where $\hat{\mathbf{y}}$ is now the output from running beam search with the teacher model.

Using the mode seems like a poor approximation for the teacher distribution $q(\mathbf{t} \mid \mathbf{s})$, as we are approximating an exponentially-sized distribution with a single sample. However, previous results showing the effectiveness of beam search decoding for NMT lead us to belief that a large portion of q's mass lies in a single output sequence. In fact, in experiments we find that with beam of size 1, $q(\hat{\mathbf{y}} \mid \mathbf{s})$ (on average) accounts for 1.3% of the distribution for German $\rightarrow$ English, and 2.3% for Thai $\rightarrow$ English (Table 1: $p(\mathbf{t} = \hat{\mathbf{y}})$).[5]

To summarize, sequence-level knowledge distillation suggests to: (1) train a teacher model, (2) run beam search over the training set with this model, (3) train the student network with cross-entropy on this new dataset. Step (3) is identical to the word-level NLL process except now on the newly-generated data set. This is shown in Figure 1 (center).

[5] Additionally there are simple ways to better approximate $q(\mathbf{t} \mid \mathbf{s})$. One way would be to consider a K-best list from beam search and renormalizing the probabilities,

$$q(\mathbf{t} \mid \mathbf{s}) \sim \frac{q(\mathbf{t} \mid \mathbf{s})}{\sum_{\mathbf{t} \in \mathcal{T}_K} q(\mathbf{t} \mid \mathbf{s})}$$

where $\mathcal{T}_K$ is the K-best list from beam search. This would increase the training set by a factor of K. A beam of size 5 captures 2.8% of the distribution for German $\rightarrow$ English, and 3.8% for Thai $\rightarrow$ English. Another alternative is to use a Monte Carlo estimate and sample from the teacher model (since $\mathcal{L}_{\text{SEQ-KD}} = \mathbb{E}_{\mathbf{t} \sim q(\mathbf{t} \mid \mathbf{s})}[-\log p(\mathbf{t} \mid \mathbf{s})]$). However in practice we found the (approximate) mode to work well.

3.3 Sequence-Level Interpolation

Next we consider integrating the training data back into the process, such that we train the student model as a mixture of our sequence-level teacher-generated data ($\mathcal{L}_{\text{SEQ-KD}}$) with the original training data ($\mathcal{L}_{\text{SEQ-NLL}}$),

$$\begin{aligned}\mathcal{L} &= (1-\alpha)\mathcal{L}_{\text{SEQ-NLL}} + \alpha\mathcal{L}_{\text{SEQ-KD}} \\ &= -(1-\alpha)\log p(\mathbf{y}\,|\,\mathbf{s}) - \alpha\sum_{\mathbf{t}\in\mathcal{T}} q(\mathbf{t}\,|\,\mathbf{s})\log p(\mathbf{t}\,|\,\mathbf{s})\end{aligned}$$

where $\mathbf{y}$ is the gold target sequence.

Since the second term is intractable, we could again apply the mode approximation from the previous section,

$$\mathcal{L} = -(1-\alpha)\log p(\mathbf{y}\,|\,\mathbf{s}) - \alpha\log p(\hat{\mathbf{y}}\,|\,\mathbf{s})$$

and train on both observed ($\mathbf{y}$) and teacher-generated ($\hat{\mathbf{y}}$) data. However, this process is non-ideal for two reasons: (1) unlike for standard knowledge distribution, it doubles the size of the training data, and (2) it requires training on both the teacher-generated sequence and the true sequence, conditioned on the same source input. The latter concern is particularly problematic since we observe that $\mathbf{y}$ and $\hat{\mathbf{y}}$ are often quite different.

As an alternative, we propose a single-sequence approximation that is more attractive in this setting. This approach is inspired by *local updating* (Liang et al., 2006), a method for discriminative training in statistical machine translation (although to our knowledge not for knowledge distillation). Local updating suggests selecting a training sequence which is close to $\mathbf{y}$ *and* has high probability under the teacher model,

$$\tilde{\mathbf{y}} = \underset{\mathbf{t}\in\mathcal{T}}{\operatorname{argmax}}\, sim(\mathbf{t},\mathbf{y})q(\mathbf{t}\,|\,\mathbf{s})$$

where sim is a function measuring closeness (e.g. Jaccard similarity or BLEU (Papineni et al., 2002)). Following local updating, we can approximate this sequence by running beam search and choosing

$$\tilde{\mathbf{y}} \approx \underset{\mathbf{t}\in\mathcal{T}_K}{\operatorname{argmax}}\, sim(\mathbf{t},\mathbf{y})$$

where $\mathcal{T}_K$ is the K-best list from beam search. We take sim to be smoothed sentence-level BLEU (Chen and Cherry, 2014).

We justify training on $\tilde{\mathbf{y}}$ from a knowledge distillation perspective with the following generative process: suppose that there is a true target sequence (which we do not observe) that is first generated from the underlying data distribution $\mathcal{D}$. And further suppose that the target sequence that we observe ($\mathbf{y}$) is a noisy version of the unobserved true sequence: i.e. (i) $\mathbf{t} \sim \mathcal{D}$, (ii) $\mathbf{y} \sim \epsilon(\mathbf{t})$, where $\epsilon(\mathbf{t})$ is, for example, a noise function that independently replaces each element in $\mathbf{t}$ with a random element in $\mathcal{V}$ with some small probability.[6] In such a case, ideally the student's distribution should match the mixture distribution,

$$\mathcal{D}_{\text{SEQ-Inter}} \sim (1-\alpha)\mathcal{D} + \alpha q(\mathbf{t}\,|\,\mathbf{s})$$

In this setting, due to the noise assumption, $\mathcal{D}$ now has significant probability mass around a neighborhood of $\mathbf{y}$ (not just at $\mathbf{y}$), and therefore the argmax of the mixture distribution is likely something other than $\mathbf{y}$ (the observed sequence) or $\hat{\mathbf{y}}$ (the output from beam search). We can see that $\tilde{\mathbf{y}}$ is a natural approximation to the argmax of this mixture distribution between $\mathcal{D}$ and $q(\mathbf{t}\,|\,\mathbf{s})$ for some α. We illustrate this framework in Figure 1 (right) and visualize the distribution over a real example in Figure 2.

4 Experimental Setup

To test out these approaches, we conduct two sets of NMT experiments: high resource (English $\rightarrow$ German) and low resource (Thai $\rightarrow$ English).

The **English-German** data comes from WMT 2014.[7] The training set has 4m sentences and we take newstest2012/newstest2013 as the dev set and newstest2014 as the test set. We keep the top 50k most frequent words, and replace the rest with UNK. The teacher model is a 4×1000 LSTM (as in Luong et al. (2015)) and we train two student models: 2×300 and 2×500. The **Thai-English** data comes from IWSLT 2015.[8] There are 90k sentences in the

[6] While we employ a simple (unrealistic) noise function for illustrative purposes, the generative story is quite plausible if we consider a more elaborate noise function which includes additional sources of noise such as phrase reordering, replacement of words with synonyms, etc. One could view translation having two sources of variance that should be modeled separately: variance due to the source sentence ($\mathbf{t} \sim \mathcal{D}$), and variance due to the individual translator ($\mathbf{y} \sim \epsilon(\mathbf{t})$).

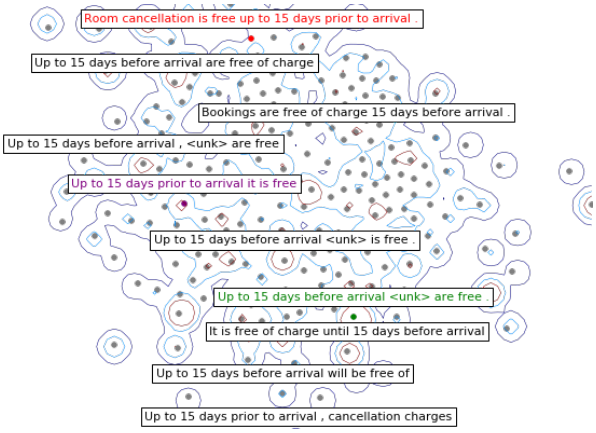

Figure 2: Visualization of sequence-level interpolation on an example German → English sentence: Bis 15 Tage vor Anreise sind Zimmer-Annullationen kostenlos. We run beam search, plot the final hidden state of the hypotheses using t-SNE and show the corresponding (smoothed) probabilities with contours. In the above example, the sentence that is at the top of the beam after beam search (green) is quite far away from gold (red), so we train the model on a sentence that is on the beam but had the highest sim (e.g. BLEU) to gold (purple).

training set and we take 2010/2011/2012 data as the dev set and 2012/2013 as the test set, with a vocabulary size is 25k. Size of the teacher model is 2×500 (which performed better than 4×1000, 2×750 models), and the student model is 2×100. Other training details mirror Luong et al. (2015).

We evaluate on tokenized BLEU with `multi-bleu.perl`, and experiment with the following variations:

Word-Level Knowledge Distillation (Word-KD) Student is trained on the original data and additionally trained to minimize the cross-entropy of the teacher distribution at the word-level. We tested $\alpha \in \{0.5, 0.9\}$ and found $\alpha = 0.5$ to work better.

Sequence-Level Knowledge Distillation (Seq-KD) Student is trained on the teacher-generated data, which is the result of running beam search and taking the highest-scoring sequence with the teacher model. We use beam size $K = 5$ (we did not see improvements with a larger beam).

Sequence-Level Interpolation (Seq-Inter) Student is trained on the sequence on the teacher's beam that had the highest BLEU (beam size $K = 35$). We adopt a fine-tuning approach where we begin training from a pretrained model (either on original data or Seq-KD data) and train with a smaller learning rate (0.1). For English-German we generate Seq-Inter data on a smaller portion of the training set ($\sim 50\%$) for efficiency.

The above methods are complementary and can be combined with each other. For example, we can train on teacher-generated data but still include a word-level cross-entropy term between the teacher/student (Seq-KD + Word-KD in Table 1), or fine-tune towards Seq-Inter data starting from the baseline model trained on original data (Baseline + Seq-Inter in Table 1).[9]

5 Results and Discussion

Results of our experiments are shown in Table 1. We find that while word-level knowledge distillation (Word-KD) does improve upon the baseline, sequence-level knowledge distillation (Seq-KD) does better on English → German and performs similarly on Thai → English. Combining them (Seq-KD + Word-KD) results in further gains for the 2×300 and 2×100 models (although not for the 2×500 model), indicating that these methods provide orthogonal means of transferring knowledge from the teacher to the student: Word-KD is transferring knowledge at the the local (i.e. word) level while Seq-KD is transferring knowledge at the global (i.e. sequence) level.

Sequence-level interpolation (Seq-Inter), in addition to improving models trained via Word-KD and Seq-KD, also improves upon the original teacher model that was trained on the actual data but fine-tuned towards Seq-Inter data (Baseline + Seq-Inter). In fact, greedy decoding with this fine-tuned model has similar performance (19.6) as beam search with the original model (19.5), allowing for faster decoding even with an identically-sized model.

We hypothesize that sequence-level knowledge distillation is effective because it allows the student network to only model relevant parts of the teacher distribution (i.e. around the teacher's mode) instead of 'wasting' parameters on trying to model the entire

[9]For instance, 'Seq-KD + Seq-Inter + Word-KD' in Table 1 means that the model was trained on Seq-KD data and fine-tuned towards Seq-Inter data with the mixture cross-entropy loss at the word-level.

Table 1: Results on English-German (newstest2014) and Thai-English (2012/2013) test sets. $\text{BLEU}_{K=1}$: BLEU score with beam size $K = 1$ (i.e. greedy decoding); $\Delta_{K=1}$: BLEU gain over the baseline model without any knowledge distillation with greedy decoding; $\text{BLEU}_{K=5}$: BLEU score with beam size $K = 5$; $\Delta_{K=5}$: BLEU gain over the baseline model without any knowledge distillation with beam size $K = 5$; PPL: perplexity on the test set; $p(\mathbf{t} = \hat{\mathbf{y}})$: Probability of output sequence from greedy decoding (averaged over the test set). Params: number of parameters in the model. Best results (as measured by improvement over the baseline) within each category are highlighted in bold.

space of translations. Our results suggest that this is indeed the case: the probability mass that Seq-KD models assign to the approximate mode is much higher than is the case for baseline models trained on original data (Table 1: $p(\mathbf{t} = \hat{\mathbf{y}})$). For example, on English → German the (approximate) argmax for the 2×500 Seq-KD model (on average) accounts for 16.9% of the total probability mass, while the corresponding number is 0.9% for the baseline. This also explains the success of greedy decoding for Seq-KD models—since we are only modeling around the teacher's mode, the student's distribution is more peaked and therefore the argmax is much easier to find. Seq-Inter offers a compromise between the two, with the greedily-decoded sequence accounting for 7.6% of the distribution.

Finally, although past work has shown that models with lower perplexity generally tend to have

Model Size	GPU	CPU	Android
Beam = 1 (Greedy)

2×500	85%	13 m	18.8	$18\times$
2×500	90%	8 m	18.5	$26\times$

Table 3: Performance of student models with varying % of the weights pruned. Top two rows are models without any pruning. Params: number of parameters in the model; Prune %: Percentage of weights pruned based on their absolute values; BLEU: BLEU score with beam search decoding ($K = 5$) after retraining the pruned model; Ratio: Ratio of the number of parameters versus the original teacher model (which has 221m parameters).

higher BLEU, our results indicate that this is not necessarily the case. The perplexity of the baseline 2×500 English $\rightarrow$ German model is 8.2 while the perplexity of the corresponding Seq-KD model is 22.7, despite the fact that Seq-KD model does significantly better for both greedy (+4.2 BLEU) and beam search (+1.4 BLEU) decoding.

5.1 Decoding Speed

Run-time complexity for beam search grows linearly with beam size. Therefore, the fact that sequence-level knowledge distillation allows for greedy decoding is significant, with practical implications for running NMT systems across various devices. To test the speed gains, we run the teacher/student models on GPU, CPU, and smartphone, and check the average number of source words translated per second (Table 2). We use a GeForce GTX Titan X for GPU and a Samsung Galaxy 6 smartphone. We find that we can run the student model 10 times faster with greedy decoding than the teacher model with beam search on GPU (1051.3 vs 101.9 words/sec), with similar performance.

5.2 Weight Pruning

Although knowledge distillation enables training faster models, the number of parameters for the student models is still somewhat large (Table 1: Params), due to the word embeddings which dominate most of the parameters.[10] For example, on the 2×500 English $\rightarrow$ German model the word embeddings account for approximately 63% (50m out of 84m) of the parameters. The size of word embeddings have little impact on run-time as the word embedding layer is a simple lookup table that only affects the first layer of the model.

We therefore focus next on reducing the memory footprint of the student models further through weight pruning. Weight pruning for NMT was recently investigated by See et al. (2016), who found that up to $80 - 90\%$ of the parameters in a large NMT model can be pruned with little loss in performance. We take our best English $\rightarrow$ German student model (2×500 Seq-KD + Seq-Inter) and prune $x\%$ of the parameters by removing the weights with the lowest absolute values. We then retrain the pruned model on Seq-KD data with a learning rate of 0.2 and fine-tune towards Seq-Inter data with a learning rate of 0.1. As observed by See et al. (2016), retraining proved to be crucial. The results are shown in Table 3.

Our findings suggest that compression benefits achieved through weight pruning and knowledge distillation are orthogonal.[11] Pruning 80% of the weight in the 2×500 student model results in a model with $13\times$ fewer parameters than the original teacher model with only a decrease of 0.4 BLEU. While pruning 90% of the weights results in a more appreciable decrease of 1.0 BLEU, the model is

[10] Word embeddings scale linearly while RNN parameters scale quadratically with the dimension size.

[11] To our knowledge combining pruning and knowledge distillation has not been investigated before.

drastically smaller with 8m parameters, which is $26\times$ fewer than the original teacher model.

5.3 Further Observations

- For models trained with word-level knowledge distillation, we also tried regressing the student network's top-most hidden layer at each time step to the teacher network's top-most hidden layer as a pretraining step, noting that Romero et al. (2015) obtained improvements with a similar technique on feed-forward models. We found this to give comparable results to standard knowledge distillation and hence did not pursue this further.

- There have been promising recent results on eliminating word embeddings completely and obtaining word representations directly from characters with character composition models, which have many fewer parameters than word embedding lookup tables (Ling et al., 2015a; Kim et al., 2016; Ling et al., 2015b; Jozefowicz et al., 2016; Costa-Jussa and Fonollosa, 2016). Combining such methods with knowledge distillation/pruning to further reduce the memory footprint of NMT systems remains an avenue for future work.

6 Related Work

Compressing deep learning models is an active area of current research. *Pruning* methods involve pruning weights or entire neurons/nodes based on some criterion. LeCun et al. (1990) prune weights based on an approximation of the Hessian, while Han et al. (2016) show that a simple magnitude-based pruning works well. Prior work on removing neurons/nodes include Srinivas and Babu (2015) and Mariet and Sra (2016). See et al. (2016) were the first to apply pruning to Neural Machine Translation, observing that that different parts of the architecture (input word embeddings, LSTM matrices, etc.) admit different levels of pruning. *Knowledge distillation* approaches train a smaller student model to mimic a larger teacher model, by minimizing the loss between the teacher/student predictions (Bucila et al., 2006; Ba and Caruana, 2014; Li et al., 2014; Hinton et al., 2015). Romero et al. (2015) additionally regress on the intermediate hidden layers of the student/teacher network as a pretraining step, while Mou et al. (2015) obtain smaller word embeddings from a teacher model via regression. There has also been work on transferring knowledge across different network architectures: Chan et al. (2015b) show that a deep non-recurrent neural network can learn from an RNN; Geras et al. (2016) train a CNN to mimic an LSTM for speech recognition. Kuncoro et al. (2016) recently investigated knowledge distillation for structured prediction by having a single parser learn from an ensemble of parsers.

Other approaches for compression involve low rank factorizations of weight matrices (Denton et al., 2014; Jaderberg et al., 2014; Lu et al., 2016; Prabhavalkar et al., 2016), sparsity-inducing regularizers (Murray and Chiang, 2015), binarization of weights (Courbariaux et al., 2016; Lin et al., 2016), and weight sharing (Chen et al., 2015; Han et al., 2016). Finally, although we have motivated sequence-level knowledge distillation in the context of training a smaller model, there are other techniques that train on a mixture of the model's predictions and the data, such as local updating (Liang et al., 2006), hope/fear training (Chiang, 2012), SEARN (Daumé III et al., 2009), DAgger (Ross et al., 2011), and minimum risk training (Och, 2003; Shen et al., 2016).

7 Conclusion

In this work we have investigated existing knowledge distillation methods for NMT (which work at the word-level) and introduced two *sequence-level* variants of knowledge distillation, which provide improvements over standard word-level knowledge distillation.

We have chosen to focus on translation as this domain has generally required the largest capacity deep learning models, but the sequence-to-sequence framework has been successfully applied to a wide range of tasks including parsing (Vinyals et al., 2015a), summarization (Rush et al., 2015), dialogue (Vinyals and Le, 2015; Serban et al., 2016; Li et al., 2016), NER/POS-tagging (Gillick et al., 2016), image captioning (Vinyals et al., 2015b; Xu et al., 2015), video generation (Srivastava et al., 2015), and speech recognition (Chan et al., 2015a). We anticipate that methods described in this paper can be used to similarly train smaller models in other domains.

Abstract

Neural encoder-decoder models have shown great success in many sequence generation tasks. However, previous work has not investigated situations in which we would like to control the length of encoder-decoder outputs. This capability is crucial for applications such as text summarization, in which we have to generate concise summaries with a desired length. In this paper, we propose methods for controlling the output sequence length for neural encoder-decoder models: two decoding-based methods and two learning-based methods.[1] Results show that our learning-based methods have the capability to control length without degrading summary quality in a summarization task.

1 Introduction

Since its first use for machine translation (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014), the encoder-decoder approach has demonstrated great success in many other sequence generation tasks including image caption generation (Vinyals et al., 2015b; Xu et al., 2015), parsing (Vinyals et al., 2015a), dialogue response generation (Li et al., 2016a; Serban et al., 2016) and sentence summarization (Rush et al., 2015; Chopra et al., 2016). In particular, in this paper we focus on sentence summarization, which as its name suggests, consists of generating shorter versions of sentences for applications such as document summarization (Nenkova and McKeown, 2011) or headline generation (Dorr et al., 2003). Recently, Rush et al. (2015) automatically constructed large training data for sentence summarization, and this has led to the rapid development of neural sentence summarization (NSS) or neural headline generation (NHG) models. There are already many studies that address this task (Nallapati et al., 2016; Ayana et al., 2016; Ranzato et al., 2015; Lopyrev, 2015; Gulcehre et al., 2016; Gu et al., 2016; Chopra et al., 2016).

One of the essential properties that text summarization systems should have is the ability to generate a summary with the desired length. Desired lengths of summaries strongly depends on the scene of use, such as the granularity of information the user wants to understand, or the monitor size of the device the user has. The length also depends on the amount of information contained in the given source document. Hence, in the traditional setting of text summarization, both the source document and the desired length of the summary will be given as input to a summarization system. However, methods for controlling the output sequence length of encoder-decoder models have not been investigated yet, despite their importance in these settings.

In this paper, we propose and investigate four methods for controlling the output sequence length for neural encoder-decoder models. The former two methods are decoding-based; they receive the desired length during the decoding process, and the training process is the same as standard encoder-decoder models. The latter two methods are

Austin, Texas, November 1-5, 2016.

learning-based; we modify the network architecture to receive the desired length as input.

In experiments, we show that the learning-based methods outperform the decoding-based methods for long (such as 50 or 75 byte) summaries. We also find that despite this additional length-control capability, the proposed methods remain competitive to existing methods on standard settings of the DUC2004 shared task-1.

2 Background

2.1 Related Work

Text summarization is one of the oldest fields of study in natural language processing, and many summarization methods have focused specifically on sentence compression or headline generation. Traditional approaches to this task focus on word deletion using rule-based (Dorr et al., 2003; Zajic et al., 2004) or statistical (Woodsend et al., 2010; Galanis and Androutsopoulos, 2010; Filippova and Strube, 2008; Filippova and Altun, 2013; Filippova et al., 2015) methods. There are also several studies of abstractive sentence summarization using syntactic transduction (Cohn and Lapata, 2008; Napoles et al., 2011) or taking a phrase-based statistical machine translation approach (Banko et al., 2000; Wubben et al., 2012; Cohn and Lapata, 2013).

Recent work has adopted techniques such as encoder-decoder (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014) and attentional (Bahdanau et al., 2015; Luong et al., 2015) neural network models from the field of machine translation, and tailored them to the sentence summarization task. Rush et al. (2015) were the first to pose sentence summarization as a new target task for neural sequence-to-sequence learning. Several studies have used this task as one of the benchmarks of their neural sequence transduction methods (Ranzato et al., 2015; Lopyrev, 2015; Ayana et al., 2016). Some studies address the other important phenomena frequently occurred in human-written summaries, such as copying from the source document (Gu et al., 2016; Gulcehre et al., 2016). Nallapati et al. (2016) investigate a way to solve many important problems capturing keywords, or inputting multiple sentences.

Neural encoder-decoders can also be viewed as statistical language models conditioned on the target sentence context. Rosenfeld et al. (2001) have proposed whole-sentence language models that can consider features such as sentence length. However, as described in the introduction, to our knowledge, explicitly controlling length of output sequences in neural language models or encoder-decoders has not been investigated.

Finally, there are some studies to modify the output sequence according some meta information such as the dialogue act (Wen et al., 2015), user personality (Li et al., 2016b), or politeness (Sennrich et al., 2016). However, these studies have not focused on length, the topic of this paper.

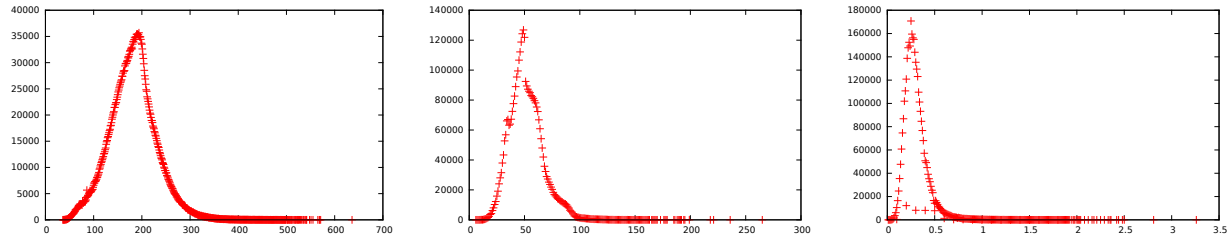
2.2 Importance of Controlling Output Length

As we already mentioned in Section 1, the most standard setting in text summarization is to input both the source document and the desired length of the summary to a summarization system. Summarization systems thus must be able to generate summaries of various lengths. Obviously, this property is also essential for summarization methods based on neural encoder-decoder models.

Since an encoder-decoder model is a completely data-driven approach, the output sequence length depends on the training data that the model is trained on. For example, we use sentence-summary pairs extracted from the Annotated English Gigaword corpus as training data (Rush et al., 2015), and the average length of human-written summary is 51.38 bytes. Figure 1 shows the statistics of the corpus. When we train a standard encoder-decoder model and perform the standard beam search decoding on the corpus, the average length of its output sequence is 38.02 byte.

However, there are other situations where we want summaries with other lengths. For example, DUC2004 is a shared task where the maximum length of summaries is set to 75 bytes, and summarization systems would benefit from generating sentences up to this length limit.

While recent NSS models themselves cannot control their output length, Rush et al. (2015) and others following use an ad-hoc method, in which the system is inhibited from generating the end-of-sentence (EOS) tag by assigning a score of $-\infty$ to the tag and



(a) first sentence (181.87) **(b)** article headline (51.38) **(c)** ratio (0.30)

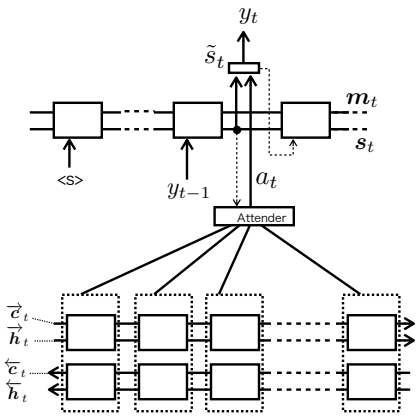

Figure 2: The encoder-decoder architecture we used as a base model in this paper.

generating a fixed number of words[2], and finally the output summaries are truncated to 75 bytes. Ideally, the models should be able to change the output sequence depending on the given output length, and to output the EOS tag at the appropriate time point in a natural manner.

3 Network Architecture: Encoder-Decoder with Attention

In this section, we describe the model architecture used for our experiments: an encoder-decoder consisting of bi-directional RNNs and an attention mechanism. Figure 2 shows the architecture of the model.

Suppose that the source sentence is represented as a sequence of words $\boldsymbol{x} = (x_1, x_2, x_3, ..., x_N)$. For a given source sentence, the summarizer generates a shortened version of the input (i.e. $N > M$), as summary sentence $\boldsymbol{y} = (y_1, y_2, y_3, ..., y_M)$. The model estimates conditional probability $p(\boldsymbol{y}|\boldsymbol{x})$ using parameters trained on large training data consisting of sentence-summary pairs. Typically, this conditional probability is factorized as the product of conditional probabilities of the next word in the sequence:

$$p(\boldsymbol{y}|\boldsymbol{x}) = \prod_{t=1}^{M} p(y_t|\boldsymbol{y}_{<t}, \boldsymbol{x}),$$

where $\boldsymbol{y}_{<t} = (y_1, y_2, y_3, ..., y_{t-1})$. In the following, we describe how to compute $p(y_t|\boldsymbol{y}_{<t}, \boldsymbol{x})$.

3.1 Encoder

We use the bi-directional RNN (BiRNN) as encoder which has been shown effective in neural machine translation (Bahdanau et al., 2015) and speech recognition (Schuster and Paliwal, 1997; Graves et al., 2013).

A BiRNN processes the source sentence for both forward and backward directions with two separate RNNs. During the encoding process, the BiRNN computes both forward hidden states $(\overrightarrow{\boldsymbol{h}}_1, \overrightarrow{\boldsymbol{h}}_2, ..., \overrightarrow{\boldsymbol{h}}_N)$ and backward hidden states $(\overleftarrow{\boldsymbol{h}}_1, \overleftarrow{\boldsymbol{h}}_2, ..., \overleftarrow{\boldsymbol{h}}_N)$ as follows:

$$\overrightarrow{\boldsymbol{h}}_t = g(\overrightarrow{\boldsymbol{h}}_{t-1}, x_t),$$
$$\overleftarrow{\boldsymbol{h}}_t = g(\overleftarrow{\boldsymbol{h}}_{t+1}, x_t).$$

While g can be any kind of recurrent unit, we use long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) networks that have memory cells for both directions ($\overrightarrow{\boldsymbol{c}}_t$ and $\overleftarrow{\boldsymbol{c}}_t$).

[2] According to the published code (https://github.com/facebook/NAMAS), the default number of words is set to 15, which is too long for the DUC2004 setting. The average number of words of human summaries in the evaluation set is 10.43.

After encoding, we set the initial hidden states $\boldsymbol{s}_0$ and memory-cell $\boldsymbol{m}_0$ of the decoder as follows:

$$\begin{aligned} \boldsymbol{s}_0 &= \overleftarrow{\boldsymbol{h}}_1, \\ \boldsymbol{m}_0 &= \overleftarrow{\boldsymbol{c}}_1. \end{aligned}$$

3.2 Decoder and Attender

Our decoder is based on an RNN with LSTM g:

$$\boldsymbol{s}_t = g(\boldsymbol{s}_{t-1}, x_t).$$

We also use the attention mechanism developed by Luong et al. (2015), which uses $\boldsymbol{s}_t$ to compute contextual information $\boldsymbol{d}_t$ of time step t. We first summarize the forward and backward encoder states by taking their sum $\bar{\boldsymbol{h}}_i = \overrightarrow{\boldsymbol{h}}_i + \overleftarrow{\boldsymbol{h}}_i$, and then calculate the context vector $\boldsymbol{d}_t$ as the weighted sum of these summarized vectors:

$$\boldsymbol{d}_t = \sum_i \boldsymbol{a}_{ti} \bar{\boldsymbol{h}}_i,$$

where $\boldsymbol{a}_t$ is the weight at the t-th step for $\bar{\boldsymbol{h}}_i$ computed by a softmax operation:

$$a_{ti} = \frac{\exp(\boldsymbol{s}_t \cdot \bar{\boldsymbol{h}}_i)}{\sum_{\bar{\boldsymbol{h}}'} \exp(\boldsymbol{s}_t \cdot \bar{\boldsymbol{h}}')}.$$

After context vector $\boldsymbol{d}_t$ is calculated, the model updates the distribution over the next word as follows:

$$\begin{aligned} \tilde{\boldsymbol{s}}_t &= \tanh(W_{hs}[\boldsymbol{s}_t; \boldsymbol{d}_t] + \boldsymbol{b}_{hs}), \\ p(y_t | \boldsymbol{y}_{<t}, \boldsymbol{x}) &= \text{softmax}(W_{so}\tilde{\boldsymbol{s}}_t + \boldsymbol{b}_{so}). \end{aligned}$$

Note that $\tilde{\boldsymbol{s}}_t$ is also provided as input to the LSTM with y_t for the next step, which is called the *input feeding* architecture (Luong et al., 2015).

3.3 Training and Decoding

The training objective of our models is to maximize log likelihood of the sentence-summary pairs in a given training set D:

$$\begin{aligned} L_t(\theta) &= \sum_{(\boldsymbol{x},\boldsymbol{y}) \in D} \log p(\boldsymbol{y}|\boldsymbol{x}; \theta), \\ p(\boldsymbol{y}|\boldsymbol{x}; \theta) &= \prod_t p(y_t | \boldsymbol{y}_{<t}, \boldsymbol{x}). \end{aligned}$$

Once models are trained, we use beam search to find the output that maximizes the conditional probability.

4 Controlling Length in Encoder-decoders

In this section, we propose our four methods that can control the length of the output in the encoder-decoder framework. In the first two methods, the decoding process is used to control the output length without changing the model itself. In the other two methods, the model itself has been changed and is trained to obtain the capability of controlling the length. Following the evaluation dataset used in our experiments, we use bytes as the unit of length, although our models can use either words or bytes as necessary.

4.1 $fixLen$: Beam Search without EOS Tags

The first method we examine is a decoding approach similar to the one taken in many recent NSS methods that is slightly less ad-hoc. In this method, we inhibit the decoder from generating the EOS tag by assigning it a score of $-\infty$. Since the model cannot stop the decoding process by itself, we simply stop the decoding process when the length of output sequence reaches the desired length. More specifically, during beam search, when the length of the sequence generated so far exceeds the desired length, the last word is replaced with the EOS tag and also the score of the last word is replaced with the score of the EOS tag (*EOS replacement*).

4.2 $fixRng$: Discarding Out-of-range Sequences

Our second decoding method is based on discarding out-of-range sequences, and is not inhibited from generating the EOS tag, allowing it to decide when to stop generation. Instead, we define the legitimate range of the sequence by setting minimum and maximum lengths. Specifically, in addition to the normal beam search procedure, we set two rules:

- If the model generates the EOS tag when the output sequence is shorter than the minimum length, we discard the sequence from the beam.
- If the generated sequence exceeds the maximum length, we also discard the sequence from the beam. We then replace its last word with the EOS tag and add this sequence to the beam

(EOS replacement in Section 4.1).[3]

In other words, we keep only the sequences that contain the EOS tag and are in the defined length range. This method is a compromise that allows the model some flexibility to plan the generated sequences, but only within a certain acceptable length range.

It should be noted that this method needs a larger beam size if the desired length is very different from the average summary length in the training data, as it will need to preserve hypotheses that have the desired length.

4.3 *LenEmb*: Length Embedding as Additional Input for the LSTM

Our third method is a learning-based method specifically trained to control the length of the output sequence. Inspired by previous work that has demonstrated that additional inputs to decoder models can effectively control the characteristics of the output (Wen et al., 2015; Li et al., 2016b), this model provides information about the length in the form of an additional input to the net. Specifically, the model uses an embedding $e_2(l_t) \in \mathbb{R}^D$ for each potential desired length, which is parameterized by a length embedding matrix $W_{le} \in \mathbb{R}^{D \times L}$ where L is the number of length types. In the decoding process, we input the embedding of the *remaining length* l_t as additional input to the LSTM (Figure 3). l_t is initialized after the encoding process and updated during the decoding process as follows:

$$
\begin{aligned}
l_1 &= length, \\
l_{t+1} &= \begin{cases} 0 & (l_t - byte(y_t) \leq 0) \\ l_t - byte(y_t) & (\text{otherwise}), \end{cases}
\end{aligned}
$$

where $byte(y_t)$ is the length of output word y_t and $length$ is the desired length. We learn the values of the length embedding matrix W_{le} during training. This method provides additional information about the amount of length remaining in the output sequence, allowing the decoder to "plan" its output based on the remaining number of words it can generate.

[3]This is a workaround to prevent the situation in which all sequences are discarded from a beam.

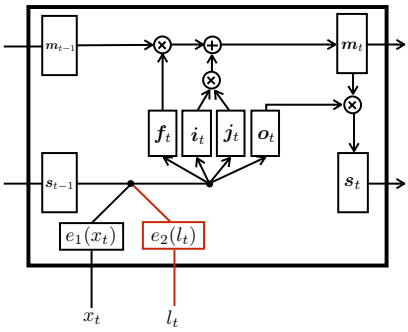

Figure 3: *LenEmb*: *remaining length* is used as additional input for the LSTM of the decoder.

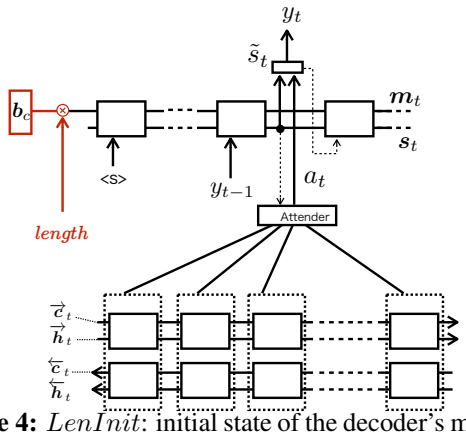

Figure 4: *LenInit*: initial state of the decoder's memory cell m_0 manages output length.

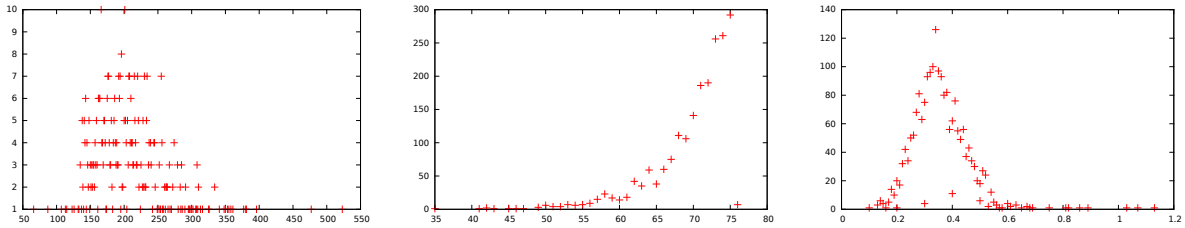
4.4 *LenInit*: Length-based Memory Cell Initialization

While *LenEmb* inputs the *remaining length* l_t to the decoder at each step of the decoding process, the *LenInit* method inputs the desired length once at the initial state of the decoder. Figure 4 shows the architecture of *LenInit*. Specifically, the model uses the memory cell $\boldsymbol{m}_t$ to control the output length by initializing the states of decoder (hidden state $\boldsymbol{s}_0$ and memory cell $\boldsymbol{m}_0$) as follows:

$$
\begin{aligned}
\boldsymbol{s}_0 &= \overleftarrow{\boldsymbol{h}}_1, \\
\boldsymbol{m}_0 &= \boldsymbol{b}_c * length, \qquad (1)
\end{aligned}
$$

where $\boldsymbol{b}_c \in \mathbb{R}^H$ is a trainable parameter and $length$ is the desired length.

While the model of *LenEmb* is guided towards the appropriate output length by inputting the remaining length at each step, this *LenInit* attempts to provide the model with the ability to manage the output length on its own using its inner state. Specifically, the memory cell of LSTM networks is suitable for this endeavour, as it is possible for LSTMs



(a) first sentence (206.91) **(b)** summary (70.00) **(c)** ratio (0.35)

Figure 5: Histograms of first sentence length, summary length, and their ratio in DUC2004.

to learn functions that, for example, subtract a fixed amount from a particular memory cell every time they output a word. Although other ways for managing the length are also possible,[4] we found this approach to be both simple and effective.

5 Experiment

5.1 Dataset

We trained our models on a part of the Annotated English Gigaword corpus (Napoles et al., 2012), which Rush et al. (2015) constructed for sentence summarization. We perform preprocessing using the standard script for the dataset[5]. The dataset consists of approximately 3.6 million pairs of the first sentence from each source document and its headline. Figure 1 shows the length histograms of the summaries in the training set. The vocabulary size is 116,875 for the source documents and 67,564 for the target summaries including the beginning-of-sentence, end-of-sentence, and unknown word tags. For $LenEmb$ and $LenInit$, we input the length of each headline during training. Note that we do not train multiple summarization models for each headline length, but a single model that is capable of controlling the length of its output.

We evaluate the methods on the evaluation set of DUC2004 task-1 (generating very short single-document summaries). In this task, summarization systems are required to create a very short summary for each given document. Summaries over the length limit (75 bytes) will be truncated and there is no bonus for creating a shorter summary. The evaluation set consists of 500 source documents and 4 human-written (reference) summaries for each source document. Figure 5 shows the length histograms of the summaries in the evaluation set. Note that the human-written summaries are not always as long as 75 bytes. We used three variants of ROUGE (Lin, 2004) as evaluation metrics: ROUGE-1 (unigram), ROUGE-2 (bigram), and ROUGE-L (longest common subsequence). The two-sided permutation test (Chinchor, 1992) was used for statistical significance testing ($p \leq 0.05$).

5.2 Implementation

We use Adam (Kingma and Ba, 2015) (α=0.001, β_1=0.9, β_2=0.999, eps=10^{-8}) to optimize parameters with a mini-batch of size 80. Before every 10,000 updates, we first sampled 800,000 training examples and made groups of 80 examples with the same source sentence length, and shuffled the 10,000 groups.

We set the dimension of word embeddings to 100 and that of the hidden state to 200. For LSTMs, we initialize the bias of the forget gate to 1.0 and use 0.0 for the other gate biases (Józefowicz et al., 2015). We use Chainer (Tokui et al., 2015) to implement our models. For $LenEmb$, we set L to 300, which is larger than the longest summary lengths in our dataset (see Figure 1-(b) and Figure 5-(b)).

For all methods except $fixRng$, we found a beam size of 10 to be sufficient, but for $fixRng$ we used a beam size of 30 because it more aggressively discards candidate sequences from its beams during decoding.

6 Result

6.1 ROUGE Evaluation

Table 1 shows the ROUGE scores of each method with various length limits (30, 50 and 75 byte). Regardless of the length limit set for the summariza-

[4]For example, we can also add another memory cell for managing the length.

tion methods, we use the same reference summaries. Note that, $fixLen$ and $fixRng$ generate the summaries with a hard constraint due to their decoding process, which allows them to follow the hard constraint on length. Hence, when we calculate the scores of $LenEmb$ and $LenInit$, we impose a hard constraint on length to make the comparison fair (i.e. $LenEmb_{(0,L)}$ and $LenInit_{(0,L)}$ in the table). Specifically, we use the same beam search as that for $fixRng$ with minimum length of 0.

For the purpose of showing the length control capability of $LenEmb$ and $LenInit$, we show at the bottom two lines the results of the standard beam search without the hard constraints on the length[6]. We will use the results of $LenEmb_{(0,\infty)}$ and $LenInit_{(0,\infty)}$ in the discussions in Sections 6.2 and 6.3.

The results show that the learning-based methods ($LenEmb$ and $LenInit$) tend to outperform decoding-based methods ($fixLen$ and $fixRng$) for the longer summaries of 50 and 75 bytes. However, in the 30-byte setting, there is no significant difference between these two types of methods. We hypothesize that this is because average compression rate in the training data is 30% (Figure 1-(c)) while the 30-byte setting forces the model to generate summaries with 15.38% in average compression rate, and thus the learning-based models did not have enough training data to learn compression at such a steep rate.

6.2 Examples of Generated Summaries

Tables 2 and 3 show examples from the validation set of the Annotated Gigaword Corpus. The tables show that all models, including both learning-based methods and decoding-based methods, can often generate well-formed sentences.

We can see various paraphrases of "#### us figure

championships"[7] and "withdrew". Some examples are generated as a single noun phrase ($LenEmb$(30) and $LenInit$(30)) which may be suitable for the short length setting.

6.3 Length Control Capability of Learning-based Models

Figure 6 shows histograms of output length from the standard encoder-decoder, $LenEmb$, and $LenInit$. While the output lengths from the standard model disperse widely, the lengths from our learning-based models are concentrated to the desired length. These histograms clearly show the length controlling capability of our learning-based models.

Table 4-(a) shows the final state of the beam when $LenInit$ generates the sentence with a length of 30 bytes for the example with standard beam search in Table 3. We can see all the sentences in the beam are generated with length close to the desired length. This shows that our method has obtained the ability to control the output length as expected. For comparison, Table 4-(b) shows the final state of the beam if we perform standard beam search in the standard encoder-decoder model (used in $fixLen$ and $fixRng$). Although each sentence is well-formed, the lengths of them are much more varied.

6.4 Comparison with Existing Methods

Finally, we compare our methods to existing methods on standard settings of the DUC2004 shared task-1. Although the objective of this paper is not to obtain state-of-the-art scores on this evaluation set, it is of interest whether our length-controllable models are competitive on this task. Table 5 shows that the scores of our methods, which are copied from Table 1, in addition to the scores of some existing methods. ABS (Rush et al., 2015) is the most standard model of neural sentence summarization and is the most similar method to our baseline setting ($fixLen$). This table shows that the score of $fixLen$ is comparable to those of the existing methods. The table also shows the $LenEmb$ and the $LenInit$ have the capability of controlling the length without decreasing the ROUGE score.

7 Conclusion

In this paper, we presented the first examination of the problem of controlling length in neural encoder-decoder models, from the point of view of summarization. We examined methods for controlling length of output sequences: two decoding-based methods ($fixLen$ and $fixRng$) and two learning-based methods ($LenEmb$ and $LenInit$). The results showed that learning-based methods generally outperform the decoding-based methods, and the learning-based methods obtained the capability of controlling the output length without losing ROUGE score compared to existing summarization methods.

Poet Admits // Mute Cypher: Beam Search to find Mutually Enciphering Poetic Texts

Cole Peterson and **Alona Fyshe**
University of Victoria
cpeterso@uvic.ca, afyshe@uvic.ca

Abstract

The Xenotext Experiment implants poetry into an extremophile's DNA, and uses that DNA to generate new poetry in a protein form. The molecular machinery of life requires that these two poems encipher each other under a symmetric substitution cipher. We search for ciphers which permit writing under the Xenotext constraints, incorporating ideas from cipher-cracking algorithms, and using n-gram data to assess a cipher's "writability". Our algorithm, Beam Verse, is a beam search which uses new heuristics to navigate the cipher-space. We find thousands of ciphers which score higher than successful ciphers used to write Xenotext constrained texts.

1 Introduction

For over a decade, poet Christian Bök has been working on The Xenotext (Bök, 2008), a literary experiment which aims to insert poetry into the DNA of an extremophile organism. In contrast to popular modern data storage mediums like paper and hard disks, DNA is more robust to accidents, and requires minimal maintenance to last hundreds or even thousands of years (Cox, 2001). Many groups are actively pursuing efficient and stable ways to use DNA to encode information (Shimanovsky et al., 2002; Goldman et al., 2013). With his project, Bök aims to leave a lasting cultural contribution inside of an organism, which, as a result of DNA's durability and self-replicating properties, could conceivably survive longer than all other existing works of art.

Furthermore, Bök aims to craft his poem so the protein it instructs the cell to produce is yet another English poem. In a sense, Bök not only turns a microbe into a genetic book, he also engineers the microbe to be, in a sense, a poet. The organism's molecular machinery powers this translation between the two texts, which, at a high level, is a symmetric substitution cipher between the letters, and is described in more detail in Section 2. The two poems (the poet's and the organism's) must both play by the rules we refer to as the Xenotext Constraints:

- Each text is valid natural language.
- The substitution cipher function applied to one text, results in the other text, and vice versa. In other words, the cipher function must be symmetric.
- Whitespace characters (space, new line) encipher themselves, and are the only characters allowed identity mappings.

After four years of work, Bök successfully wrote two English poems which satisfied the Xenotext constraints[1], becoming the first person to do so. The first challenge was finding a cipher which allows for two valid English texts to be written. Finding "writable" ciphers is difficult and is the focus of this paper.

We present Beam Verse, a language-agnostic algorithm driven by the target language's n-gram data, that searches for "writable" ciphers, and suggests words and phrases which can be written under them.

[1]The two poems used the cipher $\binom{\texttt{abcdefghijlmq}}{\texttt{tvukyspnoxrwz}}$

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1339–1347,
Austin, Texas, November 1-5, 2016.

We do not concern ourselves with the full biochemical constraints of The Xenotext (eg. the actual impact of the protein and the cell's reaction to it, or its viability after folding) and instead only consider the Xenotext constraints listed above. This problem sits at the intersection of natural language processing and cryptography, and is a prerequisite to the genetic engineering required to fully realize a living xenotext. Our algorithm uncovers new ciphers which make satisfying the Xenotext constraints in English possible, and makes it easier for a poet of any language to investigate the feasibility of writing two mutually enciphering texts in their own tongue.

2 Genetic Background

DNA provides instructions to a living cell to produce a protein. DNA has a double helix structure (reminiscent of a twisted ladder) and is made up of four nucleotides: adenine, cytosine, guanine, and thymine, commonly abbreviated as A, T, C, and G. Each nucleotide always appears paired with another across the "rung" of the ladder, A with T, C with G, and vice versa. To transfer the data in the DNA to the protein-producing ribosome, the double helix is "unzipped", separating the ladder at the rungs, and a copy of the exposed DNA sequence called an *mRNA transcript* is synthesized, pairing in the same way the DNA did, with the exception that adenine in the DNA strand pairs with uracil (U) in the mRNA. The ribosome reads the mRNA as instructions to produce a specific protein. A protein is a sequence of amino acids and each triplet of nucleotides in the mRNA (called a *codon*) represents one of the twenty amino acids (see Table 2) (Campbell and Reece, 2008).

We can write in the DNA of an organism by having a codon represent a letter. When this sequence of codons (the full poem) is read by the organism, it then writes a sequence of amino acids, each of which represent a letter, in reply[2]. The letters in each poem have a bijective relationship determined by the biochemical processes that link them. For example, as shown in Table 2, the letters E and T are mutually linked, as wherever the poet uses the letter E, the cell uses the letter T, and vice versa. If the poet was to write "mute" instead of "poet", the cell would write "poet" instead of "mute".

Poet's Letter	P	O	E	T
DNA Codon	AAC	GAG	CCG	GGC
mRNA Codon	UUG	CUC	GGC	CCG
Amino Acid	phenylalanine	leucine	glycine	proline
Cell's Letter	M	U	T	E

Table 1: Sample translation from text through DNA to new text

This view of DNA is extremely simplistic, and serves only to motivate and provide context for the rest of this paper. When using a codon to represent a poet's letter and an amino acid to represent one of the organism's letters, many complexities arise which add further constraints to the text, which we ignore in the remainder of the paper. When actually inserting his poetry into a cell, Bök struggled to get the organism to express the correct protein, because he failed to account for the full complexity of the cell and caused the cell to "censor" itself (Wershler, 2012). However, we consider these additional constraints to be future work.

3 Substitution Ciphers

Substitution ciphers are among the earliest known forms of cryptography, having existed since at least the days of Caesar (Sinkov, 1966). They work by replacing one letter in the plaintext with another to form the ciphertext. However, they are never used in modern cryptography because, despite a large keyspace, substitution ciphers do not change the letter frequency between plaintext and ciphertext. When properties of the plaintext are known (like the language it is written in), letter or word frequency data from that language can be used to quickly crack the cipher and uncover the key.

Every word has a deterministic encryption under a cipher. The encrypted word could be nonsense, or it could be another word. The word "poet", for example, can encrypt to many other words, including "mute". The "poet↔mute" word-pair forms what we call a *partial cipher*, and notate as $\binom{\texttt{poe}}{\texttt{mut}}$. We

[2]This makes the writing lipogrammatic, as there are only 20 amino acids, and one of them (Serine) must be used as the space character. Serine is used for the space because it is the only amino acid to encipher itself, as both codons AGT and TCA produce it, mirroring the constraint that the space is mapped to itself in our ciphers.

say this partial cipher has a *cardinality* of three, as it defines three letter pairings. A *full cipher* in a 26-letter language has a cardinality of 13. We also refer to $\binom{\texttt{poe}}{\texttt{mut}}$ as a *primary* cipher, because it is the lowest cardinality cipher to contain the word-pairing "poet↔mute".

As no characters except whitespace are allowed identity mappings a word-pair like "eat↔cat" is not valid, as both *a* and *t* would have to map to them selves. The symmetric Xenotext constraint prohibits "admits" from pairing with "cipher", as the letter *i* would require a mapping to both *d* and *h*. However, "admits" can pair with the alternative spelling "cypher", forming the primary cipher $\binom{\texttt{admits}}{\texttt{cypher}}$. We can combine this cipher with $\binom{\texttt{poe}}{\texttt{mut}}$, as none of the letter pairs conflict with each other – they are *compatible* with each other. Together, they form $\binom{\texttt{poeadis}}{\texttt{mutcyhr}}$. As the letter-pairs in $\binom{\texttt{poe}}{\texttt{mut}}$ and $\binom{\texttt{admits}}{\texttt{cypher}}$ are subsets of the letter-pairs in $\binom{\texttt{poeadis}}{\texttt{mutcyhr}}$, we call $\binom{\texttt{poe}}{\texttt{mut}}$ and $\binom{\texttt{admits}}{\texttt{cypher}}$ *subciphers* of $\binom{\texttt{poeadis}}{\texttt{mutcyhr}}$, and say that $\binom{\texttt{poeadis}}{\texttt{mutcyhr}}$ *extends* $\binom{\texttt{poe}}{\texttt{mut}}$ and $\binom{\texttt{admits}}{\texttt{cypher}}$. For any two ciphers ϕ_1 and ϕ_2, we use the notation $\phi_1 \subset \phi_2$ to denote that ϕ_1 is a subcipher of ϕ_2.

If we applied $\binom{\texttt{poeadis}}{\texttt{mutcyhr}}$ to "Poet Admits" (the first part of this paper's title), it would result "Mute Cypher" (the second part of the paper's title). The title refers to the difficulty of writing under the Xenotext constraint, as it is hard to find a cipher where writing is possible, most of the ciphers are mute. Once all of the possible word pairs of a target language have been discovered (Section 7) the challenge becomes navigating the tradeoffs of including a letter pair, as each letter pair eliminates the possibility of using some word-pairs, while including other word-pairs.

If a language has an odd number of characters a symmetric substitution cipher is not possible using every letter. We must decide which letter to leave out of our texts. This is accomplished by inserting a null letter (which appears nowhere in the language) into our letter set, thus giving the language an even number of characters. At the conclusion of Beam Verse the letter paired with null is the character to leave out.

4 Scoring a Cipher's "Writability"

When scoring a cipher, an important consideration is what makes one cipher more "writable" than another. We might score a cipher on the number of valid words under it, as having more words at your disposal makes it easier to write, but this is not necessarily so if all the words are all rare and useless. To combat this, we weight words based upon their frequency in language, so that better, more frequent words contribute more to a ciphers overall score. This values highly frequent and syntactically important words, like "the" or "and", while also allowing a large number of infrequent words to also contribute significantly to the score. However, a word's usefulness when writing mutually enciphering texts is explicitly tied to its sister word under the cipher. "The" looses its usefulness if every time it is used in one poem, a less frequent word like "nag' must be used in the other. We propose that since a word pair is only as good as its weakest word, that ciphers be scored by taking the sum of all available word pairs, counting the minimum frequency of the two words. This means that the word pair "the↔nag" would count the frequency of "nag".

Multiple different word pairings can form the same primary cipher. For example, $\binom{\texttt{th}}{\texttt{ea}}$ is formed by both "the↔eat" and "he↔at", and would count the score of both word-pairs. As there are always less or equal primary ciphers than word-pairs, it is more memory efficient to store the score of all the primary ciphers than to store the scores of all the word-pairs. We count the score of a primary cipher ϕ_p towards a full cipher ϕ_f if it is a subcipher of ϕ_f. Formally, if P is the set of all primary ciphers and $\phi_p \in P$, the score of ϕ_f is $\sum_{\phi_p \subset \phi_f} score(\phi_p)$.

Alternatively, this could be expressed as a dot product between a vector where every element is the score of a primary (the score vector, s), and a vector indicating whether a primary cipher is a subcipher (the heuristic vector, h), as seen in equation 1. In section 8 we show how h can be calculated efficiently, and also how it can be use to provide an upper and lower bound the score of a full cipher extended from a partial cipher.

$$score = s \cdot h \tag{1}$$

The concept of a word-pair can easily be extended

to include longer word-level n-grams. Like words, every n-gram either enciphers to nonsense or has a sister n-gram it is locked to under a cipher. All n-gram pairs also have an associated frequency in the language, and so can contribute to the score of a cipher in the same way as single words do: by the minimum of the two n-gram's frequency counting as the weight of the pair. Using n-grams also indirectly captures some syntactic structure, and allows for generation of sample phrase and sentence generation from the cipher by chaining together n-grams. These small phrases can be used to quickly prototype poetry. For our word list and frequency data, we use Google's n-grams (Michel et al., 2011), but any dataset could be used, and would give different ciphers depending on the data's source.

5 Graphical and Combinatoric Representation

There are 7,905,853,580,625 possible symmetric substitution ciphers in a 26 letter language like English. Even with the efficient means of scoring ciphers shown in section 8 (which can calculate a full cipher's score in $\sim$ 300 microseconds) the brute force solution would take over 75 years of computing time. To avoid this expensive full calculation, we formulate the problem as a graph of partial ciphers and use beam search to navigate the graph to high valued full solutions. We regret that the smallest non-trivial graph (of a 6 letter language) is too large to be included here; it requires 75 nodes arranged in three layers which takes up an entire page, but it can be found on our website[3]. An incomplete graph is shown in Figure 1. As we search the cipher space we trace edges up through the graph to a full cipher solution.

The size of the m^{th} layer of a n letter language is defined by equations 2-4. The counts for a 26-letter language and a derivation of this equation can be seen on our website.

$$f(m,0) = 1 \quad (2)$$

$$f(1,n) = n \times (n-1)/2 \quad (3)$$

$$f(m,n) = f(m-1,n) \times f(1, n-2\times(m-1))/m \quad (4)$$

[3] http://www.langlearnlab.cs.uvic.ca/beamverse

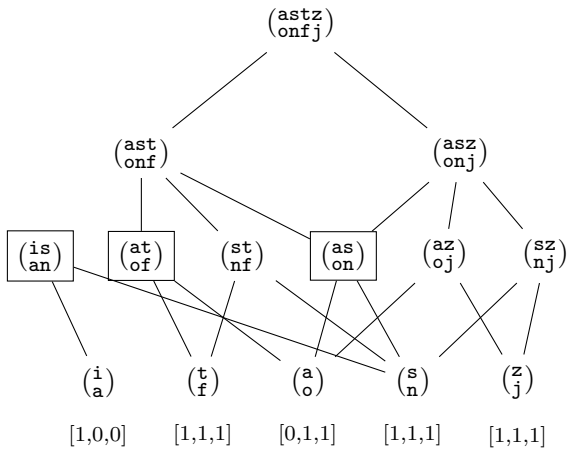

Figure 1: An incomplete cipher-graph, showing some of the partial ciphers which descend from $\binom{\text{astz}}{\text{onfj}}$. Three primary ciphers are shown in boxes, and are the same example primary ciphers used in Section 8. Compatibility vectors (discussed in Section 8.1) are shown for every letter-pair. Edges in this graph represent a difference of a letter-pair between ciphers. Each cardinality of partial cipher has a layer in the graph, which is our beam in the search.

6 Beam Search

A beam search algorithm does not require us to store all of this graph in memory, as we only examine a subset of the ciphers anticipated to be the best. Beam search works by enumerating all possibilities for one step of a solution (one layer of the cipher graph), sorting those options by a heuristic, keeping the best n partial solutions, and pruning the rest (Edelkamp and Schroedl, 2011). We fully expand one step further on the best n partial solutions, repeating the pruning and expanding process until a set of full solutions are reached. Beam search can effectively crack substitution ciphers, as shown by Nuhn et al. (2013).

A static beam size could be used (keeping the best thousand partial ciphers at each step, for example), however, the lower cardinality the partial, the more possibilities it generates. Every cardinality-1 partial cipher generates 276 possible cardinality-2 partial ciphers, whereas a cardinality-12 partial cipher only generates one possible full cipher (as there are only two unpaired letters remaining, therefore they must pair together). A constant beam size will limit the algorithm's performance in later stages of the search

if this is not accounted for.

We can rearrange our recursive definition in Equations 2 to 4 to determine the beam size which will generate exactly as many partial ciphers as we can hold in memory. If we want to generate B ciphers in an n letter language, and are at layer m, we should prune the beam to $b(m, n)$. This can be found by replacing replacing $f(m, n)$ for B, and $f(m-1, n)$ for $b(m, n)$ in equation 4 and rearranging to produce equation 5, removing m from equation 4 because we cannot assume duplicates will be generated.

$$b(m, n) = \frac{B}{f(1, n - 2 \times (m-1))} \tag{5}$$

7 Generating Primary Ciphers

In order to generate the primary ciphers, we must find all words which can encipher with each other, and record their score. Rather than checking every word against every other word, many useless checks can be avoided by hashing each word or n-gram according to the pattern of its letters, a concept which Hauer et al. (2014) called "pattern-equivalence" and used to crack substitution ciphers. We use a key which represents each letter in the n-gram with a number or symbol, ordered by first occurrence of the letter, while maintaining whitespace (eg. "and we are" $\rightarrow$ "123 45 165"). Another trigram like "his or her" would also generate the same key, and so the two trigrams would be checked against each other to see if they validly encipher, which they do, forming a primary partial cipher $\binom{\texttt{andwr}}{\texttt{hisoe}}$.

A match on the hash key does not guarantee that the words form a valid pairing. Many words which share a key form invalid word-pairings due to the symmetric or identity restrictions of the Xenotext constraint (eg. "cat↔eat", which share the key "123", or "admits↔cipher", which share the key "123456" are both invalid word-pairings). The score of a primary cipher is the sum of the score of all word-pairs which generate the primary. The algorithm is shown in Algorithm 1.

Algorithm 1 Generating Primary Ciphers

```
function GENERATE PRIMARIES(ngrams)
  for word_1 ← ngrams do
    key ← pattern(word_1)
    for word_2 ← patternDict[key] do
      if mutually-encipher(word, word_2) then
        primaries[encipher(word_1, word_2)] +=
  minScore(word_1, word_2)
      end if
    end for
    patternDict[key].add(word_1)
  end for
  return primaries
end function
```

8 Beam Search Heuristics

Recall from Section 3 that, in a full cipher, all letters have a defined mapping (the cipher has a cardinality of 13), while in a partial cipher some letters have undefined defined mappings, and that a primary cipher is the minimal cardinality partial cipher to contain a particular word-pair and is the building block of a cipher's score. We explore three different heuristics which calculate the true score for full ciphers, and estimate the score of full ciphers extended from a partial cipher by forming an upper and lower bound. All heuristics produce a vector h, which forms the score for a cipher when dotted with the score vector s (Equation 1). For full ciphers this vector will be the same regardless of the heuristic used, and the score from Equation 1 will be the true score of the full cipher, whereas different heuristics will give different values for a partial cipher, and thus guide Beam Verse in different directions. We implement these heuristics using bitwise operations, making them both memory and CPU efficient.

To demonstrate the calculation of the heuristics, we use the following primary ciphers as a running example, $\binom{\texttt{is}}{\texttt{an}}$ (score: 100), $\binom{\texttt{at}}{\texttt{of}}$ (score: 82), and $\binom{\texttt{on}}{\texttt{as}}$ (score: 76), which are the same primary ciphers as are shown in Figure 1. These three primaries would form the score vector, which is shared amongst all heuristics, is $s = [100, 82, 76]$. Thus $P = \{\binom{\texttt{is}}{\texttt{an}}, \binom{\texttt{at}}{\texttt{of}}, \binom{\texttt{on}}{\texttt{as}}\}$, and $|P| = 3$. We show the heuristic calculation for all three heuristics on the partial cipher $\binom{\texttt{asz}}{\texttt{onj}}$.

8.1 Upper Bound: Compatibility Vector

Recall that two ciphers are compatible if they have no conflicting letter-pairs. If two ciphers are compatible, it is possible to combine them. Every cipher ϕ has a vector representing compatibility with the

primary ciphers P. This vector is $|P|$ long, and contains a 1 in the i^{th} element if ϕ is compatible with the i^{th} primary cipher, and a 0 if it is not.

We use a superscript c on a cipher to notate its compatibility vector. Here are the compatibility vectors for four letter-pairs, using the primary ciphers outlined above, and are shown in Figure 1:

$(\substack{\texttt{i}\\\texttt{a}})^c = [1,0,0]$, $(\substack{\texttt{s}\\\texttt{n}})^c = [1,1,1]$,
$(\substack{\texttt{a}\\\texttt{o}})^c = [0,1,1]$, $(\substack{\texttt{z}\\\texttt{j}})^c = [1,1,1]$.

This is an upper-bound because the primary ciphers compatible with ϕ may not be compatible with each other. For example, the null cipher, which has no letter pairings, is compatible with all primary ciphers, but no full cipher contains all primaries. When we combine two ciphers ϕ_1 and ϕ_2, which have compatibility vectors ϕ_1^c and ϕ_2^c, the resulting cipher ϕ_3 has a compatibility vector $\phi_3^c = \phi_1^c \wedge \phi_2^c$, where $\wedge$ is the bitwise AND operation. We calculate the compatibility vector for every letter-pair, and can combine those vectors to determine the compatibility vector for any cipher. The heuristic's score for $(\substack{\texttt{asz}\\\texttt{onj}})$ follows.

$h = (\substack{\texttt{asz}\\\texttt{onj}})^c = (\substack{\texttt{a}\\\texttt{o}})^c \wedge (\substack{\texttt{s}\\\texttt{n}})^c \wedge (\substack{\texttt{z}\\\texttt{j}})^c = [0,1,1]$
$score(\substack{\texttt{asz}\\\texttt{onj}}) = 100 \cdot 0 + 82 \cdot 1 + 76 \cdot 1 = 158$

8.2 Lower Bound: Guarantee Vector

We can calculate another vector, g for every cipher ϕ which represents whether each primary cipher is a subcipher of ϕ. This forms a lower bound guarantee because any cipher which extends from ϕ will also contain the primary ciphers in g, plus potentially more. The null cipher in this case would have a heuristic vector g of all zeros, as it does not contain any of the primary ciphers. Likewise, in this P, all of the individual letter pairs $((\substack{\texttt{a}\\\texttt{o}}), (\substack{\texttt{s}\\\texttt{n}}), (\substack{\texttt{z}\\\texttt{j}}))$ would have a heuristic vector of all zeros, as all of the primaries require at least two letter-pairs.

Efficiently implementing this heuristic is slightly more challenging than the compatibility heuristic. Our method, which uses bitwise operations and is cacheable like the compatibility vector. Using this heuristic, g of $(\substack{\texttt{asz}\\\texttt{onj}})$ is $[0,0,1]$, as $(\substack{\texttt{is}\\\texttt{an}}) \not\subset (\substack{\texttt{asz}\\\texttt{onj}})$, $(\substack{\texttt{at}\\\texttt{of}}) \not\subset (\substack{\texttt{asz}\\\texttt{onj}})$, and $(\substack{\texttt{as}\\\texttt{on}}) \subset (\substack{\texttt{asz}\\\texttt{onj}})$.

This heuristic therefore scores $(\substack{\texttt{asz}\\\texttt{onj}})$ as follows:

$score(\substack{\texttt{asz}\\\texttt{onj}}) = 100 \cdot 0 + 82 \cdot 0 + 76 \cdot 1 = 76$

8.3 Middle Ground: Medium Vector

Both of the two aforementioned heuristics have weaknesses. The optimistic, max heuristic does not differentiate between a primary cipher it already has and one that it potentially has, and the conservative min heuristic is greedy and short-sighted. Our third heuristic incorporates elements from the first two, to ideally form a measure that is neither overly optimistic, or overly short-sighted. Unlike the lower bound heuristic in Section 8.2, which requires all letter pairings to count a primary cipher, this medium heuristic counts some of the primary cipher's score if some of the letter-pairs are present. For example, if a partial cipher has $3/4$ of the required letter pairings for a primary, it would count 75% of the score.

For example, $(\substack{\texttt{asz}\\\texttt{onj}})$ has one of the two letter pairings of the first primary, $(\substack{\texttt{is}\\\texttt{an}})$; one of the two letter pairings of the second primary, $(\substack{\texttt{at}\\\texttt{of}})$; and two of the two letter pairings of the third primary, $(\substack{\texttt{on}\\\texttt{as}})$. We represent this as [0.5,0.5,1]. However, we know from Section 8.2 that the first primary is incompatible with $(\substack{\texttt{asz}\\\texttt{onj}})$, and so we do not count its score. That makes the heuristic vector $h = [0, 0.5, 1]$, and $score(\substack{\texttt{asz}\\\texttt{onj}}) = 100 \cdot 0 + 82 \cdot .5 + 76 \cdot 1 = 117$.

We have now evaluated the same cipher using three different heuristics, all which produce a different score. These scores are guaranteed to converge to the same value at the full cipher.

8.4 Speed improvements

Table 8.4 shows the massive performance gains of the heuristics, which are over 3000 times faster than the simplistic means of scoring by iterating over every word and checking if it enciphers to anything useful.

9 Related Work

Nuhn et al. (2013) use a beam search algorithm to crack substitution ciphers. Our work differs from their's in several key ways: in Nuhn et al. (2013) there are two distinct symbol spaces, that of the ciphertext and that of the plaintext and so there is no concept of symmetry. Each step of Nuhn et al.'s beam search explores pairing a ciphertext character with a plaintext character, and decides upon the "extension-order" to pair the ciphertext letters, whereas each step of our search pairs two characters

Heuristic	Time	Memory
word	$1 \times 10^6 \mu s$	all words +1int/word
med 8.3	$3 \times 10^3 \mu s$	n bits/primary + 1 int/primary
min 8.2	$2 \times 10^3 \mu s$	n bits/primary + 1 int/primary
max 8.1	$3 \times 10^2 \mu s$	1 bit/primary + 1 int/primary

Table 2: Time to score a cipher using different means, and each mean's memory requirements. The word method stores the strings of all words and enciphers them and checks if they are valid words. It will produce the same value as the min heuristic.

together. As such, we make 13 decisions, not 26.

Additionally, the search space of the non-symmetric and symmetric ciphers are characteristically different. If the "extension-order" is predetermined as in Nuhn et al.'s work, there is only one path from the bottom of the graph to a full solution. In contrast, our graph has 13! different paths to any full solution, as all the permutations of the 13 different letter pairs are valid paths. On the one hand, this highly connected property of the graph means that we can prune our beam to a smaller size, as failing to expand a partial cipher does not eliminate it from appearing as a subcipher in a future solution like it does for Nuhn et al..

However, the connectedness of our cipher graph does present new challenges. As the Xenotext constraints are not satisfied by one cipher, we want to maximize the number of different solutions presented to the writer which each allow for unique expressive potential. We observe, however, that the connectedness property results in a final beam which is smaller and less diverse than would be anticipated. This is caused by multiple partial ciphers in a beam sharing the same "propensity" to become an identical full cipher. We solve this by enforcing that every partial cipher in the beam be incompatible with every other, thereby guaranteeing that no two partial ciphers can share the same "propensity", and that all possibilities generated from them in all future layers will be unique. As there are many ($\mathcal{O}(n^2)$) compatibility comparisons to be made at every beam, we limit only enforce compatibility for the first thousand ciphers in the beam.

Our scoring function is also entirely different from what would be used to crack a substitution cipher. Unlike Beam Verse, cracking software is tied to a ciphertext, and typically uses character-level n-gram data to calculate the probability that a decipherment is valid. Beam Verse, on the other hand, uses word-level n-grams as the basis of scoring, and is not tied to any given text, but suggests fragments of text which satisfy the Xenotext constraint.

10 Results

The raw score of a cipher changes according to the dataset, and so we report the score divided by highest scored cipher across all of the heuristics. Table 10 shows results using unigrams, while Table 10 shows results for primary ciphers generated from bigrams.

Heuristic	High	Low	End Beam Size
max	0.74	0.53	12160
min	0.98	0.97	4223
med	0.93	0.73	13043
max incomp	0.71	0.59	12160
min incomp	1.00	0.97	4181
med incomp	0.85	0.74	13043
Bök	0.39		

Table 3: Normalized scores for three different heuristics on highest 2^{16} **unigram** primary ciphers, and a variable beam aiming for 2^{15} ciphers. "Incomp" means that we enforce that all partial ciphers in the beam be incompatible with each other. The low value is the normalized score of the index of the shortest end beam. This is a better comparison that the last cipher in the beam, as the length of the beams is variable across heuristics.

Heuristic	High	Low	End Beam Size
max	0.81	0.73	9631
min	1.00	0.94	5777
med	0.97	0.88	13291
max incomp	0.81	0.73	9631
min incomp	0.97	0.88	13301
med incomp	0.97	0.84	13291
Bök	0.23		

Table 4: Normalized scores for different heuristics on highest 2^{20} **bigram** primary ciphers, and a variable beam aiming for 2^{15} ciphers.

We note that all ciphers we generate, regardless

of heuristic, score higher than the cipher Bök used to write his poems. This suggests that there are many ciphers other than Bök's which can be used to write Xenotext constrained poetry. Poems written using ciphers generated from Beam Verse can be found on our website. However, attempting to write with some high-scoring ciphers has revealed that our scoring metric may be only loosely correlated with the true "writability", as some ciphers which score higher that Bök's we find more difficult to write with.

Bök's cipher also scores relatively worse than the top ciphers using a bigram model (Table 10). Many of the bigrams Bök uses in his poems are not frequent enough to be in the Google bigrams. Anecdotally, we find ciphers generated using bigram data to be more writable, as bigram models begin to capture syntactic structure of the language.

Enforcing that each cipher in the beam be incompatible with every other showed minimal gains with some heuristics and minimal losses in others. It does, however, guarantee that more ciphers will be generated. Enforcing incompatibility is probably not worth the processing time if memory permits increasing the size of the beam instead.

The top scoring cipher[4] according to the unigram model performs similarly to the Bök cipher when scored against the bigram model, accumulating only 24% of the points the highest scoring bigram cipher does. The top bigram cipher[5] scores 68% of the top unigram cipher's score when using unigram scoring, not as drastic of a difference, but still low enough to be pruned by Beam Verse and not be discovered. The discrepancy in scores between models suggests that "writable" ciphers are excluded from our final results, and also encourages running Beam Verse on additional datasets to find new ciphers. A score which incorporates elements from multiple models of language might be explored, searching for ciphers which perform well across all datasets.

11 Further Work

Work in Kao (2011) sets out to quantify good poetic style and techniques. We note that some poetic techniques, like alliteration and anaphora, are preserved through the substitution cipher. We could boost alliterative n-grams to encourage Beam Verse to include alliterative n-grams.

As Beam Verse is language agnostic, all of the work here is applicable to other languages. The Xenotext constraints might be more easily satisfied in a different language than English, perhaps a language with a smaller character set like Hawaiian (which only consists of thirteen letters). Additionally, The Xenotext project as defined here only minimally uses the organism to actively write – the organism does not have any degree of freedom to express itself as its poem is precisely determined by the author's poem. However, DNA possesses computational power (Paun et al., 2005), which could be leveraged to generate natural language. By taking advantage of the complexity of the cell, its output could be more loosely defined, and change according to mutations in the DNA.

Further investigation can also be done into quantifying the "writability" of a limited vocabulary (perhaps using semantic and grammar data), and constrained text generation under constraint. Poetic endeavours with rigid mathematical constraints are not only attempted by Bök. Any work in the traditions of the Oulipo, a primarily French-speaking group of writers who explore the creative potential of mathematical and logical constraints, would stand to benefit immensely from software tools designed to aid constrained writing. Whereas visual artists and musicians have been quick to use computers to produce images and sounds which would have been impossible by traditional means, writers have been slow to use computers to produce works which would have been impossible to create otherwise.

12 Conclusion

In this paper we present a new metric to quantify "writability" of a symmetric substitution cipher. We experiment using three different heuristics in a beam search, an algorithm we call Beam Verse. We find that our score for "writability", which takes the minimum frequency of a word or n-gram pair, is effective at finding candidate ciphers, but is not a perfect metric of "writability" in this constrained environment. "Writability" is highly subjective, and possibly requires more data than just n-gram frequency

[4] $\begin{pmatrix} \texttt{abcdegijkmnqv} \\ \texttt{fhlryutpswozx} \end{pmatrix}$

[5] $\begin{pmatrix} \texttt{abcdefjklnpqx} \\ \texttt{ightomuvrswzy} \end{pmatrix}$

(eg. semantic and grammar information). Luckily, beam search is highly flexible, and any scoring function, perhaps using a more sophisticated model of writability, could be used in place of the one used here.

Source code and highly scoring ciphers are available for download[6].

All Fingers are not Equal: Intensity of References in Scientific Articles

Tanmoy Chakraborty

ramasurn@in.ibm.com

Abstract

Research accomplishment is usually measured by considering all citations with equal importance, thus ignoring the wide variety of purposes an article is being cited for. Here, we posit that measuring the intensity of a reference is crucial not only to perceive better understanding of research endeavor, but also to improve the quality of citation-based applications. To this end, we collect a rich annotated dataset with references labeled by the intensity, and propose a novel graph-based semi-supervised model, `GraLap` to label the intensity of references. Experiments with AAN datasets show a significant improvement compared to the baselines to achieve the true labels of the references (46% better correlation). Finally, we provide four applications to demonstrate how the knowledge of reference intensity leads to design better real-world applications.

1 Introduction

With more than one hundred thousand new scholarly articles being published each year, there is a rapid growth in the number of citations for the relevant scientific articles. In this context, we highlight the following interesting facts about the process of citing scientific articles: (i) the most commonly cited paper by Gerard Salton, titled "A Vector Space Model for Information Retrieval" (alleged to have been published in 1975) does not actually exist in reality (Dubin, 2004), (ii) the scientific authors read only 20% of the works they cite (Simkin and Roychowdhury, 2003), (iii) one third of the references in a paper are redundant and 40% are perfunctory (Moravcsik and Murugesan, 1975), (iv) 62.7% of the references could not be attributed a specific function (definition, tool etc.) (Teufel et al., 2006). Despite these facts, the existing bibliographic metrics consider that all citations are *equally significant*.

In this paper, we would emphasize the fact that *all the references of a paper are not equally influential*. For instance, we believe that for our current paper, (Wan and Liu, 2014) is more influential reference than (Garfield, 2006), although the former has received lower citations (9) than the latter (1650) so far[1]. Therefore the influence of a cited paper completely depends upon the context of the citing paper, not the overall citation count of the cited paper. We further took the opinion of the original authors of few selective papers and realized that around 16% of the references in a paper are highly influential, and the rest are trivial (Section 4). This motivates us to design a prediction model, `GraLap` to automatically label the influence of a cited paper with respect to a citing paper. Here, we label paper-reference pairs rather than references alone, because a reference that is influential for one citing paper may not be influential with equal extent for another citing paper.

We experiment with ACL Anthology Network (AAN) dataset and show that `GraLap` along with the novel feature set, quite efficiently, predicts the intensity of references of papers, which achieves (Pearson) correlation of 0.90 with the human annotations. Finally, we present four interesting appli-

[1]The statistics are taken from Google Scholar on June 2, 2016.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1348–1358,
Austin, Texas, November 1-5, 2016.

cations to show the efficacy of considering unequal intensity of references, compared to the uniform intensity.

The contributions of the paper are four-fold: (i) we acquire a rich annotated dataset where paper-reference pairs are labeled based on the influence scores (Section 4), which is perhaps the first gold-standard for this kind of task; (ii) we propose a graph-based label propagation model `GraLap` for semi-supervised learning which has tremendous potential for any task where the training set is less in number and labels are non-uniformly distributed (Section 3); (iii) we propose a diverse set of features (Section 3.3); most of them turn out to be quite effective to fit into the prediction model and yield improved results (Section 5); (iv) we present four applications to show how incorporating the reference intensity enhances the performance of several state-of-the-art systems (Section 6).

2 Defining Intensity of References

All the references of a paper usually do not carry equal intensity/strength with respect to the citing paper because some papers have influenced the research more than others. To pin down this intuition, here we discretize the reference intensity by numerical values within the range of 1 to 5, (5: most influential, 1: least influential). The appropriate definitions of different labels of reference intensity are presented in Figure 1, which are also the basis of building the annotated dataset (see Section 4):

Note that "reference intensity" and "reference similarity" are two different aspects. It might happen that two similar reference are used with different intensity levels in a citing paper – while one is just mentioned somewhere in the paper and other is used as a baseline. Here, we address the former problem as a semi-supervised learning problem with clues taken from content of the citing and cited papers.

3 Reference Intensity Prediction Model

In this section, we formally define the problem and introduce our prediction model.

- **Label-1:** The reference is related to the citing article with *very limited extent* and can be *removed* without compromising the competence of the references (e.g., (Garfield, 2006) for this paper).
- **Label-2:** The reference is *little mentioned* in the citing article and can be *replaced* by others without compromising the adequacy of the references (e.g., (Zhu et al., 2015) for this paper).
- **Label-3:** The reference occurs separately in a sentence within the citing article and has *no significant impact on the current problem* (e.g., references to metrics, tools) (e.g., (Porter, 1997) for this paper).
- **Label-4:** The reference is *important* and highly related to the citing article. It is usually mentioned several times in the article with long reference context (e.g., (Singh et al., 2015) for this paper).
- **Label-5:** The reference is *extremely important* and occurs (is emphasized) multiple times within the citing article. It generally points to the cited article from where the citing article borrows main ideas (and can be treated as a baseline) (e.g., (Wan and Liu, 2014) for this paper).

Figure 1: Definitions of the intensity of references.

3.1 Problem Definition

We are given a set of papers $\mathbb{P} = \{P_1, P_2, ..., P_M\}$ and a sets of references $\mathbb{R} = \{R_1, R_2, ..., R_M\}$, where R_i corresponds to the set of references (or cited papers) of P_i. There is a set of papers $P_L \in \mathbb{P}$ whose references $R_L \in \mathbb{R}$ are already labeled by $\ell \in L = \{1, ..., 5\}$ (each reference is labeled with exactly one value). Our objective is to define a predictive function f that labels the references $R_U \in \{\mathbb{R} \setminus R_L\}$ of the papers $P_U \in \{\mathbb{P} \setminus P_L\}$ whose reference intensities are unknown, i.e., $f : (\mathbb{P}, \mathbb{R}, P_L, R_L, P_U, R_L) \longrightarrow L$.

Since the size of the annotated (labeled) data is much smaller than unlabeled data ($|P_L| \ll |P_U|$), we consider it as a semi-supervised learning problem.

Definition 1. (Semi-supervised Learning) *Given a set of entries X and a set of possible labels Y_L, let us assume that (x_1, y_1), (x_2, y_2),..., (x_l, y_l) be the set of labeled data where x_i is a data point and $y_i \in Y_L$ is its corresponding label. We assume that at least one instance of each class label*

is present in the labeled dataset. Let (x_{l+1}, y_{l+1}), (x_{l+2}, y_{l+2}),..., (x_{l+n}, y_{l+u}) be the unlabeled data points where $Y_U = \{y_{l+1}, y_{l+2}, ...y_{l+u}\}$ are unknown. Each entry $x \in X$ is represented by a set of features $\{f_1, f_2, ..., f_D\}$. The problem is to determine the unknown labels using X and Y_L.

3.2 `GraLap`: A Prediction Model

We propose `GraLap`, a variant of label propagation (LP) model proposed by (Zhu et al., 2003) where a node in the graph propagates its associated label to its neighbors based on the proximity. We intend to assign same label to the vertices which are closely connected. However unlike the traditional LP model where the original values of the labels continue to fade as the algorithm progresses, we systematically handle this problem in `GraLap`. Additionally, we follow a post-processing in order to handle "class-imbalance problem".

Graph Creation. The algorithm starts with the creation of a *fully connected weighted graph* $G = (X, E)$ where nodes are data points and the weight w_{ij} of each edge $e_{ij} \in E$ is determined by the radial basis function as follows:

$$w_{ij} = exp\left(- \frac{\sum_{d=1}^{D}(x_i^d - x_j^d)^2}{\sigma^2} \right) \quad (1)$$

The weight is controlled by a parameter σ. Later in this section, we shall discuss how σ is selected. Each node is allowed to propagate its label to its neighbors through edges (the more the edge weight, the easy to propagate).

Transition Matrix. We create a probabilistic transition matrix $T_{|X|\times|X|}$, where each entry T_{ij} indicates the probability of jumping from j to i based on the following: $T_{ij} = P(j \rightarrow i) = \frac{w_{ij}}{\sum_{k=1}^{|X|} w_{kj}}$.

Label Matrix. Here, we allow a soft label (interpreted as a distribution of labels) to be associated with each node. We then define a label matrix $Y_{|X|\times|L|}$, where ith row indicates the label distribution for node x_i. Initially, Y contains only the values of the labeled data; others are zero.

Label Propagation Algorithm. This algorithm works as follows:

After initializing Y and T, the algorithm starts by disseminating the label from one node to its neighbors (including self-loop) in one step (Step 3). Then we normalize each entry of Y by the sum of its corresponding row in order to maintain the interpretation of label probability (Step 4). Step 5 is crucial; here we want the labeled sources X_L to be persistent. During the iterations, the initial labeled nodes X_L may fade away with other labels. Therefore we forcefully restore their actual label by setting $y_{il} = 1$ (if $x_i \in X_L$ is originally labeled as l), and other entries ($\forall_{j \neq l} y_{ij}$) by zero. We keep on "pushing" the labels from the labeled data points which in turn pushes the class boundary through high density data points and settles in low density space. In this way, our approach intelligently uses the unlabeled data in the intermediate steps of the learning.

1: Initialize T and Y
2: **while** (Y does not converge) **do**
3: $\quad Y \leftarrow TY$
4: $\quad$ Normalize rows of Y, $y_{ij} = \frac{y_{ij}}{\sum_k y_{ik}}$
5: $\quad$ Reassign original labels to X_L

Assigning Final Labels. Once Y_U is computed, one may take the most likely label from the label distribution for each unlabeled data. However, this approach does not guarantee the label proportion observed in the annotated data (which in this case is not well-separated as shown in Section 4). Therefore, we adopt a *label-based normalization* technique. Assume that the label proportions in the labeled data are $c_1, ..., c_{|L|}$ (s.t. $\sum_{i=1}^{|L|} c_i = 1$). In case of Y_U, we try to balance the label proportion observed in the ground-truth. The label mass is the column sum of Y_U, denoted by $Y_{U_{.1}}, ..., Y_{U_{.|L|}}$, each of which is scaled in such a way that $Y_{U_{.1}} : ... : Y_{U_{.|L|}} = c_1 : ... : c_{|L|}$. The label of an unlabeled data point is finalized as the label with maximum value in the row of Y.

Convergence. Here we briefly show that our algorithm is guaranteed to converge. Let us combine Steps 3 and 4 as $Y \leftarrow \hat{T}Y$, where $\hat{T} = T_{ij}/\sum_k T_{ik}$. Y is composed of $Y_{L_{l\times|L|}}$ and $Y_{U_{u\times|L|}}$, where Y_U never changes because of the reassignment. We can split $\hat{T}$ at the boundary of labeled and unlabeled data as follows:

$$\hat{F} = \begin{bmatrix} \hat{T}_{ll} & \hat{T}_{lu} \\ \hat{T}_{ul} & \hat{T}_{uu} \end{bmatrix}$$

Therefore, $Y_U \leftarrow \hat{T}_{uu}Y_U + \hat{T}_{ul}Y_L$, which can lead to $Y_U = \lim_{n\rightarrow\infty} \hat{T}_{uu}^n Y^0 + [\sum_{i=1}^{n} \hat{T}_{uu}^{(i-1)}]\hat{T}_{ul}Y_L$, where Y^0 is the shape of Y at iteration 0. We need

to show $\hat{T}^n_{uu_{ij}} Y^0 \leftarrow 0$. By construction, $\hat{T}_{ij} \geq 0$, and since $\hat{T}$ is row-normalized, and $\hat{T}_{uu}$ is a part of $\hat{T}$, it leads to the following condition: $\exists \gamma < 1$, $\sum_{j=1}^{u} \hat{T}_{uu_{ij}} \leq \gamma$, $\forall i = 1, ..., u$. So,

$$\begin{aligned}\sum_j \hat{T}^n_{uu_{ij}} &= \sum_j \sum_k \hat{T}^{(n-1)}_{uu_{ik}} \hat{T}_{uu_{kj}} \\ &= \sum_k \hat{T}^{(n-1)}_{uu_{ik}} \sum_j \hat{T}_{uu_{ik}} \\ &\leq \sum_k \hat{T}^{(n-1)}_{uu_{ik}} \gamma \\ &\leq \gamma^n\end{aligned}$$

Therefore, the sum of each row in $\hat{T}^n_{uu_{ij}}$ converges to zero, which indicates $\hat{T}^n_{uu_{ij}} Y^0 \leftarrow 0$.

Selection of σ. Assuming a spatial representation of data points, we construct a minimum spanning tree using Kruskal's algorithm (Kruskal, 1956) with distance between two nodes measured by Euclidean distance. Initially, no nodes are connected. We keep on adding edges in increasing order of distance. We choose the distance (say, d_f) of the first edge which connects two components with different labeled points in them. We consider d_f as a heuristic to the minimum distance between two classes, and arbitrarily set $\sigma = d_0/3$, following 3σ rule of normal distribution (Pukelsheim, 1994).

3.3 Features for Learning Model

We use a wide range of features that suitably represent a paper-reference pair (P_i, R_{ij}), indicating P_i refers to P_j through reference R_{ij}. These features can be grouped into six general classes.

3.3.1 Context-based Features (CF)

The "reference context" of R_{ij} in P_i is defined by three-sentence window (sentence where R_{ij} occurs and its immediate previous and next sentences). For multiple occurrences, we calculate its average score. We refer to "reference sentence" to indicate the sentence where R_{ij} appears.

(i) *CF:Alone*. It indicates whether R_{ij} is mentioned alone in the reference context or together with other references.

(ii) *CF:First*. When R_{ij} is grouped with others, this feature indicates whether it is mentioned first (e.g., "[2]" is first in "[2,4,6]").

Next four features are based on the occurrence of words in the corresponding lists created manually (see Table 1) to understand different aspects.

(iii) *CF:Relevant*. It indicates whether R_{ij} is explicitly mentioned as relevant in the reference context (`Rel` in Table 1).

(iv) *CF:Recent*. It tells whether the reference context indicates that R_{ij} is new (`Rec` in Table 1).

(v) *CF:Extreme*. It implies that R_{ij} is extreme in some way (`Ext` in Table 1).

(vi) *CF:Comp*. It indicates whether the reference context makes some kind of comparison with R_{ij} (`Comp` in Table 1).

Note we do not consider any sentiment-based features as suggested by (Zhu et al., 2015).

3.3.2 Similarity-based Features (SF)

It is natural that the high degree of semantic similarity between the contents of P_i and P_j indicates the influence of P_j in P_i. We assume that although the full text of P_i is given, we do not have access to the full text of P_j (may be due to the subscription charge or the unavailability of the older papers). Therefore, we consider only the title of P_j as a proxy of its full text. Then we calculate the cosine-similarity[2] between the title (*T*) of P_j and (i) *SF:TTitle.* the title, (ii) *SF:TAbs*. the abstract, *SF:TIntro*. the introduction, (iv) *SF:TConcl*. the conclusion, and (v) *SF:TRest*. the rest of the sections (sections other than abstract, introduction and conclusion) of P_i.

We further assume that the "reference context" (*RC*) of P_j in P_i might provide an alternate way of summarizing the usage of the reference. Therefore, we take the same similarity based approach mentioned above, but replace the title of P_j with its *RC* and obtain five more features: (vi) *SF:RCTitle*, (vii) *SF:RCAbs*, (viii) *SF:RCIntro*, (ix) *SF:RCConcl* and (x) *SF:RCRest*. If a reference appears multiple times in a citing paper, we consider the aggregation of all RCs together.

3.3.3 Frequency-based Feature (FF)

The underlying assumption of these features is that a reference which occurs more frequently in a citing paper is more influential than a single occurrence (Singh et al., 2015). We count the frequency of R_{ij} in (i) *FF:Whole*. the entire content, (ii) *FF:Intro*. the introduction, (iii) *FF:Rel*. the related work, (iv) *FF:Rest*. the rest of the sections (as

[2]We use the vector space based model (Turney and Pantel, 2010) after stemming the words using Porter stammer (Porter, 1997).

Rel	pivotal, comparable, innovative, relevant, relevantly, inspiring, related, relatedly, similar, similarly, applicable, appropriate, pertinent, influential, influenced, original, originally, useful, suggested, interesting, inspired, likewise
Rec	recent, recently, latest, later, late, latest, up-to-date, continuing, continued, upcoming, expected, update, renewed, extended subsequent, subsequently, initial, initially, sudden, current, currently, future, unexpected, previous, previously, old, ongoing, imminent, anticipated, unprecedented, proposed, startling, preliminary, ensuing, repeated, reported, new, earlier, earliest, early, existing, further, revised, improved
Ext	greatly, awfully, drastically, intensely, acutely, almighty, exceptionally, excessively, exceedingly, tremendously, importantly significantly, notably, outstandingly
Comp	easy, easier, easiest, vague, vaguer, vaguest, weak, weaker, weakest, strong, stronger, strongest, bogus, unclear

Table 1: Manually curated lists of words collected from analyzing the reference contexts. The lists are further expanded using the Wordnet:Synonym with different lexical variations. Note that while searching the occurrence of these words in reference contexts, we use different lexical variations of the words instead of exact matching.

mentioned in Section 3.3.2) of P_i. We also introduce (v) *FF:Sec.* to measure the fraction of different sections of P_i where R_{ij} occurs (assuming that appearance of R_{ij} in different sections is more influential). These features are further normalized using the number of sentences in P_i in order to avoid unnecessary bias on the size of the paper.

3.3.4 Position-based Features (PF)

Position of a reference in a paper might be a predictive clue to measure the influence (Zhu et al., 2015). Intuitively, the earlier the reference appears in the paper, the more important it seems to us. For the first two features, we divide the entire paper into two parts equally based on the sentence count and then see whether R_{ij} appears (i) *PF:Begin.* in the beginning or (ii) *PF:End.* in the end of P_i. Importantly, if R_{ij} appears multiple times in P_i, we consider the fraction of times it occurs in each part.

For the other two features, we take the entire paper, consider sentences as atomic units, and measure position of the sentences where R_{ij} appears, including (iii) *PF:Mean.* mean position of appearance, (iv) *PF:Std.* standard deviation of different appearances. These features are normalized by the total length (number of sentences) of P_i. , thus ranging from 0 (indicating beginning of P_i) to 1 (indicating the end of P_i).

3.3.5 Linguistic Features (LF)

The linguistic evidences around the context of R_{ij} sometimes provide clues to understand the intrinsic influence of P_j on P_i. Here we consider word level and structural features.

(i) *LF:NGram.* Different levels of n-grams (1-grams, 2-grams and 3-grams) are extracted from the reference context to see the effect of different word combination (Athar and Teufel, 2012).

(ii) *LF:POS.* Part-of-speech (POS) tags of the words in the reference sentence are used as features (Jochim and Schütze, 2012).

(iii) *LF:Tense.* The main verb of the reference sentence is used as a feature (Teufel et al., 2006).

(iv) *LF:Modal.* The presence of modal verbs (e.g., "can", "may") often indicates the strength of the claims. Hence, we check the presence of the modal verbs in the reference sentence.

(v) *LF:MainV.* We use the main-verb of the reference sentence as a direct feature in the model.

(vi) *LF:hasBut.* We check the presence of conjunction "but", which is another clue to show less confidence on the cited paper.

(vii) *LF:DepRel.* Following (Athar and Teufel, 2012) we use all the dependencies present in the reference context, as given by the dependency parser (Marneffe et al., 2006).

(viii) *LF:POSP.* (Dong and Schfer, 2011) use seven regular expression patterns of POS tags to capture syntactic information; then seven boolean features mark the presence of these patterns. We also utilize the same regular expressions as shown below [3] with the examples (the empty parenthesis in each example indicates the presence of a reference token R_{ij} in the corresponding sentence; while few examples are complete sentences, few are not):

- ".*\\(\\) VV[DPZN].*": *Chen () showed that cohesion is held in the vast majority of cases for English-French.*
- ".*(VHP|VHZ) VV.*": *while Cherry and Lin () have shown it to be a strong feature for word alignment...*
- ".*VH(D|G|N|P|Z) (RB)*VBN.*": *Inducing features for taggers by clustering has been tried by several researchers ().*
- ".*MD (RB)*VB(RB)* VVN.*": *For example, the likelihood of those generative procedures can be accumulated to get the likelihood of the phrase pair ().*

[3] The meaning of each POS tag can be found in `http://nlp.stanford.edu/software/tagger.shtml`(Toutanova and Manning, 2000).

- "[IW.]*VB(D|P|Z) (RB)*VV[ND].*": *Our experimental set-up is modeled after the human evaluation presented in ().*
- "(RB)*PP (RB)*V.*": *We use CRF () to perform this tagging.*
- ".*VVG (NP)*(CC)*(NP).*": *Following (), we provide the annotators with only short sentences: those with source sentences between 10 and 25 tokens long.*

These are all considered as Boolean features. For each feature, we take all the possible evidences from all paper-reference pairs and prepare a vector. Then for each pair, we check the presence (absence) of tokens for the corresponding feature and mark the vector accordingly (which in turn produces a set of Boolean features).

3.3.6 Miscellaneous Features (MS)

This group provides other factors to explain why is a paper being cited. (i) *MS:GCount*. To answer whether a highly-cited paper has more academic influence on the citing paper than the one which is less cited, we measure the number of other papers (except P_i) citing P_j.
(ii) *MS:SelfC*. To see the effect of self-citation, we check whether at least one author is common in both P_i and P_j.
(iii) *MG:Time*. The fact that older papers are rarely cited, may not stipulate that these are less influential. Therefore, we measure the difference of the publication years of P_i and P_j.
(iv) *MG:CoCite*. It measures the co-citation counts of P_i and P_j defined by $\frac{|R_i \cap R_j|}{|R_i \cup R_j|}$, which in turn answers the significance of reference-based similarity driving the academic influence (Small, 1973).

Following (Witten and Frank, 2005), we further make one step normalization and divide each feature by its maximum value in all the entires.

4 Dataset and Annotation

We use the AAN dataset (Radev et al., 2009) which is an assemblage of papers included in ACL related venues. The texts are preprocessed where sentences, paragraphs and sections are properly separated using different markers. The filtered dataset contains 12,843 papers (on average 6.21 references per paper) and 11,092 unique authors.

Next we use *Parscit* (Councill et al., 2008) to identify the reference contexts from the dataset and then extract the section headings from all the papers. Then each section heading is mapped into one of the following broad categories using the method proposed by (Liakata et al., 2012): Abstract, Introduction, Related Work, Conclusion and Rest.

Dataset Labeling. The hardest challenge in this task is that there is no publicly available dataset where references are annotated with the intensity value. Therefore, we constructed our own annotated dataset in two different ways. (i) *Expert Annotation*: we requested members of our research group[4] to participate in this survey. To facilitate the labeling process, we designed a portal where all the papers present in our dataset are enlisted in a drop-down menu. Upon selecting a paper, its corresponding references were shown with five possible intensity values. The citing and cited papers are also linked to the original texts so that the annotators can read the original papers. A total of 20 researchers participated and they were asked to label as many paper-reference pairs as they could based on the definitions of the intensity provided in Section 2. The annotation process went on for one month. Out of total 1640 pairs annotated, 1270 pairs were taken such that each pair was annotated by at least two annotators, and the final intensity value of the pair was considered to be the average of the scores. The Pearson correlation and Kendell's τ among the annotators are 0.787 and 0.712 respectively. (ii) *Author Annotation*: we believe that the authors of a paper are the best experts to judge the intensity of references present in the paper. With this intension, we launched a survey where we requested the authors whose papers are present in our dataset with significant numbers. We designed a web portal in similar fashion mentioned earlier; but each author was only shown her own papers in the drop-down menu. Out of 35 requests, 22 authors responded and total 196 pairs are annotated. This time we made sure that each paper-reference pair was annotated by only one author. The percentages of labels in the overall annotated dataset are as follows: 1: 9%, 2: 74%, 3: 9%, 4: 3%, 5: 4%.

5 Experimental Results

In this section, we start with analyzing the importance of the feature sets in predicting the reference

[4] All were researchers with the age between 25-45 working on document summarization, sentiment analysis, and text mining in NLP.

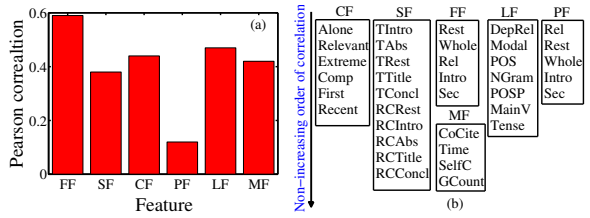

Figure 2: Pearson correlation coefficient between the features and the gold-standard annotations. (a) Group-wise average correlation, and (b) ranking of features in each group based on the correlation.

intensity, followed by the detailed results.

Feature Analysis. In order to determine which features highly determine the gold-standard labeling, we measure the Pearson correlation between various features and the ground-truth labels. Figure 2(a) shows the average correlation for each feature group, and in each group the rank of features based on the correlation is shown in Figure 2(b). Frequency-based features (*FF*) turn out to be the best, among which *FF:Rest* is mostly correlated. This set of features is convenient and can be easily computed. Both *CF* and *LF* seem to be equally important. However, PF tends to be less important in this task.

Model	*RMSE*	ρ	R^2
Uniform	2.09	-0.05	3.21
SVR+W	1.95	0.54	1.34
SVR+O	1.92	0.56	1.29
C4.5SSL	1.99	0.46	2.46
GLM	1.98	0.52	1.35

(a) Baselines

No.	Model	*RMSE*	ρ	R^2
(1)	GraLap+ FF	1.10	0.79	1.05
(2)	(1) + LF	0.98	0.84	0.95
(3)	(2) + CF	0.90	0.87	0.87
(4)	(3) + MF	0.95	0.89	0.84
(5)	(4) + SF	0.92	0.90	0.82
(6)	(5) + PF	0.91	0.90	0.80

(b) Our model

Table 2: Performance of the competing models. The features are added greedily into the GraLap model.

Results of Predictive Models. For the purpose of evaluation, we report the average results after 10-fold cross-validation. Here we consider five baselines to compare with GraLap: (i) Uniform: assign 3 to all the references assuming equal intensity, (ii) SVR+W: recently proposed Support Vector Regression (SVR) with the feature set mentioned in (Wan and Liu, 2014), (iii) SVR+O: SVR model with our feature set, (iv) C4.5SSL: C4.5 semi-supervised algorithm with our feature set (Quinlan, 1993), and (v) GLM: the traditional graph-based LP model with our feature set (Zhu et al., 2003). Three metrics are used to compare the results of the competing models with the annotated labels: *Root Mean Square Error* (*RMSE*), *Pearson's correlation coefficient* (ρ), and *coefficient of determination* (R^2)[5].

Table 2 shows the performance of the competing models. We incrementally include each feature set into GraLap greedily on the basis of ranking shown in Figure 2(a). We observe that GraLap with only FF outperforms SVR+O with 41% improvement of ρ. As expected, the inclusion of PF into the model improves the model marginally. However, the overall performance of GraLap is significantly higher than any of the baselines ($p < 0.01$).

6 Applications of Reference Intensity

In this section, we provide four different applications to show the use of measuring the intensity of references. To this end, we consider all the labeled entries for training and run GraLap to predict the intensity of rest of the paper-reference pairs.

6.1 Discovering Influential Articles

Influential papers in a particular area are often discovered by considering *equal weights* to all the citations of a paper. We anticipate that considering the reference intensity would perhaps return more meaningful results. To show this, Here we use the following measures individually to compute the influence of a paper: (i) RawCite: total number of citations per paper, (ii) RawPR: we construct a citation network (nodes: papers, links: citations), and measure PageRank (Page et al., 1998) of each node n: $PR(n) = \frac{1-q}{N} + q\sum_{m\in M(n)} \frac{PR(m)}{|L(m)|}$; where, q, the damping factor, is set to 0.85, N is the total number of nodes, $M(n)$ is the set of nodes that have edges to n, and $L(m)$ is the set of nodes that m has an edge to, (iii) InfCite: the weighted version of RawCite, measured by the sum of intensities of all citations of a paper, (iv) InfPR: the weighted version of RawPR: $PR(n) = \frac{1-q}{N} + q\sum_{m\in M(n)} \frac{Inf(m\to n)PR(m)}{\sum_{a\in L(m)Inf(m\to a)}}$, where Inf indicates the influence of a reference. We rank all the articles based on these four measures separately. Table 3(a) shows the Spearman's rank correlation between pair-wise measures. As expected, (i) and (ii) have high correlation (same for (iii) and (iv)), whereas across two types of measures the correlation is less. Further, in order to know which mea-

[5]The less (*resp.* more) the value of $RMSE$ and R^2 (*resp.* ρ), the better the performance of the models.

sure is more relevant, we conduct a subjective study where we select top ten papers from each measure and invite the experts (not authors) who annotated the dataset, to make a binary decision whether a recommended paper is relevant. [6]. The average pair-wise inter-annotator's agreement (based on Cohen's kappa (Cohen, 1960)) is 0.71. Table 3(b) presents that out of 10 recommendations of `InfPR`, 7 (5) papers are marked as influential by majority (all) of the annotators, which is followed by `InfCite`. These results indeed show the utility of measuring reference intensity for discovering influential papers. Top three papers based on `InfPR` from the entire dataset are shown in Table 4.

	RowCite	RowPR	InfCite	InfPR
RowCite	1	0.82	0.61	0.54
RowPR	0.82	1	0.52	0.63
InfCite	0.61	0.52	1	0.84
InfPR	0.54	0.63	0.84	1

(a)

Metric	All	Majority
RowCite	2	5
RowPR	2	4
InfCite	4	5
InfPR	5	7

(b)

Table 3: (a) Spearman's rank correlation among influence measures and (b) expert evaluation of the ranked results (for top 10 recommendations).

6.2 Identifying Influential Authors

H-index, a measure of impact/influence of an author, considers each citation with equal weight (Hirsch, 2005). Here we incorporate the notion of reference intensity into it and define `hif-index`.

Definition 2. *An author A with a set of papers $P(A)$ has an* `hif-index` *equals to h, if h is the largest value such that $|\{p \in P(A) | Inf(p) \geq h\}| \geq h$; where $Inf(p)$ is the sum of intensities of all citations of p.*

We consider 37 ACL fellows as the list of gold-standard influential authors. For comparative evaluation, we consider the total number of papers (`TotP`), total number of citations (`TotC`) and average citations per paper (`AvgC`) as three competing measures along with `h-index` and `hif-index`. We arrange all the authors in our dataset in decreasing order of each measure. Figure 3(a) shows the Spearman's rank correlation among the common elements across pair-wise rankings. Figure 3(b) shows the $Precision@k$ for five competing measures at identifying ACL fellows. We observe that `hif-index` performs significantly well with an overall precision of 0.54, followed by `AvgC` (0.37), h-index (0.35), `TotC` (0.32) and `TotP` (0.34). This result is an encouraging evidence that the reference-intensity could improve the identification of the influential authors. Top three authors based on `hif-index` are shown in Table 4.

	TopP	TopC	AvgC	H–index	Hif–index
TopP	1	0.27	0.34	0.24	0.21
TopC	0.27	1	0.35	0.32	0.28
AvgC	0.34	0.35	1	0.24	0.38
H–index	0.24	0.32	0.24	1	0.31
Hif–index	0.21	0.28	0.38	0.31	1

6.3 Effect on Recommendation System

Here we show the effectiveness of reference-intensity by applying it to a real paper recommendation system. To this end, we consider `FeRoSA`[7] (Chakraborty et al., 2016), a new (probably the first) framework of faceted recommendation for scientific articles, where given a query it provides facet-wise recommendations with each facet representing the purpose of recommendation (Chakraborty et al., 2016). The methodology is based on random walk with restarts (RWR) initiated from a query paper. The model is built on AAN dataset and considers both the citation links and the content information to produce the most relevant results. Instead of using the unweighted citation network, here we use the weighted network with each edge labeled by the intensity score. The final recommendation of `FeRoSA` is obtained by performing RWR with the transition probability proportional to the edge-weight (we call it `Inf-FeRoSA`). We observe that `Inf-FeRoSA` achieves an average precision of 0.81 at top 10 recommendations, which is 14% higher then `FeRoSA` while considering the flat version and 12.34% higher than `FeRoSA` while considering the faceted version.

6.4 Detecting Citation Stacking

Recently, Thomson Reuters began screening for journals that exchange large number of anomalous citations with other journals in a cartel-like arrangement, often known as "citation stacking" (Jump, 2013; Hardcastle, 2015). This sort of citation stacking is much more pernicious and difficult to detect.

[6] We choose papers from the area of "sentiment analysis" on which experts agree on evaluating the papers.

3.	A maximum entropy approach to natural language processing (Berger et al., 1996)	Dan Klein

Table 4: Top three papers and authors based on `InfPR` and `Hif-index` respectively.

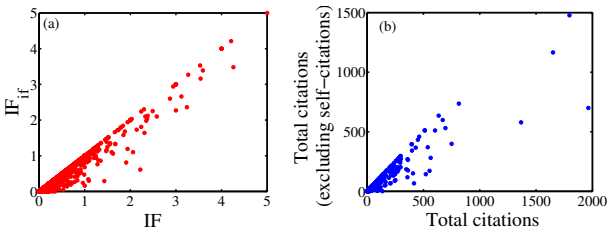

Figure 4: Correlation between (a) IF and IF_{if} and (b) number of citations before and after removing self-journal citations.

We anticipate that this behavior can be detected by the reference intensity. Since the AAN dataset does not have journal information, we use DBLP dataset (Singh et al., 2015) where the complete metadata information (along with reference contexts and abstract) is available, except the full content of the paper (559,338 papers and 681 journals; more details in (Chakraborty et al., 2014)). From this dataset, we extract all the features mentioned in Section 3.3 except the ones that require full text, and run our model using the existing annotated dataset as training instances. We measure the traditional impact factor (IF) of the journals and impact factor after considering the reference intensity (IF_{if}). Figure 4(a) shows that there are few journals whose IF_{if} significantly deviates (3σ from the mean) from IF; out of the suspected journals 70% suffer from the effect of self-journal citations as well (shown in Figure 4(b)), example including *Expert Systems with Applications* (current IF of 2.53). One of the future work directions would be to predict such journals as early as possible after their first appearance.

7 Related Work

Although the citation count based metrics are widely accepted (Garfield, 2006; Hirsch, 2010), the belief that mere counting of citations is dubious has also been a subject of study (Chubin and Moitra, 1975). (Garfield, 1964) was the first who explained the reasons of citing a paper. (Pham and Hoffmann, 2003) introduced a method for the rapid development of complex rule bases for classifying text segments. (Dong and Schfer, 2011) focused on a less manual approach by learning domain-insensitive features from textual, physical, and syntactic aspects To address concerns about h-index, different alternative measures are proposed (Waltman and van Eck, 2012). However they too could benefit from filtering or weighting references with a model of influence. Several research have been proposed to weight citations based on factors such as the prestige of the citing journal (Ding, 2011; Yan and Ding, 2010), prestige of an author (Balaban, 2012), frequency of citations in citing papers (Hou et al., 2011). Recently, (Wan and Liu, 2014) proposed a SVR based approach to measure the intensity of citations. Our methodology differs from this approach in at lease four significant ways: (i) they used six very shallow level features; whereas we consider features from different dimensions, (ii) they labeled the dataset by the help of independent annotators; here we additionally ask the authors of the citing papers to identify the influential references which is very realistic (Gilbert, 1977); (iii) they adopted SVR for labeling, which does not perform well for small training instances; here we propose `GraLap` , designed specifically for small training instances; (iv) four applications of reference intensity mentioned here are completely new and can trigger further to reassessing the existing bibliometrics.

8 Conclusion

We argued that the equal weight of all references might not be a good idea not only to gauge success of a research, but also to track follow-up work or recommending research papers. The annotated dataset would have tremendous potential to be utilized for other research. Moreover, `GraLap` can be used for any semi-supervised learning problem. Each application mentioned here needs separate attention. In future, we shall look into more linguistic evidences to improve our model.

Improving Users' Demographic Prediction via the Videos They Talk about

Yuan Wang, Yang Xiao, Chao Ma, and Zhen Xiao
Department of Computer Science, Peking University, Beijing 100871, China
{wangyuan, xiaoyang, machao, xiaozhen}@net.pku.edu.cn

Abstract

In this paper, we improve microblog users' demographic prediction by fully utilizing their video related behaviors. First, we collect the describing words of currently popular videos, including video names, actor names and video keywords, from video websites. Secondly, we search these describing words in users' microblogs, and build the direct relationships between users and the appeared words. After that, to make the sparse relationship denser, we propose a Bayesian method to calculate the probability of connections between users and other video describing words. Lastly, we build two models to predict users' demographics with the obtained direct and indirect relationships. Based on a large real-world dataset, experiment results show that our method can significantly improve these words' demographic predictive ability.

1 Introduction

Recent studies have indicated that users' demographics can be predicted from their linguistic characteristics. A typical practice is cutting the text into a bag of words and training a linear classifier. Although this practice can achieve an acceptable result in simple tasks such as predicting gender and age, it loses some important information about the text structure and does not fully use the relationship between words.

Nowadays, people spend a lot of time on videos and social media which provide them with access to post views and comments. Weibo is one of the biggest microblogging platforms in China. More than one third of the "Weibo Trends"[1] are about videos. Generally, people with different demographic attributes usually have different tastes for videos (Abisheva et al., 2014). For example, in China people who watch English drama tend to be well-educated. Here is a question: if the video related information in users' weibo messages can be fully used, will the users' demographic prediction be improved?

One challenge is that many users do not directly mention the video names in their weibo messages. Instead, they make comments on the actors or the plots. If a person likes "Big Bang Theory", he may post "*Will the Big Bang Theory last into the next century?*" where the sitcom's name is mentioned directly, or "*Sheldon is so cool, I love him!*" which talks about an actor of the sitcom. Both posts indicate the user is interested in "Big Bang Theory". When involving the demographic prediction, however, the traditional "bag of words based" model cannot extract the above information effectively. Some previous works use topic models such as LIWC (Pennebaker et al., 2001) or LDA (Blei et al., 2003) to detect the relations among users' words. Usually, they suffer from the short length of weibo messages and the number of topics. In addition, the lifespan of most popular video programs is not very long, which renders traditional topic models inefficient.

Fortunately, there exist some third-party video websites, such as *youtube.com* and *youku.com*, from which we can get the most popular videos. For each video, there is usually a homepage with a actor list

[1] http://d.weibo.com/100803

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1359–1368,
Austin, Texas, November 1-5, 2016.

and also a comments section, and we can calculate the video's Top TF-IDF words (keywords) based on these comments. Here we define the *video name*, *actor name* and *keyword* to be three different kinds of "video describing words". The relationships among these words can be used to better understand weibo users' video related behaviors. This approach can be applied to other kinds of words, such as describing words on books and music. This paper focuses on the video as an example.

After obtaining the video describing words, we build three matrices to represent the direct and indirect relationships between weibo users and these words. They are User-Video Matrix, User-Actor Matrix and User-Keyword Matrix, respectively. At beginning, these three matrices are sparse because they only represent the direct relationships, which means that only when the words appear in user's weibos, the corresponding position will be set. After that, we propose a "hidden layer" to detect the indirect relationships, making them denser.

With these indirect relationships, we can improve users' demographic predictions, including *gender*, *age*, *education background*, and *marital status*. This paper makes the followings three contributions:

1. By construct three matrices, we detect the direct and indirect relationships between weibo users and video describing words.

2. Two models are proposed to predict users' demographics by using both direct and indirect relationships.

3. Experiment results prove that our efforts can significantly improve the predictive accuracy, compared with the existing research.

The rest of this paper is organized as follows. Section 2 introduces the dataset and demographics. Section 3 introduces how to make full use of video related behaviors. Section 4 presents experimental results. Finally, we review related work in Section 5, and draw conclusions in Section 6.

2 Dataset and Demographics

2.1 Dataset

We collected 2,970,642 microblog users from Weibo (http://weibo.com), the largest microblog service in China, as our dataset. To avoid spam users (sometimes called robot users), we only collected *verified users* and *users followed by verified user*. Weibo conducts manual verifications to make sure the verified users provide real and authentic profile information. Table 1 presents four target demographic attributes and the completion rates (ratio of effective users). All data is either through Open API or publicly available. No private data is used in the experiment.

We also collected 847 popular video programs from YISQ (4 popular video websites in China: *youku*, *iqiyi*, *sohu*, *qq*). These videos mainly fall into three types: movie, tv play, and variety shows. We downloaded these videos' Homepages and extracted their actors and TOP20 TF-IDF words. The statistics are shown in Table 2.

2.2 Ground Truth

One problem of our dataset is it contains celebrities, while our model mainly targets ordinary weibo users. We implement a filter to exclude celebrities based on their large numbers of followers (>50000 as default), making the ground truth more representative. Besides, users with less than 100 messages are discarded. At last, we obtain 742,323 accounts with both their demographics and messages.

2.3 Demographics

As Table 1 shows, the demographic attributes concerned in this paper include gender, age, education background, and marital status:

Gender (Binary): the gender prediction is a typical binary classification task: male, female.

Age (4-Class): because there is only a handful of(<1%) user older than 45, we classify users into the following four age groups: Teenage (<18), Youngster (18-24), Young (25-34), Mid-age (>34).

Education Background (Binary): we categorize users' education background into two groups: university, non-university.

Marital Status (Binary): marital status is also simplified to a binary classification task: single, non-single.

3 Our Model

In this section, we introduce the framework, which contains four steps.

Attribute	Completion Rate	Categories
Gender	95.019%	Male, Female
Age	18.604%	Teenage (<18), Youngster (18-24), Young (25-34), Mid-age(>34)
Education BG	17.443%	University, Non-University
Marital Status	2.203%	Single, Non-Single

Table 1: Demographic attributes and corresponding categories

	Video	Actor	Keyword
Variety show	344	1007	2925
Movie	306	741	2049
TV	197	515	1302
Total	**847**	1422	4094

Table 2: Statics of video relevant information (There is an overlap between the three collections of actors and keywords.)

The first step generates the "Video describing words" and represents user as two vectors (V_v, V_o). V_v consists of user's "video describing words" and V_o consists of user's "other words". At first, V_v only contains user's direct relationships.

> *V_v: video describing words (direct)*
> *V_o: other words*
> *V_a: V_v + V_o*

The second step detects the indirect relationships between users and videos. For example, if a user mentioned "Robert Downey Jr", we believe he has an indirect relationships with "Iron Man" movie. By doing so, we add user's indirect relationships into his V_v, getting a denser vector V_v'.

> *V_v': video describing words (direct+indirect)*
> *V_a': V_v' + V_o*

The third step proposes two models respectively to evaluate whether those indirect relationships, discovered in second step, can be used to develop a more accurate prediction model.

The fourth step represents weibo user with the combination of V_v' and V_o, and use the combination to train a linear SVM to evaluate whether this effort can make the prediction better.

3.1 Discover Indirect Relationships

If a user mentioned a video's name directly, we believe there is a direct relationship between them. The rests are unobvious relationships. In this part, we calculate whether these unobvious relationships can be transformed into indirect ones.

3.1.1 User-Video Matrix

Firstly, we detect whether a user directly mentioned a video program in his weibo messages. There are two scenarios: the first is this user posts a message containing the video's name directly, and the other is this user reposts a message containing the video's name. In this paper, we believe these two scenarios both indicate there is a direct relationship between the user and the video, and do not make a distinction between them. Till now, we construct a Direct User-Video Matrix (DUVM) to denote all the direct relationships between users and videos.

Step 1: We know each video program v_n contains some actors a_{nj} and keywords w_{ni}. We can calculate $P(v_n)$, $P(a_{nj}|v_n)$ and $P(w_{ni}|v_n)$ in Step 1. $P(v_n)$ represents the probability that a person has watched the n_{th} video. $P(w_{ni}|v_n)$ represents the probability that a person, who has watched the n_{th} video, mention the ni_{th} keyword. $P(a_{nj}|v_n)$ is the probability that a person, who has watched the n_{th} video, mention the nj_{th} actor.

$P(v_n)$ = num (users watched the n_{th} video) / num (users)

$P(w_{ni}|v_n)$ = num (users watched the n_{th} video and mentioned the ni_{th} keyword) / num (users watched the n_{th} video)

$P(a_{nj}|v_n)$ = num (users watched the n_{th} video and mentioned the nj_{th} actor) / num (users watched the n_{th} video)

Step 2: In step 2, If a user doesn't mention a video's name directly, but mentions the video's related actors (A_k) and keywords (W_m), we can update his unobvious user-video relationships according to a Bayesian framework.

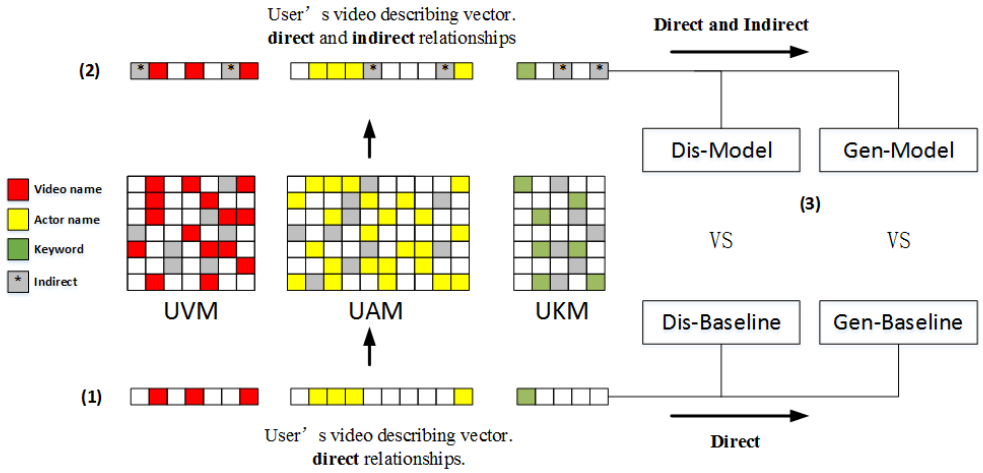

Figure 1: (1) At first, identify the describing words from users microblogs, which builds the direct relationships between users and these words. (2) By construct three matrices, we detect the indirect relationships between weibo users and video describing words. (3)Two models are proposed to predict users demographics by using both direct and indirect relationships.

$$P(v_n|W_m, A_k) = \frac{P(W_m, A_k|v_n) * P(v_n)}{P(W_m, A_k)}$$
$$= \frac{\prod_{w_{ni} \in W_m} P(w_{ni}|v_n) * \prod_{a_{nj} \in A_k} P(a_{nj}|v_n) * P(v_n)}{P(W_m, A_k)} \quad (1)$$

Through Step 2, we can discover some new indirect relationships and update UVM. Go back to Step 1 and iterate until converges, we can get the Final UVM at last.

3.1.2 User-Actor Matrix

Every video program has several actors, and the relationships between weibo users and actors may contribute to the demographic prediction either. So we build the UAM, where each row represents a weibo user and each column represents an actor.

There are two case that the element of UAM will be set to true: (1) the user 'i' directly mentioned actor 'j' in his weibo messages (including post and repost); (2) the user 'i' has watched video 'v', and actor 'j' participate in video 'v'. The second case needs UVM's help. We suppose these two cases affect the value equally in this paper.

3.1.3 User-Keyword Matrix

We can find several keywords to describe each video from their Homepages. For instance, we get "Paul Walker", "fight", and "car" to describe "Furious 7".

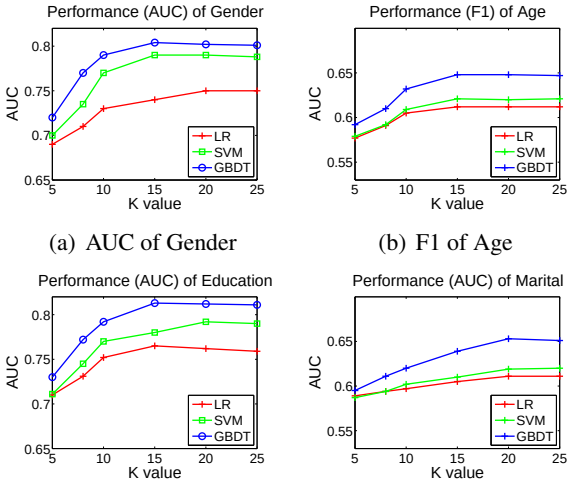
Each row of UKM represents a weibo user and each column represents a keyword of a certain video. (1) If we find a user has watched the "Furious 7", no matter direct or indirect relationship, we can set the columns of user's "Furious 7" keywords to true. (2) The value can be set to true either if the user directly mentioned these keywords.

3.2 Two Indirect Relationship Based Models

In this part, two models are proposed to predict users' demographics by using both direct and indirect relationships.

3.2.1 Discriminant Model (Dis-Model)

Given three matrices, the intuitive way to predict users' demographics is using Collaborative Filtering. However, finding the similar users directly based on the vector similarity is not a good idea, because a substantial part of users have ever watched no more than 10 videos. Matrix Factorization has been proven useful to address data sparsity, for the reduced orthogonal dimensions are less noisy than the original data and can capture the latent associations between users and videos. In our Dis-Model, we utilize the factorization machines (Rendle, 2010) to deal with UVM, UAM, and UKM, reducing the length of user's dimensionality from videos' number (actors' number, keywords'



(a) AUC of Gender (b) F1 of Age

(c) AUC of Education BG (d) AUC of Marital Status

Figure 2: Performance of different classifiers (LR, SVM, GBDT) for Dis-Model with varying K.

number) to a smaller value K. Every weibo user can be represented by the combination of these three K-length vectors.

Over the last several decades, many kinds of discriminant classifier have been created. For our four tasks, we compared Logistic Regression (LR), Support Vector Machine (SVM), and Gradient Boosted Decision Tree (GBDT). Figure 2 illustrates their performance, where GBDT performs the best in all K values. When K increases from 5 to 20, all classifiers' results are all getting better and tend to be stable when K is bigger than 20. So we choose GBDT as our default base classifier and K=20 as default value.

3.2.2 Generative Model (Gen-Model)

We start with introducing an important concept: video demographic tendency, which means to what extent a video belongs to a specified demographic group. For example, if 90% audiences of a movie are males, we define its demographic tendency on male as 90%. The actor tendency and keyword tendency can be calculated in the same way.

In the Gen-Model, (1) we firstly calculate each video's (actor, keyword) demographic tendency according to its audiences (known demographics). (2) Based on the demographic tendency of videos (actors, keywords), we predict user's (unknown) demographics via a Bayesian method. (3) At last, we propose a smooth step to adjust the result.

(1) Calculate video demographic tendency

At first, we calculate every video demographic tendency as Equation 2:

$$p(c|v_j) = \frac{\sum_{i=1}^{n}(r_{ij} * u_i(c))}{\sum_{i=1}^{n} r_{ij}} \tag{2}$$

$P(c|v_j)$ represents the j_{th} video's demographic tendency on c, where c is the demographic attribute. r_{ij} will be set to 1 if the i_{th} user has watched the j_{th} video, otherwise set to 0. $u_i(c)$ is a boolean, representing whether the i_{th} user has the attribute c.

(2) Calculate user demographic attribute

In this step, we predict users' demographics according to the demographic tendency of the videos they has watched. Suppose user's viewing habits are independent, we can calculate the probability of $P(c|u_i)$ as Equation 3:

$$\begin{aligned} P(c|u_i) &\propto P(c|\{V\}) \\ &\propto P(\{V\}|c) * P(c) \\ &\propto \prod_{v_j \in \{V\}} P(v_j|c) * P(c) \\ &= \frac{\prod_{v_j \in \{V\}} P(c|v_j) * P(v_j)}{P(c)} * P(c) \\ &\propto \prod_{v_j \in \{V\}} P(c|v_j) \end{aligned} \tag{3}$$

$\{V\}$ represents the collection of videos watched by u_i. $P(c|v_j)$ is the j_{th} video's demographic tendency on c, as the previous part described.

(3) Smooth the result

Based on the fact that people in same demographic group may have similar behaviors, we deploy a smooth component to adjust the value of $P(c|v_j)$ and $P(c|u_i)$ according to their top *n* neighbors. As mentioned above, we use factorization machines to transform the user and video vectors into low-dimensional (K=20) ones. The distance is calculated by Euclidean Distance. The video, actor, and word have the same treating process, so we introduce the video as representative.

Smooth the Video's Demographic Tendency: Base on video v_j's top n neighbors, we can calculate its neighbors' average demographic tendency $P(c|nbr(v_j))$, where $P(c|v_{nbj})$ is v_j's nbj_{th} neighbor's demographic tendency.

$$p(c|nbr(v_j)) = \frac{\sum_{j=1}^{n} P(c|v_{nbj})}{n} \quad (4)$$

Therefore, we can smooth v_j's demographic tendency by:

$$P(c|v_j) = \alpha * P(c|v_j) + (1-\alpha) * P(c|nbr(v_j)) \quad (5)$$

α is the parameter to control the top n neighbors' influence. In this paper, we compared ten values of α and chose 0.7 as default. With the same process, n is set to 10 as default.

Smooth the User's Demographic Result: The user side smooth procedure is similar to the video side, except user's $P(c|nbr(u_i))$ is affected by three kinds of neighbors (u_{nbvi}, u_{nbai}, u_{nbwi}).

$$p(c|nbr(u_i)) = \frac{\sum_{i=1}^{n} P(c|u_{nbvi})}{3n} + \frac{\sum_{i=1}^{n} P(c|u_{nbai})}{3n} + \frac{\sum_{i=1}^{n} P(c|u_{nbwi})}{3n} \quad (6)$$

Just like video's smooth process, we adjust u_i's demographic attributes by:

$$P(c|u_i) = \alpha * P(c|u_i) + (1-\alpha) * P(c|nbr(u_i)) \quad (7)$$

The smooth component is deployed as an iterative procedure, and keeps running until each $P(c|u_i)$ became stable.

Two Baselines: To validate whether those indirect relationships can improve the predictions, we build two baseline models: Dis-Baseline and Gen-Baseline. While our two models use the V_v' as input, these two baseline models use the raw V_v. These two baseline models adopt the same architecture with our proposed two models. The only difference is the input data.

3.3 Fusion Model

As described above, we discovered the indirect relationships between users and video describing words, and demonstrated this effort can leading a better result than directly train the classifier.

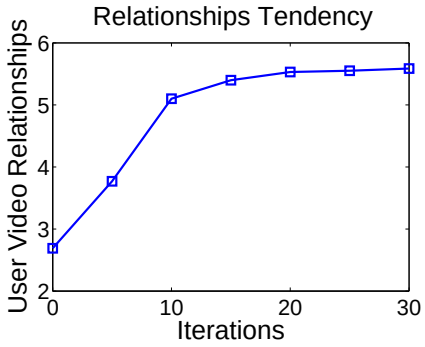


Figure 3: Tendency of User-Video relationship number.

But pre-existing models commonly utilize all the words in user's weibo messages. So we need to find out whether our hard-earned improvement would be submerged by those "Non video describing words". We train a Fusion Model using all the words in weibo messages and indirect relationships together, and compare it with a baseline model, who only use all the words (without indirect relationships).

Fusion Baseline: Many pre-existing methods (Burger et al., 2011; Tu et al., 2015) chose linear model as their text classifier, for linear model is suitable for text categorization tasks. We choose L1-regularized linear SVM as our Fusion Model and Fusion-Baseline's classifier. The only difference between them is the input data (V_v' + V_o **vs** V_v + V_o).

4 Experiment Results

We conducted a 10-fold cross validation to demonstrate our framework's effectiveness, where 8 parts for training, 1 parts for validation and 1 parts for testing by default. The performance of presented methods were evaluated using the Precision, Recall and Macro-F1 measures. Binary classification tasks were also measured by Area Under the ROC Curve (AUC).

4.1 Indirect Relationships Evaluation

In our dataset, each user directly mention 2.6 video programs on average and only 0.7% has more than 10 direct relationships. As shown in Figure 3, more and more indirect relationships arise along with the iterations. User's relationship number (direct + indirect) stabilized at 5.7 on average and 13% of them is bigger than 10.

To answer whether these indirect relationships

		Precision	Recall	F1	AUC
Gender	Dis-Baseline	0.720	0.714	0.717	0.730
	Dis-Model	0.786	0.779	0.783	**0.812** ↑ 11.2%
	Gen-Baseline	0.701	0.687	0.694	0.707
	Gen-Model	0.799	0.802	0.801	**0.825** ↑ 16.7%
Age	Dis-Baseline	0.569	0.541	0.554	*
	Dis-Model	0.642	0.653	**0.648** ↑ 16.8%	*
	Gen-Baseline	0.529	0.504	0.516	*
	Gen-Model	0.663	0.645	**0.654** ↑ 26.7%	*
Education BG	Dis-Baseline	0.707	0.716	0.711	0.730
	Dis-Model	0.788	0.801	0.795	**0.809** ↑ 11.1%
	Gen-Baseline	0.680	0.659	0.669	0.690
	Gen-Model	0.790	0.808	0.799	**0.812** ↑ 17.7%
Marital Status	Dis-Baseline	0.565	0.549	0.557	0.571
	Dis-Model	0.657	0.640	0.648	**0.659** ↑ 15.4%
	Gen-Baseline	0.572	0.550	0.560	0.581
	Gen-Model	0.682	0.691	0.687	**0.696** ↑ 19.8%

Table 3: Prediction accuracy based on users' video describing words. Classes have been balanced.

can make the prediction better, we compared our two models (Dis-Model & Gen-Model) with two baseline models. We also compared their performance on different user groups categorized by user-video relationship number.

Gender: As Table 3 shows, our two models both have a significant improvement compared to the baseline models. The Gen-Model achieve the best performance (AUC 0.825) in terms of all the measurement. As Figure 4(a) shows, with the number growth, our two models' AUC scores are both getting better. Surprisingly, when the number is bigger than 10, the Gen-Model even get a similar performance of the model using all of the user's words.

Age: In the age task, our two models both outperformed the baseline models significantly, and the generative model performs better (F1 0.654) too. We analyzed the result and found the "youngster" and "young" share the similar watching habits in Weibo. It's hard to pick out a 23 years old user from the 28 years old group. As Figure 4(b) shows, our two models' F1 scores are both getting better along with the growth of user-video relationship number.

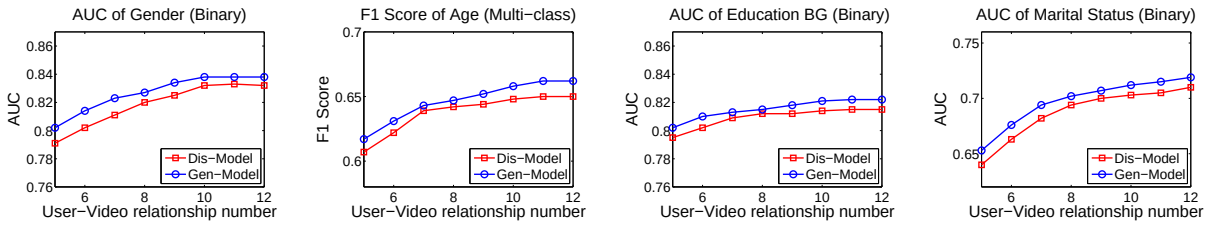
Education Background: Not surprisingly, our two models obviously outperform the result over two baseline models. This result indicates that people in different education background has visible different tastes on video programs.

Marital Status: Table 3 presents the results of marital status. We notice that the performance of our two model is still reasonable, but is worse than gender and education tasks. In addition to that this task is more difficulty, another reason is when a user gets married, he might not update the information in his online profile.

Remark: Experiment results show that our method can significantly improve these words' demographic predictive ability by more than 15% on average. 10 videos is good enough to portray a weibo user, and can achieve reasonable results in these 4 inference tasks. The video related behavior is efficient on predicting gender and education, for people on these two tasks have visible different inclinations. Inferring age and marital status is not easy, but our two models still achieve reasonable improvements. In general, our two models both get significantly better results than baselines. The Gen-Model is a better choice by contrast.

4.2 Fusion Model Evaluation

After we obtained the potential predictive ability of indirect relationships, we also need to find out whether it can help pre-existing model perform



(a) AUC of Gender (b) F1 Score of Age (c) AUC of Education BG (d) AUC of Marital Status

Figure 4: Prediction result with varying User-Video relationship numbers.

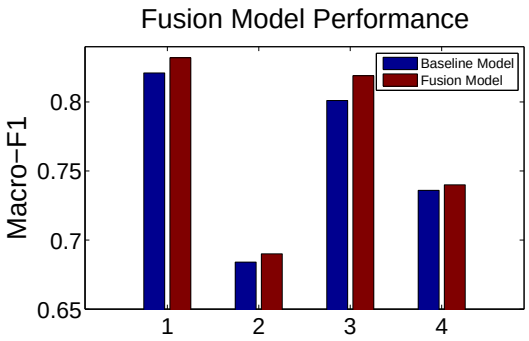


Figure 5: Results of Fusion Model evaluation (Macro-F1).

better. We compare the Fusion Baseline (V_v+V_o) with our Fusion Model (V_v'+V_o). As Figure 5 shows, Fusion Model's performance is better than Fusion Baseline's in all four tasks. The improvement is about 2-3% on average. As above mentioned, our approach can be applied to other kinds of words, such as describing words on books and music. So there is some room for improvement.

5 Related work

In this section, we briefly review the research works related to our work.

Many researches (Kumar and Tomkins, 2010; Goel et al., 2012) found users belong to different demographic groups behave differently. (Hu et al., 2007; Murray and Durrell, 2000; Goel et al., 2012; Kosinski et al., 2012) showed that age, gender, education level, and even personality can be predicted from people's webpage browsing logs. (Kosinski et al., 2013; Schwartz et al., 2013; Youyou et al., 2015) showed computers' judgments of people's personalities based on their Facebook Likes are more accurate and valid than judgments made by their close acquaintances. (Malmi and Weber, 2016) showed users' demographics also can be predicted based on theirs apps. Apart from the browsing behaviors, there also exist some works based on user's linguistic characteristics. (Schler et al., 2006) analyzed tens of thousands of blogs and indicated significant differences in writing style and word usage between different gender and age groups. The similar result also showed in (Luyckx and Daelemans, 1998; Oberlander and Nowson, 2006; Mairesse et al., 2007; Nowson, 2007; Gill et al., 2009; Rosenthal and McKeown, 2011). There are some works (Bi et al., 2013; Weber and Jaimes, 2011; Weber and Castillo, 2010) on predicting search engine user's demographics based on their search queries. (Hovy, 2015) investigated the influence of user's demographics on better understanding their online reviews. (Otterbacher, 2010) used logistic regression model to infer users gender based on the content of movie reviews.

Many researches focused on the twitter users. In the Author Profiling task at PAN 2015 (Rangel et al., 2015), participants approached the task of identifying age, gender and personality traits from Twitter. (Nguyen et al., 2013) explored users' age prediction task based on their tweets, achieving better performance than humans. (Burger et al., 2011) studied the gender predictive ability of twitter linguistic characteristics, reached 92% accuracy. (Pennacchiotti and Popescu, 2011) proposed a GB-DT model to predict users' age, gender, political orientation and ethnicity by leveraging their observable information. (Culotta et al., 2015) predicted the demographics of Twitter users based on whom they follow, and (Zhong et al., 2015) predicted the microblog user's demographic attributes only by their chick-ins. In (Li et al., 2014), job and education attributes are extracted by combining a rule based approach with a probabilistic system. There are also some works based on users' social relationships

(Mislove et al., 2010; Henderson et al., 2012; Zhao et al., 2013).

6 Conclusion

Our motivation on writing this paper is user's video related behavior is usually under-utilized on demographic prediction tasks. With the help of third-party video sites, we detect the direct and calculate the indirect relationships between users and video describing words, and demonstrate this effort can improve the accuracy of users' demographic predictions. To our knowledge, this is the first work which explores demographic prediction by fully using users' video describing words. This framework has good scalability and can be applied on other concrete features, such as user's book reading behaviors and music listening behaviors.

Abstract

Distant supervision has been widely used in current systems of fine-grained entity typing to automatically assign categories (entity types) to entity mentions. However, the types so obtained from knowledge bases are often incorrect for the entity mention's local context. This paper proposes a novel embedding method to separately model "clean" and "noisy" mentions, and incorporates the given type hierarchy to induce loss functions. We formulate a joint optimization problem to learn embeddings for mentions and type-paths, and develop an iterative algorithm to solve the problem. Experiments on three public datasets demonstrate the effectiveness and robustness of the proposed method, with an average 15% improvement in accuracy over the next best compared method[1].

1 Introduction

Assigning types (*e.g.*, `person`, `organization`) to mentions of entities in context is an important task in natural language processing (NLP). The extracted entity type information can serve as primitives for relation extraction (Mintz et al., 2009) and event extraction (Ji and Grishman, 2008), and assists a wide range of downstream applications including knowledge base (KB) completion (Dong et al., 2014), question answering (Lin et al., 2012) and entity recommendation (Yu et al., 2014). While traditional named entity recognition systems (Ratinov and Roth, 2009; Nadeau and Sekine, 2007) focus on a small set of coarse types (typically fewer than 10), recent studies (Ling and Weld, 2012; Yosef et al., 2012) work on a much larger set of fine-grained types (usually over 100) which form a tree-structured hierarchy (see the blue region of Fig. 1). Fine-grained typing allows one mention to have multiple types, which together constitute a *type-path* (not necessarily ending in a leaf node) in the given type hierarchy, *depending on the local context* (*e.g.*, sentence). Consider the example in Fig. 1, "*Arnold Schwarzenegger*" could be labeled as {`person`, `businessman`} in S3 (investment). But he could also be labeled as {`person`, `politician`} in S1 or {`person`, `artist`, `actor`} in S2. Such fine-grained type representation provides more informative features for other NLP tasks. For exam-

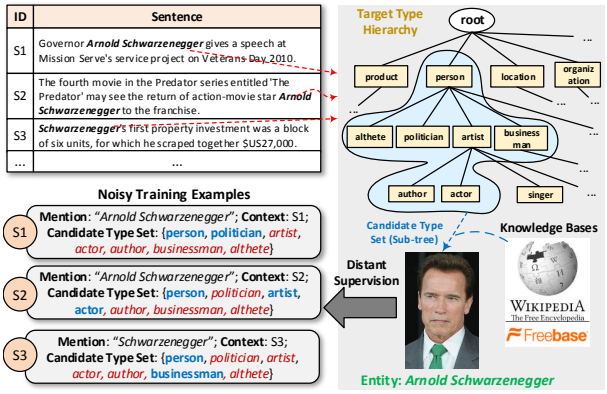

Figure 1: Current systems may detect *Arnold Schwarzenegger* in sentences S1-S3 and assign the same types to all (listed within braces), when only some types are correct for context (blue labels within braces).

[*]Equal contribution.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1369–1378,
Austin, Texas, November 1-5, 2016.

ple, since relation and event extraction pipelines rely on entity recognizer to identify possible arguments in a sentence, fine-grained argument types help distinguish hundreds or thousands of different relations and events (Ling and Weld, 2012).

Traditional named entity recognition systems adopt manually annotated corpora as training data (Nadeau and Sekine, 2007). But the process of manually labeling a training set with large numbers of fine-grained types is too expensive and error-prone (hard for annotators to distinguish over 100 types consistently). Current fine-grained typing systems annotate training corpora automatically using knowledge bases (*i.e.*, *distant supervision*) (Ling and Weld, 2012; Ren et al., 2016a). A typical workflow of distant supervision is as follows (see Fig. 1): (1) identify entity mentions in the documents; (2) link mentions to entities in KB; and (3) assign, to the candidate type set of each mention, all KB types of its KB-linked entity. However, existing distant supervision methods encounter the following limitations when doing automatic fine-grained typing.

• **Noisy Training Labels.** Current practice of distant supervision may introduce *label noise* to training data since it fails to take a mention's local contexts into account when assigning type labels (*e.g.*, see Fig. 1). Many previous studies ignore the label noises which appear in a majority of training mentions (see Table. 1, row (1)), and assume *all* types obtained by distant supervision are "correct" (Yogatama et al., 2015; Ling and Weld, 2012). The noisy labels may mislead the trained models and cause negative effect. A few systems try to denoise the training corpora using simple pruning heuristics such as deleting mentions with conflicting types (Gillick et al., 2014). However, such strategies significantly reduce the size of training set (Table 1, rows (2a-c)) and lead to performance degradation (later shown in our experiments). The larger the target type set, the more severe the loss.

• **Type Correlation.** Most existing methods (Yogatama et al., 2015; Ling and Weld, 2012) treat every type label in a training mention's candidate type set *equally* and *independently* when learning the classifiers but ignore the fact that types in the given hierarchy are semantically correlated (*e.g.*, `actor` is more relevant to `singer` than to `politician`). As a consequence, the learned classifiers may bias toward popular types but perform poorly on infrequent types since training data on infrequent types is scarce. Intuitively, one should pose smaller penalty on types which are semantically more relevant to the true types. For example, in Fig. 1 `singer` should receive a smaller penalty than `politician` does, by knowing that `actor` is a true type for "*Arnold Schwarzenegger*" in S2. This provides classifiers with additional information to distinguish between two types, especially those infrequent ones.

Dataset	Wiki	OntoNotes	BBN	NYT
# of target types	113	89	47	446
(1) noisy mentions (%)	27.99	25.94	22.32	51.81
(2a) sibling pruning (%)	23.92	16.09	22.32	39.26
(2b) min. pruning (%)	28.22	8.09	3.27	32.75
(2c) all pruning (%)	45.99	23.45	25.33	61.12

Table 1: A study of label noise. (1): %mentions with multiple *sibling types* (*e.g.*, `actor`, `singer`); (2a)-(2c): %mentions deleted by the three pruning heuristics (2014) (see Sec. 4), for three experiment datasets and New York Times annotation corpus (2014).

In this paper, we approach the problem of *automatic fine-grained entity typing* as follows: (1) Use different objectives to model training mentions with correct type labels and mentions with noisy labels, respectively. (2) Design a novel *partial-label loss* to model true types within the noisy candidate type set which requires only the "*best*" candidate type to be relevant to the training mention, and progressively estimate the best type by leveraging various text features extracted for the mention. (3) Derive type correlation based on two signals: (i) the given type hierarchy, and (ii) the shared entities between two types in KB, and incorporate the correlation so induced by enforcing *adaptive margins* between different types for mentions in the training set. To integrate these ideas, we develop a novel embedding-based framework called **AFET**. First, it uses distant supervision to obtain candidate types for each mention, and extract a variety of text features from the mentions themselves and their local contexts. Mentions are partitioned into a "clean" set and a "noisy" set based on the given type hierarchy. Second, we embed mentions and types jointly into a low-dimensional space, where, in that space, objects (*i.e.*, features and types) that are semantically close to each other also have similar representations. In the proposed objective, an adaptive margin-based rank loss is pro-

posed to model the set of clean mentions to capture type correlation, and a partial-label rank loss is formulated to model the "best" candidate type for each noisy mention. Finally, with the learned embeddings (*i.e.*, mapping matrices), one can predict the type-path for each mention in the test set in a top-down manner, using its text features. The major contributions of this paper are as follows:

1. We propose an automatic fine-grained entity typing framework, which reduces label noise introduced by distant supervision and incorporates type correlation in a principle way.
2. A novel optimization problem is formulated to jointly embed entity mentions and types to the same space. It models noisy type set with a partial-label rank loss and type correlation with adaptive-margin rank loss.
3. We develop an iterative algorithm for solving the joint optimization problem efficiently.
4. Experiments with three public datasets demonstrate that AFET achieves significant improvement over the state of the art.

2 Automatic Fine-Grained Entity Typing

Our task is to automatically uncover the type information for entity mentions (*i.e.*, token spans representing entities) in natural language sentences. The task takes a document collection $\mathcal{D}$ (automatically labeled using a KB Ψ in conjunction with a target type hierarchy $\mathcal{Y}$) as input and predicts a type-path in $\mathcal{Y}$ for each mention from the test set $\mathcal{D}_t$.

Type Hierarchy and Knowledge Base. Two key factors in distant supervision are the target type hierarchy and the KB. A *type hierarchy*, $\mathcal{Y}$, is a tree where nodes represent types of interests from Ψ. Previous studies manually create several clean type hierarchies using types from Freebase (Ling and Weld, 2012) or WordNet (Yosef et al., 2012). In this study, we adopt the existing hierarchies constructed using Freebase types[2]. To obtain types for entities $\mathcal{E}_\Psi$ in Ψ, we use the human-curated entity-type facts in Freebase, denoted as $\mathcal{F}_\Psi = \{(e, y)\} \subset \mathcal{E}_\Psi \times \mathcal{Y}$.

[2]We use the Freebase dump as of 2015-06-30.

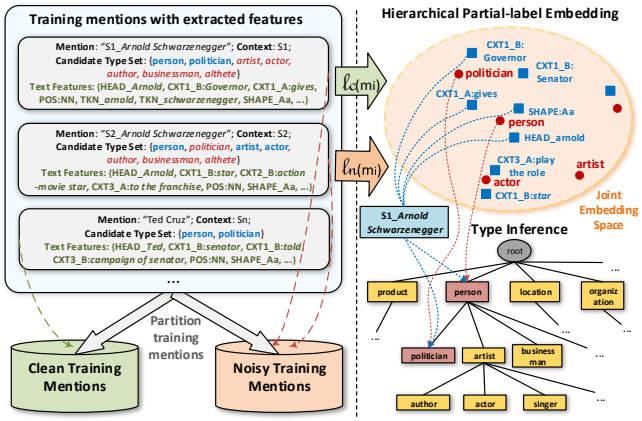

Figure 2: Framework Overview of AFET.

Automatically Labeled Training Corpora. There exist publicly available labeled corpora such as Wikilinks (Singh et al., 2012) and ClueWeb (Gabrilovich et al., 2013). In these corpora, entity mentions are identified and mapped to KB entities using anchor links. In specific domains (*e.g.*, product reviews) where such public corpora are unavailable, one can utilize distant supervision to automatically label the corpus (Ling and Weld, 2012). Specifically, an entity linker will detect mentions m_i and map them to one or more entity e_i in $\mathcal{E}_\Psi$. Types of e_i in KB are then associated with m_i to form its type set $\mathcal{Y}_i$, *i.e.*, $\mathcal{Y}_i = \{y \mid (e_i, y) \in \mathcal{F}_\Psi,\ y \in \mathcal{Y}\}$. Formally, a training corpus $\mathcal{D}$ consists of a set of extracted *entity mentions* $\mathcal{M} = \{m_i\}_{i=1}^N$, the *context* (*e.g.*, sentence, paragraph) of each mention $\{c_i\}_{i=1}^N$, and the candidate *type sets* $\{\mathcal{Y}_i\}_{i=1}^N$ for each mention. We represent $\mathcal{D}$ using a set of triples $\mathcal{D} = \{(m_i, c_i, \mathcal{Y}_i)\}_{i=1}^N$.

Problem Description. For each test mention, we aim to predict the correct type-path in $\mathcal{Y}$ based on the *mention's context*. More specifically, the test set $\mathcal{T}$ is defined as a set of mention-context pairs (m, c), where mentions in $\mathcal{T}$ (denoted as $\mathcal{M}_t$) are extracted from their sentences using existing extractors such as named entity recognizer (Finkel et al., 2005). We denote the gold type-path for a test mention m as $\mathcal{Y}^*$. This work focuses on learning a typing model from the noisy training corpus D, and estimating $\mathcal{Y}^*$ from $\mathcal{Y}$ for each test mention m (in set $\mathcal{M}_t$), based on mention m, its context c, and the learned model.

Framework Overview. At a high level, the AFET framework (see also Fig. 2) learns low-dimensional representations for entity types and text features, and

infers type-paths for test mentions using the learned embeddings. It consists of the following steps:

1. Extract text features for entity mentions in training set $\mathcal{M}$ and test set $\mathcal{M}_t$ using their surface names as well as the contexts. (Sec. 3.1).
2. Partition training mentions $\mathcal{M}$ into a clean set (denoted as $\mathcal{M}_c$) and a noisy set (denoted as $\mathcal{M}_n$) based on their candidate type sets (Sec. 3.2).
3. Perform joint embedding of entity mentions $\mathcal{M}$ and type hierarchy $\mathcal{Y}$ into the same low-dimensional space where, in that space, close objects also share similar types (Secs. 3.3-3.6).
4. For each test mention m, estimate its type-path $\mathcal{Y}^*$ (on the hierarchy $\mathcal{Y}$) in a top-down manner using the learned embeddings (Sec. 3.6).

3 The AFET Framework

This section introduces the proposed framework and formulates an optimization problem for learning embeddings of text features and entity types jointly.

3.1 Text Feature Generation

We start with a representation of entity mentions. To capture the shallow syntax and distributional semantics of a mention $m_i \in \mathcal{M}$, we extract various features from both m_i itself and its context c_i. Table 2 lists the set of text features used in this work, which is similar to those used in (Yogatama et al., 2015; Ling and Weld, 2012). We denote the set of M unique features extracted from $\mathcal{D}$ as $\mathcal{F} = \{f_j\}_{j=1}^{M}$.

3.2 Training Set Partition

A training mention m_i (in set $\mathcal{M}$) is considered as a "clean" mention if its candidate type set obtained by distant supervision (*i.e.*, $\mathcal{Y}_i$) is not ambiguous, *i.e.*, candidate types in $\mathcal{Y}_i$ can form a *single* path in tree $\mathcal{Y}$. Otherwise, a mention is considered as "noisy" mention if its candidate types form *multiple* type-paths in $\mathcal{Y}$. Following the above hypothesis, we judge each mention m_i (in set $\mathcal{M}$) and place it in either the "clean" set $\mathcal{M}_c$, or the "noisy" set $\mathcal{M}_n$. Finally, we have $\mathcal{M} = \mathcal{M}_c \cup \mathcal{M}_n$.

3.3 The Joint Mention-Type Model

We propose to learn mappings into low-dimensional vector space, where, both entity mentions and type

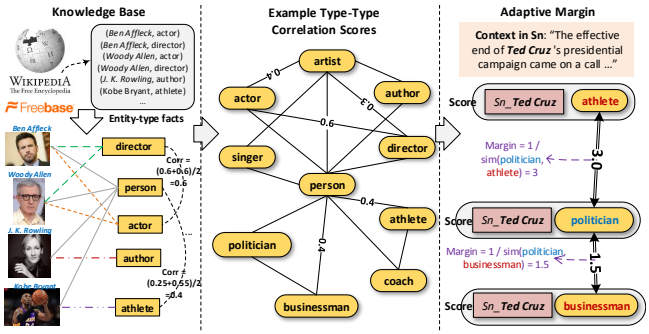

Figure 3: An illustration of KB-based type correlation computation, and the proposed adaptive margin.

labels (in the training set) are represented, and in that space, *two objects are embedded close to each other if and only if they share similar types*. In doing so, we later can derive the representation of a test mention based on its text features and the learned mappings. Mapping functions for entity mentions and entity type labels are different as they have different representations in the *raw* feature space, but are jointly learned by optimizing a global objective of interests to handle the aforementioned challenges.

Each entity mention $m_i \in M$ can be represented by a M-dimensional feature vector $\mathbf{m}_i \in \mathbb{R}^M$, where $m_{i,j}$ is the number of occurrences of feature f_j (in set $\mathcal{F}$) for m_i. Each type label $y_k \in \mathcal{Y}$ is represented by a K-dimensional binary indicator vector $\mathbf{y}_k \in \{0,1\}^K$, where $\mathbf{y}_{k,k} = 1$, and 0 otherwise.

Specifically, we aim to learn a mapping function from the mention's feature space to a low-dimensional vector space, *i.e.*, $\Phi_{\mathcal{M}}(\mathbf{m}_i) : \mathbb{R}^M \mapsto \mathbb{R}^d$ and a mapping function from type label space to the same low-dimensional space, *i.e.*, $\Phi_{\mathcal{Y}}(\mathbf{y}_k) : \mathbb{R}^K \mapsto \mathbb{R}^d$. In this work, we adopt linear maps, as similar to the mapping functions used in (Weston et al., 2011).

$$\Phi_{\mathcal{M}}(\mathbf{m}_i) = \mathbf{U}\mathbf{m}_i; \quad \Phi_{\mathcal{Y}}(\mathbf{y}_k) = \mathbf{V}\mathbf{y}_k, \qquad (1)$$

where $\mathbf{U} \in \mathbb{R}^{d \times M}$ and $\mathbf{V} \in \mathbb{R}^{d \times K}$ are the projection matrices for mentions and type labels, respectively.

3.4 Modeling Type Correlation

In type hierarchy (tree) $\mathcal{Y}$, types closer to each other (*i.e.*, shorter path) tend to be more related (*e.g.*, `actor` is more related to `artist` than to `person` in the right column of Fig. 2). In KB Ψ, types assigned to similar sets of entities should be more related to each other than those assigned to quite different entities (Jiang et al., 2015) (*e.g.*, `actor` is

Feature	Description	Example
Head	Syntactic head token of the mention	"HEAD_Turing"
Token	Tokens in the mention	"Turing", "Machine"
POS	Part-of-Speech tag of tokens in the mention	"NN"
Character	All character trigrams in the head of the mention	":tu", "tur", ..., "ng:"
Word Shape	Word shape of the tokens in the mention	"Aa" for "Turing"
Length	Number of tokens in the mention	"2"
Context	Unigrams/bigrams before and after the mention	"CXT_B:Maserati ,", "CXT_A:and the"
Brown Cluster	Brown cluster ID for the head token (learned using $\mathcal{D}$)	"4_1100", "8_1101111", "12_111011111111"
Dependency	Stanford syntactic dependency (Manning et al., 2014) associated with the head token	"GOV:nn", "GOV:turing"

Table 2: Text features used in this paper. "*Turing Machine*" is used as an example mention from "*The band's former drummer Jerry Fuchs—who was also a member of Maserati,* ***Turing Machine*** *and The Juan MacLean—died after falling down an elevator shaft.*".

more related to `director` than to `author` in the left column of Fig. 3). Thus, type correlation between y_k and $y_{k'}$ (denoted as $w_{kk'}$) can be measured either using the *one over the length of shortest path in* $\mathcal{Y}$, or using the *normalized number of shared entities in KB*, which is defined as follows.

$$w_{kk'} = \Big(|\mathcal{E}_k \cap \mathcal{E}_{k'}|/|\mathcal{E}_k| + |\mathcal{E}_k \cap \mathcal{E}_{k'}|/|\mathcal{E}_{k'}|\Big)/2. \quad (2)$$

Although a shortest path is efficient to compute, its accuracy is limited—It is not always true that a type (*e.g.*, `athlete`) is more related to its parent type (*i.e.*, `person`) than to its sibling types (*e.g.*, `coach`), or that all sibling types are equally related to each other (*e.g.*, `actor` is more related to `director` than to `author`). We later compare these two methods in our experiments.

With the type correlation computed, we propose to apply *adaptive* penalties on different negative type labels (for a training mention), instead of treating all of the labels *equally* as in most existing work (Weston et al., 2011). The hypothesis is intuitive: given the positive type labels for a mention, we force the negative type labels which are related to the positive type labels to receive smaller penalty. For example, in the right column of Fig. 3, negative label `businessman` receives a smaller penalty (*i.e.*, margin) than `athele` does, since `businessman` is more related to `politician`.

Hypothesis 1 (Adaptive Margin) *For a mention, if a negative type is correlated to a positive type, the margin between them should be smaller.*

We propose an adaptive-margin rank loss to model the set of "clean" mentions (*i.e.*, $\mathcal{M}_c$), based on the above hypothesis. The intuition is simple: for each mention, rank all the positive types ahead of negative types, where the ranking score is measured by similarity between mention and type. We denote

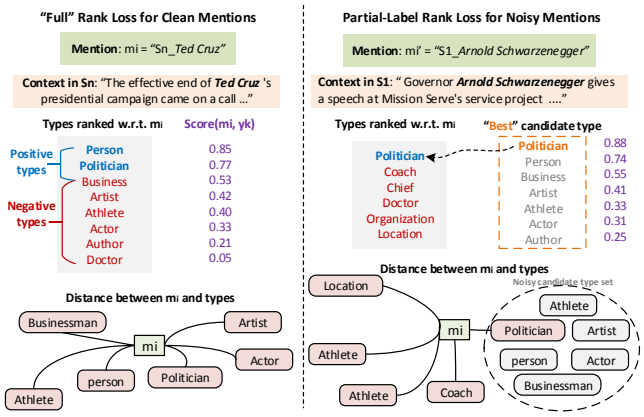

Figure 4: An illustration of the partial-label rank loss.

$f_k(m_i)$ as the similarity between (m_i, y_k) and is defined as the inner product of $\Phi_{\mathcal{M}}(\mathbf{m}_i)$ and $\Phi_{\mathcal{Y}}(\mathbf{y}_k)$.

$$\ell_c(m_i, \mathcal{Y}_i, \overline{\mathcal{Y}}_i) = \sum_{y_k \in \mathcal{Y}_i} \sum_{y_{\bar{k}} \in \overline{\mathcal{Y}}_i} L\Big\lfloor \mathrm{rank}_{y_k}\Big(f(m_i)\Big)\Big\rfloor \Theta_{i,k,\bar{k}};$$

$$\Theta_{i,k,\bar{k}} = \max\Big\{0, \gamma_{k,\bar{k}} - f_k(m_i) + f_{\bar{k}}(m_i)\Big\};$$

$$\mathrm{rank}_{y_k}\Big(f(m_i)\Big) = \sum_{y_{\bar{k}} \in \overline{\mathcal{Y}}_i} \mathbb{1}\Big(\gamma_{k,\bar{k}} + f_{\bar{k}}(m_i) > f_k(m_i)\Big).$$

Here, $\gamma_{k,\bar{k}}$ is the adaptive margin between positive type k and negative type $\bar{k}$, which is defined as $\gamma_{k,\bar{k}} = 1 + 1/(w_{k,\bar{k}} + \alpha)$ with a smooth parameter α. $L(x) = \sum_{i=1}^{x} \frac{1}{i}$ transforms rank to a weight, which is then multiplied to the max-margin loss $\Theta_{i,k,\bar{k}}$ to optimize precision at x (Weston et al., 2011).

3.5 Modeling Noisy Type Labels

True type labels for noisy entity mentions $\mathcal{M}_n$ (i.e., mentions with ambiguous candidate types in the given type hierarchy) in each sentence are not available in knowledge bases. To effectively model the set of noisy mentions, we propose not to treat *all*

candidate types (*i.e.*, $\{\mathcal{Y}_i\}$ as true labels. Instead, we model the "true" label among the candidate set as *latent value*, and try to infer that using text features.

Hypothesis 2 (Partial-Label Loss) *For a noisy mention, the maximum score associated with its candidate types should be greater than the scores associated with any other non-candidate types*

We extend the partial-label loss in (Nguyen and Caruana, 2008) (used to learn linear classifiers) to enforce Hypothesis 2, and integrate with the adaptive margin to define the loss for m_i (in set $\mathcal{M}_n$).

$$\ell_n(m_i, \mathcal{Y}_i, \overline{\mathcal{Y}}_i) = \sum_{\bar{k} \in \overline{\mathcal{Y}}_i} L\Big\lfloor \text{rank}_{y_{k^*}}\Big(f(m_i)\Big)\Big\rfloor \Omega_{i,\bar{k}};$$

$$\Omega_{i,k} = \max\Big\{0, \gamma_{k^*,\bar{k}} - f_{k^*}(m_i) + f_{\bar{k}}(m_i)\Big\};$$

$$\text{rank}_{y_{k^*}}\Big(f(m_i)\Big) = \sum_{y_{\bar{k}} \in \overline{\mathcal{Y}}_i} \mathbb{1}\Big(\gamma_{k^*,\bar{k}} + f_{\bar{k}}(m_i) > f_{k^*}(m_i)\Big)$$

where we define . $y_{k^*} = \text{argmax}_{y_k \in \mathcal{Y}_i} f_k(m_i)$ and $y_{\bar{k}^*} = \text{argmax}_{y_k \in \overline{\mathcal{Y}}_i} f_k(m_i)$.

Minimizing ℓ_n encourages a *large margin* between the maximum scores $\max_{y_k \in \mathcal{Y}_i} f_{y_k}(m_i)$ and $\max_{y_{\bar{k}} \in \overline{\mathcal{Y}}_i} f_{y_k}(m_i)$. This forces m_i to be embedded closer to the most "relevant" type in the noisy candidate type set, *i.e.*, $y^* = \text{argmax}_{y_k \in \mathcal{Y}_i} f_{y_k}(m_i)$, than to *any other* non-candidate types (*i.e.*, Hypothesis 2). This constrasts sharply with multi-label learning (Yosef et al., 2012), where a large margin is enforced between *all* candidate types and non-candidate types without considering noisy types.

3.6 Hierarchical Partial-Label Embedding

Our goal is to embed the heterogeneous graph G into a d-dimensional vector space, following the three proposed hypotheses in the section. Intuitively, one can *collectively* minimize the objectives of the two kinds of loss functions ℓ_c and ℓ_n, across all the training mentions. To achieve the goal, we formulate a joint optimization problem as follows.

$$\min_{\mathbf{U},\,\mathbf{V}} \mathcal{O} = \sum_{m_i \in \mathcal{M}_c} \ell_c(m_i, \mathcal{Y}_i, \overline{\mathcal{Y}}_i) + \sum_{m_i \in \mathcal{M}_n} \ell_n(m_i, \mathcal{Y}_i, \overline{\mathcal{Y}}_i).$$

We use an alternative minimization algorithm based on block-wise coordinate descent (Tseng, 2001) to *jointly* optimize the objective $\mathcal{O}$. One can also apply stochastic gradient descent to do online update.

Type Inference. With the learned mention embeddings $\{\mathbf{u}_i\}$ and type embeddings $\{\mathbf{v}_k\}$, we perform top-down search in the given type hierarchy $\mathcal{Y}$ to estimate the correct type-path $\mathcal{Y}_i^*$. Starting from the tree's root, we recursively find the best type among the children types by measuring the dot product of the corresponding mention and type embeddings, *i.e.*, $\text{sim}(\mathbf{u}_i, \mathbf{v}_k)$. The search process stops when we reach a leaf type, or the similarity score is below a pre-defined threshold $\eta > 0$.

Table 3: Statistics of the datasets.

4 Experiments

4.1 Data Preparation

Datasets. Our experiments use three public datasets. (1) **Wiki** (Ling and Weld, 2012): consists of 1.5M sentences sampled from Wikipedia articles; (2) **OntoNotes** (Weischedel et al., 2011): consists of 13,109 news documents where 77 test documents are manually annotated (Gillick et al., 2014); (3) **BBN** (Weischedel and Brunstein, 2005): consists of 2,311 Wall Street Journal articles which are manually annotated using 93 types. Statistics of the datasets are shown in Table 3.

Training Data. We followed the process in (Ling and Weld, 2012) to generate training data for the Wiki dataset. For the BBN and OntoNotes datasets, we used DBpedia Spotlight[3] for entity linking. We discarded types which cannot be mapped to Freebase types in the BBN dataset (47 of 93).

Table 2 lists the set of features used in our experiments, which are similar to those used in (Yogatama et al., 2015; Ling and Weld, 2012) except for topics and ReVerb patterns. We discarded the features which occur only once in the corpus.

4.2 Evaluation Settings

For the Wiki and OntoNotes datasets, we used the provided test set. Since BBN corpus is fully annotated, we followed a 80/20 ratio to partition it into

[3] http://spotlight.dbpedia.org/

training/test sets. We report Accuracy (Strict-F1), Micro-averaged F1 (Mi-F1) and Macro-averaged F1 (Ma-F1) scores commonly used in the fine-grained type problem (Ling and Weld, 2012; Yogatama et al., 2015). Since we use the gold mention set for testing, the Accuracy (**Acc**) we reported is the same as the Strict F1.

Baselines. We compared the proposed method (AFET) and its variant with state-of-the-art typing methods, embedding methods and partial-label learning methods [4]: (1) **FIGER** (Ling and Weld, 2012); (2) **HYENA** (Yosef et al., 2012); (3) **FIGER/HYENA-Min** (Gillick et al., 2014): removes types appearing only once in the document; (4) **ClusType** (Ren et al., 2015): predicts types based on co-occurring relation phrases; (5) **HNM** (Dong et al., 2015): proposes a hybrid neural model without hand-crafted features; (6) **DeepWalk** (Perozzi et al., 2014): applies Deep Walk to a feature-mention-type graph by treating all nodes as the same type; (7) **LINE** (Tang et al., 2015b): uses a second-order LINE model on feature-type bipartite graph; (8) **PTE** (Tang et al., 2015a): applies the PTE joint training algorithm on feature-mention and type-mention bipartite graphs. (9) **WSABIE** (Yogatama et al., 2015): adopts WARP loss to learn embeddings of features and types; (10) **PL-SVM** (Nguyen and Caruana, 2008): uses a margin-based loss to handle label noise. (11) **CLPL** (Cour et al., 2011): uses a linear model to encourage large average scores for candidate types.

We compare AFET and its variant: (1) **AFET**: complete model with KB-induced type correlation; (2) **AFET-CoH**: with hierarchy-induced correlation (*i.e.*, shortest path distance); (3) **AFET-NoCo**: without type correlation (*i.e.*, all margin are "1") in the objective $\mathcal{O}$; and (4) **AFET-NoPa**: without label partial loss in the objective $\mathcal{O}$.

4.3 Performance Comparison and Analyses

Table 4 shows the results of AFET and its variants.

Comparison with the other typing methods. AFET outperforms both FIGER and HYENA systems, demonstrating the predictive power of the learned embeddings, and the effectiveness of modeling type correlation information and noisy candidate types. We also observe that pruning methods do not always improve the performance, since they aggressively filter out rare types in the corpus, which may lead to low Recall. ClusType is not as good as FIGER and HYENA because it is intended for coarse types and only utilizes relation phrases.

Comparison with the other embedding methods. AFET performs better than all other embedding methods. HNM does not use any linguistic features. None of the other embedding methods consider the label noise issue and treat the candidate type sets as clean. Although AFET adopts the WARP loss in WSABIE, it uses an adaptive margin in the objective to capture the type correlation information.

Comparison with partial-label learning methods. Compared with PL-SVM and CLPL, AFET obtains superior performance. PL-SVM assumes that only *one* candidate type is correct and does not consider type correlation. CLPL simply averages the model output for all candidate types, and thus may generate results biased to frequent false types. Superior performance of AFET mainly comes from modeling type correlation derived from KB.

Comparison with its variants. AFET always outperforms its variant on all three datasets. It gains performance from capturing type correlation, as well as handling type noise in the embedding process.

4.4 Case Analyses

Example output on news articles. Table 5 shows the types predicted by AFET, FIGER, PTE and WSABIE on two news sentences from OntoNotes dataset: AFET predicts fine-grained types with better accuracy (*e.g.*, `person_title`) and avoids overly-specific predictions (*e.g.*, `news_company`). Figure 5 shows the types estimated by AFET, PTE and WSABIE on a training sentence from OntoNotes dataset. We found AFET could discover the best type from noisy candidate types.

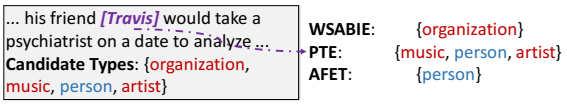

Figure 5: Example output of AFET and the compared methods on a training sentence from **OntoNotes** dataset.

[4] We used the published code for FIGER, ClusType, HNM, LINE, PTE, and DeepWalk, and implemented other baselines which have no public code. Our implementations yield comparable performance as those reported in the original papers.

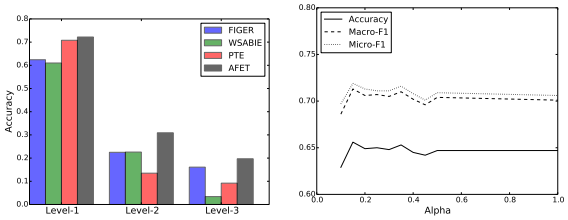
(a) Varying training set size (b) Varying d

Figure 6: Performance change with respect to (a) sampling ratio of training mentions on the Wiki dataset; and (b) embedding dimension d on the BBN dataset.



(a) Test at different levels (b) Varying α

Figure 7: Performance change (a) at different levels of the type hierarchy on the OntoNotes dataset; and (b) with respect to smooth parameter α on the BBN dataset.

Testing the effect of training set size and dimension. Experimenting with the same settings for model learning, Fig. 6(a) shows the performance trend on the Wiki dataset when varying the sampling ratio (subset of mentions randomly sampled from the training set $\mathcal{D}$). Fig. 6(b) analyzes the performance sensitivity of AFET with respect to d—the embedding dimension on the BBN dataset. Accuracy of AFET improves as d becomes large but the gain decreases when d is large enough.

Testing sensitivity of the tuning parameter. Fig. 7(b) analyzes the sensitivity of AFET with respect to α on the BBN dataset. Performance increases as α becomes large. When α is large than 0.5, the performance becomes stable.

Testing at different type levels. Fig. 7(a) reports the Ma-F1 of AFET, FIGER, PTE and WSABIE at different levels of the target type hierarchy (*e.g.*, person and location on level-1, politician and artist on level-2, author and actor on level-3). The results show that it is more difficult to distinguish among more fine-grained types. AFET always outperforms the other two method, and achieves a 22.36% improvement in Ma-F1, compared to FIGER on level-3 types. The gain mainly comes from explicitly modeling the noisy candidate types.

Testing for frequent/infrequent types. We also

Type	animal	city
# of Training Mentions	1882	12421

WSABIE	0.176	0.546
FIGER	0.167	0.648
PTE	0.222	0.677
AFET	**0.400**	**0.766**

Table 6: Example output of AFET and other methods on frequent/infrequent type from **OntoNotes** dataset.

evaluate the performance on frequent and rare types (Table 6). Note that we use a different evaluation metric, which is introduced in (Yosef et al., 2012) to calculate the F1 score for a type. We find **AFET** can always perform better than other baselines and it works for both frequent and rare types.

5 Related Work

There has been considerable work on named entity recognition (NER) (Manning et al., 2014), which focuses on three types (*e.g.*, `person`, `location`) and cast the problem as multi-class classification following the type mutual exclusion assumption (*i.e.*, one type per mention) (Nadeau and Sekine, 2007).

Recent work has focused on a much larger set of fine-grained types (Yosef et al., 2012; Ling and Weld, 2012). As the type mutual exclusion assumption no longer holds, they cast the problem as multi-label multi-class (hierarchical) classification problems (Gillick et al., 2014; Yosef et al., 2012; Ling and Weld, 2012). Embedding techniques are also recently applied to jointly learn feature and type representations (Yogatama et al., 2015; Dong et al., 2015). Del Corro *et al.* (2015) proposed an unsupervised method to generate context-aware candidates types, and subsequently select the most appropriate type. Gillick *et al.* (2014) discuss the label noise issue in fine-grained typing and propose three pruning heuristics. However, these heuristics aggressively delete training examples and may suffer from low recall (see Table. 4).

In the context of distant supervision, label noise issue has been studied for other information extraction tasks such as relation extraction (Takamatsu et al., 2012). In relation extraction, label noise is introduced by the false positive textual matches of entity pairs. In entity typing, however, label noise comes from the assignment of types to entity mentions without considering their contexts. The forms of distant supervision are different in these two problems. Recently, (Ren et al., 2016b) has tackled the problem of label noise in fine-grained entity typing, but focused on how to generate a clean training set instead of doing entity typing.

Partial label learning (PLL) (Zhang, 2014; Nguyen and Caruana, 2008; Cour et al., 2011) deals with the problem where each training example is associated with a set of candidate labels, where *only one is correct*. Unlike existing PLL methods, our method considers type hierarchy and correlation.

6 Conclusion and Future Work

In this paper, we study *automatic fine-grained entity typing* and propose a *hierarchical partial-label embedding* method, AFET, that models "clean" and "noisy" mentions separately and incorporates a given type hierarchy to induce loss functions. AFET builds on a joint optimization framework, learns embeddings for mentions and type-paths, and iteratively refines the model. Experiments on three public datasets show that AFET is effective, robust, and outperforms other comparing methods.

As future work, it would be interesting to study topical features as the context cues of the entity mentions, to leverage multi-sensing embedding to represent linguistic features with multiple senses, and to exploits other effective modeling methods to inject type hierarchy information. The proposed objective function is general and can be considered to incorporate various language features, to conduct integrated modeling of multiple sources, and to be extended to distantly-supervised relation extraction.

Abstract

Deep inference on a large-scale knowledge base (KB) needs a mass of formulas, but it is almost impossible to create all formulas manually. Data-driven methods have been proposed to mine formulas from KBs automatically, where random sampling and approximate calculation are common techniques to handle big data. Among a series of methods, Random Walk is believed to be suitable for knowledge graph data. However, a pure random walk without goals still has a poor efficiency of mining useful formulas, and even introduces lots of noise which may mislead inference. Although several heuristic rules have been proposed to direct random walks, they do not work well due to the diversity of formulas. To this end, we propose a novel goal-directed inference formula mining algorithm, which directs random walks by the specific inference target at each step. The algorithm is more inclined to visit benefic structures to infer the target, so it can increase efficiency of random walks and avoid noise simultaneously. The experiments on both WordNet and Freebase prove that our approach is has a high efficiency and performs best on the task.

1 Introduction

Recently, various knowledge bases (KBs), such as Freebase (Bollacker et al., 2008), WordNet (Miller, 1995), Yago (Hoffart et al., 2013), have been built, and researchers begin to explore how to make use of structural information to promote performances of several inference-based NLP applications, such as text entailment, knowledge base completion, question and answering. Creating useful formulas is one of the most important steps in inference, and an accurate and high coverage formula set will bring a great promotion for an inference system. For example, *Nationality(x, y)* $\wedge$ *Nationality(z, y)* $\wedge$ *Language(z, w)* $\Rightarrow$ *Language(x, w)* is a high-quality formula, which means people with the same nationality probably speak the same language. However, it is a challenge to create formulas for open-domain KBs, where there are a great variety of relation types and it is impossible to construct a complete formula set by hand.

Several data-driven methods, such as Inductive Logic Programming (ILP) (Muggleton and De Raedt, 1994) and Markov Logic Network (MLN) (Richardson and Domingos, 2006), have been proposed to mine formulas automatically from KB data, which transform frequent sub-structures of KBs, e.g., paths or loops, into formulas. Figure 1.a shows a sub-graph extracted from Freebase, and the formula mentioned above about *Language* can be generated from the loop in Figure 1.d. However, the running time of these traditional probabilistic inference methods is unbearable over large-scale KBs. For example, MLN needs grounding for each candidate formula, i.e., it needs to enumerate all paths. Therefore, the computation complexity of MLN increases exponentially with the scale of a KB.

In order to handle large-scale KBs, the random walk is usually employed to replace enumerating all possible sub-structures. However, random walk is inefficient to find useful structures due to its completely randomized mechanism. For example in Fig-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1379–1388,
Austin, Texas, November 1-5, 2016.

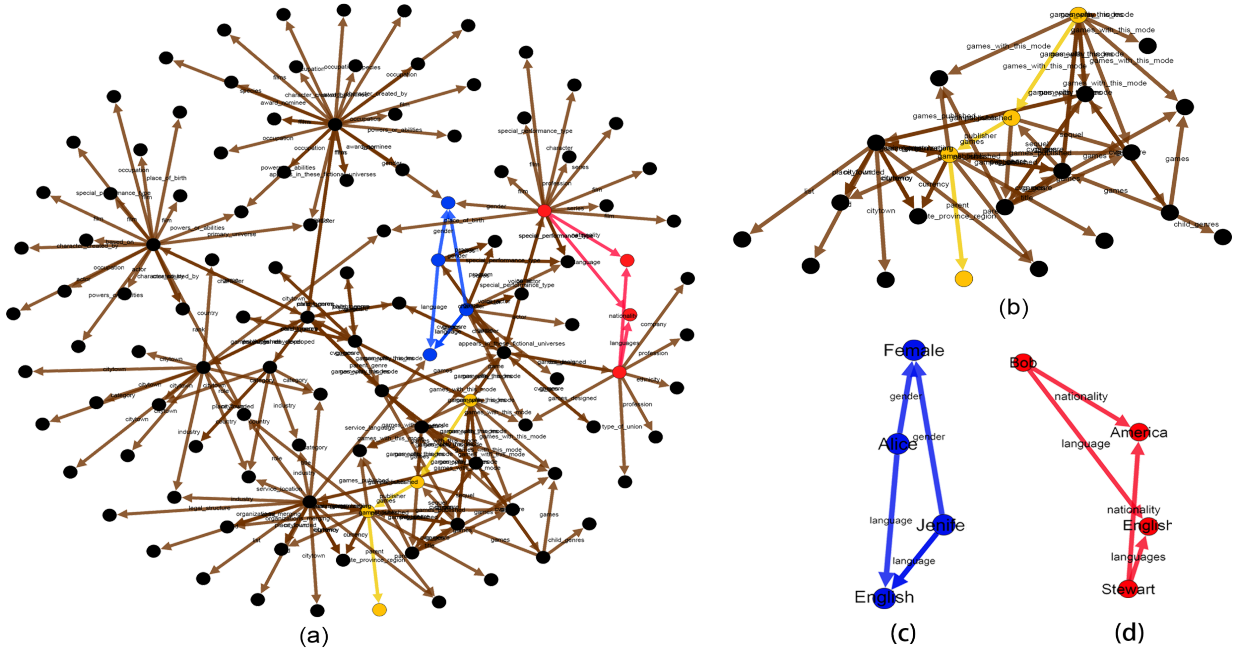

Figure 1: a) shows a subgraph extracted from Freebase. b) shows the searching space of finding the yellow path. c) shows a loop which can generate a false formula. d) shows a loop which can generate a true formula.

ure 1.b, the target path (yellow one) has a small probability to be visited, the reason is that the algorithm may select all the neighboring entity to transfer with an equal probability. This phenomenon is very common in KBs, e.g., each entity in Freebase has more than 30 neighbors in average, so there will be about 810,000 paths with length 4, and only several are useful. There have been two types of methods proposed to improve the efficiency of random walks, but they still meet serious problems, respectively.

1) **Increasing rounds of random walks.** More rounds of random walks will find more structures, but it will simultaneously introduce more noise and thus generate more false formulas. For example, the loop in Figure 1.c exists in Freebase, but it produces a false formula, *Gender(x, y)* $\wedge$ *Gender(z, y)* $\wedge$ *Language(z, w)* $\Rightarrow$ *Language(x, w)*, which means people with the same gender speak the same language. This kind of structures frequently occur in KBs even the formulas are mined with a high confidence, because there are a lot of sparse structures in KBs which will lead to inaccurate confidence. According to our statistics, more than 90 percent of high-confidence formulas produced by random walk are noise.

2) **Employing heuristic rules to direct random walks.** This method directs random walks to find useful structures by rewriting the state transition probability matrix, but the artificial heuristic rules may only apply to a little part of formulas. For example, PRA (Lao and Cohen, 2010; Lao et al., 2011) assumes the more narrow distributions of elements in a formula are, the higher score the formula will obtain. However, formulas with high scores in PRA are not always true. For example, the formula in Figure 1.c has a high score in PRA, but it is not true. Oppositely, formulas with low scores in PRA are not always useless. For example, the formula, $Father(x, y) \wedge Father(y, z) \Rightarrow Grandfather(x, t)$, has a low score when x and y both have several sons, but it obviously is the most effective to infer $Grandfather$. According to our investigations, the situations are common in KBs.

In this paper, we propose a Goal-directed Random Walk algorithm to resolve the above problems. The algorithm employs the specific inference target as the direction at each step in the random walk process. In more detail, to achieve such a goal-directed mechanism, at each step of random walk, the algorithm dynamically estimates the potentials for each neighbor by using the ultimate goal, and assigns higher probabilities to the neighbors with higher potentials. Therefore, the algorithm is more inclined to visit structures which are beneficial to infer

the target and avoid transferring to noise structures. For example in Figure 1, when the inference target is *what language a person speaks*, the algorithm is more inclined to walk along *Nationality* edge than *Gender*, because *Nationality* has greater potential than *Gender* to infer *Language*. We build a real potential function based on low-rank distributional representations. The reason of replacing symbols by distributional representations is that the distributional representations have less parameters and latent semantic relationship in them can contribute to estimate potentials more precisely. In summary, the contributions of this paper are as follows.

• Compared with the basic random walk, our approach direct random walks by the inference target, which increases efficiency of mining useful formulas and has a great capability of resisting noise.

• Compared with the heuristic methods, our approach can learn the strategy of random walk automatically and dynamically adjust the strategy for different inference targets, while the heuristic methods need to write heuristic rules by hand and follow the same rule all the time.

• The experiments on link prediction task prove that our approach has a high efficiency on mining formulas and has a good performance on both WN18 and FB15K datasets.

The rest of this paper is structured as follows, Section 2 introduces the basic random walk for mining formulas. Section 3 describes our approach in detail. The experimental results and related discussions are shown in Section 4. Section 5 introduces some related works, and finally, Section 6 concludes this paper.

2 Mining Formulas by Random Walk

2.1 Frequent Pattern Mining

Mining frequent patterns from source data is a problem that has a long history, and for different specific tasks, there are different types of source data and different definitions of pattern. Mining formulas is more like frequent subgraph mining, which employs paths or loops as frequent patterns and mines them from a KB. For each relation type R, the algorithm enumerates paths from entity H to entity T for each triplet $R(H,T)$. These paths are normalized to formulas by replacing entities to variables. For example, the loop in Figure 1.d, *Nationality(Bob, America)* $\wedge$ *Nationality(Stewart, America)* $\wedge$ *Language(Bob, English)* $\Rightarrow$ *Language(Stewart, English)*, can be normalized to the formula, *Nationality(x, y)* $\wedge$ *Nationality(z, y)* $\wedge$ *Language(z, w)* $\Rightarrow$ *Language(x, w)*. Support and confidence are employed to estimate a formula, where the support value of a formula $f : X \Rightarrow Y$, noted as S_f, is defined as the proportion of paths in the KB which contains the body X, and the confidence value of $X \Rightarrow Y$, noted as C_f, is defined as the proportion of the paths that contains X which also meets $X \Rightarrow Y$. C_f is calculated as follows,

$$C_f = \frac{N_f}{N_X} \tag{1}$$

where N_f is the total number of instantiated formula f and N_X is the total number of instantiated X.

2.2 Random Walk on Knowledge Graph

Enumerating paths is a time consuming process and does not apply to large-scale KBs. Therefore, random walk on the graph is proposed to collect frequent paths instead of enumerating. Random walk randomly chooses a neighbor to jump unlike enumerating which needs to search all neighbors. To estimate a formula f, the algorithm employs f's occurrence number during random walks $N_f^{'}$ to approximate the total number N_f in Equation (1), and similarly employs $N_X^{'}$ to approximate N_X. Therefore, f's confidence C_f can be approximatively estimated by $N_f^{'}$ and $N_X^{'}$, noted as $C_f^{'}$.

Random walk maintains a state transition probability matrix P, and P_{ij} means the probability of jumping from entity i to entity j. To make the confidence $C_f^{'}$ as close to the true confidence C_f as possible, the algorithm sets P as follows,

$$P_{ij} = \begin{cases} 1/d_i, & j \in Adj(i) \\ 0, & j \notin Adj(i) \end{cases} \tag{2}$$

where d_i is the out-degree of the entity i, $Adj(i)$ is the set of adjacent entities of i, and $\sum_{j=1}^{N} P_{ij} = 1$. Such a transition matrix means the algorithm may jump to all the neighboring entities with an equal probability. Such a random walk is independent from the inference target, so we call this type of random walk as a goalless random walk. The goalless mechanism causes the inefficiency of mining useful structures. When we want to mine paths for $R(H,T)$, the algorithm cannot arrive at T from H

in the majority of rounds. Even though the algorithm recalls several paths for $R(H,T)$, some of them may generate noisy formulas for inferring $R(H,T)$.

To solve the above problem, several methods direct random walks by statically modifying P. For example, PRA sets $P_{r_{ij}} = \frac{P(j|i;r)}{|R_i|}$, $P(j|i;r) = \frac{r(i,j)}{r(i,*)}$, where $P(j|i;r)$ is the probability of reaching node j from node i under the specific relation r, $r(i,*)$ is the number of edges from i under r, and R_i is the number of relation types from i. Such a transition matrix implies the more narrow distributions of elements in a formula are, the higher score the formula will obtain, which can be viewed as the heuristic rule of PRA.

3 Our Approach

3.1 Goal-Directed Random Walk

We propose to use the inference target, $\rho = R(H,T)$, to direct random walks. When predicting ρ, our approach always directs random walks to find useful structures which may generate formulas to infer ρ. For different ρ, random walks are directed by modifying the transition matrix P in different ways. Our approach dynamically calculates $P_{r_{ij}}$ when jumping from entity i to entity j under relation r as follows,

$$P_{r_{ij}} = \begin{cases} \dfrac{\Phi(r(i,j),\rho)}{\sum_{k\in Adj(i)}\Phi(r(i,k),\rho)}, & j \in Adj(i) \\ 0, & j \notin Adj(i) \end{cases} \tag{3}$$

where $\Phi(r(i,j),\rho)$ is the $r(i,j)$'s potential which measures the potential contribution to infer ρ after walking to j.

Intuitively, if $r(i,j)$ exits in a path from H to T and this path can generate a benefic formula to infer $R(H,T)$, the probability of jumping from i to j should larger and thus $\Phi(r(i,j),\rho)$ also should be larger. Reversely, if we cannot arrive at T within the maximal steps after jumping to j, or if the path produces a noisy formula leading to a wrong inference, P_{ij} and $\Phi(r(i,j),\rho)$ should both be smaller.

To explicitly build a bridge between the potential Φ and the inference goal ρ, we maximize the likelihood of paths which can infer ρ. First, we recursively define the likelihood of a path from H to t as $P_{p_{Ht}} = P_{p_{Hs}} \cdot P_{r_{st}}$, where $P_{r_{st}}$ is defined in Equation (3). We then classify a path p_{Ht} into three separate categories: a) $t = T$ and p_{Ht} can produce a benefic formula to infer $R(H,T)$; b) $t \neq T$; c) $t = T$ but p_{Ht} may generate a noisy formula which misleads inference. Finally, we define the likelihood function as follows,

$$\max P_{\mathbb{P}} = \prod_{p_{Ht}\in\mathbb{P}} P_{p_{Ht}}^{a}(1-P_{p_{Ht}})^{b+c} \tag{4}$$

where $\mathbb{P}$ is all paths found in the process of performing random walks for $R(H,T)$, and t may be equal to T or not. a, b, c are three 0-1 variables corresponding to the above categories a), b), c). Only one in a, b, c can be 1 when P_{Ht} belongs to the corresponding category. We then transform maximizing $P_{\mathbb{P}}$ to minimizing $L_{rw} = -\log P_{\mathbb{P}}$ and employ SGD to train it. In practice, there is not a clear-cut boundary between a) and c), so we divide the loss into two parts: $L_{rw} = L_{rw}^{t} + \lambda L_{rw}^{inf}$. L_{rw}^{t} is the loss of that $t \neq T$, and L_{rw}^{inf} is the loss of that p_{HT} generates a noisy formula leading to a wrong inference. λ is a super parameter to balance the two losses. L_{rw}^{t} and L_{rw}^{inf} have the same expression but are optimized in different stages. L_{rw}^{t} can be optimized during random walks, while L_{rw}^{inf} should be optimized in the inference stage. We rewrite L_{rw} for a specific path p as follows,

$$L_{rw}(p) = -y\log P_p - (1-y)\log(1-P_p) \tag{5}$$

where y is the label of the path p and $y = 1$ if p is beneficial to infer ρ. To obtain the best Φ, we compute gradients of L_{rw} as follows,

$$\begin{aligned} &\nabla L_{rw}(p) = (\nabla L_{rw}(r_{12}), \nabla L_{rw}(r_{23}), ...) \\ &\nabla L_{rw}(r_{ij}) = (\frac{\partial L_{rw}(r_{ij})}{\partial \Phi_{r_{ij}}}, \frac{\partial L_{rw}(r_{ij})}{\partial \Phi_{r_{ik_1}}}, \frac{\partial L_{rw}(r_{ij})}{\partial \Phi_{r_{ik_2}}}, ...) \\ &\frac{\partial L_{rw}(r_{ij})}{\partial \Phi_{r_{ij}}} = \frac{(P_p - y)\cdot(1-P_{r_{ij}})}{\Phi_{r_{ij}}\cdot(1-P_p)} \\ &\frac{\partial L_{rw}(r_{ij})}{\partial \Phi_{r_{ik}}} = -\frac{(P_p - y)\cdot P_{r_{ij}}}{\Phi_{r_{ij}}\cdot(1-P_p)} \end{aligned} \tag{6}$$

where $\nabla L_{rw}(r_{ij})$ is the component of $\nabla L_{rw}(p)$ at r_{ij}. $\Phi(r(i,j),\rho)$ and $\Phi(r(i,k),\rho)$ are the potentials for all triplets $r(i,j) \in p$ and $r(i,k) \notin p$, and r_{ij} is short for $r(i,j)$. After iteratively updating $\Phi_{r_{ij}}$ and $\Phi_{r_{ik}}$ by the gradient of L_{rw}^{t}, the random walks can

be directed to find more paths from H to T, and consequently it increases efficiency of the random walk. After updating $\Phi_{r_{ij}}$ and $\Phi_{r_{ik}}$ by the gradient of L_{rw}^{inf}, random walk is more likely to find high-quality paths but not noise. Therefore, the goal-directed random walk increases efficiency of mining benefic formulas and has a great capability of resisting noise.

3.2 Distributional Potential Function

The potential $\Phi(r(i,j),\rho)$ measures an implicit relationship between two triplets in the KB, so the total number of parameters is the square of the KB size. It is hard to precisely estimate all Φ because of the sparsity of training data. To reduce the number of parameters, we represent each entity or relation in the KB as a low-rank numeric vector which is called embeddings (Bordes et al., 2013), and then we build a potential function Ψ on embeddings as $\Phi(r(i,j),\rho) = \Psi(E_{r(i,j)}, E_{R(H,T)})$, where $E_{r(i,j)}$ and $E_{R(H,T)}$ are the embeddings of triplets. In practice, we set $E_{r(i,j)} = [E_r, E_j]$ and $E_{R(H,T)} = [E_R, E_T]$ because E_i is the same for all triplets $r(i,*)$, where [] is a concatenation operator.

In the view of the neural network, our goal-directed mechanism is analogous to the attention mechanism. At each step, the algorithm estimates attentions for each neighboring edges by Ψ. Therefore, there are several existing expressions of Ψ, e.g., the dot product (Sukhbaatar et al., 2015) and the single-layer perceptron (Bahdanau et al., 2015). We will not compare different forms of Ψ, the detail comparison has been presented in the work (Luong et al., 2015). We directly employ the simplest dot product for Ψ as follows,

$$\Psi(E_{r(i,j)}, E_{R(H,T)}) = \sigma(E_{r(i,j)} \cdot E_{R(H,T)}) \quad (7)$$

where σ is a nonlinear function and we set it as an exponential function. Ψ has no parameters beside KB embeddings which are updated during the training period.

3.3 Integrated Inference Model

To handle the dependence between goal-directed random walk and subsequent inference, we combine them into an integrated model and optimize them together. To predict $\rho = R(H,T)$, the integrated model first collects formulas for $R(H,T)$, and then merges estimations of different formulas as features into a score function χ,

$$\chi(\rho) = \sum_{f \in F_\rho} \delta(f) \quad (8)$$

where F_ρ is the formula set obtained by random walks for ρ, and $\delta(f)$ is an estimation of formula f. The original frequent pattern mining algorithm employs formulas' confidence as $\delta(f)$ directly, but it does not produce good results (Galárraga et al., 2013). There are two ways to solve the problem: one is selecting another more suitable measure of f as $\delta(f)$ (Tan et al., 2002); the other is attaching a weight to each formula and learning weights with supervision, e.g., MLN (Richardson and Domingos, 2006) . We employ the latter method and set $\delta(f) = w_f \cdot n_f$. Finally, we employ a logistic regression classifier to predict $R(H,T)$, and the posterior probability of $R(H,T)$ is shown as follows,

$$\begin{aligned} P(\rho = y|\chi) &= \mathcal{F}(\chi)^y (1 - \mathcal{F}(\chi))^{1-y} \\ \mathcal{F}(\chi) &= \frac{1}{1+e^{-\chi}} \end{aligned} \quad (9)$$

where y is a 0-1 label of ρ. Similar to L_{rw}^t in Equation (5), we treat the negative logarithm of $P(\rho = y|\chi)$ as the loss of inference, $L_{inf} = -\log P(\rho = y|\chi)$, and turn to minimize it. Moreover, the loss L_{rw}^{inf} of the above goal-directed random walk is influenced by the result of predicting $R(H,T)$, so $\Phi_{r_{ij}}$ and $\Phi_{r_{ik}}$ will be also updated. Algorithm 1 shows the main process of training, where Ξ is the triplet set for training, Ψ is the potential function in Equation (7), F is the formula set, f_p is

Algorithm 1: Train Integrated Inference Model

Input: KB, Ξ
Output: Ψ, W, F
For $\rho = R(H,T) \in \Xi$
  Repeat ρ-directed Random Walk from H to t
    Update Ψ by L_{rw}^t
    If $t = T$, then $F = F \cap f_p$
  Calculate L_{inf} and L_{rw}^{inf} by ρ
  Update W by L_{inf}
  Update Ψ by L_{rw}^{inf}
Remove $f \in F$ with little w_f
Output Ψ, W, F

Dataset	Relation	Entity	Train	Valid	Test
WN18	18	40,943	141,442	5,000	5,000
FB15K	1,345	14,951	483,142	50,000	59,071

Table 1: Statistics of WN18 and FB15K

a formula generated from the path p, and H, T, t are entities in the KB. To predict $\rho = R(H, T)$, the algorithm first performs multi rounds of random walks, and each random walk can find a path p_{Ht} (at line 2). Then the algorithm decides to update Ψ by L^t_{rw} based on whether t is T (at line 3), and adds the formula p_f into the formula set when $t = T$ (at line 4). After random walks, the inference model predicts ρ, and computes L_{inf} and L^{inf}_{rw} according to the prediction result (at line 5). Finally W and Ψ are updated by L_{inf} and L^{inf}_{rw} (at line 6-7), respectively. After training by all triplets in Ξ, the algorithm removes formulas with low weights from F (at line 8) and outputs the model (at line 9). When we infer a new triplet by this model, the process is similar to Algorithm 1.

4 Experiments

We first compare our approach with several state-of-art methods on link prediction task to explore our approach's overall ability of inference. Subsequently, we evaluate formulas mined by different random walk methods to explore whether the goal-directed mechanism can increase efficiency of mining useful structures. Finally, we dive deep into the formulas generated by our approach to analyze the characters of our approach.

4.1 Datasets and Evaluation Setup

We conduct experiments on both WN18 and FB15K datasets which are subsets sampled from WordNet (Miller, 1995) and Freebase (Bollacker et al., 2008), respectively, and Table 1 shows the statistics of them. For the link prediction task, we predict the missing h or t for a triplet $r(h, t)$ in test set. The detail evaluation method is that t in $r(h, t)$ is replaced by all entities in the KB and methods need to rank the right answer at the top of the list, and so does h in $r(h, t)$. We report the mean of those true answer ranks and the Hits@10 under both 'raw' and 'filter' as TransE (Bordes et al., 2013) does, where Hits@10 is the proportion of correct entities ranked in the top 10.

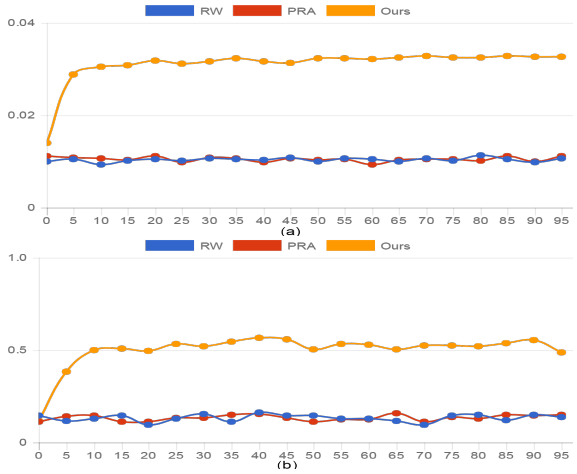

Figure 2: $Arr@10$ of three random walk algorithms and the horizontal axis represents epochs and the vertical axis represents $Arr@10$. Figure 2.a shows results on relation *_derivationally_related_form* in WN18, and Figure 2.b shows results on relation *form_of_government* in FB15K.

4.2 Baselines

We employ two types of baselines. One type is based on random walks including: a) the basic random walk algorithm whose state transition probability matrix is shown in Equation (2); b) PRA in (Lao et al., 2011) which is a typical heuristic random walk algorithm. The other type is based on KB embeddings including TransE (Bordes et al., 2013), Rescal (Nickel et al., 2011), TransH (Wang et al., 2014b), TransR (Lin et al., 2015b). These embedding-based methods have no explicit formulas, so we will not evaluate their performances on mining formulas.

4.3 Settings

We implement three random walk methods under a unified framework. To predict $r(h, *)$ quickly, we first select Top-K candidate instances, $t_{1 \to K}$, by TransE as (Wei et al., 2015), and then the algorithm infers each $r(h, t_i)$ and ranks them by inference results. We adjust parameters for our approach with the validate dataset, and the optimal configurations are set as follows. The rounds of random walk is 10, learning rate is 0.0001, training epoch is 100, the size of candidate set is 500 for WN18 and 100 for FB15K, the embeddings have 50 dimensionalities for WN18 and 100 dimensionalities for FB15K, and the embeddings are initialized by TransE. For some relations, random walk truly finds no practicable formulas, so we employ TransE to improve per-

	Dataset	WN18				FB15K			
	Metric	Mean Rank		Hits@10(%)		Mean Rank		Hits@10(%)	
		Raw	Filt	Raw	Filt	Raw	Filt	Raw	Filt

Table 2: Link Prediction Results on both WN18 and FB15K

formance for these relations. For embedding-based methods, we use reported results directly since the evaluation datasets are identical.

4.4 Results on Link Prediction

We show the results of link prediction for our approach and all baselines in Table 2 (* means the mean of ranks for random walk methods are evaluated in the Top-K subset), and we can obtain the following observations:

1) Our approach achieves good performances on both WN18 and FB15K. On the FB15K, our approach outperforms all baselines. It indicates that our approach is effective for inference. On the WN18, three random walk methods have similar performances. The reason is that most entities in WN18 only have a small number of neighbors, so RW and PRA can also find useful structures in a few rounds.

2) For FB15K, the performances of RW and PRA are both poor and even worse than a part of embedding-based methods, but the performance of our approach is still the best. The reason is that there are too many relation types in FB15K, so goalless random walks introduce lots of noise. Oppositely, our approach has a great capability of resisting noise for the goal-directed mechanism.

3) RW and PRA have similar performances on both datasets, which indicates the heuristic rule of PRA does not apply to all relations and formulas.

4.5 Paths Recall by Random Walks

To further explore whether the goal-directed mechanism can increase efficiency of mining paths, we compare the three random walk methods by the number of paths mined. For each triplet $R(H, T)$ in the training set, we perform 10 rounds of random walks from H and record the number of times which arrive at T, noted as Arr@10. We respectively select one relation type from WN18 and FB15K and show the comparison result in Figure 2. We can obtain the following observations:

1) With the increase of training epochs, $Arr@10$ of the goal-directed random walk first increases and then stays around a high value on both WN18 and FB15K, but the $Arr@10$ of RW and PRA always stay the same. This phenomenon indicates that the goal-directed random walk is a learnable model and can be trained to find more useful structures with epochs increasing, but RW and PRA are not.

2) RW and PRA always have similar $Arr@10$, which means PRA has not found more formulas. This indicates that the heuristic rule of PRA is not always be beneficial to mining more structures for all relations.

4.6 Example Formulas

In Table 3, we show a small number of formulas mined by our approach from FB15K, and the formulas represent different types. Some formulas contain clear logic, e.g, Formula 1 means that if the writer x contributes a story to the film y and y is adapted from the book z, x is the writer of the book z. Some formulas have a high probability of being satisfied, e.g., Formula 3 means the wedding place probably is also the burial place for some people, and Formula 7 means the parent of the person x died of the disease and thus the person x has a high risk of suffering from the disease. Some formulas depend on synonyms, e.g., *story_by* and *works_written* have the similar meaning in Formula 2. However, there are still useless formulas, e.g, Formula 8 is useless be-

Relation	Formula
works_written	
1	film_story_contributor(x,y) ∧ adapted_from(y,z) ⇒ works_written(x,z)
2	story_by(y,x) ⇒ works_written(x,y)
place_of_burial	
3	place_of_death(x,y) ⇒ place_of_burial(x,y)
4	marriage_type_of_union(x,y) ∧ marriage_location_of_ceremony(y,z) ⇒ place_of_burial(x,z)
service_language	
5	service_location(x,y) ∧ imported_from(y,z) ∧ official_language(z,w) ⇒ service_language(x,w)
6	service_location(x,y) ∧ exported_to(y,z) ∧ languages_spoken(z,w) ⇒ service_language(x,w)
disease_risk_factors	
7	parent_cause_of_death(x,y) ∧ disease_risk_factors(y,z) ⇒ disease_risk_factors(x,z)
8	disease_risk_factors(x,y)∧ -disease_risk_factors(y,x) ⇒ disease_risk_factors(x,y)

Table 3: Example Formulas Obtained by Goal-directed Random Walk

cause the body of the formula is same as the head. Such useless formula can be removed by a super-rule, which is that the head of a formula cannot occur in its body.

5 Related Work

Our work has two aspects, which are related to mining formula automatically and inference on KBs, respectively.

Inductive Logic Programming (ILP) (Muggleton and De Raedt, 1994) and Association Rule Mining (ARM) (Agrawal et al., 1993) are both early works on mining formulas. FOIT (Quinlan, 1990) and SHERLOCK (Schoenmackers et al., 2010) are typical ILP systems, but the former one usually need a lot of negative facts and the latter one focuses on mining formulas from text. AMIE (Galárraga et al., 2013) is based on ARM and proposes a new measure for formulas instead of the confidence. Several structure learning algorithms (Kok and Domingos, 2005; Kok and Domingos, 2009; Kok and Domingos, 2010) based on Markov Logic Network (MLN) (Richardson and Domingos, 2006) can also learn first order logic formulas automatically, but they are too slow to run on large KBs. ProPPR (Wang et al., 2013; Wang et al., 2014a) performs structure learning by depth first searching on the knowledge graph, which is still not efficient enough to handle web-scale KBs. PRA (Lao and Cohen, 2010; Lao et al., 2011) is a method based on random walks and employs heuristic rules to direct random walks. PRA is closely related to our approach, but unlike it, our approach dynamically calculates state transition probabilities. Another method based on random walks (Wei et al., 2015) merges embedding similarities of candidates into the random walk as a priori, while our approach employs KB embeddings to calculate potentials for neighbors.

The majority of mining formula methods can perform inference on KBs, and besides them, a dozen methods based KB embeddings can also achieve the inference goal, and the typical ones of them are TransE (Bordes et al., 2013), Rescal (Nickel et al., 2011), TransH (Wang et al., 2014b), TransR (Lin et al., 2015b). These embedding-based methods take advantage of the implicit relationship between elements of the KB and perform inference by calculating similarities. There are also methods which combine inference formulas and KB embeddings, such as PTransE (Lin et al., 2015a) and ProPPR+MF (Wang and Cohen, 2016).

6 Conclusion and Future Works

In this paper, we introduce a goal-directed random walk algorithm to increase efficiency of mining useful formulas and decrease noise simultaneously. The approach employs the inference target as the direction at each steps in the random walk process and is more inclined to visit structures helpful to inference. In empirical studies, we show our approach achieves good performances on link prediction task over large-scale KBs. In the future, we are interested in exploring mining formulas directly in the distributional spaces which may resolve the sparsity of formulas.

Abstract

Methods based on representation learning currently hold the state-of-the-art in many natural language processing and knowledge base inference tasks. Yet, a major challenge is how to efficiently incorporate commonsense knowledge into such models. A recent approach regularizes relation and entity representations by propositionalization of first-order logic rules. However, propositionalization does not scale beyond domains with only few entities and rules. In this paper we present a highly efficient method for incorporating implication rules into distributed representations for automated knowledge base construction. We map entity-tuple embeddings into an approximately Boolean space and encourage a partial ordering over relation embeddings based on implication rules mined from WordNet. Surprisingly, we find that the strong restriction of the entity-tuple embedding space does not hurt the expressiveness of the model and even acts as a regularizer that improves generalization. By incorporating few commonsense rules, we achieve an increase of 2 percentage points mean average precision over a matrix factorization baseline, while observing a negligible increase in runtime.

1 Introduction

Current successful methods for automated knowledge base construction tasks heavily rely on learned distributed vector representations (Nickel et al., 2012; Riedel et al., 2013; Socher et al., 2013; Chang et al., 2014; Neelakantan et al., 2015; Toutanova et al., 2015; Nickel et al., 2015; Verga et al., 2016; Verga and McCallum, 2016). Although these models are able to learn robust representations from large amounts of data, they often lack commonsense knowledge. Such knowledge is rarely explicitly stated in texts but can be found in resources like PPDB (Ganitkevitch et al., 2013) or WordNet (Miller, 1995).

Combining neural methods with symbolic commonsense knowledge, for instance in the form of implication rules, is in the focus of current research (Rocktäschel et al., 2014; Wang et al., 2014; Bowman et al., 2015; Wang et al., 2015; Vendrov et al., 2016; Hu et al., 2016; Rocktäschel and Riedel, 2016; Cohen, 2016). A recent approach (Rocktäschel et al., 2015) regularizes entity-tuple and relation embeddings via first-order logic rules. To this end, every first-order rule is propositionalized based on observed entity-tuples, and a differentiable loss term is added for every propositional rule. This approach does not scale beyond only a few entity-tuples and rules. For example, propositionalizing the rule $\forall x : \texttt{isMan}(x) \Rightarrow \texttt{isMortal}(x)$ would result in a very large number of loss terms on a large database.

In this paper, we present a method to incorporate simple rules while maintaining the computational efficiency of only modeling training facts. This is achieved by minimizing an upper bound of the loss that encourages the implication between relations to hold, entirely independent from the number of entity pairs. It only involves representations of the relations that are mentioned in rules, as well as a general rule-independent constraint on the entity-tuple embedding space. In the example given above, if we require that every component of the

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1389–1399,
Austin, Texas, November 1-5, 2016.

vector representation of `isMan` is smaller than the corresponding component of relation `isMortal`, then we can show that the rule holds for any *non-negative* representation of an entity-tuple. Hence our method avoids the need for separate loss terms for every ground atom resulting from propositionalizing rules. In statistical relational learning this type of approach is often referred to as *lifted* inference or learning (Poole, 2003; Braz, 2007) because it deals with groups of random variables at a first-order level. In this sense our approach is a lifted form of rule injection. This allows for imposing large numbers of rules while learning distributed representations of relations and entity-tuples. Besides drastically lower computation time, an important advantage of our method over Rocktäschel et al. (2015) is that when these constraints are satisfied, the injected rules always hold, even for unseen but inferred facts. While the method presented here only deals with implications and not general first-order rules, it does not rely on the assumption of independence between relations, and is hence more generally applicable.

Our contributions are fourfold: (i) we develop a very efficient way of regularizing relation representations to incorporate first-order logic implications (§3), (ii) we reveal that, against expectation, mapping entity-tuple embeddings to non-negative space does not hurt but instead improves the generalization ability of our model (§5.1) (iii) we show improvements on a knowledge base completion task by injecting mined commonsense rules from WordNet (§5.3), and finally (iv) we give a qualitative analysis of the results, demonstrating that implication constraints are indeed satisfied in an asymmetric way and result in a substantially increased structuring of the relation embedding space (§5.6).

2 Background

In this section we revisit the matrix factorization relation extraction model by Riedel et al. (2013) and introduce the notation used throughout the paper. We choose the matrix factorization model for its simplicity as the base on which we develop implication injection.

Riedel et al. (2013) represent every relation $r \in \mathcal{R}$ (selected from Freebase (Bollacker et al., 2008) or extracted as textual surface pattern) by a k-dimensional latent representation $\boldsymbol{r} \in \mathbb{R}^k$. A particular *relation instance* or *fact* is the combination of a relation r and a tuple t of entities that are engaged in that relation, and is written as $\langle r, t\rangle$. We write $\mathcal{O}$ as the set of all such input facts available for training. Furthermore, every entity-tuple $t \in \mathcal{T}$ is represented by a latent vector $\boldsymbol{t} \in \mathbb{R}^k$ (with $\mathcal{T}$ the set of all entity-tuples in $\mathcal{O}$).

Model F by Riedel et al. (2013) measures the compatibility between a relation r and an entity-tuple t using the dot product $\boldsymbol{r}^\top \boldsymbol{t}$ of their respective vector representations. During training, the representations are learned such that valid facts receive high scores, whereas negative ones receive low scores. Typically no negative evidence is available at training time, and therefore a Bayesian Personalized Ranking (BPR) objective (Rendle et al., 2009) is used. Given a pair of facts $f_p := \langle r_p, t_p\rangle \notin \mathcal{O}$ and $f_q := \langle r_q, t_q\rangle \in \mathcal{O}$, this objective requires that

$$\boldsymbol{r_p}^\top \boldsymbol{t_p} \leq \boldsymbol{r_q}^\top \boldsymbol{t_q}. \tag{1}$$

The embeddings can be trained by minimizing a convex loss function ℓ_R that penalizes violations of that requirement when iterating over the training set. In practice, each positive training fact $\langle r, t_q\rangle$ is compared with a randomly sampled unobserved fact $\langle r, t_p\rangle$ for the same relation. The overall loss can hence be written as

$$\mathcal{L}_R = \sum_{\substack{\langle r,t_q\rangle \in \mathcal{O} \\ t_p \in \mathcal{T},\ \langle r,t_p\rangle \notin \mathcal{O}}} \ell_R\big(\boldsymbol{r}^\top [\boldsymbol{t_p} - \boldsymbol{t_q}]\big). \tag{2}$$

and measures how well observed valid facts are ranked above unobserved facts, thus reconstructing the ranking of the training data. We will henceforth call $\mathcal{L}_R$ the *reconstruction loss*, to make a distinction with the *implication loss* that we will introduce later. Riedel et al. (2013) use the logistic loss $\ell_R(s) := -\log \sigma(-s)$, where $\sigma(s) := (1 + e^{-x})^{-1}$ denotes the sigmoid function. In order to avoid overfitting, an L_2 regularization term on the $\boldsymbol{r}$ and $\boldsymbol{t}$ embeddings is added to the reconstruction loss. The overall objective to minimize hence is

$$\mathcal{L}_F = \mathcal{L}_R + \alpha\big(\textstyle\sum_{\boldsymbol{r}} \|\boldsymbol{r}\|_2^2 + \sum_{\boldsymbol{t}} \|\boldsymbol{t}\|_2^2\big) \tag{3}$$

where α is the regularization strength.

3 Lifted Injection of Implications

In this section, we show how an implication

$$\forall t \in \mathcal{T} : \langle r_p, t\rangle \Rightarrow \langle r_q, t\rangle, \tag{4}$$

can be imposed independently of the entity-tuples. For simplicity, we abbreviate such implications as $r_p \Rightarrow r_q$ (*e.g.*, `professorAt` $\Rightarrow$ `employeeAt`).

3.1 Grounded Loss Formulation

The implication rule can be imposed by requiring that every tuple $t \in \mathcal{T}$ is at least as compatible with relation r_p as with r_q. Written in terms of the latent representations, eq. (4) therefore becomes

$$\forall t \in \mathcal{T} : \boldsymbol{r_p}^\top \boldsymbol{t} \leq \boldsymbol{r_q}^\top \boldsymbol{t} \tag{5}$$

If $\langle r_p, t\rangle$ is a true fact with a high score $\boldsymbol{r_p}^\top \boldsymbol{t}$, and the fact $\langle r_q, t\rangle$ has an even higher score, it must also be true, but not vice versa. We can therefore inject an implication rule by minimizing a loss term with a separate contribution from every $t \in \mathcal{T}$, adding up to the total loss if the corresponding inequality is not satisfied. In order to make the contribution of every tuple t to that loss independent of the magnitude of the tuple embedding, we divide both sides of the above inequality by $\|\boldsymbol{t}\|_1$. With $\tilde{\boldsymbol{t}} := \boldsymbol{t}/\|\boldsymbol{t}\|_1$, the implication loss for the rule $r_p \Rightarrow r_q$ can be written as

$$\mathcal{L}_I = \sum_{\forall t \in \mathcal{T}} \ell_I\big([\boldsymbol{r_p} - \boldsymbol{r_q}]^\top \tilde{\boldsymbol{t}}\big) \tag{6}$$

for an appropriate convex loss function ℓ_I, similarly to eq. (2). In practice, the summation can be reduced to those tuples that occur in combination with r_p or r_q in the training data. Still, the propositionalization in terms of training facts leads to a heavy computational cost for imposing a single implication, similar to the technique introduced in Rocktäschel et al. (2015). Moreover, with that simplification there is no guarantee that the implication between both relations would generalize towards inferred facts not seen during training.

3.2 Lifted Loss Formulation

The problems mentioned above can be avoided if instead of $\mathcal{L}_I$, a tuple-independent upper bound is minimized. Such a bound can be constructed, provided all components of $\boldsymbol{t}$ are restricted to a non-negative embedding space, *i.e.*, $\mathcal{T} \subseteq \mathbb{R}^{k,+}$. If this holds, Jensen's inequality allows us to transform eq. (6) as follows

$$\mathcal{L}_I = \sum_{\forall t \in \mathcal{T}} \ell_I\Big(\sum_{i=1}^{k} \tilde{t}_i \,[\boldsymbol{r_p} - \boldsymbol{r_q}]^\top \mathbf{1}_i\Big) \tag{7}$$

$$\leq \sum_{i=1}^{k} \ell_I\big([\boldsymbol{r_p} - \boldsymbol{r_q}]^\top \mathbf{1}_i\big) \sum_{\forall t \in \mathcal{T}} \tilde{t}_i \tag{8}$$

where $\mathbf{1}_i$ is the unit vector along dimension i in tuple-space. This is allowed because the $\{\tilde{t}_i\}_{i=1}^k$ form convex coefficients ($\tilde{t}_i > 0$, and $\sum_i \tilde{t}_i = 1$), and ℓ_I is a convex function. If we define

$$\mathcal{L}_I^U := \sum_{i=1}^{k} \ell_I\big([\boldsymbol{r_p} - \boldsymbol{r_q}]^\top \mathbf{1}_i\big) \tag{9}$$

we can write

$$\mathcal{L}_I \leq \beta \mathcal{L}_I^U \tag{10}$$

in which β is an upper bound on $\sum_t \tilde{t}_i$. One such bound is $|\mathcal{T}|$, but others are conceivable too. In practice we rescale β to a hyper-parameter $\tilde{\beta}$ that we use to control the impact of the upper bound to the overall loss. We call $\mathcal{L}_I^U$ the *lifted loss*, as it no longer depends on any of the entity-tuples; it is grounded over the unit tuples $\mathbf{1}_i$ instead.

The implication $r_p \Rightarrow r_q$ can thus be imposed by minimizing the lifted loss $\mathcal{L}_I^U$. Note that by minimizing $\mathcal{L}_I^U$, the model is encouraged to satisfy the constraint $\boldsymbol{r_p} \leq \boldsymbol{r_q}$ on the relation embeddings, where $\leq$ denotes the component-wise comparison. In fact, a sufficient condition for eq. (5) to hold, is

$$\boldsymbol{r_p} \leq \boldsymbol{r_q} \;\text{ and }\; \forall t \in \mathcal{T} : \; \boldsymbol{t} \geq \mathbf{0} \tag{11}$$

with $\mathbf{0}$ the k-dimensional null vector. This corresponds to a single relation-specific loss term, and the general restriction $\mathcal{T} \subseteq \mathbb{R}^{k,+}$ on the tuple-embedding space.

3.3 Approximately Boolean Entity Tuples

In order to impose implications by minimizing a lifted loss $\mathcal{L}_I^U$, the tuple-embedding space needs to be restricted to $\mathbb{R}^{k,+}$. We have chosen to restrict the tuple space even more than required, namely to the hypercube $\boldsymbol{t} \in [0,1]^k$, as approximately Boolean embeddings (Kruszewski et al., 2015). The tuple

embeddings are constructed from real-valued vectors $\boldsymbol{e}$, using the component-wise sigmoid function

$$\boldsymbol{t} = \sigma(\boldsymbol{e}), \quad \boldsymbol{e} \in \mathbb{R}^k. \tag{12}$$

For minimizing the loss, the gradients are hence computed with respect to $\boldsymbol{e}$, and the L_2 regularization is applied to the components of $\boldsymbol{e}$ instead of $\boldsymbol{t}$.

Other choices for ensuring the restriction $\boldsymbol{t} \geq \boldsymbol{0}$ in eq. (11) are possible, but we found that our approach works better in practice than those (*e.g.*, the exponential transformation proposed by Demeester et al. (2016)). It can also be observed that the unit tuples over which the implication loss is grounded, form a special case of approximately Boolean embeddings.

In order to investigate the impact of this restriction even when not injecting any rules, we introduce model FS: the original model F, but with sigmoidal entity-tuples:

$$\mathcal{L}_{FS} = \sum_{\substack{\langle r,t_q\rangle \in \mathcal{O} \\ t_p \in \mathcal{T},\, \langle r,t_p\rangle \notin \mathcal{O}}} \ell_R\big(\boldsymbol{r}^\top [\sigma(\boldsymbol{e_p}) - \sigma(\boldsymbol{e_q})]\big) + \alpha\big(\textstyle\sum_{\boldsymbol{r}} \|\boldsymbol{r}\|_2^2 + \sum_{\boldsymbol{e}} \|\boldsymbol{e}\|_2^2\big) \tag{13}$$

Here, $\boldsymbol{e_p}$ and $\boldsymbol{e_q}$ are the real-valued representations as in eq. (12), for tuples t_p and t_q, respectively.

With the above choice of a non-negative tuple-embedding space we can now state the full lifted rule injection model (FSL):

$$\mathcal{L}_{FSL} = \mathcal{L}_{FS} + \tilde{\beta} \sum_{I \in \mathcal{I}} \mathcal{L}_I^U \tag{14}$$

$\mathcal{L}_I^U$ denotes a lifted loss term for every rule in a set $\mathcal{I}$ of implication rules that we want to inject.

3.4 Convex Implication Loss

The logistic loss ℓ_R (see §2) is not suited for imposing implications because once the inequality in eq. (11) is satisfied, the components of $\boldsymbol{r_p}$ and $\boldsymbol{r_q}$ do not need to be separated any further. However, with ℓ_R this would continue to happen due to the small non-zero gradient. In the reconstruction loss $\mathcal{L}_R$ this is a desirable effect which further separates the scores for positive from negative examples. However, if an implication is imposed between two relations that are almost equivalent according to the training data, we still want to find almost equivalent embedding vectors. Hence, we propose to use the loss

$$\ell_I(s) = \max(0, s + \delta) \tag{15}$$

with δ a small positive margin to ensure that the gradient does not disappear before the inequality is actually satisfied. We use $\delta = 0.01$ in all experiments.

The main advantage of the presented approach over earlier methods that impose the rules in a grounded way (Rocktäschel et al., 2015; Wang et al., 2015) is the computational efficiency of imposing the lifted loss. Evaluating $\mathcal{L}_I^U$ or its gradient for one implication rule is comparable to evaluating the reconstruction loss for one pair of training facts. In typical applications there are much fewer rules than training facts and the extra computation time needed to inject these rules is therefore negligible.

4 Related Work

Recent research on combining rules with learned vector representations has been important for new developments in the field of knowledge base completion. Rocktäschel et al. (2014) and Rocktäschel et al. (2015) provided a framework to jointly maximize the probability of observed facts and propositionalized first-order logic rules. Wang et al. (2015) demonstrated how different types of rules can be incorporated using an Integer Linear Programming approach. Wang and Cohen (2016) learned embeddings for facts and first-order logic rules using matrix factorization. Yet, all of these approaches ground the rules in the training data, limiting their scalability towards large rule sets and KBs with many entities. As argued in the introduction, this forms an important motivation for the lifted rule injection model put forward in this work, which by construction does not suffer from that limitation. Wei et al. (2015) proposed an alternative strategy to tackle the scalability problem by reasoning on a filtered subset of grounded facts.

Wu et al. (2015) proposed to use a path ranking approach for capturing long-range interactions between entities, and to add these as an extra loss term, besides the loss that models pairwise relations. Our model FSL differs substantially from their approach, in that we consider tuples instead of separate entities, and we inject a given set of rules. Yet, by cre-

ating a partial ordering in the relation embeddings as a result of injecting implication rules, model FSL can also capture interactions beyond direct relations. This will be demonstrated in §5.3 by injecting rules between surface patterns only and still measuring an improvement on predictions for structured Freebase relations.

Combining logic and distributed representations is also an active field of research outside of automated knowledge base completion. Recent advances include the work by Faruqui et al. (2014), who injected ontological knowledge from WordNet into word representations. Furthermore, Vendrov et al. (2016) proposed to enforce a partial ordering in an embeddings space of images and phrases. Our method is related to such order embeddings since we define a partial ordering on relation embeddings. However, to ensure that implications hold for all entity-tuples we also need a restriction on the entity-tuple embedding space and derive bounds on the loss. Another important contribution is the recent work by Hu et al. (2016), who proposed a framework for injecting rules into general neural network architectures, by jointly training on the actual targets and on the rule-regularized predictions provided by a teacher network. Although quite different at first sight, their work could offer a way to use our model in various neural network architectures, by integrating the proposed lifted loss into the teacher network.

This paper builds upon our previous workshop paper (Demeester et al., 2016). In that work, we tested different tuple embedding transformations in an ad-hoc manner. We used approximately Boolean representations of relations instead of entity-tuples, strongly reducing the model's degrees of freedom. We now derive the FSL model from a carefully considered mathematical transformation of the grounded loss. The FSL model only restricts the tuple embedding space, whereby relation vectors remain real valued. Furthermore, previous experiments were performed on small-scale artificial datasets, whereas we now test on a real-world relation extraction benchmark.

Finally, we explicitly discuss the main differences with respect to the strongly related work from Rocktäschel et al. (2015). Their method is more general, as they cover a wide range of first-order logic rules, whereas we only discuss implications. Lifted rule injection beyond implications will be studied in future research contributions. However, albeit less general, our model has a number of clear advantages:

Scalability – Our proposed model of lifted rule injection scales according to the number of implication rules, instead of the number of rules times the number of observed facts for every relation present in a rule.

Generalizability – Injected implications will hold even for facts not seen during training, because their validity only depends on the order relation imposed on the relation representations. This is not guaranteed when training on rules grounded in training facts by Rocktäschel et al. (2015).

Training Flexibility – Our method can be trained with various loss functions, including the rank-based loss as used in Riedel et al. (2013). This was not possible for the model of Rocktäschel et al. (2015) and already leads to an improved accuracy as seen from the zero-shot learning experiment in §5.2.

Independence Assumption – In Rocktäschel et al. (2015) an implication of the form $a_p \Rightarrow a_q$ for two ground atoms a_p and a_q is modeled by the logical equivalence $\neg(a_p \wedge \neg a_q)$, and its probability is approximated in terms of the elementary probabilities $\pi(a_p)$ and $\pi(a_q)$ as $1 - \pi(a_p)\big(1 - \pi(a_q)\big)$. This assumes the independence of the two atoms a_p and a_q, which may not hold in practice. Our approach does not rely on that assumption and also works for cases of statistical dependence. For example, the independence assumption does not hold in the trivial case where the relations r_p and r_q in the two atoms are equivalent, whereas in our model, the constraints $\boldsymbol{r}_p \leq \boldsymbol{r}_q$ and $\boldsymbol{r}_p \geq \boldsymbol{r}_q$ would simply reduce to $\boldsymbol{r}_p = \boldsymbol{r}_q$.

5 Experiments and Results

We now present our experimental results. We start by describing the experimental setup and hyperparameters. Before turning to the injection of rules, we compare model F with model FS, and show that restricting the tuple embedding space has a regularization effect, rather than limiting the expressiveness of the model (§5.1). We then demonstrate that model FSL is capable of zero-shot learning (§5.2), and show that injecting high-quality WordNet rules

Table 1: Weighted mean average precision for our reimplementation of the matrix factorization model (F) compared to restricting the entity-pair space (FS) and injecting WordNet rules (FSL). Model F results by Riedel et al. (2013) are denoted as R13-F.

leads to an improved precision (§5.3). We proceed with a visual illustration of the relation embeddings with and without injected rules (§5.4), provide details on time efficiency of the lifted rule injection method (§5.5), and show that it correctly captures the asymmetry of implication rules (§5.6).

All models were implemented in TensorFlow (Abadi et al., 2015). We use the hyperparameters of Riedel et al. (2013), with $k = 100$ hidden dimensions and a weight of $\alpha = 0.01$ for the L_2 regularization loss. We use ADAM (Kingma and Ba, 2014) for optimization with an initial learning rate of 0.005 and a mini-batch size of 8192. The embeddings are initialized by sampling uniformly from $[-0.1, 0.1]$ and we use $\tilde{\beta} = 0.1$ for the implication loss throughout our experiments.

5.1 Restricted Embedding Space

Before incorporating external commonsense knowledge into relation representations, we were curious how much we lose by restricting the entity-tuple space to approximately Boolean embeddings. We evaluate our models on the New York Times dataset introduced by Riedel et al. (2013). Surprisingly, we find that the expressiveness of the model does not suffer from this strong restriction. From Table 1 we see that restricting the tuple-embedding space seems to perform slightly better (FS) as opposed to a real-valued tuple-embedding space (F), suggesting that this restriction has a regularization effect that improves generalization. We also provide the original results for model F by Riedel et al. (2013) (denoted as R13-F) for comparison. Due to a different implementation and optimization procedure, the results for our model F and R13-F are not identical.

Inspecting the top relations for a sampled dimension in the embedding space reveals that the relation space of model FS more closely resembles clusters than that of model F (Table 2). We hypothesize that this might be caused by approximately Boolean entity-tuple representations in model FS, resulting in attribute-like entity-tuple vectors that capture which relation clusters they belong to.

5.2 Zero-shot Learning

The zero-shot learning experiment performed in Rocktäschel et al. (2015) leads to an important finding: when injecting implications with right-hand sides for Freebase relations for which no or very limited training facts are available, the model should be able to infer the validity of Freebase facts for those relations based on rules and correlations between textual surface patterns.

We inject the same hand-picked relations as used by Rocktäschel et al. (2015), after removing all Freebase training facts. The lifted rule injection (model FSL) reaches a weighted MAP of 0.35, comparable with 0.38 by the Joint model from Rocktäschel et al. (2015) (denoted R15-Joint). Note that for this experiment we initialized the Freebase relations implied by the rules with negative random vectors (sampled uniformly from $[-7.9, -8.1]$). The reason is that without any negative training facts for these relations, their components can only go up due to the implication loss, and we do not want to get values that are too high before optimization.

Figure 1 shows how the relation extraction performance improves when more Freebase relation training facts are added. It effectively measures how well the proposed models, matrix factorization (F), propositionalized rule injection (R15-Joint), and our model (FSL), can make use of the provided rules and correlations between textual surface form pat-

Table 2: Top patterns for a randomly sampled dimension in non-restricted and restricted embedding space .

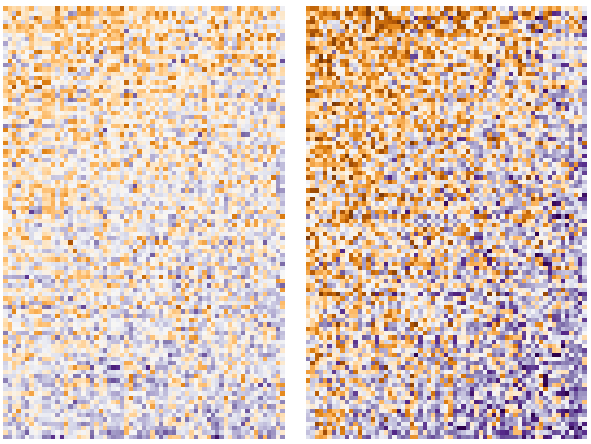
terns and increased fractions of Freebase training facts. Although FSL starts at a lower performance than R15-Joint when no Freebase training facts are present, it outperforms R15-Joint and a plain matrix factorization model by a substantial margin when provided with more than 7.5% of Freebase training facts. This indicates that, in addition to being much faster than R15-Joint, it can make better use of provided rules and few training facts. We attribute this to the Bayesian personalized ranking loss instead of the logistic loss used in Rocktäschel et al. (2015). The former is compatible with our rule-injection method, but not with the approach of maximizing the expectation of propositional rules used by R15-Joint.

5.3 Injecting Knowledge from WordNet

The main purpose of this work is to be able to incorporate rules from external resources for aiding relation extraction. We use WordNet hypernyms to generate rules for the NYT dataset. To this end we iterate over all surface form patterns in the dataset and attempt to replace words in the pattern by their hypernyms. If the resulting pattern is contained in the dataset, we generate the corresponding rule. For instance, we generate a rule `appos->diplomat->amod` ⇒ `appos->official->amod` since both patterns are contained in the NYT dataset and we know from WordNet that a diplomat is an official. This leads to 427 rules from WordNet that we subsequently annotate manually to obtain 36 high-quality rules. Note that none of these rules directly imply a Freebase relation. Although the test relations all originate from Freebase, we still hope to see improvements by transitive effects, *i.e.*, better surface form representations that in turn help to predict Freebase facts.

We show results obtained by injecting these WordNet rules in Table 1 (column FSL). The weighted MAP measure increases by 2% with respect to model FS, and 4% compared to our reimplementation of the matrix factorization model F. This demonstrates that imposing a partial ordering based on implication rules can be used to incorporate logical commonsense knowledge and increase the quality of information extraction systems. Note that our evaluation setting guarantees that only indirect effects of the rules are measured, *i.e.*, we do not use any rules directly implying test relations. This shows that injecting such rules influences the relation embedding space beyond only the relations explicitly stated in the rules. For example, injecting the rule `appos<-father->appos` ⇒ `poss<-parent->appos` can contribute to improved predictions for the test relation `parent/child`.



(a) (b)

Figure 2: Visualization of embeddings (columns) for the relations that appear in the high-quality WordNet rules, (a) without and (b) with injection of these rules. Values range from -1 (orange) via 0 (white) to 1 (purple). Best viewed in color.

5.4 Visualizing Relation Embeddings

We provide a visual inspection of how the structure of the relation embedding space changes when rules are imposed. We select all relations involved in the WordNet rules, and gather them as columns in a single matrix, sorted by increasing ℓ_1 norm (values in the 100 dimensions are similarly sorted). Figures 2a and 2b show the difference between model F (without injected rules) and FSL (with rules). The values of the embeddings in model FSL are more polarized, *i.e.*, we observe stronger negative or positive components than for model F. Furthermore, FSL also reveals a clearer difference between the leftmost (mostly negative, more specific) and right-most (predominantly positive, more general) embeddings (*i.e.*, a clearer separation between positive and negative values in the plot), which results from imposing the order relation in eq. (11) when injecting implications.

5.5 Efficiency of Lifted Injection of Rules

In order to get an idea of the time efficiency of injecting rules, we measure the time per epoch when restricting the program execution to a single 2.4GHz CPU core. We measure on average 6.33s per epoch without rules (model FS), against 6.76s and 6.97s when injecting the 36 high-quality WordNet rules and the unfiltered 427 rules (model FSL), respectively. Increasing the amount of injected rules from 36 to 427 leads to an increase of only 3% in computation time, even though in our setup all rule losses are used in every training batch. This confirms the high efficiency of our lifted rule injection method.

5.6 Asymmetric Character of Implications

In order to demonstrate that injecting implications conserves their asymmetric nature, we perform the following experiment. After incorporating high-quality Wordnet rules $r_p \Rightarrow r_q$ into model FSL we select all of the tuples t_p that occur with relation r_p in a training fact $\langle r_p, t_p \rangle$. Matching these with relation r_q should result in high values for the scores $\boldsymbol{r_q}^\top \boldsymbol{t_p}$, if the implication holds. If however the tuples t_q are selected from the training facts $\langle r_q, t_q \rangle$, and matched with relation r_p, the scores $\boldsymbol{r_p}^\top \boldsymbol{t_q}$ should be much lower if the inverse implication does not hold (in other words, if r_q and r_p are not equivalent). Table 3 lists the averaged results for 5 example rules, and the average over all relations in WordNet rules, both for the case with injected rules (model FSL), and without rules (model FS). For easier comparison, the scores are mapped to the unit interval via the sigmoid function. This quantity $\sigma(\boldsymbol{r}^\top \boldsymbol{t})$ is often interpreted as the probability that the corresponding fact holds (Riedel et al., 2013), but because of the BPR-based training, only differences between scores play a role here. After injecting rules, the average scores of facts inferred by these rules (*i.e.*, column $\sigma(\boldsymbol{r_q}^\top \boldsymbol{t_p})$ for model FSL) are always higher than for facts (incorrectly) inferred by the inverse rules (column $\sigma(\boldsymbol{r_p}^\top \boldsymbol{t_q})$ for model FSL). In the fourth example, the inverse rule leads to high scores as well (on average 0.79, vs. 0.98 for the actual rule). This is due to the fact that the `daily` and `newspaper` relations are more or less equivalent, such that the components of $\boldsymbol{r_p}$ are not much below those of $\boldsymbol{r_q}$. For the last example (the `ambassador` $\Rightarrow$ `diplomat` rule), the asymmetry in the implication is maintained, although the absolute scores are rather low for these two relations.

The results for model FS reflect how strongly the implications in either direction are latently present in the training data. We can only conclude that model FS manages to capture the similarity be-

rule			model FSL		model FS	
r_p	$\Rightarrow$	r_q	$\sigma(\boldsymbol{r_q}^\top \boldsymbol{t_p})$	$\sigma(\boldsymbol{r_p}^\top \boldsymbol{t_q})$	$\sigma(\boldsymbol{r_q}^\top \boldsymbol{t_p})$	$\sigma(\boldsymbol{r_p}^\top \boldsymbol{t_q})$
appos->party->amod	$\Rightarrow$	appos->organization->amod	0.99	0.22	0.70	0.86
poss<-father->appos	$\Rightarrow$	poss<-parent->appos	0.96	0.00	0.72	0.89
appos->prosecutor->nn	$\Rightarrow$	appos->lawyer->nn	0.99	0.01	0.87	0.80
appos->daily->amod	$\Rightarrow$	appos->newspaper->amod	0.98	0.79	0.90	0.86
appos->ambassador->amod	$\Rightarrow$	appos->diplomat->amod	0.31	0.05	0.93	0.84
average over 36 high-quality Wordnet rules			0.95	0.28	0.74	0.70

Table 3: Average of $\sigma(\boldsymbol{r_q}^\top \boldsymbol{t})$ over all inferred facts $\langle r_q, t_p \rangle$ for tuples $\boldsymbol{t_p}$ from training items for relation r_p, and vice versa, for Wordnet implications $\boldsymbol{r_p} \Rightarrow \boldsymbol{r_q}$, and model FSL (injected rules) vs. model FS (no rules).

tween relations, but not the asymmetric character of implications. For example, purely based on the training data, it appears to be more likely that the `parent` relation implies the `father` relation, than vice versa. This again demonstrates the importance and added value of injecting external rules capturing commonsense knowledge.

6 Conclusions

We presented a novel, fast approach for incorporating first-order implication rules into distributed representations of relations. We termed our approach 'lifted rule injection', as it avoids the costly grounding of first-order implication rules and is thus independent of the size of the domain of entities. By construction, these rules are satisfied for any observed or unobserved fact. The presented approach requires a restriction on the entity-tuple embedding space. However, experiments on a real-world dataset show that this does not impair the expressiveness of the learned representations. On the contrary, it appears to have a beneficial regularization effect.

By incorporating rules generated from WordNet hypernyms, our model improved over a matrix factorization baseline for knowledge base completion. Especially for domains where annotation is costly and only small amounts of training facts are available, our approach provides a way to leverage external knowledge sources for inferring facts.

In future work, we want to extend the proposed ideas beyond implications towards general first-order logic rules. We believe that supporting conjunctions, disjunctions and negations would enable to debug and improve representation learning based knowledge base completion. Furthermore, we want to integrate these ideas into neural methods beyond matrix factorization approaches.

Abstract

Directly reading documents and being able to answer questions from them is an unsolved challenge. To avoid its inherent difficulty, question answering (QA) has been directed towards using Knowledge Bases (KBs) instead, which has proven effective. Unfortunately KBs often suffer from being too restrictive, as the schema cannot support certain types of answers, and too sparse, e.g. Wikipedia contains much more information than Freebase. In this work we introduce a new method, Key-Value Memory Networks, that makes reading documents more viable by utilizing different encodings in the addressing and output stages of the memory read operation. To compare using KBs, information extraction or Wikipedia documents directly in a single framework we construct an analysis tool, WIKIMOVIES, a QA dataset that contains raw text alongside a preprocessed KB, in the domain of movies. Our method reduces the gap between all three settings. It also achieves state-of-the-art results on the existing WIKIQA benchmark.

1 Introduction

Question answering (QA) has been a long standing research problem in natural language processing, with the first systems attempting to answer questions by directly reading documents (Voorhees and Tice, 2000). The development of large-scale Knowledge Bases (KBs) such as Freebase (Bollacker *et al.*, 2008) helped organize information into structured forms, prompting recent progress to focus on answering questions by converting them into logical forms that can be used to query such databases (Berant *et al.*, 2013; Kwiatkowski *et al.*, 2013; Fader *et al.*, 2014).

Unfortunately, KBs have intrinsic limitations such as their inevitable incompleteness and fixed schemas that cannot support all varieties of answers. Since information extraction (IE) (Craven *et al.*, 2000), intended to fill in missing information in KBs, is neither accurate nor reliable enough, collections of raw textual resources and documents such as Wikipedia will always contain more information. As a result, even if KBs can be satisfactory for closed-domain problems, they are unlikely to scale up to answer general questions on any topic. Starting from this observation, in this work we study the problem of answering by directly reading documents.

Retrieving answers directly from text is harder than from KBs because information is far less structured, is indirectly and ambiguously expressed, and is usually scattered across multiple documents. This explains why using a satisfactory KB—typically only available in closed domains—is preferred over raw text. We postulate that before trying to provide answers that are not in KBs, document-based QA systems should first reach KB-based systems' performance in such closed domains, where clear comparison and evaluation is possible. To this end, this paper introduces WIKIMOVIES, a new analysis tool that allows for measuring the performance of QA systems when the knowledge source is switched from a KB to unstructured documents. WIKIMOVIES contains $\sim$100k questions in the movie domain, and was designed to be answerable by using either a perfect KB (based on OMDb[1]), Wikipedia pages or an imper-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1400–1409,
Austin, Texas, November 1-5, 2016.

fect KB obtained through running an engineered IE pipeline on those pages.

To bridge the gap between using a KB and reading documents directly, we still lack appropriate machine learning algorithms. In this work we propose the Key-Value Memory Network (KV-MemNN), a new neural network architecture that generalizes the original Memory Network (Sukhbaatar *et al.*, 2015) and can work with either knowledge source. The KV-MemNN performs QA by first storing facts in a key-value structured memory before reasoning on them in order to predict an answer. The memory is designed so that the model learns to use keys to address relevant memories with respect to the question, whose corresponding values are subsequently returned. This structure allows the model to encode prior knowledge for the considered task and to leverage possibly complex transforms between keys and values, while still being trained using standard backpropagation via stochastic gradient descent.

Our experiments on WIKIMOVIES indicate that, thanks to its key-value memory, the KV-MemNN consistently outperforms the original Memory Network, and reduces the gap between answering from a human-annotated KB, from an automatically extracted KB or from directly reading Wikipedia. We confirm our findings on WIKIQA (Yang *et al.*, 2015), another Wikipedia-based QA benchmark where no KB is available, where we demonstrate that KV-MemNN can reach state-of-the-art results—surpassing the most recent attention-based neural network models.

2 Related Work

Early QA systems were based on information retrieval and were designed to return snippets of text containing an answer (Voorhees and Tice, 2000; Banko *et al.*, 2002), with limitations in terms of question complexity and response coverage. The creation of large-scale KBs (Auer *et al.*, 2007; Bollacker *et al.*, 2008) have led to the development of a new class of QA methods based on semantic parsing (Berant *et al.*, 2013; Kwiatkowski *et al.*, 2013; Fader *et al.*, 2014; Yih *et al.*, 2015) that can return precise answers to complicated compositional questions. Due to the sparsity of KB data, however, the main challenge shifts from finding answers to developing efficient information extraction methods to populate KBs automatically (Craven *et al.*, 2000; Carlson *et al.*, 2010)—not an easy problem.

For this reason, recent initiatives are returning to the original setting of directly answering from text using datasets like TRECQA (Wang *et al.*, 2007), which is based on classical TREC resources (Voorhees *et al.*, 1999), and WIKIQA (Yang *et al.*, 2015), which is extracted from Wikipedia. Both benchmarks are organized around the task of answer sentence selection, where a system must identify the sentence containing the correct answer in a collection of documents, but need not return the actual answer as a KB-based system would do. Unfortunately, these datasets are very small (hundreds of examples) and, because of their answer selection setting, do not offer the option to directly compare answering from a KB against answering from pure text. Using similar resources as the dialog dataset of Dodge *et al.* (2016), our new benchmark WIKIMOVIES addresses both deficiencies by providing a substantial corpus of question-answer pairs that can be answered by either using a KB or a corresponding set of documents.

Even though standard pipeline QA systems like AskMR (Banko *et al.*, 2002) have been recently revisited (Tsai *et al.*, 2015), the best published results on TRECQA and WIKIQA have been obtained by either convolutional neural networks (Santos *et al.*, 2016; Yin and Schütze, 2015; Wang *et al.*, 2016) or recurrent neural networks (Miao *et al.*, 2015)—both usually with attention mechanisms inspired by (Bahdanau *et al.*, 2015). In this work, we introduce KV-MemNNs, a Memory Network model that operates a symbolic memory structured as $(key, value)$ pairs. Such structured memory is not employed in any existing attention-based neural network architecture for QA. As we will show, it gives the model greater flexibility for encoding knowledge sources and helps shrink the gap between directly reading documents and answering from a KB.

3 Key-Value Memory Networks

The Key-Value Memory Network model is based on the Memory Network (MemNNs) model (Weston *et al.*, 2015; Sukhbaatar *et al.*, 2015) which has proven useful for a variety of document reading and question answering tasks: for reading children's books and answering questions about them (Hill *et al.*, 2016), for complex reasoning over sim-

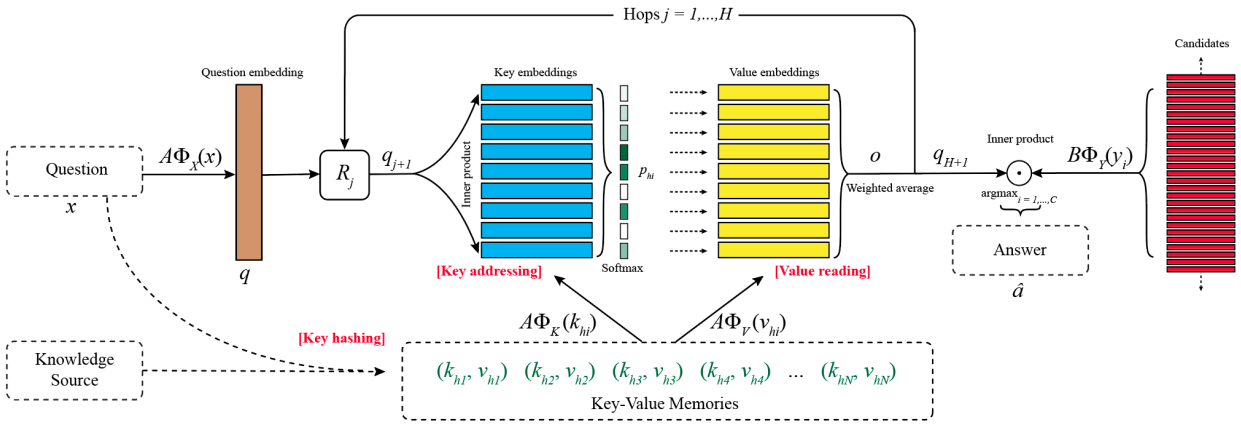

Figure 1: The Key-Value Memory Network model for question answering. See Section 3 for details.

ulated stories (Weston *et al.*, 2016) and for utilizing KBs to answer questions (Bordes *et al.*, 2015).

Key-value paired memories are a generalization of the way context (e.g. knowledge bases or documents to be read) are stored in memory. The lookup (addressing) stage is based on the key memory while the reading stage (giving the returned result) uses the value memory. This gives both (i) greater flexibility for the practitioner to encode prior knowledge about their task; and (ii) more effective power in the model via nontrivial transforms between key and value. The key should be designed with features to help match it to the question, while the value should be designed with features to help match it to the response (answer). An important property of the model is that the entire model can be trained with key-value transforms while still using standard backpropagation via stochastic gradient descent.

3.1 Model Description

Our model is based on the end-to-end Memory Network architecture of Sukhbaatar *et al.* (2015). A high-level view of both models is as follows: one defines a memory, which is a possibly very large array of slots which can encode both long-term and short-term context. At test time one is given a query (e.g. the question in QA tasks), which is used to iteratively address and read from the memory (these iterations are also referred to as "hops") looking for relevant information to answer the question. At each step, the collected information from the memory is cumulatively added to the original query to build context for the next round. At the last iteration, the final retrieved context and the most recent query are combined as features to predict a response from a list of candidates.

Figure 1 illustrates the KV-MemNN model architecture.

In KV-MemNNs we define the memory slots as pairs of vectors $(k_1, v_1) \ldots, (k_M, v_M)$ and denote the question x. The addressing and reading of the memory involves three steps:

- **Key Hashing:** the question can be used to preselect a small subset of the possibly large array. This is done using an inverted index that finds a subset $(k_{h_1}, v_{h_1}), \ldots, (k_{h_N}, v_{h_N})$ of memories of size N where the key shares at least one word with the question with frequency $< F = 1000$ (to ignore stop words), following Dodge *et al.* (2016). More sophisticated retrieval schemes could be used here, see e.g. Manning *et al.* (2008),

- **Key Addressing:** during addressing, each candidate memory is assigned a relevance probability by comparing the question to each key:

$$p_{h_i} = \text{Softmax}(A\Phi_X(x) \cdot A\Phi_K(k_{h_i}))$$

  where $\Phi_\cdot$ are feature maps of dimension D, A is a $d \times D$ matrix and $\text{Softmax}(z_i) = e^{z_i} / \sum_j e^{z_j}$. We discuss choices of feature map in Sec. 3.2.

- **Value Reading:** in the final reading step, the values of the memories are read by taking their weighted sum using the addressing probabilities,

and the vector o is returned:

$$o = \sum_i p_{h_i} A\Phi_V(v_{h_i}) \ .$$

The memory access process is conducted by the "controller" neural network using $q = A\Phi_X(x)$ as the query. After receiving the result o, the query is updated with $q_2 = R_1(q + o)$ where R is a $d \times d$ matrix. The memory access is then repeated (specifically, only the addressing and reading steps, but not the hashing), using a different matrix R_j on each hop, j. The key addressing equation is transformed accordingly to use the updated query:

$$p_{h_i} = \text{Softmax}(q_{j+1}^\top A\Phi_K(k_{h_i})) \ .$$

The motivation for this is that new evidence can be combined into the query to focus on and retrieve more pertinent information in subsequent accesses. Finally, after a fixed number H hops, the resulting state of the controller is used to compute a final prediction over the possible outputs:

$$\hat{a} = \text{argmax}_{i=1,\ldots,C}\text{Softmax}(q_{H+1}^\top B\Phi_Y(y_i))$$

where y_i are the possible candidate outputs, e.g. all the entities in the KB, or all possible candidate answer sentences in the case of a dataset like WIKIQA (see Sec. 5.2). The $d \times D$ matrix B can also be constrained to be identical to A. The whole network is trained end-to-end, and the model learns to perform the iterative accesses to output the desired target a by minimizing a standard cross-entropy loss between $\hat{a}$ and the correct answer a. Backpropagation and stochastic gradient descent are thus used to learn the matrices A, B and $R_1, \ldots, R_H$.

To obtain the standard End-To-End Memory Network of Sukhbaatar *et al.* (2015) one can simply set the key and value to be the same for all memories. Hashing was not used in that paper, but is important for computational efficiency for large memory sizes, as already shown in Dodge *et al.* (2016). We will now go on to describe specific applications of key-value memories for the task of reading KBs or documents.

3.2 Key-Value Memories

There are a variety of ways to employ key-value memories that can have important effects on overall performance. The ability to encode prior knowledge in this way is an important component of KV-MemNNs, and we are free to define Φ_X, Φ_Y, Φ_K and Φ_V for the query, answer, keys and values respectively. We now describe several possible variants of Φ_K and Φ_V that we tried in our experiments, for simplicity we kept Φ_X and Φ_Y fixed as bag-of-words representations.

KB Triple Knowledge base entries have a structure of triple "subject *relation* object" (see Table 1 for examples). The representation we consider is simple: the key is composed of the left-hand side entity (subject) and the relation, and the value is the right-hand side entity (object). We double the KB and consider the reversed relation as well (e.g. we now have two triples "Blade Runner *directed_by* Ridley Scott" and "Ridley Scott *!directed_by* Blade Runner" where *!directed_by* is a different entry in the dictionary than *directed_by*). Having the entry both ways round is important for answering different kinds of questions ("Who directed Blade Runner?" vs. "What did Ridley Scott direct?"). For a standard MemNN that does not have key-value pairs the whole triple has to be encoded into the same memory slot.

Sentence Level For representing a document, one can split it up into sentences, with each memory slot encoding one sentence. Both the key and the value encode the entire sentence as a bag-of-words. As the key and value are the same in this case, this is identical to a standard MemNN and this approach has been used in several papers (Weston *et al.*, 2016; Dodge *et al.*, 2016).

Window Level Documents are split up into windows of W words; in our tasks we only include windows where the center word is an entity. Windows are represented using bag-of-words. Window representations for MemNNs have been shown to work well previously (Hill *et al.*, 2016). However, in Key-Value MemNNs we encode the key as the entire window, and the value as only the center word, which is not possible in the MemNN architecture. This makes sense because the entire window is more likely to be pertinent as a match for the question (as the key), whereas the entity at the center is more pertinent as a match for the answer (as the value). We will compare these approaches in our experiments.

Window + Center Encoding Instead of representing the window as a pure bag-of-words, thus mixing

the window center with the rest of the window, we can also encode them with different features. Here, we double the size, D, of the dictionary and encode the center of the window and the value using the second dictionary. This should help the model pick out the relevance of the window center (more related to the answer) as compared to the words either side of it (more related to the question).

Window + Title The title of a document is commonly the answer to a question that relates to the text it contains. For example "What did Harrison Ford star in?" can be (partially) answered by the Wikipedia document with the title "Blade Runner". For this reason, we also consider a representation where the key is the word window as before, but the value is the document title. We also keep all the standard (window, center) key-value pairs from the window-level representation as well, thus doubling the number of memory slots in comparison. To differentiate the two keys with different values we add an extra feature "_window_" or "_title_" to the key, depending on the value. The "_title_" version also includes the actual movie title in the key. This representation can be combined with center encoding. Note that this representation is inherently specific to datasets in which there is an apparent or meaningful title for each document.

4 The WikiMovies Benchmark

The WIKIMOVIES benchmark consists of question-answer pairs in the domain of movies. It was built with the following goals in mind: (i) machine learning techniques should have ample training examples for learning; and (ii) one can analyze easily the performance of different representations of knowledge and break down the results by question type. The dataset can be downloaded from `http://fb.ai/babi`.

4.1 Knowledge Representations

We construct three forms of knowledge representation: (i) Doc: raw Wikipedia documents consisting of the pages of the movies mentioned; (ii) KB: a classical graph-based KB consisting of entities and relations created from the Open Movie Database (OMDb) and MovieLens; and (iii) IE: information extraction performed on the Wikipedia pages to build a KB in a similar form as (ii). We take care to construct QA pairs such that they are all potentially answerable from either the KB from (ii) or the original Wikipedia documents from (i) to eliminate data sparsity issues. However, it should be noted that the advantage of working from raw documents in real applications is that data sparsity is less of a concern than for a KB, while on the other hand the KB has the information already parsed in a form amenable to manipulation by machines. This dataset can help analyze what methods we need to close the gap between all three settings, and in particular what are the best methods for reading documents when a KB is not available. A sample of the dataset is shown in Table 1.

Doc: Wikipedia Article for Blade Runner (partially shown)
Blade Runner is a 1982 American neo-noir dystopian science fiction film directed by Ridley Scott and starring Harrison Ford, Rutger Hauer, Sean Young, and Edward James Olmos. The screenplay, written by Hampton Fancher and David Peoples, is a modified film adaptation of the 1968 novel "Do Androids Dream of Electric Sheep?" by Philip K. Dick. The film depicts a dystopian Los Angeles in November 2019 in which genetically engineered replicants, which are visually indistinguishable from adult humans, are manufactured by the powerful Tyrell Corporation as well as by other "mega-corporations" around the world. Their use on Earth is banned and replicants are exclusively used for dangerous, menial, or leisure work on off-world colonies. Replicants who defy the ban and return to Earth are hunted down and "retired" by special police operatives known as "Blade Runners". . . .

Table 1: WIKIMOVIES: Questions, Doc, KB and IE sources.

Doc We selected a set of Wikipedia articles about movies by identifying a set of movies from OMDb[2] that had an associated article by title match. We keep the title and the first section (before the contents box) for each article. This gives ∼17k documents (movies) which comprise the set of documents our models will read from in order to answer questions.

[2] `http://beforethecode.com/projects/omdb/download.aspx`

KB Our set of movies were also matched to the MovieLens dataset[3]. We built a KB using OMDb and MovieLens metadata with entries for each movie and nine different relation types: director, writer, actor, release year, language, genre, tags, IMDb rating and IMDb votes, with ∼10k related actors, ∼6k directors and ∼43k entities in total. The KB is stored as triples; see Table 1 for examples. IMDb ratings and votes are originally real-valued but are binned and converted to text ("unheard of", "unknown", "well known", "highly watched", "famous"). We finally only retain KB triples where the entities also appear in the Wikipedia articles[4] to try to guarantee that all QA pairs will be equally answerable by either the KB or Wikipedia document sources.

IE As an alternative to directly reading documents, we explore leveraging information extraction techniques to transform documents into a KB format. An IE-KB representation has attractive properties such as more precise and compact expressions of facts and logical key-value pairings based on subject-verb-object groupings. This can come at the cost of lower recall due to malformed or completely missing triplets. For IE we use standard open-source software followed by some task-specific engineering to improve the results. We first employ coreference resolution via the Stanford NLP Toolkit (Manning *et al.*, 2014) to reduce ambiguity by replacing pronominal ("he", "it") and nominal ("the film") references with their representative entities. Next we use the SENNA semantic role labeling tool (Collobert *et al.*, 2011) to uncover the grammatical structure of each sentence and pair verbs with their arguments. Each triplet is cleaned of words that are not recognized entities, and lemmatization is done to collapse different inflections of important task-specific verbs to one form (e.g. stars, starring, star → starred). Finally, we append the movie title to each triple similar to the "Window + Title" representation of Sec. 3.2, which improved results.

4.2 Question-Answer Pairs

Within the dataset's more than 100,000 question-answer pairs, we distinguish 13 classes of question corresponding to different kinds of edges in our KB. They range in scope from specific—such as *actor to movie*: "What movies did Harrison Ford star in?" and *movie to actors*: "Who starred in Blade Runner?"—to more general, such as *tag to movie*: "Which films can be described by *dystopian*?"; see Table 4 for the full list. For some question there can be multiple correct answers.

Using SimpleQuestions (Bordes *et al.*, 2015), an existing open-domain question answering dataset based on Freebase, we identified the subset of questions posed by human annotators that covered our question types. We created our question set by substituting the entities in those questions with entities from all of our KB triples. For example, if the original question written by an annotator was "What movies did Harrison Ford star in?", we created a pattern "What movies did [@actor] star in?", which we substitute for any other actors in our set, and repeat this for all annotations. We split the questions into disjoint training, development and test sets with ∼96k, 10k and 10k examples, respectively. The same question (even worded differently) cannot appear in both train and test sets. Note that this is much larger than most existing datasets; for example, the WIKIQA dataset (Yang *et al.*, 2015) for which we also conduct experiments in Sec. 5.2 has only ∼1000 training pairs.

Method	KB	IE	Doc
(Bordes *et al.*, 2014) QA system	93.5	56.5	N/A
Supervised Embeddings	54.4	54.4	54.4
Memory Network	78.5	63.4	69.9
Key-Value Memory Network	**93.9**	**68.3**	**76.2**

Table 2: Test results (% hits@1) on WIKIMOVIES, comparing human-annotated KB (KB), information extraction-based KB (IE), and directly reading Wikipedia documents (Doc).

Memory Representation	Doc
Sentence-level	52.4
Window-level	66.8
Window-level + Title	74.1
Window-level + Center Encoding + Title	**76.9**

[3] http://grouplens.org/datasets/movielens/

[4] The dataset also includes the slightly larger version without this constraint.

5 Experiments

This section describes our experiments on WIKIMOVIES and WIKIQA.

5.1 WikiMovies

We conducted experiments on the WIKIMOVIES dataset described in Sec. 4. Our main goal is to compare the performance of KB, IE and Wikipedia (Doc) sources when trying varying learning methods. We compare four approaches: (i) the QA system of Bordes *et al.* (2014) that performs well on existing datasets WebQuestions (Berant *et al.*, 2013) and SimpleQuestions (Bordes *et al.*, 2015) that use KBs only; (ii) supervised embeddings that do not make use of a KB at all but learn question-to-answer embeddings directly and hence act as a sanity check (Dodge *et al.*, 2016); (iii) Memory Networks; and (iv) Key-Value Memory Networks. Performance is reported using the accuracy of the top hit (single answer) over all possible answers (all entities), i.e. the hits@1 metric measured in percent. In all cases hyperparameters are optimized on the development set, including the memory representations of Sec. 3.2 for MemNNs and KV-MemNNs. As MemNNs do not support key-value pairs, we concatenate key and value together when they differ instead.

The main results are given in Table 2. The QA system of Bordes *et al.* (2014) outperforms Supervised Embeddings and Memory Networks for KB and IE-based KB representations, but is designed to work with a KB, not with documents (hence the N/A in that column). However, Key-Value Memory Networks outperform all other methods on all three data source types. Reading from Wikipedia documents directly (Doc) outperforms an IE-based KB (IE), which is an encouraging result towards automated machine reading though a gap to a human-annotated KB still remains (93.9 vs. 76.2). The best memory representation for directly reading documents uses "Window-level + Center Encoding + Title" ($W = 7$ and $H = 2$); see Table 3 for a comparison of results for different representation types. Both center encoding and title features help the window-level representation, while sentence-level is inferior.

QA Breakdown A breakdown by question type comparing the different data sources for KV-MemNNs is given in Table 4. IE loses out especially to Doc (and KB) on Writer, Director and Actor to Movie, perhaps because coreference is difficult in these cases – although it has other losses elsewhere too. Note that only 56% of subject-object pairs in IE match the triples in the original KB, so losses are expected. Doc loses out to KB particularly on Tag to Movie, Movie to Tags, Movie to Writer and Movie to Actors. Tag questions are hard because they can reference more or less any word in the entire Wikipedia document; see Table 1. Movie to Writer/Actor are hard because there is likely only one or a few references to the answer across all documents, whereas for Writer/Actor to Movie there are more possible answers to find.

Question Type	KB	IE	Doc
Writer to Movie	97	72	91
Tag to Movie	85	35	49
Movie to Year	95	75	89
Movie to Writer	95	61	64
Movie to Tags	94	47	48
Movie to Language	96	62	84
Movie to IMDb Votes	92	92	92
Movie to IMDb Rating	94	75	92
Movie to Genre	97	84	86
Movie to Director	93	76	79
Movie to Actors	91	64	64
Director to Movie	90	78	91
Actor to Movie	93	66	83

Table 4: Breakdown of test results (% hits@1) on WIKIMOVIES for Key-Value Memory Networks using different knowledge representations.

Knowledge Representation	KV-MemNN
KB	93.9
One Template Sentence	82.9
All Templates Sentences	80.0
One Template + Coreference	76.0
One Template + Conjunctions	74.0
All Templates + Conj. + Coref.	72.5
Wikipedia Documents	76.2

Table 5: Analysis of test set results (% hits@1) for KB vs. Synthetic Docs on WIKIMOVIES.

KB vs. Synthetic Document Analysis To further understand the difference between using a KB versus reading documents directly, we conducted an experiment where we constructed synthetic documents using the KB. For a given movie, we use a simple grammar to construct a synthetic "Wikipedia" doc-

Method	MAP	MRR
Word Cnt	0.4891	0.4924
Wgt Word Cnt	0.5099	0.5132
2-gram CNN (Yang *et al.*, 2015)	0.6520	0.6652
AP-CNN (Santos *et al.*, 2016)	0.6886	0.6957
Attentive LSTM (Miao *et al.*, 2015)	0.6886	0.7069
Attentive CNN (Yin and Schütze, 2015)	0.6921	0.7108
L.D.C. (Wang *et al.*, 2016)	0.7058	0.7226
Memory Network	0.5170	0.5236
Key-Value Memory Network	**0.7069**	**0.7265**

Table 6: Test results on WikiQA.

ument based on the KB triples: for each relation type we have a set of template phrases (100 in total) used to generate the fact, e.g. "Blade Runner came out in 1982" for the entry BLADE RUNNER RELEASE_YEAR 1982. We can then parameterize the complexity of our synthetic documents: (i) using one template, or all of them; (ii) using conjunctions to combine facts into single sentences or not; and (iii) using coreference between sentences where we replace the movie name with "it".[5] The purpose of this experiment is to find which aspects are responsible for the gap in performance to a KB. The results are given in Table 5. They indicate that some of the loss (93.9% for KB to 82.9% for One Template Sentence) in performance is due directly to representing in sentence form, making the subject, relation and object harder to extract. Moving to a larger number of templates does not deteriorate performance much (80%). The remaining performance drop seems to be split roughly equally between conjunctions (74%) and coreference (76%). The hardest synthetic dataset combines these (All Templates + Conj. + Coref.) and is actually harder than using the real Wikipedia documents (72.5% vs. 76.2%). This is possibly because the amount of conjunctions and coreferences we make are artificially too high (50% and 80% of the time, respectively).

5.2 WikiQA

WIKIQA (Yang *et al.*, 2015) is an existing dataset for answer sentence selection using Wikipedia as the knowledge source. The task is, given a question, to select the sentence coming from a Wikipedia document that best answers the question, where performance is measured using mean average precision (MAP) and mean reciprocal rank (MRR) of the ranked set of answers. The dataset uses a pre-built information retrieval step and hence provides a fixed set of candidate sentences per question, so systems do not have to consider ranking all of Wikipedia. In contrast to WIKIMOVIES, the training set size is small ($\sim$1000 examples) while the topic is much more broad (all of Wikipedia, rather than just movies) and the questions can only be answered by reading the documents, so no comparison to the use of KBs can be performed. However, a wide range of methods have already been tried on WIKIQA, thus providing a useful benchmark to test if the same results found on WIKIMOVIES carry across to WIKIQA, in particular the performance of Key-Value Memory Networks.

Due to the size of the training set, following many other works (Yang *et al.*, 2015; Santos *et al.*, 2016; Miao *et al.*, 2015) we pre-trained the word vectors (matrices A and B which are constrained to be identical) before training KV-MemNNs. We employed Supervised Embeddings (Dodge *et al.*, 2016) for that goal, training on all of Wikipedia while treating the input as a random sentence and the target as the subsequent sentence. We then trained KV-MemNNs with dropout regularization: we sample words from the question, memory representations and the answers, choosing the dropout rate using the development set. Finally, again following other successful methods (Yin and Schütze, 2015), we combine our approach with exact matching word features between question and answers. Key hashing was not used as candidates were already pre-selected. To represent the memories, we used the Window-Level representation (the best choice on the dev set was $W = 7$) as the key and the whole sentence as the value, as the value should match the answer which in this case is a sentence. Additionally, in the representation all numbers in the text and the phrase "how many" in the question were replaced with the feature "_number_". The best choice of hops was also $H = 2$ for KV-MemNNs.

The results are given in Table 6. Key-Value Memory Networks outperform a large set of other methods, although the results of the L.D.C. method of (Wang *et al.*, 2016) are very similar. Memory Networks, which cannot easily pair windows to sentences, perform much worse, highlighting the importance of key-value memories.

[5] This data is also part of the WIKIMOVIES benchmark.

6 Conclusion

We studied the problem of directly reading documents in order to answer questions, concentrating our analysis on the gap between such direct methods and using human-annotated or automatically constructed KBs. We presented a new model, Key-Value Memory Networks, which helps bridge this gap, outperforming several other methods across two datasets, WIKIMOVIES and WIKIQA. However, some gap in performance still remains. WIKIMOVIES serves as an analysis tool to shed some light on the causes. Future work should try to close this gap further.

Key-Value Memory Networks are versatile models for reading documents or KBs and answering questions about them—allowing to encode prior knowledge about the task at hand in the key and value memories. These models could be applied to storing and reading memories for other tasks as well, and future work should try them in other domains, such as in a full dialog setting.

Abstract

We present an unsupervised model for the discovery and clustering of latent "personas" (characterizations of entities). Our model simultaneously clusters documents featuring similar collections of personas. We evaluate this model on a collection of news articles about immigration, showing that personas help predict the coarse-grained framing annotations in the Media Frames Corpus. We also introduce automated model selection as a fair and robust form of feature evaluation.

1 Introduction

Social science tells us that communication almost inescapably involves **framing**—choosing "a few elements of perceived reality and assembling a narrative that highlights connections among them to promote a particular interpretation" (Entman, 2007). Memorable examples include loaded phrases (*death tax*, *war on terror*), but the literature attests a much wider range of linguistic means toward this end (Pan and Kosicki, 1993; Greene and Resnik, 2009; Choi et al., 2012; Baumer et al., 2015).

Framing is associated with several phenomena to which NLP has been applied, including *ideology* (Lin et al., 2006; Hardisty et al., 2010; Iyyer et al., 2014), *sentiment* (Pang and Lee, 2008; Feldman, 2013), and *stance* (Walker et al., 2012; Hasan and Ng, 2013). Although such author attributes are interesting, framing scholarship is concerned with persistent patterns of representation of particular issues—without necessarily tying these to the states or intentions of authors—and the effects that such patterns may have on public opinion and policy. We also note that NLP has often been used in large-scale studies of news and its relation to other social phenomena (Leskovec et al., 2009; Gentzkow and Shapiro, 2010; Smith et al., 2013; Niculae et al., 2015).

Can framing be automatically recognized? If so, social-scientific studies of framing will be enabled by new *measurements*, and new applications might bring framing effects to the consciousness of everyday readers. Several recent studies have begun to explore unsupervised framing analysis of political text using autoregressive and hierarchical topic models (Nguyen et al., 2013; Nguyen et al., 2015; Tsur et al., 2015), but most of these conceptualize framing along a single dimension. Rather than trying to place individual articles on a continuum from liberal to conservative or positive to negative, we are interested in discovering broad-based patterns in the ways in which the media communicate about issues.

Here, our focus is on the narratives found in news stories, specifically the participants in those stories. Insofar as journalists make use of archetypal narratives (e.g., the struggle of an individual against a more powerful adversary), we expect to see recurring representations of characters in these narratives (Schneider and Ingram, 1993; Van Gorp, 2010). A classic example is the contrast between "worthy" and "unworthy" victims (Herman and Chomsky, 1988). More recently, Glenn Greenwald has pointed out how he was repeatedly characterized as an *activist* or *blogger*, rather than a *journalist* during his reporting on the NSA (Greenwald, 2014).

Our model builds on the "Dirichlet persona model" (DPM) introduced by Bamman et al. (2013)

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1410–1420,
Austin, Texas, November 1-5, 2016.

for the unsupervised discovery of what they called "personas" in short film summaries (e.g., the "dark hero"). As in the DPM, we operationalize personas as mixture of textually-expressed characteristics: what they do, what is done to them, and their descriptive attributes. We begin by providing a description of our full model, after which we highlight the differences from the DPM.

This paper's main contributions are:

- We strengthen the DPM's assumptions about the *combinations* of personas found in documents, applying a Dirichlet process prior to infer patterns of coocurrence (§3). The result is a clustering of documents based on the collections of personas they use, discovered simultaneously with those personas.
- Going beyond named characters, we allow Bamman-style personas to account for entities like institutions, objects, and concepts (§5).
- We find that our model produces interpretable clusters that provide insight into our corpus of immigration news articles (§6).
- We propose a new kind of evaluation based on Bayesian optimization. Given a supervised learning problem, we treat the inclusion of a candidate feature set (here, personas) as a hyperparameter to be optimized alongside other hyperparameters (§7).
- In the case of U.S. news stories about immigration, we find that personas are, in many cases, helpful for automatically inferring the coarse-grained framing and tone employed in a piece of text, as defined in the Media Frames Corpus (Card et al., 2015) (§7).

2 Model Description

The plate diagram for the new model is shown in Figure 1 (right), with the original DPM (Bamman et al., 2013) shown on the left.

As evidence, the model considers tuples $\langle w, r, e, i\rangle$, where w is a word token and r is the category of syntactic relation[1] it bears to an entity with index e mentioned in document with index i. The model's generative story explains this evidence

[1]We adopt the terminology from Bamman et al. (2013) of "agent", "patient", and "attribute", even though these categories of relations are defined in terms of syntactic dependences.

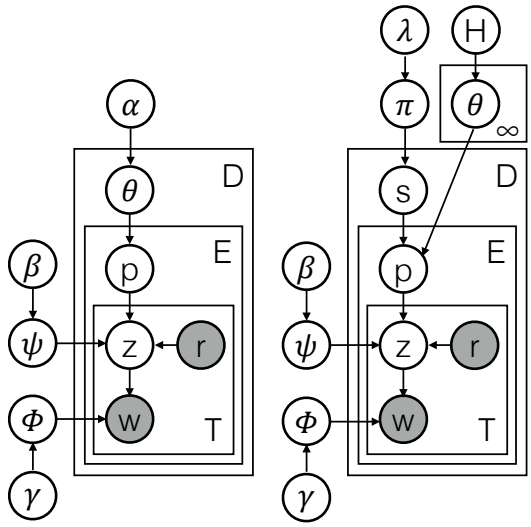

Figure 1: Plate diagrams for the DPM (left), and for the new model (right).

as follows:

1. Let there be K topics as in LDA (Blei et al., 2003). Each topic $\phi_k \sim \text{Dir}(\gamma)$ is a multinomial over the V words in the vocabulary, drawn from a Dirichlet parameterized by γ.
2. For each of P personas p, and for each syntactic relation type r, define a multinomial $\psi_{p,r}$ over the K topics, each drawn from a Dirichlet parameterized by β.
3. Assume an infinite set of distributions over personas drawn from a base distribution H. Each of these $\theta_j \sim \text{Dir}(\alpha)$ is a multinomial over the P personas, with an associated probability of being selected π_j, drawn from the stick-breaking process with hyperparameter λ.
4. For each document i:
   (a) Draw a cluster assignment $s_i \sim \pi$, with corresponding multinomial distribution over personas θ_{s_i}.
   (b) For each entity e participating in i:
      i. Draw e's persona $p_e \sim \theta_{s_i}$.
      ii. For every $\langle r, w\rangle$ tuple associated with e in i, draw $z \sim \psi_{p_e,r}$ then $w \sim \phi_z$.

The DPM (Figure 1, left) has a similar generative story, except that each document has a unique distribution over personas. As such, step 4(a) is replaced with a draw from a symmetric Dirichlet distribution $\theta_i \sim \text{Dir}(\alpha)$.

3 Clustering Stories

The DPM assumes that each document has a unique distribution (θ_i) from which its personas are drawn. However, for entities mentioned in news articles (as well as for the dramatis personae of films), we would expect certain types of personas to occur together frequently, such as articles about lawmakers and laws. Thus we would like to cluster documents based on their "casts" of personas. To do this, we have added a Dirichlet process (DP) prior on the document-specific distribution over personas (step 3), which allows the number of clusters to adapt to the size and complexity of the corpus (Antoniak, 1974; Escobar and West, 1994).

Although the model admits an unbounded number of distributions over personas, the properties of DPs are such that the number used by D documents will tend to be much less than D. As a result, inference under this model provides topics ϕ (distributions over words) interpretable as textual descriptors of entities, personas ψ (distributions over reusable topics), and clusters of articles s with associated distributions over personas θ.

Following Bamman et al. (2013), we perform inference using collapsed Gibbs sampling, collapsing out the distributions over words (ϕ), topics (ψ), and personas (θ), as well as π. On each iteration, we first sample a cluster for each document, followed by a persona for each entity, followed by a topic for each tuple. Because we assume a conjugate base measure, sampling clusters can be done efficiently using the Chinese restaurant process (Aldous, 1985) for story types, personas, and topics, with slice sampling for hyperparameters (α, β, γ, λ). Because such algorithms are well known to NLP readers, we have relegated details to the supplementary material.

During sampling, we discard samples from the first 10,000 iterations, and collect one sample from every tenth iteration for following 1,000 iterations. We sample hyperparameters every 20 iterations for the first 500 iterations, and every 100 thereafter.

4 Dataset

The Media Frames Corpus (MFC; Card et al., 2015) consists of annotations for approximately 4,200 articles about immigration taken from 13 U.S. newspapers over the years 1980–2012. The annotations for these articles are in terms of a set of 15 general-purpose "framing dimensions" (such as Politics and Legality), developed to be broadly applicable to a variety of issues, and to be recognizable in text (by trained annotators). Each article has been annotated with a "primary frame" (the overall dominant aspect of immigration being emphasized), as well as an overall "tone" (pro, neutral, or anti), which is the extent to which a pro-immigration advocate would like to see the article in print, without implying any any stance taken by the author.[2] The MFC contains at least two independent annotations for each article; agreement on the primary frame and tone was established through discussion in cases of initial disagreement. A complete list of these framing dimensions is given in the supplementary material.

In order to train our model on a larger collection of articles, we use the original corpus of articles from which the annotated articles in the MFC were drawn. This produces a corpus of approximately 37,000 articles about immigration; we train the persona model on this larger dataset, only using the smaller set for evaluation on a secondary task. Note that the MFC annotations are not used by our model; rather, we hypothesize that the personas it discovers may serve as features to help predict framing—this serves as one of our evaluations (§7).

5 Identifying Entities

The original focus of the DPM was on *named* characters in movies, which could be identified using named entity recognition and pronominal coreference (Bamman et al., 2013), or name matching for pre-defined characters (Bamman et al., 2014). Here, we are interested in applying our model to entities about which we assume no specific prior knowledge.

In order to include a broader set of entities, we preprocess the corpus and apply a series of filters. First, we obtain lemmas, part-of-speech tags, dependencies, coreference resolution, and named entities from the Stanford CoreNLP pipeline (Manning et al., 2014), as well as supersense tags from the AMALGrAM tagger (Schneider and Smith, 2015). For each document, we consider all tokens with a

[2]The MFC also contains more fine-grained annotations of spans of text which cue each of the framing dimensions, but we do not make use of those here.

NN* or PRP part of speech as possible entities, partially clustered by coreference. We then merge all clusters (including singletons) within each document that share a non-pronomial mention word.

Next, we exclude all clusters lacking at least one mention classified as a person, organization, location, group, object, artifact, process, or act (by CoreNLP or AMALGrAM). From these, we extract $\langle w, r, e, i \rangle$ tuples using extraction patterns lightly adapted from (Bamman et al., 2013). (The complete set of patterns are given in the supplementary material.) To further restrict the set of entities to those that have sufficient evidence, we construct a vocabulary for each of the three relations, and exclude words that appear less than three times in the corresponding vocabulary.[3] We then apply one last filter to exclude entities that have fewer than three qualifying tuples across all mentions. From the dataset described in §4, we extract 128,655 entities, mentioned using 11,262 different mention words, with 575,910 tuples and 11,104 distinct $\langle r, w \rangle$ pairs.

6 Exploratory Analysis

Here we discuss our model, as estimated on the corpus of 37,000 articles discussed in §4 with 50 personas and 100 topics; these values were not tuned. A cursory examination of topics shows that each tends to be a group of either verbs or attributes. Personas, on the other hand, blend topics to include all three relation types. The estimated Dirichlet hyperparameters are all $\ll 1$, giving sparse (and hence easily scanned) distributions over personas, topics, and words.

Table 1 shows all 50 personas. For each p, we show (i) the mention words most strongly associated with p, and (ii) $\langle r, w \rangle$ pairs associated with the persona. (To save space, "I" denotes *immigrant*.) Recall that, like the Dirichlet persona model, our model says nothing about the mention words; they are *not* included as evidence during inference.[4] Nonetheless, each persona is strongly associated with a sparse handful of mention words, and we find that labeling each persona by its most strongly associated mention word (excluding *immigrant*) is often sensible (these are capitalized in Table 1, though in some cases the relation words differentiate strongly (e.g., the *group* personas, IDs 17 and 18 in Table 1).

The model finds expected participants (such as *workers*, political *candidates*, and *refugees*), but also more conceptual entities, such as *laws*, *bills* (IDs 3, 37), and the U.S.-Mexican *border* (ID 5), which looms large in the immigration debate. Some interesting distinctions are discovered, such as two of the *worker* personas, one high-skilled and residing legally (ID 48), the other illegal (ID 49).

Using the original publication dates of the articles, we can estimate the frequency of appearance of each persona within immigration coverage by summing the posterior distribution over personas for each entity mention, and plotting these frequencies across time. (Note that time metadata is not given to the model as evidence.) We find immediately that personas can signal events. Figure 2 shows these temporal trajectories for a small, selected set of personas. Although *bills* and *laws* are conceptually similar, and have similar trajectories from 1980 to 2005, they are strongly divergent in 2006 and 2010. These are particularly notable years for immigration policy, corresponding to the failed Comprehensive Immigration Reform Act of 2006 (Senate bill S.2611) and Arizona's controversial anti-immigration laws from 2010.[5] Refugees, by contrast, show a marked spike around the year 2000. Inspection showed this persona to be strongly tied to the case of Elián González, which received a great deal of media attention in that year.

The main advantage of the extended model over the DPM is being able to cluster articles by "casts." During sampling, thousands of clusters are created (and mostly destroyed). Ultimately, our inference procedure settled on approximately 110 clusters, and we consider two examples. Figure 3 shows the temporal trajectories of the two clusters with the greatest representation of the *refugee* persona. Both show the characteristic spike around the year 2000. The top personas for these two clusters are given in Table

[3] We also exclude the lemma "say" as a stopword, as it is the most common verb in the corpus by an order of magnitude

[4] We did explore adding mention words as evidence, but they tended to dominate the relation tuples. Because our interest is in a richer set of framing devices than simply the words used to refer to people (and other entities), we consider here only the model based on the surrounding context.

[5] Other notable events which appear to be represented include the Illegal Immigration Reform and Immigrant Responsibility Act of 1996, and the Secure Fence Act of 2006.

Table 1: Personas with their associated mention words and relation tuples (a = agent, p patient, m = modifier/attribute); I denotes "immigrant."

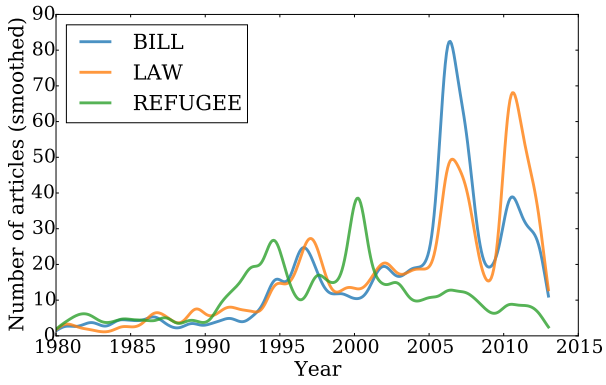

Figure 2: Temporal patterns of the mentions of selected personas.

Refugee story cluster A		
Frequency	Persona	ID
0.49	REFUGEE immigrant boy	44
0.10	BUSH official mcnary	6
0.06	IMMIGRANT man alien	29
0.05	ASYLUM crime refugee	2
Refugee story cluster B		
Frequency	Persona	ID
0.29	MAN immigrant woman	38
0.23	REFUGEE immigrant boy	44
0.12	COURT lawsuit suit	13
0.10	GOVERNMENT court judge	16

Table 2: Truncated distribution over personas for the two clusters depicted in Figure 3. IDs index into Table 1.

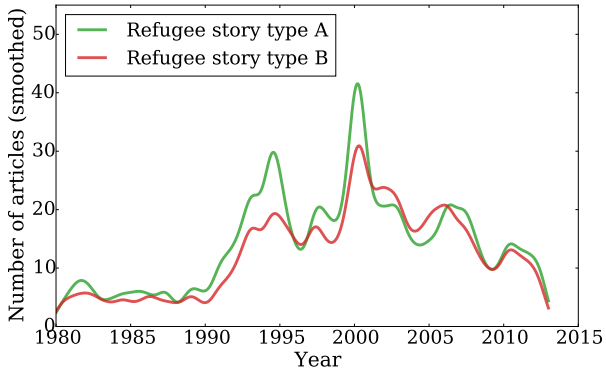

Figure 3: Temporal patterns of two clusters with the greatest overall representation of the *refugee* persona.

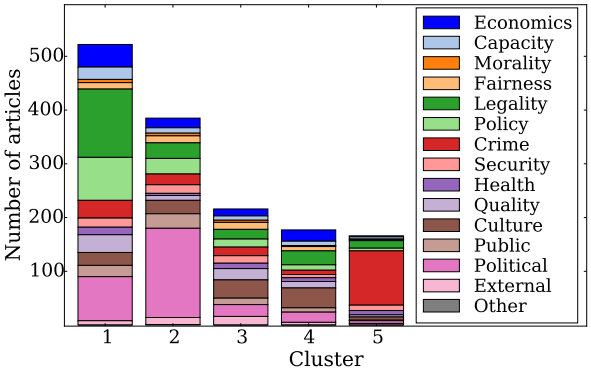

Figure 4: Number of annotated articles in each of the five most frequent clusters, with colors showing the proportion of articles annotated with each primary frame.

2. Type A, which includes a story with the headline "Protesters vow to keep Elián in U.S.," emphasizes political aspects, while type B (e.g., "Court says no to rights for refugees") emphasizes legal aspects. Note that *Political* and *Legality* are two of the framing dimensions used in the MFC.

Do these persona-cast clusters relate to frames? For the five most common story clusters, (which have no overlap with the two refugee story types), Figure 4 shows the number of annotated articles with each of the primary frames if we assign each article to its most likely cluster. The second and fifth clusters correlate particularly well with primary frames (*Political* and *Crime*, respectively). This is further reinforced by looking at the most frequent persona for each of these story clusters which are *candidate* (ID 7) for the second and *immigrant* (ID 22), characterized by illegal$_m$ and arrest$_p$, for the fifth.

7 Experiments: Personas and Framing

We evaluate personas as features for automatic analysis of framing and tone, as defined in the MFC (§4). Specifically, we build multi-class text classifiers (separately) for the primary frame and the tone of a news article, for which there are 15 and 3 classes, respectively. Because there are only a few thousand annotated articles, we applied 10-fold cross-validation to estimate performance.

Features are derived from our model by considering each persona and each story cluster as a potential feature. A document's feature values for story types are the proportion of samples in which it was assigned to each cluster. Persona feature values are similarly derived by the proportion of samples in which each entity was assigned to each persona, with the persona values for each entity in each document summed into a single set of persona values per

Primary frame					
Features:	MF	(W)	(W,P_1)	(W,P_2)	(W,P_2,S)
Accuracy:	0.174	0.529	0.537	*0.540	0.537
# Features:	0	3.9k	3.5k	3.5k	2.8k
Tone					
Accuracy:	0.497	0.628	0.631	0.628	0.630
# Features:	0	5.0k	5.0k	5.0k	4.0k

Table 3: Evaluation using a direct comparison to a simple baseline. Each model uses the union of listed features. (W = unigrams and bigrams, P_1 = personas from DPM, P_2 = personas from our model, S = story clusters; MF = always predict most frequent class.) * indicates a statistically significant difference compared to the (W) baseline ($p<0.05$).

document. We did not use the topics (z) discovered by our model as features.

7.1 Experiment 1: Direct Comparison

For the first experiment, we train independent multiclass logistic regression classifiers for predicting primary frame and tone. We consider adding persona and/or story cluster features to baseline classifiers based only on unigrams and bigrams with binarized counts, a simple but robust baseline (Wang and Manning, 2012).[6] In all cases, we use L_1 regularization and use 5-fold cross validation within each split's training set to determine the strength of regularization. We then repeat this for each of the 10 folds, thereby producing one prediction (of primary frame and tone) for every annotated article. The results of this experiment are given in Table 3; for predicting the primary frame, classifiers that used persona and/or story cluster features achieve higher accuracy than the bag-of-words baseline (W); the classifier using personas from our model but not story clusters is significantly better than the baseline.[7] The enhanced models are also more compact, on average, using fewer effective features. A benefit to predicting tone is also observed, but it did not reach statistical significance.

7.2 Experiment 2: Automatic Evaluation

Although bag-of-n-grams models are known to be a strong baseline for text classification, researchers familiar with the extensive catalogue of features offered by NLP will potentially see them as a straw man. We propose a new and more rigorous method of comparison, in which a wide range of features are offered to an automatic model selection algorithm for each of the prediction tasks, with the features to be evaluated withheld from the baseline.

Because no single combination of features and regularization strength is best for all situations, it is an empirical question which features are best for each task. We therefore make use of Bayesian optimization (Bayesopt) to make as many modeling decisions as possible (Pelikan, 2005; Snoek et al., 2012; Bergstra et al., 2015; Yogatama et al., 2015).

In particular, let F be the set of features that might be used as input to any text classification algorithm. Let f be a new feature that is being proposed. Allow the inclusion or exclusion of each feature in the feature set to be a hyperparameter to be optimized, along with any additional decisions such as input transformations (e.g., lowercasing), and feature transformations (e.g., normalization). Using an automatic model selection algorithm such as Bayesian optimization, allow the performance on the validation set to guide choices about all of these hyperparameters on each iteration, and set up two independent experiments.

For the first condition, A_1, allow the algorithm access to all features in F. For the second, A_2, allow the algorithm access to all features in $F \cup f$. After R iterations of each, choose the best model or the best set of models from each of A_1 and A_2 (M_1 and M_2, respectively), based on performance on the validation set. Finally, compare the selected models in terms of performance on the test set (using an appropriate metric such as F_1), and examine the features included in each of the best models. If f is a helpful feature, we should expect to see that, a) $F_1(M_2) > F_1(M_1)$, and b), f is included in the best model(s) found by A_2.

If $F_1(M_2) > F_1(M_1)$ but f is not included in the best models from A_2, this suggests that the performance improvement may simply be a matter of chance, and there is no evidence that f is helpful. By contrast, if f is included in the best models, but $F_1(M_2)$ is not significantly better than $F_1(M_1)$, this suggests that f is offering some value, perhaps in a more compressed form of the useful signal from other features, but does not actually offer better per-

[6] We also binarized the persona feature values.

[7] Two-tailed McNemar's test ($p<0.05$).

Features:	(B)	(B,P_1)	(B,P_2)	(B,P_2,S)
Primary frame	0.566	0.568	0.568	0.567
Tone	0.667	0.671	0.667	0.671

Table 4: Mean accuracy of the best three iterations from Bayesian optimization (chosen based on validation accuracy). (B = features from many NLP tools, P_1=personas from the DPM, P_2 = personas from our model, S=story clusters.)

formance.

For this experiment, we use the tree-structured Parzen estimator for Bayesian optimization (Bergstra et al., 2015), with L_1-regularized logistic regression as the underlying classifier, and set $R = 40$. In addition to the entities and story clusters identified by these models, we allow these classifiers access to a large set of features, including unigrams, bigrams, parts of speech, named entities, dependency tuples, ordinal sentiment values (Manning et al., 2014), multi-word expressions (Justeson and Katz, 1995), supersense tags (Schneider and Smith, 2015), Brown clusters (Brown et al., 1992), frame semantic features (Das et al., 2010), and topics produced by standard LDA (Blei et al., 2003). The inclusion or exclusion of each feature is determined automatically on each iteration, along with feature transformations (removal of rare words, lowercasing, and binary or normalized counts).

The baseline, denoted "B," offers all features except personas and story clusters to Bayesopt; we consider adding DPM personas, our model's personas, and our model's personas and story clusters. Table 4 shows test-set accuracy for each setup, averaged across the three best models returned by Bayesopt.

Using this more rigorous form of evaluation, approximately the same accuracy is obtained in all experimental conditions. However, we can still gain insight into which features are useful by examining those selected by the best models in each condition. For primary frame prediction, both personas and story clusters are included by the best models in every case where they have been offered as possible features, as are unigrams, dependency tuples, and semantic frames. Other commonly-selected features include bigrams and part of speech tags. For predicting tone, personas are only included by half of the best models, with the most common features being unigrams, bigrams, semantic frames, and Brown clusters. As expected, the best models in each condition obtain better performance than the models from experiment 1, thanks to the inclusion of additional features and transformations.

This secondary evaluation suggests that for this task, persona features are useful in predicting the primary frame, but are unable to offer improved performance over existing features, such as semantic frames. However, the fact that that both personas and story clusters are included by all the best models for predicting the primary frame suggests that they are competitive with other features, and perhaps offer useful information in a more compact form.

8 Qualitative Evaluation

Prior to exposure to any output of our model, one of the co-authors on this paper (Gross, who has expertise in both framing and the immigration issue) prepared a list of personas he expected to frequently occur in American news coverage of immigration. Given the example of the "skilled immigrant," he listed 22 additional named personas, along with a few examples of things they do, things done to them, and attributes.

The list he prepared includes several different characterizations of immigrants (low-skilled, unauthorized, legal, citizen children, undocumented children, refugees, naturalized citizens), non-immigrant personas (U.S. workers, smugglers, politicians, officials, border patrol, vigilantes), related pairs (pro / anti advocacy groups, employers / guest workers, criminals / victims), and a few more conceptual entities (the border, bills, executive actions). Of these, almost all are arguably represented in the personas we have discovered. However, there is rarely a perfect one-to-one mapping: predefined personas are sometimes merged (e.g., "the border" and "border patrols") or split (e.g., legislation, employers, and various categories of immigrants). Personas which don't emerge from our model include smugglers, guest workers, vigilantes, and victims of immigrant criminals. On the other hand, our model proposes far more non-person entities, such as ID cards, courts, companies, jobs, and programs.

These partial matchings between predefined personas and the results of our model are generally

identifiable by comparing the names given to the predefined personas to the the most commonly occurring mention words and attributes of our discovered personas. The attributes and action words given to the predefined personas are harder to evaluate, as many of them are rare (e.g. politicians "vacillate") or compound phrases (e.g. low-skilled immigrants "do jobs Americans won't do") that tend to miss the more obvious properties captured by our model. For example, the *employer* persona captured by our model engages in actions like *hire*, *employ*, and *pay*. By contrast, the terms given for the predefined "business owners" persona are "lobby" and "rely on immigrant labor." Our unsupervised discovery of this persona can clearly be matched to the predefined persona in this case, but doesn't provide such fine-grained insight into how they might be characterized.

The best match between predefined and discovered personas is the U.S.-Mexican border. Of the words given for the predefined persona, almost all are more frequently associated with *border* than with any other discovered persona ("Mexican-U.S.," "lawless," "porous," "unprotected," "guarded," and "militarized"). The most commonly associated words discovered by our model that are missing from the predefined description include *crossed*, *secured*, *southern*, and *closed*.

While this qualitative evaluation helps to demonstrate the face validity of our model, it would be better to have a more comprehensive set of predefined personas, based on input from additional experts. Moreover, it also illustrates the challenge of trying to match the output of an unsupervised model to expected results. Not only is some merging and splitting of categories inevitable, there was a mismatch in this case in the types of entities to be described (people as opposed to more abstract entities), and the ways of describing them (rare but specific words as opposed to more generic but potentially obvious terms).

9 Related Work

Much NLP has focused on identifying entities or events (Ratinov and Roth, 2009; Ritter et al., 2012), analyzing schemes or narrative events in terms of characters (Chambers and Jurafsky, 2009), inferring the relationships between entities (O'Connor et al., 2013; Iyyer et al., 2016), and predicting personality types from text (Flekova and Gurevych, 2015). Bamman also applied variants of the DPM to characters in novels (Bamman et al., 2014).

Previous work on sentiment, stance, and opinion mining has focused on recognizing stance or political sentiment in online ideological debates (Somasundaran and Wiebe, 2010; Hasan and Ng, 2014; Sridhar et al., 2015), and other forms of social media (O'Connor et al., 2010; Agarwal et al., 2011), and recently through the lens of connotation frames (Rashkin et al., 2016). Opinion mining and sentiment analysis are the subject of ongoing research in NLP and have long served as test platforms for new methodologies (Socher et al., 2013; İrsoy and Cardie, 2014; Tai et al., 2015)

Framing is arguably one of the most important concepts in the social sciences, with roots in to sociology, psychology, and mass communication (Gitlin, 1980; Benford and Snow, 2000; D'Angelo and Kuypers, 2010); the scope and relevance of framing is widely debated (Rees et al., 2001), with many authors applying the concept of framing to analyzing documents on particular issues (Baumgartner et al., 2008; Berinsky and Kinder, 2006).

10 Conclusion

We have extended models for discovering latent personas to simultaneously cluster documents by their "casts" of personas. Our exploration of the model's inferences and their incorporation into a challenging text analysis task—characterizing coarse-grained framing in news articles—demonstrate that personas are a useful abstraction when applying NLP to social-scientific inquiry. Finally, we introduced a Bayesian optimization approach to rigorously assess the usefulness of new features in machine learning tasks.

The Teams Corpus and Entrainment in Multi-Party Spoken Dialogues

Abstract

When interacting individuals *entrain*, they begin to speak more like each other. To support research on entrainment in cooperative multi-party dialogues, we have created a corpus where teams of three or four speakers play two rounds of a cooperative board game. We describe the experimental design and technical infrastructure used to collect our corpus, which consists of audio, video, transcriptions, and questionnaire data for 63 teams (47 hours of audio). We illustrate the use of our corpus as a novel resource for studying team entrainment by 1) developing and evaluating team-level acoustic-prosodic entrainment measures that extend existing dyad measures, and 2) investigating relationships between team entrainment and participation dominance.

1 Introduction

Linguistic entrainment[1] refers to the convergence of (para)linguistic features across speakers during conversation (Brennan and Clark, 1996; Porzel et al., 2006). Research has found that speakers entrain to both human and computer conversational partners, with the amount of entrainment often positively related to conversational and task success. However, most prior work has focused on the study of entrainment during two-party dialogues, rather than during the multi-party conversations typical of teams.

To support the study of entrainment during multi-party cooperative dialogue, we have created a large-scale corpus (over 47 hours of recordings) of teams of three or four speakers playing a cooperative board game requiring conversation. The corpus consists of audio, video, transcriptions, and questionnaire data for 63 teams. The goal of the corpus is to provide a freely-available data resource for the development and evaluation of multi-party entrainment measures that can be 1) computed using language technologies, 2) motivated and validated by the literature on teams, and 3) associated with measures of task and dialogue success.

In this paper, we first describe the experimental design and technical infrastructure used to create our corpus. We then present two case studies illustrating the use of our corpus as a novel resource for studying team entrainment: quantifying acoustic-prosodic entrainment at the team-level rather than the dyad-level, and incorporating a construct from the teamwork literature into the study of entrainment.

2 Background and Related Work

The development of methods for automatically quantifying entrainment in text and speech data is an active research area, as entrainment has been shown to correlate with success measures or with social variables for a variety of phenomena, e.g., acoustic-prosodic, lexical, and syntactic (Nenkova et al., 2008; Reitter and Moore, 2007; Mitchell et al., 2012; Levitan et al., 2012; Lee et al., 2011; Stoyanchev and Stent, 2009; Lopes et al., 2013; Lubold and Pon-Barry, 2014; Moon et al., 2014; Sinha and Cassell, 2015). Such research, in turn, requires corpora with certain properties. A high-quality spoken language corpus for studying entrain-

[1] Other terms in the literature include accommodation, adaptation, alignment, convergence, coordination and priming.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1421–1431,
Austin, Texas, November 1-5, 2016.

ment would include transcriptions suitable for natural language processing, audio recordings suitable for signal processing, and meta-data such as task success or speaker demographics.

While most research has focused on quantifying the amount of entrainment between pairs of speakers, recent work has started to develop measures for quantifying entrainment between larger groups of speakers (Friedberg et al., 2012; Danescu-Niculescu-Mizil et al., 2012; Gonzales et al., 2010). To date, however, mainly simple methods such as unweighted averaging have been used to move from pairs to groups, and the focus of prior work has been on text rather than speech (e.g., Wikipedia, computer-mediated discussions, lexical analysis of transcriptions). In this paper we both investigate group acoustic-prosodic entrainment and examine relationships between group entrainment and a factor from the teamwork literature called participation equality / dominance (Paletz and Schunn, 2011).

Also, while freely available speech corpora have supported the study of entrainment in two-party dialogues (e.g., Switchboard, Maptask, the Columbia Games Corpus, Let's Go), few community resources exist for the study of multi-party entrainment. Some multi-party resources are only text-based (e.g., the online Slashdot forum (Allen et al., 2014), chat dialogues (Afantenos et al., 2015)). Those speech resources that do exist are often less than ideal as they were created for other purposes (e.g., Supreme Court arguments (Beňuš et al., 2014; Danescu-Niculescu-Mizil et al., 2012), the AMI meeting corpus (Carletta et al., 2006)). Although not created to study entrainment, the KTH-Idiap Group-Interviewing corpus (Oertel et al., 2014) is perhaps most relevant as it was explicitly designed to support research on group dynamics. However, the corpus contains only 5 hours of speech, and participants were PhD students so did not differ on variables such as age and social status.

The Teams corpus presented and used in this paper was designed to add several notable extensions to existing multi-party spoken dialogue resources. In particular, the Teams corpus was experimentally collected to constrain the team processes, tasks, and outcomes in ways that facilitate an investigation of team entrainment. First, the corpus consists of over 45 hours of cooperative task-oriented dialogues between three or four speakers, where audio and video files were collected and transcribed using best practices for computational processing. Second, the corpus was collected using an experimental manipulation informed by the organizational and social psychological literature on team processes in order to create high versus low-entrainment conditions. Third, since the social psychological literature suggests that team dynamics are more complex than an average of dyadic interactions, validated questionnaires were used to collect relevant variables of interest to researchers on teams, and individual participants were recruited so that teams would exhibit diversity with respect to these variables.

3 Experimental Study

The Teams corpus was collected in a laboratory experiment. The laboratory setting enabled high-quality audio and video capture, while the experimental study allowed manipulations to vary entrainment and to collect measures of team processes.[2]

3.1 Design

Our data collection was via an experiment with a 2 by 2 within-and-between subjects design. Teams of 3-4 participants spent 2-3 hours in our lab taking self-report questionnaires and being audio and video-taped playing a cooperative board game. Two manipulations were designed to increase the likelihood of task success and entrainment [3]. For the first manipulation, half the teams were given a *teamwork* training intervention in which participants were given specific advice based on a needs analysis of the team skills important to the game (Gregory et al., 2013). Such mixed teamwork/taskwork training has been shown to improve team process outcomes (Salas et al., 2008). The other half only had

[2] A lab experiment involving a two-player game requiring spoken communication was similarly used to collect the Columbia Games Corpus of 12 spontaneous task-oriented dyadic conversations, which has been used in multiple studies of two-party entrainment (Levitan and Hirschberg, 2011; Levitan et al., 2012; Levitan et al., 2011). Our corpus is approximately 5 times larger, includes speech from teams rather than from dyads, and relatedly includes new types of team-related meta-data. Our corpus also contains both video and audio as our dialogues were face-to-face rather than restricted to voice.

[3] As discussed in Section 2, prior research has often found positive relationships between success and entrainment.

M: And then [I'm here.]
E: [Oh.]
P: [Yeah] probably wanna save [Whispering Garden.]
E: [Whispering- Yeah.]
M: [Uh yeah, that's one,] [two,]
P: [Yeah.]
M: [three.]
P: [Perfect.]

Figure 1: Dialogue excerpt from a Forbidden Island^{TM} game. E=Engineer, M=Messenger, and P=Pilot roles in the game. Square brackets indicate overlapping speech.

training on the rules of the game, which all teams received.

For the second manipulation, each team played two isomorphic versions of the game. The game was originally designed to be played multiple times, with each session unique depending on the random placement of specific board tiles and the order of deck cards. To maintain experimental control, two specific deck card orders and board tile patterns that had the same underlying opportunities and obstacles were created. 33 teams played one game first, and 30 teams played the other game first. In either case, by the second time, the team should have a better grasp of the game and appropriate strategies.

3.2 Task

For the team task, we chose the cooperative board game Forbidden Island^{TM}, where players take on the roles of adventurers seeking treasures on an island before it is flooded. We chose this game because it both demands collaboration and is logistically feasible for our experiment. The cooperative task-oriented nature of the game requires players to communicate to achieve their goals (e.g., discussing cards and strategies in real time, see Figure 1), lending itself directly to eliciting entrainment. Further, the game gives each player a different role to achieve the team goals, as well as game-specific terminology, generalizing to real-world situations with teamwork (e.g. aviation, health care). Logistically, Forbidden Island^{TM} can be played equally well with three or four players. This feature allowed us to schedule teams of four participants, but still play the game even if only three showed up. A typical game is also short enough to be played twice within an experimental session. Game rules were adapted to ensure the game difficulty was suitable for novice players (e.g., requiring three rather than four treasures be found before completing the game). As noted in Section 3.1, two isomorphic versions of the game were constructed so that the first and second games would appear visually different but the difficulty level would be identical between and within teams. This isomorphism was accomplished by maintaining the position of tiles and cards that determined order-of-play and game difficulty, while systematically shifting the position of non-critical tiles and cards.

3.3 Recruitment

Participants aged 18 years and older who are native speakers of American English were recruited via electronic and hardcopy flyers and paid for their time. They were males and females of any ethnicity from a university and its surrounding community. To increase ethnicity, race, and age diversity (rare in corpora typically drawn only from student samples), we advertised in non-student locations in predominantly ethnic minority neighborhoods.

3.4 Procedure

As a team's participants arrived in the lab, each completed a questionnaire to collect personality, demographic, and other information such as experience with the game Forbidden Island^{TM}. Participants were then taught how to play the game by watching a video and playing a tutorial game, then given a few minutes to ask specific questions. Teams in the intervention condition (the between-subjects manipulation of our experimental design) were given an extra 10 minutes before the first game to receive training about teamwork strategies such as team roles, communication needs, and how to coordinate their actions (Gregory et al., 2013), as well as additional information adapted for the Forbidden Island^{TM} task itself. Then each team played the game twice for no more than 35 minutes per game. Teams were told that not completing a game in 35 minutes counted as a loss, and that winning scores for the rest of the games would be inversely related to game length (a timer was displayed on a computer monitor during each game). The intervention condition teams were also given an additional 5 minutes before the second game to discuss what went well and poorly with their team processes. Finally, both between and after the two games, all participants filled out question-

naires regarding their team processes.

3.5 Data Capture

Game participants were located around a round table 48 inches in diameter in our game-playing lab, enabling comfortable participant access to the game board. Each participant sat in a particular location depending on their role in the game. The survey data were collected in a separate workstation lab using Qualtrics, a web-based, survey software tool.

To collect high-quality speech data with minimal cross-talk, audio was recorded using Sennheiser ME 3-ew close-talk microphones. Each microphone was connected to a Presonus AudioBox 1818VSL multichannel audio interface sampling at 96k, 24 bits. Audio recordings were monitored using Reaper Digital Audio Workstation v 4.76. Each game yielded one stereo recording with the synchronized speech from all speakers, along with 3 or 4 individual files (one per participant) representing the audio recording from each microphone. Reaper was used to render .WAV files with a 48000 Hz sampling rate and a 16 bit PCM Wav bit depth.

To complement the speech, four wall-mounted Zoom Q4 cameras captured WVGA/30 .MOV video recordings. The audio streams recorded from the cameras are at the central room, not the individual, level. A master audio signal was used to synchronize the videos with each other and with the audio from the microphones. Note that the videos also provide backup audio streams (recording at 256kbps AAC) for the microphones. In addition, the videos provide information about the games that are not always obvious from the audio[4], as well as non-verbal data for future analysis (e.g., of gesture or posture).

4 The Teams Corpus

Our experiment ran from February through August 2015, yielding over 47 hours of recordings from 63 teams[5] (216 individuals).

4.1 Descriptive Statistics

The 216 participants in our experiment were on average 25.3 years old (min=18, max=67, *SD*=11.3).

	Control (n=31)		Intervention (n=32)	
	3-per.	4-per.	3-per.	4-per.
# of teams	20	11	16	16
avg g1 time	26.6	28.0	26.4	27.3
avg g2 time	18.0	17.7	18.2	19.7

Table 1: Team descriptives ($n = 63$).

There were 135 females (62.5%) and 81 males (37.5%). The highest level of education (whether completed or not) ranged from high school (28 participants, 13.0%) to undergraduate (153 participants, 70.8%) to postgraduate/professional (35 participants, 16.2%). 145 participants (67.1%) were currently students. 35 participants (16.2%) knew at least one of their team members. The most frequent self-reported ethnicity/races were Caucasian (166), Asian (31), Black (24), and Hispanic (10) (multiple ethnicities were allowed). Thus, our recruitment yielded demographically diverse participants in ways that are useful for team research.

Table 1 shows the distribution of the teams in our corpus by experimental condition (control versus intervention) and team size (3 versus 4 person). For each of these groups of teams, the table also shows the average time they took in minutes to play games 1 and 2, respectively. A 3-way ANOVA shows a significant within-team effect for game, with first games taking significantly longer than second games (27.1 vs. 18.4 minutes, $p < .001$). The average game length did not significantly differ by experimental condition ($p > .7$) or by team size ($p > .3$), and there were also no interaction effects.

Our team-level data provides preliminary evidence for the success of one of our experimental manipulations, as second games were significantly shorter than first games. [6]

4.2 Audio Segmentation and Transcription

After the experiment was completed, our multiple audio track speech was manually segmented and transcribed using the Higgins Annotation Tool[7].

[4] We are currently using the videos to annotate game-specific measures of task success.

[5] A power analysis for our experiment yielded a minimum target sample size of 52 teams.

[6] The time to complete a game is an easy to compute but a shallow (inverse) success measure. We are currently annotating our data for game-specific and dialogue-based success measures, and will also examine success in terms of team process measures computable from the questionnaires (Section 4.3).

[7] http://www.speech.kth.se/hat/

Each audio track, which corresponds to each individual player, appears on a separate line in Higgins. A time stamp line applies to all of the (synchronized) audio tracks. To do transcription, each participant's speech is first segmented into inter-pausal units, pause-free chunks of speech from a single speaker (Levitan and Hirschberg, 2011). The threshold used for pause length (i.e., silence) for our corpus is 200 milliseconds. Once speech is segmented in a specific audio track, a corresponding text line appears where the transcriber manually types in the text for the corresponding audio segment. Within each transcription, text segments may also be defined and assigned values. We are using segments to annotate non-lexical aspects such as laughs.

4.3 Questionnaire Data

The pre-game questionnaire was used to collect individual demographic information such as discussed in Section 4.1, and self-reported data related to personality (John et al., 1991), cognitive styles (Miron et al., 2004), and collective orientation ("the propensity to work in a collective manner in team settings" (Driskell et al., 2010)). The between and post-game questionnaires elicited perceptions of team processes such as cohesion, satisfaction, and potency/efficacy (Wendt et al., 2009; Wageman et al., 2005; Guzzo et al., 1993). Such information was collected as a novel resource for studying multi-party entrainment, since team processes have been shown to be positively related to performance (Beal et al., 2003; Mullen and Copper, 1994).

4.4 Public Release

The Teams corpus will be freely available for research purposes[8], with the first release coordinated with the publication of this paper. The team level contents of the first release will consist of 63 game 1 and 62 [9] game 2 WAV files. The individual level contents of this release will consist of the demographic responses for the 216 participants in XLSX format. Later corpus releases will include associated audio segmentations and transcriptions in XML format, game-level video files, and personality and team process measures.

[8] https://sites.google.com/site/teamentrainmentstudy/corpus

[9] One audio file was not properly saved during the experiment. The corresponding single-channel audio extracted from the game's video will be provided instead.

5 Case Studies Using the Teams Corpus

This section presents results from two case studies illustrating the use of the Teams corpus for novel research in multi-party dialogue entrainment. The first study proposes new team level measures that build on existing dyad-level measures of proximity and convergence, then uses these team measures to investigate whether prior dyad-level acoustic-prosodic entrainment findings generalize to teams. The second study investigates relationships between team convergence and participation equality / dominance.

5.1 Acoustic-Prosodic Team Entrainment

Speakers do not entrain on all linguistic features of conversations, and when they do entrain, they may entrain in different ways on different features. In this section we examine whether teams entrain on different acoustic-prosodic features during each of their two game conversations. Our current approach to measuring team-level entrainment is based on averaging dyad-level measures. We build on two dyad measures, namely, proximity and convergence (Levitan and Hirschberg, 2011). In a conversation, proximity measures feature similarity over the entire conversation, while convergence measures an increase in feature proximity over time.

5.1.1 Feature Extraction from Speaker Audio

We focus on the acoustic-prosodic dimensions of pitch, intensity, and voice quality, following previous work on dyad entrainment (Levitan and Hirschberg, 2011; Lubold and Pon-Barry, 2014; Borrie et al., 2015). Pitch is related to the frequency of the sound wave. Intensity describes the rate of energy flow. Jitter and shimmer are measures of variations of frequency and energy, respectively, which are descriptive of voice quality. We use the Praat software (Boersma and Heuven, 2002) to extract the following 9 acoustic-prosodic features: minimum (min), maximum (max), mean and standard deviation (SD) of pitch; min, max, mean of intensity;

local jitter[10]; and local shimmer[11]. Features are extracted separately for each speaker and for each game. Before feature extraction, each game-level audio file for each speaker is pre-processed to remove silences (using a threshold of 1 second).

5.1.2 Measuring Team Proximity

Proximity quantifies the similarity of a feature value between conversational partners over their entire conversation. Intuitively, if a team has entrained on a feature in terms of proximity during a particular game, speakers within the same team should be more similar (or equivalently, less different) to each other than to all the other speakers in the corpus who are not on their team and are playing the same game (i.e., game 1 or game 2). For each game we computed a team-level partner difference ($TDiff_p$) and a team-level other difference ($TDiff_o$). In Section 5.1.4 we report paired t-test analyses to infer entrainment within a game when $TDiff_p$ is significantly smaller than $TDiff_o$.

The partner difference for a speaker in a dyad (Levitan and Hirschberg, 2011) is the absolute difference between the feature value for a speaker and her partner. For each team, we averaged these absolute values for all members of the team:

$$TDiff_p = \frac{\sum_{\forall i \neq j \in team}(|speaker_i - speaker_j|)}{|team| * (|team| - 1)} \quad (1)$$

The other difference for a speaker in a dyad (Levitan and Hirschberg, 2011) is the mean of the absolute differences between the speaker's value for a feature and the values of each of the speakers in the corpus (for the same game number) with whom the speaker was not partnered (set X in Formula 2). For each team, we averaged these means for all the members of the team:

$$TDiff_o = \frac{\sum_{\forall i \in team}(\frac{\sum_j |speaker_i - X_j|}{|X|})}{|team|} \quad (2)$$

For proximity, all of the feature values were normalized within a game based on gender[12] using z-scores ($z = \frac{v_{ij} - \mu_j}{\sigma_j}$; v_{ij} = value of speaker i in game j where $j \in \{1, 2\}$, μ_j = gender mean in game j, and σ_j = gender standard deviation in game j.)

Feature	Game1	Game2
Pitch-min	0.844	0.193
Pitch-max	−1.092	0.022
Pitch-mean	−1.297	−1.294
Pitch-sd	−0.407	−1.652
Intensity-mean	−4.469*	−4.911*
Intensity-min	−2.653*	−2.069*
Intensity-max	−3.625*	−2.853*
Shimmer-local	−2.390*	−2.782*
Jitter-local	−1.242	−2.702*

Table 2: Proximity t-values of a paired t-test comparing team-level partner ($TDiff_p$) vs. other ($TDiff_o$). Negative t-values indicate that partner differences are smaller than other differences. * $p < .05$. $n = 62$.

5.1.3 Measuring Team Convergence

Intuitively, there is evidence of convergence when speakers within a conversation become more similar to each other later in the conversation. While feature value differences are compared across teams to infer proximity entrainment, feature value differences within a single team are compared across time for convergence entrainment. Since differing time intervals have been examined in the dyad literature, we compared features extracted from the first versus last three, five, and seven minutes of each game, as well as from the two game halves.[13] Convergence was inferred via paired t-tests when the partner differences (Equation 1) in the second time interval were significantly smaller than in the earlier time interval (e.g., the $TDiff_p$ in the last 3 minutes of game 1 is smaller than $TDiff_p$ in the first 3 minutes of game 1). To break the games into different time intervals for feature extraction, we used the raw audio files to extract the breaking points of the conversation and then mapped these points to each of the processed audio files where silence was removed.

5.1.4 Team-Level Entrainment Results

The proximity results are shown in Table 2. Negative t-values indicate that differences between speak-

[10]The average absolute difference between the amplitudes of consecutive periods, divided by the average amplitude.

[11]The average absolute difference between consecutive periods, divided by the average amplitude.

[12]Normalization is done only for proximity, since comparisons for convergence are within (rather than between) teams.

[13](Levitan and Hirschberg, 2011) also looked for convergence between the two halves of the first game in their corpus.

	First vs. last 3 minutes		First vs. last 5 minutes		First vs. last 7 minutes		First vs. second half	
Feature	Game1	Game2	Game1	Game2	Game1	Game2	Game1	Game2
Pitch-min	**2.474***	−0.709	1.487	−1.299	1.359	−1.622	0.329	−0.884
Pitch-max	**4.947***	1.260	1.892	−0.468	1.348	−0.424	0.457	0.627
Pitch-mean	−2.687*	0.109	−2.900*	0.417	−2.965*	−0.361	−1.905	−0.266
Pitch-sd	1.364	0.409	1.919	0.591	1.807	0.576	1.271	0.089
Intensity-mean	−0.275	−2.946*	−0.454	−2.245*	−0.229	−1.825	−0.360	−1.540
Intensity-min	0.595	−3.188*	−0.136	−4.335*	0.009	−3.317*	−0.972	−3.324*
Intensity-max	0.328	0.327	−0.731	1.081	−0.140	0.511	−0.222	0.469
Shimmer-local	**2.896***	−0.476	**3.396***	−1.941	**3.006***	−1.704	**2.794***	−0.914
Jitter-local	**3.205***	0.725	**2.796***	0.242	**2.867***	0.469	**2.973***	0.260

Table 3: Convergence t-values of paired t-tests comparing team-level partner differences ($TDiff_p$) of first 3, 5, 7 minutes vs. last 3, 5, 7 minutes, respectively, and of first vs. second game half, for each game. Positive t-values indicate convergence (i.e., that partner differences in the second interval are smaller than in the first). Negative t-values indicate divergence. Significant convergence results are in bold. * $p < .05$. $n = 62$.

ers who are all within the same team are smaller than differences between team members and other speakers in the corpus. Thus, negative values are indicative of team entrainment. The results show that the team members were significantly more similar to each other than to other speakers on intensity mean, min, and max and on shimmer for both games. Team-level entrainment on jitter was significant for only the second game.

The convergence results are shown in Table 3 for four different temporal comparison intervals. Comparison of the significant game 1 results shows that teams entrained on pitch min, pitch max, shimmer, and jitter in at least one of the intervals. Both shimmer and jitter converged for all choices of temporal units. For pitch, convergence was instead only seen using the first and last 3 minutes, which are the intervals farthest in the game from each other. The only feature that diverged during game 1 is pitch-mean. The rest of the features did not show significant team-level partner differences during game 1 for any temporal interval and thus exhibited maintenance, meaning that the team members neither converged nor diverged. During game 2, we observed maintenance for all features except for intensity-mean and intensity-min, which diverged. Together our results suggest that when teams in our corpus converged on a feature, they did so earlier in the experiment (namely, just during the first game, and sometimes just in the earliest part of the first game).

As a divergent validity check for convergence, for each of the 62 teams, we constructed artificial versions of the real conversations between team members: For each member of the team, we randomly permuted the silence and speech intervals extracted by Praat. Ideally, we should not see evidence of convergence within these constructed conversations. Our results confirm that there was no significant entrainment on either of the two constructed games, for all temporal comparison intervals and all features.

In summary, team acoustic-prosodic entrainment did not occur for all features. For the features that did show entrainment, results varied depending on whether proximity or convergence was examined, and by the time intervals compared. With respect to type of entrainment, when looking at the entire game 1, there was significant evidence of entrainment (proximity) on mean, min, max intensity, and shimmer. Although there was no significant proximity for min, max pitch and jitter, they did become more similar (converged) over time. With respect to time, team convergence was found for shimmer and jitter independently of temporal interval examined, but for pitch only when comparing the most distant temporal intervals in game 1.

5.2 Participation Equality / Dominance

Within psychology, equality of participation has been associated with successful team performance and decision-making (e.g., (Mesmer-Magnus and DeChurch, 2009; Stasser and Titus, 1987)). Within computational linguistics, balance of participation with respect to proposal of ideas was associated with more productive small group (online) conversations (Niculae and Danescu-Niculescu-Mizil, 2016).

Extending this literature, we perform a novel in-

	Model 1			Model 2		
	B	SEB	β	B	SEB	β
Session Length	0.187	0.067	0.328*	0.197	0.064	0.344*
Team Size	108.706	47.398	0.269*	69.721	47.980	0.173
Participation Dominance				−1077.747	429.130	−0.299*
Model R^2		0.186			0.266	
Model F		6.761*			7.015*	

Table 4: Summary of hierarchical regression analysis for variables predicting entrainment on pitch-max. * $p < .05$. $n = 62$.

vestigation of the association between participation equality/dominance and team entrainment, focusing on the time interval showing the most significant convergence results in Section 5.1.4 (entrainment on pitch-max, pitch-min, jitter, and shimmer from the first to last 3 minutes of game 1).

Equation 3 defines the participation of player i in a team, where $speech\_length_i$ is the sum of the lengths of the speech intervals of player i:

$$participation_i = \frac{speech\_length_i}{\sum_{m \in team} speech\_length_m} \quad (3)$$

Participation dominance in turn is the standard deviation of the participation for all team members:

$$Dominance = \sigma(Participation),$$
$$Participation = \{participation_i | i \in team\} \quad (4)$$

Higher standard deviations indicate a greater range of participation from team members, and lower standard deviations indicate more participation equality.

We performed a hierarchical regression analysis for each of the four acoustic-prosodic features noted above as the target entrainment variable. As in the convergence section, we measured entrainment as the average differences ($TDiff_p$) of the team in the first interval minus the second interval. Larger positive numbers are indicative of more entrainment. The independent variables we included in our analysis are: team size, session length, average age of the team members, percentage of the female players in each team, and participation dominance. The first four are covariates that have been found to be or are likely related to team communication and/or dynamics. We hypothesized that participation dominance would be related to entrainment above and beyond these other potential variables.

Table 4 presents the results with pitch-max for entrainment. (The other 3 entrainment variables did not show significant relationships with participation.) The standardized βs indicate the effect size and direction of the individual variables on pitch-max, whereas the R^2 indicates the effect size of the model of all the variables together. Average age and percent female were not significantly related to entrainment on pitch-max, so were excluded from the final analyses.

First, both team size and session length were entered as potential independent variables into the regression analysis with pitch-max as the dependent variable. This model (Model 1) was significant. Specifically, team size and session length were both significantly positively associated with entrainment on pitch-max. That is, as team size or session length increased, entrainment also increased.

Participation dominance was then entered to create Model 2, which included team size, session length, and participation dominance. The amount of variance explained for participation dominance was significant above and beyond the variables entered in Model 1, $\Delta R^2 = 0.08$, $\Delta F(1, 58) = 6.307$, $p = 0.015$. Specifically, there was a significant negative association between participation dominance and entrainment on pitch-max, such that greater participation equality was related to greater entrainment. This suggests that the more each team member is given a chance to equally contribute, the more likely they are to entrain on their maximum pitch.

6 Summary and Broader Implications

The long-term goal of our research is to use speech and language processing, informed by the teamwork literature, to develop computational measures of conversational team entrainment that will be useful for predicting team success. We first described the design and contents of the Teams corpus, which is being made freely available for research purposes. Experimental manipulations, high-quality

audio and video with time-aligned transcriptions, and self-reported team process data make the corpus a unique resource for studying multi-party dialogue entrainment. We provided two examples illustrating the use of the Teams corpus to facilitate new directions in the study of entrainment: quantifying acoustic-prosodic entrainment at the team rather than the dyad-level, and incorporating the teamwork construct of participation dominance into the study of entrainment. Our current plans include continued corpus development (recall Section 4.4), and using more sophisticated methods than dyad averaging (e.g., using weighting based on team process measures) to move from dyads to teams.

With respect to broader impact, our entrainment measures could be used to mine existing corpora for naturalistic successful and unsuccessful conversations, or to trigger online interventions by dialogue systems participating in multi-party conversations. After additional research understanding the important thresholds for entrainment, organizations could unobtrusively measure team effectiveness during entrainment, and intervene with training to aid teams with low entrainment. Similar interventions would be useful for conversational agents that monitor and facilitate group interactions (e.g., in education via computer-supported collaborative learning). Our work could also support the development of data mining applications for corpora such as team meetings or discussions, from classrooms to boardrooms. Finally, our corpus could support natural language processing research regarding any other aspect of teamwork (e.g., affect, conflict, topic modeling). In sum, the Teams Corpus should provide usable, multi-channel data for examining team processes for a range of purposes and research disciplines.

Personalized Emphasis Framing for Persuasive Message Generation

Tao Ding and **Shimei Pan**

Abstract

In this paper, we present a study on personalized emphasis framing which can be used to tailor the content of a message to enhance its appeal to different individuals. With this framework, we directly model content selection decisions based on a set of psychologically-motivated domain-independent personal traits including personality (e.g., extraversion) and basic human values (e.g., self-transcendence). We also demonstrate how the analysis results can be used in automated personalized content selection for persuasive message generation.

1 Introduction

Persuasion is an integral part of our personal and professional lives. The topic of generating persuasive messages has been investigated in different fields with varied focuses. Psychologists focus on the cognitive, social and emotional processes of a persuader and a persuadee to understand what makes a communication persuasive (Hovland et al., 1953; Petty and Cacioppo, 1986; Smith and Petty, 1996). Marketing researchers are interested in applying theories of persuasion in promoting consumer products (Szybillo and Heslin, 1973; Han and Shavitt, 1994; Campbell and Kirmani, 2000; Kirmani and Campbell, 2004; Ford, 2005; Hirsh et al., 2012). Natural Language Generation (NLG) researchers are interested in studying the relation between language usage and persuasion in order to build automated systems that produce persuasive messages (Guerini et al., 2011; Reiter et al., 2003).

It is also generally believed that persuasion is more effective when it is custom-tailored to reflect the interests and concerns of the intended audience (Noar et al., 2007; Dijkstra, 2008; Hirsh et al., 2012). A proven tailoring tactic commonly used by politicians, marketing executives, as well as public health advocators is content framing (Meyerowitz and Chaiken, 1987; Maheswaran and Meyers-Levy, 1990; Grewal et al., 1994; Rothman and Salovey, 1997). Previous framing research has mainly focused on two types of framing strategies: *emphasis framing* and *equivalence framing*. To *emphasis frame* a message is to simplify reality by focusing on a subset of the aspects of a situation or an issue and make them more prominent in a communication to promote certain definition, causal interpretation and moral evaluation (Entman and Rojecki, 1993). For example, in political debating, the topic of *nuclear energy* can be framed as an *economic development* issue, a *safety* issue or an *environmental* issue. In marketing, the same car can be framed as a *low cost* car, a *performance* car, or a *green* car. With different framing strategies, the authors try to appeal to individuals with different beliefs and concerns. In contrast, *equivalence framing* focuses on presenting content as either loss-framed or gain-framed messages. For example, a smoking cessation message can employ a gain-frame like "You will live longer if you quit smoking", or a loss-frame such as "You will die sooner if you do not quit smoking". Even though the messages are equivalent factually, the frames can influence a receiver's behavior either to encourage a desirable behavior or to avoid an unwanted outcome (Tversky and Kahneman, 1981). In this study, we focus on personalized *emphasis framing* which selectively emphasize the aspects of an entity (e.g., a car) to enhance its appeal to a given receiver.

Using emphasis framing as the framework for personalized content selection, we can take advantage of rich findings in prior framing research that link content selection decisions to a set of psychologically-motivated domain-independent personal characteristics. This has made our work more generalizable than those relying on application-specific user characteristics (e.g., use an individual's smoking habit to tailor a smoke cessation message). Since content framing is a part of the content determination process, the model we propose is a part of the *content planner* in a Natural Language Generation (NLG) system (Reiter and

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1432–1441,
Austin, Texas, November 1-5, 2016.

Dale, 1997).

There are three main contributions of this work.

1. To the best of our knowledge, this is the first effort in building an automated model of emphasis framing for personalized persuasive message generation.

2. We made content selection decisions based on a set of psychologically-motivated application-independent user traits, such as personality and basic human values, which makes our work more generalizable than those relying on domain-specific user characteristics and preferences.

3. We propose a cascade content selection model that integrates personalized content selection patterns in automated persuasive message generation.

2 Related Work

In the following, we summarize the research that is most relevant to our work including prior psychology and communication studies that link emphasis framing with personal traits. Since building computational models of emphasis framing was not the primary goal in these studies, we also include literature on personalized Natural Language Generation.

2.1 Emphasis framing and Personal Traits

There is a large body of social, marketing and communication theories on framing effects. (Zaller, 1992; Zaller and Feldman, 1992) point out that framing essentially reorganizes information to increase accessibility of an issue dimension by highlighting one cognitive path that had previously been in the dark. Others argue that the framing effect is due to a change in the rank order of the values associated with different aspects through the interaction with the content found within a message (Nelson et al., 1997; Chong and Druckman, 2007; Jacoby, 2000). The human decisions are controlled partly by the formulation of the problem and partly by the norms, habits, and personal characteristics of the decision-maker (Tversky and Kahneman, 1981).

Although most research agrees that the characteristics of a receiver play an important role in framing effectiveness, there is a significant disagreement in what characteristics of a receiver result in framing effects. For example, (Anderson, 2010) states that people with prior attitudes toward an issue can be influenced by frames, while Slothuus (Slothuus, 2008) and Tabor et al. (Taber et al., 2009) did not find a framing effect for those with strong values associated with an issue prior to exposure to the frame. The mixed results may be due to the fact that many of these studies did not take into account that people with different traits (e.g., different personality) may react to framing strategies differently.

Recently, personalized framing, especially personality-based framing research has become a hot topic. Among them, Hirsh (2012) investigates whether a persuasive appeal's effectiveness can be increased by aligning message framing with a recipient's personality profile. In this study, for a given mobile phone, they constructed five advertisements, each designed to target one of the five major personality traits. Their results indicate that advertisements were evaluated more positively when they cohered with participants' personality. In a separate study, (Conroy et al., 2012) found that certain personality traits, particularly openness, agreeableness, and conscientiousness mediate framing effects when participants were presented with different frames of political and health issues such as civil liberties, medical treatments, energy, affirmative action, and gun control.

Inspired by the above research, we also employ psychologically-motivated trait models to capture individual characteristics. In addition to personality, we also incorporate basic human values since framing effects were also shown to be related to personal beliefs and motivations. As a result, we have significantly increased the scope of our study over prior research. Moreover, unlike prior research where only messages hand-crafted by experts were used, we are interested in building computational models to automatically select a subset of the aspects to highlight based on personal traits.

2.2 Personalized NLG

There is also a large body of work on personalized Natural Language Generation (NLG). For example, STOP is a Natural Language Generation (NLG) system that generates tailored smoking cessation letters based on a user's responses to a four-page

smoking questionnaire (Reiter et al., 2003); PERSIVAL customizes the content of search summaries based on its relevance to a given patient's health record (McKeown et al., 2003); MATCH (Johnston et al., 2002) is a multimodal dialogue system that tailors the content of its responses based on a user's restaurant preferences; M-PIRO (Burenhult, 2002) tailors the words and the complexity of museum object descriptions for different audiences (e.g. adults, children, and experts); PERSONAGE (Mairesse and Walker, 2011) and CRAG 2 (Gill et al., 2012) vary linguistic styles to project intended personality in spoken utterances. In addition, Carenini and Moore (Carenini and Moore, 2006) employed a multiattribute utility theory-based user preference model for personalized evaluative argument generation. Among them, STOP, PERSIVAL and MATCH use domain-specific user models while M-PIRO, PERSONAGE and GRAG2 employ domain independent user properties, such as expertise and personality. For PERSONAGE and GRAG2, personality traits are mainly used to adapt linguistic styles. So far, there has not been much work focusing on using domain-independent user traits to automatically adapt message content to improve its persuasive appeal.

3 Acquiring Personal Traits

Since prior study often links framing effects to individual characteristics such as personality and individual motivations and beliefs, here we focus on two widely-accepted trait models in psychology: the Big5 personality model (Goldberg, 1993) and Schwartz's basic human value model (Schwartz, 2003). Figure 1 shows the description of each of the Big5 personality traits along with each of the five basic human value traits.

To acquire the personality and value traits of a person, traditionally, psychometric tests, such as the IPIP test for Big 5 personality (Yarkoni, 2010a) and the PVQ survey for values (Schwartz, 2003), were used. Recent research in the field of psycholinguistics has shown that it is possible to automatically infer personal traits from one's linguistic footprint, such as tweets, Facebook posts and blogs (Yarkoni, 2010b; Celli and Polonio, 2013; Chen et al., 2014). Unlike psychometric tests, automated trait analysis

Model	Factors	Description
Big5 Personality Model	Openness to Experience	The degree of intellectual curiosity, creativity and a preference for novelty and variety a person has.
	Conscientiousness	A tendency to be organized and dependable, show self-discipline, act dutifully, and prefer planned rather than spontaneous behavior
	Extraversion	Energy, positive emotions, assertiveness, sociability and the tendency to seek stimulation in the company of others, and talkativeness.
	Agreeableness	A tendency to be compassionate and cooperative. Also a measure of one's trusting, helpful, well-tempered nature.
	Neuroticism	The tendency to experience unpleasant emotions easily, of low emotional stability and impulse control.
Schwartz's basic human values	Openness to change	the desire for independence and new, novel, exciting and challenging experiences:
	Self-enhancement	The pursuit of self-interests including social status, prestige, resources and personal success through demonstrating competence
	Conservation	Self-restriction and conform to tradition, social expectations and norms; Pursue safety, harmony and stability; resist to change
	Hedonism	Pursuit of pleasure and sensuous gratification for oneself.
	Self-transcendence	Concern and pursue the enhancement and protection of the welfare and interests of others as well as the protection for nature.

Figure 1: Description of Two Trait Models

allows us to infer personal traits for a large number of people, which makes it possible to scale up automated personal persuasion for a very large population (e,g., millions of social media users).

4 Acquiring Author Framing Strategy

Framing effects are often subtle and may be influenced by many factors, such as the credibility of the authors, the personality of the receivers and the context of the communication. In the first study, we investigate whether it is feasible to build a personalized content selection model based on a writer's (a.k.a. an author's) content framing strategies.

To investigate this, we first randomly generated ten cars, each include eight aspects: *safety, fuel economy, quality, style, price, luxury, performance and durability*. The value of each aspect was randomly generated on a 5-point Likert scale: "1 (very bad)", "2 (bad)", "3 (average)", "4 (good)", and "5 (excellent)". We also conducted a large-scale personality and basic human value survey on Amazon Mechanical Turk (AMT). We used the 50-item IPIP survey (Goldberg, 1993) to obtain a Amazon Mechanical Turk worker (a.k.a. Turker)'s personality scores and the 21-item PVQ survey (Schwartz, 2003) to obtain his/her basic value scores. To en-

sure the quality of the data from AMT, we added two qualification criteria. A qualified Turker must (1) have submitted over 5000 tasks (2) with an acceptance rate over 95%. The survey also included several validation questions, which are pairs of questions that are paraphrases of each other. If the answers to a pair of validation questions are significantly different, the user data were excluded from our analysis. After removing invalid data, we collected the traits of 836 Turkers. The raw personality scores, ranging from 10 to 50, and raw value scores, ranging from 1 to 6, were computed directly from the survey answers. The normalized trait scores, ranging from 0 to 1, were computed using their rank percentiles in this population.

In addition, we designed two Human Intelligence Tasks (HITs) on AMT: a content customization task and a validation task. In the content customization task (a.k.a. Task 1), a Turker was asked to select one car aspect to emphasize in his message for a receiver. The validation task (a.k.a. Task 2) was used to validate whether a receiver prefers the message customized for her or not.

Specifically, in Task 1, the Turkers were asked to imagine that they work for a marketing firm on a campaign to promote a new car. Each Turker was given the specification of a car (randomly selected from the 10 randomly generated cars) and a receiver (randomly selected from the 836 Turkers whose trait scores were known to us). The Turker was asked to write a campaign message to persuade the receiver to buy the car. But the Turker can only select one of the eight car aspects to include in his message. Since customizing a message based on an interaction of all ten traits can be very challenging for a Turker, we used a simplified trait profile in our study. The simplified trait profile contains only two traits: the most prominent personality trait and the most prominent value trait. The prominence of a trait was defined based on the normalized trait score. The more different a trait score is from the median (.50), the more prominent the trait is. For comparison, for the same car, we also asked the same writer to select a car aspect for someone who has an opposite trait profile. The opposite trait profile is defined as the one that is most different from the given trait profile (with the lowest cosine similarity). After the writer selected a car aspect, he also wrote a campaign message using the selected aspect. Overall, after removing invalid data, we collected 490 pairs of messages for 131 pairs of receivers.

To validate the framing effect, in Task 2, we asked a new set of Turkers (receivers) to first complete an IPIP personality survey and a PVQ human value survey. Based on the survey results, we computed the trait profile for each of them. In addition, for each receiver in Task 2, we matched his/her trait profile with the 131 pairs of trait profiles collected in Task 1. The profile with the highest matching score (computed based on cosine similarity) was selected and its associated message pair was retrieved.

Then we presented the receiver with a pair of messages, one created for someone with matching trait profile, the other for someone with the opposite trait profile. We also randomized the order these messages were presented. Finally, we asked the receivers to rate which message they prefer more. If the framing strategies used by the Turkers (authors) in Task 1 were effective, then the Turkers (receivers) in Task 2 will prefer the messages tailored for them more than the ones tailored for someone with the opposite trait profile. Overall, after filtering out invalid data, we have collected the results from 145 receivers. Among them, 77 prefer the messages written for them, while 68 prefer the messages written for someone with the opposite trait profiles. We performed a *sign test* to determine whether the difference is statistically significant and the result was negative ($p < 0.2$).

Although moderate personalization effects were found in previous framing research, only expert-crafted messages were used (Hirsh et al., 2012). Here, when Turkers (mostly non-experts) were asked to customize the messages based on a receiver's traits, no significant effects were found. Since authors' emphasis framing strategies were not effective, we can not directly use authors' data to learn their emphasis framing strategies. Next, we present several experiments designed to automatically derive emphasis framing strategies based on a receiver's traits and his/her aspect selection decisions.

5 Learning Emphasis Framing Strategies

To derive emphasis framing patterns based on a receiver's traits and his/her aspect selection decisions, we designed another HIT (Task 3) on AMT to collect data. In Task 3, each Turker was asked to take the IPIP and PVQ surveys so that we can obtain his/her Big5 personality and value scores. In addition, we also asked him/her to rank all eight car aspects based on their importance to him/her. To control the influence of the value of a car aspect on a user's aspect selection decision (e.g., if the value of "safety" is "poor" and the value of "fuel economy" is "good", to promote the car, people almost always describe it as "a car with good fuel economy", not "an unsafe car", regardless of a receiver's personality). In this study, we kept the values of all car aspects unspecified. After removing invalid data, our dataset has 594 responses, each contains a Turker's personality and value scores as well as his/her rank of the eight car aspects. In the following, we describe how we analyze the relationship between aspect rank and personal traits.

5.1 Pattern Discovery with Regression

In our first study, we employed regression analysis to identify significant correlations between personal traits and aspect ranks. Specifically, we trained eight linear regression models, one for each of the eight car aspects. The dependent variable in each model is the rank of an aspect (from 1 to 8) and the independent variables are the ten user traits. In the regression analysis, we only focused on the main effects since a full interaction model with ten traits will require much more data to train. Since the raw scores of the personality and value traits use different scales, we normalized these scores so that they are all from 0 to 1. Table 1 shows the regression results.

Several interesting patterns were discovered in this analysis: (a) a positive correlation between the rank of "luxury" and "self-enhancement", a trait often associated with people who pursue self-interests and value social status, prestige and personal success ($p < 0.0001$). This pattern suggests that to promote a car to someone who scores high on "self-enhancement", we need to highlight the "luxury" aspect of a car. (b) the rank of "safety" is positively correlated with "conservation", a trait associated with people who conform to tradition and pursue safety, harmony, and stability ($p < 0.005$). This result suggests that for someone values "conservation", it is better to emphasize "car safety" in a personalized sales message. (c) "self-transcendence", a trait often associated with people who pursue the protection of the welfare of others and the nature, is positively correlated with the rank of "fuel economy" ($p < 0.005$) but negatively correlated with the rank of "style" ($p < 0.005$). This suggests that for someone who values "self-transcendence", it is better to emphasize "fuel economy", but not so much on "style". Other significant correlations uncovered in this analysis include a negative correlation between car "price" and "conservation" ($p < 0.005$), a negative correlation between car "safety" and "conscientiousness" ($p < 0.05$), and a positive correlation between "openness to change" and car "performance" ($p < 0.05$).

5.2 Pattern Discovery with Constrained Clustering

In the regression analysis, we only considered the main framing effects. In order to discover high-order interaction patterns with limited data, we want to use clustering to group people with similar traits together. In addition, we also want that the people in a cluster share similar aspect preferences. Otherwise, we won't be able to link the trait patterns discovered in a cluster with specific aspect preferences. Thus, we employed constrained clustering in this analysis. With constrained clustering, we can ensure the homogeneity of the aspect preferences within each resulting cluster.

To facilitate this analysis, first we mapped the aspect ranks obtained in Task 3 into discrete categories. For a complete rank of eight car aspects, we mapped the top three ranked aspects to an "Important" class, bottom three to a "Not-Important" class, and the middle two to a "Neutral" class. In addition, we encoded the aspect homogeneity requirement as constraints. Typically, constrained clustering incorporates either a set of must-link constraints, a set of cannot-link constraints, or both. A must-link constraint is used to specify that the two data instances in the must-link relation should be placed in the same cluster. A cannot-link constraint is used

Table 1: Results of the Regression Analysis

	Safety	Fuel	Quality	Style	Price	Luxury	Perf	Durab
Agreeableness	0.39	-0.52	-0.53	0.54	0.81	0.004	-0.62	-0.27

to specify that the two instances in the cannot-link relation should not be put in the same cluster. These constraints act as a guide for which a constrained clustering algorithm will use to find clusters that satisfy these requirements.

To encode the homogeneity constraint, for each car aspect (e.g. safety), we can simply add must-links between every pair of Turkers if they share the same aspect preference (e.g., both consider "safety" important) and add cannot-links for every pair of Turkers who do not share the same aspect preferences (e.g., one Turker considers "safety" "Important", the other considers it "Not-Important"). But with both must-links and cannot-links, it is very likely we will get three big clusters, each is related to one of the three categories: Important, Neutral and Not-Important. Although the resulting clusters satisfy the aspect preference homogeneity requirement, they fail to group people with similar traits together. As a result, in this analysis, we only used cannot-links, which not only guarantees the homogeneity of aspect preferences, but also creates smaller clusters that group people with similar traits together.

We employed the Metric Pairwise Constrained KMeans algorithm (MPCK-MEANS) (Bilenko et al., 2004) to incorporate the aspect preference homogeneity requirement. The optimal cluster number K was determined empirically by running MPCK-MEANS with different Ks, $K \in [3, 20]$ (3 is the minimum number of clusters since we have 3 different aspect preference categories).

To determine whether the resulting clusters capture any interesting patterns, we used two pattern selection criteria (a) a homogeneity criterion which requires that there is at least one trait whose values in the cluster is relatively homogeneous; (b) a distinctiveness criterion which requires that for the traits identified in (a), their cluster means need to be significantly different from the population means. For (a), we used the coefficient of variation (CV) as the homogeneity measure. CV, also known as relative standard deviation (RSD), is a standardized measure of dispersion of a probability or count distribution. It is often expressed as a percentage and is defined as the ratio of the standard deviation σ to the mean $|\mu|$. In the study, we required that all the CVs of

homogeneous traits to be lower than 0.12. For (b) we required that the differences of the means need to be significant based on an independent sample t-test with $p < 0.001$ and the difference of means is greater than 0.2.

Table 2 highlights some of the patterns discovered using this approach. In this table, we list the cluster id, cluster label (Important, Not-Important, Neutral), clustering accuracy, and significant traits in the cluster ("+" indicates that the cluster mean is higher than population mean, "-" means the opposite). For example, based on the Safety-1 pattern, people who are more extraverted (extrave (+)) and more neurotic (neurotic (+)) tend to consider "car safety" important. Similarly, based on pattern Safety-3, people who are more conscientious (conscie(+)) but less open (open(-)) tend to consider "safety" important. Other interesting patterns include: people who are less open (open(-)) and do not value hedonism (hedomis (-)) don't consider performance very important (performance-3), and people who are more extraverted (extrave(+)), value hedonism and self-enhancement (hedonis(+), self-en(+)) do not think durability important (durability-1).

6 Apply Emphasis Framing in NLG

The patterns derived in the previous section can be used in personalized content selection for Natural Language Generation. In general, to promote a car, people tend to highlight the good aspects and avoid the bad aspects, regardless of a receiver's personality. For example, people will likely to highlight the fuel economy aspect if a car is very fuel efficient while de-highlight the same aspect if a car is not fuel efficient. Thus, during content selection, to take the value of an aspect into consideration, we employ a cascade NLG model that integrates value-based content selection with trait-based personalization.

The input to the cascade content selection model includes: (1) the values of all the car aspects; (2) the trait scores of a receiver; (3) the eight linear-regression models learned in Section 5.2, one for each aspect; (4) the interaction rules learned in Section 5.3; (5) *n*, the number of aspects needed in the output; (6) the value difference threshold δ_1 that determines whether the values of two or more aspects are significantly different; (7) the rank difference threshold δ_2 that determines whether the ranks of two or more aspects predicted by the linear regression models are significantly different.

To select *n* aspects to emphasize, our system first ranks all the aspects based on their values. If the value of the n-th aspect v_n is significantly better than that of the (n+1)-th aspect v_{n+1} (i.e., their difference is greater than δ_1), we output the top n aspects directly. Otherwise, for all the aspects whose values are either the same or not significantly worse than v_n, their ranks will be determined by the trait-based linear regression models. Moreover, after re-ranking relevant aspects based on the predicted ranks from the regression models, if the predicted rank of the n-th aspect r_n is significantly better than that of the (n+1)-th aspect r_{n+1} (i.e., the rank difference is greater than δ_2), we just output the top n aspects in this list. Otherwise, for those aspects whose ranks predicted by the linear regression models are not significantly lower than r_n, we use the interaction rules discovered in Section 5.3 to further adjust their ranking scores (i.e., increase the rank by δ_2 if the cluster label is "Important", or decrease by δ_2 if "Not-Important"). For each aspect, if more than one interaction rule applies, more accurate rules take precedence over less accurate rules. Finally, the system will output the top n aspects in the final list.

We use an example shown in Figure 2 to illustrate the cascade aspect selection process. In this example, we assume n=3, δ_1=1 and δ_2=0.5. We first sorted all the aspects based on their values. Since the values of "Fuel Economy" and "Luxury" are significantly better than the 3rd-ranked aspect "Price", their ranks are not affected by personalized aspect selection. Similarly, since the values of "Performance" and "Style" are significantly lower than that of the 3rd-ranked aspect, their ranks are also not affected by personalization. Since the value differences among the rest 4 aspects, "Price", "Durability", "Quality" and "Safety" are all equal or not significant worse than v_3, we used trait-based personalized ranks predicted by the regression models to re-rank them (the output ranks from the regression models are shown in the parentheses in the column "Regression-based Re-Ranking"). After re-ranking these aspects based on the predicted ranks, since the rank of the 3rd-ranked aspect "Price" (2.2) and that of "Safety" (2.5) is within δ_2, we use the learned

Aspect	Value	Regression-based Re-Ranking	Interaction Rule-based Re-Ranking	Final Rank
Fuel Economy	5(Excellent)	**1**	**1**	1*
Luxury	5(Excellent)	**2**	**2**	2*
Price	3(Average)	3(2.2)	**4(2.2)**	4
Durability	3(Average)	6(6.7)	6(6.7)	6
Quality	3(Average)	5(4.5)	5(4.5)	5
Safety	3(Average)	4(2.5)	3(2.0)	3*
Performance	1(Very Bad)	7	7	7
Style	1(Very Bad)	8	8	8

Figure 2: A Cascade Content Selection Example

interaction rules to adjust their ranks. Since the predicted ranks of "Durability" and "Quality" are much worse than that of "Price", their ranks are not affected by the interaction rules. To apply the interaction rules, assume for a given receiver, both his extraversion and neuroticism scores are much higher than the population average, the Safety-1, Quality-1 and Performance-1 rules are applicable. Since the Safety-1 rule predicts that "Safety" is "Important" to the receiver while none of the rules affects "Price", the predicted rank for "Safety" is increased by δ_2 . After this adjustment, the ranks of all the aspects are shown in the "Final Rank" column. The top 3 aspects based on the final ranks are selected as the output (those marked with a *).

To evaluate the performance of the cascade content selection model, we conducted an additional AMT study. Given the specifications of the ten cars in Task1, we asked each AMT participant to select the top-n aspects to emphasize. Here n=1 and 3. In this task, aspect selection not only depends on the importance of an aspect to a receiver, but also the values of the aspects of a given car. We also acquired the personality and value scores of each Turker based on the IPIP personality and PVQ value survey. Finally, we compared the output of our model with the aspects selected by the Turkers. We used top-n overlapping percentage as the evaluation metrics. Overall, we collected the aspect selection results from 38 Turkers, each on ten different cars. In total, we collected 380 data instances in our ground truth dataset. We have tested different $\delta 1$ and $\delta 2$, the best results were obtained when $\delta 1 = 0$ and $\delta 2 = 0.5$. We compared our model with a baseline system which relies solely on the values of aspects to determine their ranks in the baseline system. If two or more aspects have the same value (e.g., the values of both "Price" and "Durability" are "3(Average)", their ranks were determined randomly. Table 3 shows the evaluation results. If only 1 aspect is needed in the output, the Top-1 agreement is 62% for the cascade model versus the baseline's 54%. Similarly, if 3 aspects are needed in the output, the Top-3 agreement is 87% for the cascade model versus the baseline's 46%. All the differences are statistically significant based on paired-t test ($p \leq 0.05$).

Table 3: Cascade Content Selection Evaluation

	Cascade	Baseline
Top-1 agreement	0.62	0.54
Top-3 agreement	0.87	0.46

7 Discussion

In general, there are two main challenges in adapting a personalized content selection model trained in one domain to another domain: (1) adapting the *data model* from one domain (e.g., restaurant data) to another (e.g., movie data); (2) adapting a domain-specific *user model* (e.g., a user' preferences of restaurant features such as "cuisine type") to a different domain (e.g., a user's preferences of movie features such as "movie genre"). Although our data model is in the automobile domain, we adopted a domain-independent user model motivated by psychological theories(e.g., personality and basic human values), instead of a domain-dependent user preference models (e.g, a user's preferences of "fuel economy"). This allows us to more easily apply typical domain adaptation methods such as instance-based (Zadrozny, 2004) or feature-based transfer learning (Blitzer et al., 2006) to further adapt the system and generalize the current results.

8 Conclusions

In this study, we analyzed the relationship between an individual's traits and his/her aspect framing decisions. Our analysis has uncovered interesting patterns that can be used to automatically customize a message's content to enhance its appeal to its receivers. We also proposed a cascade content selection model to automatically incorporate the analysis results in automated persuasive message generation. Our evaluation results have demonstrated the effectiveness of this approach.

Abstract

For AI systems to reason about real world situations, they need to recognize which processes are at play and which entities play key roles in them. Our goal is to extract this kind of role-based knowledge about processes, from multiple sentence-level descriptions. This knowledge is hard to acquire; while semantic role labeling (SRL) systems can extract sentence level role information about individual mentions of a process, their results are often noisy and they do not attempt create a globally consistent characterization of a process.

To overcome this, we extend standard *within sentence* joint inference to inference across multiple sentences. This *cross sentence* inference promotes role assignments that are compatible across different descriptions of the same process. When formulated as an Integer Linear Program, this leads to improvements over within-sentence inference by nearly 3% in F1. The resulting role-based knowledge is of high quality (with a F1 of nearly 82).

1 Introduction

Knowledge about processes is essential for AI systems in order to understand and reason about the world. At the simplest level, even knowing which class of entities play key roles can be useful for tasks involving recognition and reasoning about processes. For instance, given a description "a puddle drying in the sun", one can recognize this as an instance of the process *evaporation* using a macro-level role knowledge: Among others, the typical *undergoer* of evaporation is a kind of liquid (the puddle), and the *enabler* is usually a heat source (the sun).

1) Evaporation is the process by which liquids are converted to their gaseous forms.
2) Evaporation is the process by which water is converted into water vapor.
3) Water vapor rises from water due to evaporation.
4) Clouds arise as water evaporates in the sun.

Table 1: Example sentences for the process *evaporation*. Underlined spans correspond to fillers for the *undergoer* role.

Our goal is to acquire this kind of role-based knowledge about processes from sentence-level descriptions in grade level texts. Semantic role labeling (SRL) systems can be trained to identify these process specific roles. However, these were developed for sentence-level interpretation and only ensure *within sentence* consistency of labels (Punyakanok et al., 2004; Toutanova et al., 2005; Lewis et al., 2015), limiting their ability to generate coherent characterizations of the process overall. In particular, the same process participant may appear in text at different syntactic positions, with different wording, and with different verbs, which makes it hard to extract globally consistent descriptions. In this work, we propose a cross sentence inference method to address this problem.

To illustrate the challenge consider some example sentences on *evaporation* shown in Table 1.The underlined spans correspond to fillers for an *undergoer* role i.e., the main entity that is undergoing evaporation. However, the filler *water* occurs as different syntactic arguments with different main actions. Without large amounts of process-specific training data, a supervised classifier will not able to

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1442–1451,
Austin, Texas, November 1-5, 2016.

learn these variations reliably. Nevertheless, since all these sentences are describing *evaporation*, it is highly likely that *water* plays a single role. This expectation can be encoded as a factor during inference to promote consistency and improve accuracy, and is the basis of our approach.

We formalize this *cross sentence* joint inference idea as an Integer Linear Program (ILP). Our central idea is to collect all sentences for a single process, generate candidate arguments, and assign roles that are globally consistent for all arguments within the process. This requires a notion of consistency, which we model as pairwise alignment of arguments that should receive the same label. Argument-level entailment alone turns out to be ineffective for this purpose.

Therefore, we develop an alignment classifier that uses the compatibility of contexts in which the candidate arguments are embedded. We transform the original role-label training data to create alignment pairs from arguments that get assigned the same label, thus avoiding the need for additional labeling. Finally, the ILP combines the output of the SRL classifier and the alignment classifier in an objective function in order to find globally consistent assignments.

An empirical evaluation on a process dataset shows that proposed *cross sentence* formulation outperforms a strong *within sentence* joint inference baseline, which uses scores from a custom built role classifier that is better suited for the target domain.

In summary, this work makes the following contributions:

1. A cross-sentence, collective role-labeling and alignment method for harvesting process knowledge.

2. A high quality semantic resource that provides knowledge about scientific processes discussed in grade-level texts including physical, biological, and natural processes.

3. An evaluation which shows that the proposed cross sentence inference yields high quality process knowledge.

2 Related Work

Role-based representations have been shown to be useful for Open-domain factoid question answering (Shen and Lapata, 2007; Pizzato and Mollá, 2008), grade-level science exams (Jauhar et al., 2016) , and comprehension questions on process descriptions (Berant et al., 2014). Similar to process comprehension work, we target semantic representations about processes but we focus only on a high-level summary of the process, rather than detailed sequential representation of sub-events involved. Moreover, we seek to aggregate knowledge from multiple descriptions rather than understand a single discourse about each process.

There has been substantial prior work on semantic role labeling itself, that we leverage in this work. First, there are several systems trained on the PropBank dataset, e.g., EasySRL (Lewis et al., 2015), Mate (Björkelund et al., 2009), Generalized-Inference (Punyakanok et al., 2004). Although useful, the PropBank roles are verb (predicate) specific, and thus do not produce consistent labels for a *process* (that may be expressed using several different verbs). In constrast, frame-semantic parsers, e.g., SEMAFOR (Das et al., 2010), trained on FrameNet-annotated data (Baker et al., 1998) do produce concept (frame)-specific labels, but the FrameNet training data has poor ($< 50\%$) coverage of the grade science process terms. Building a resource like FrameNet for a list of scientific processes is expensive.

Several unsupervised, and semi-supervised approaches have been proposed to address these issues for PropBank style predicate-specific roles (Swier and Stevenson, 2004; Lang and Lapata, 2011; Fürstenau and Lapata, 2009; Fürstenau and Lapata, 2012; Lang and Lapata, 2010; Klementiev, 2012). A key idea here is to cluster syntactic signatures of the arguments and use the discovered clusters as roles. Another line of research has sought to perform joint training for syntactic parsing and semantic role labeling (Lewis et al., 2015), and in using PropBank role labels to improve FrameNet processing using pivot features (Kshirsagar et al., 2015).

Some SRL methods account for context information from multiple sentences (Ruppenhofer et al., 2010; Roth and Lapata, 2015). They focus on an-

Process	Undergoer	Enabler	Action	Result
evaporation	liquid water	heat heat energy	changes convert	gas water vapor
weathering	rock solid material	weather heating	disintegration breaking down	smaller rocks smaller particles
photosynthesis	carbon dioxide CO2	solar energy light energy	convert transforms	energy food

Table 2: Examples of Target Knowledge Roles

notating individual event mentions in a document using discourse-level evidence such as co-reference chains. Our task is to aggregate knowledge about processes from multiple sentences in different documents. Although both tasks require raw SRL-style input, the different nature of the process task means that a different solution framework is needed.

Our goal is to acquire high quality semantic role based knowledge about processes. This allows us an unique opportunity to jointly interpret sentences that are discussing the same process. We build on ideas from previous within sentence joint inference (Punyakanok et al., 2004), argument similarity notions in semi and unsupervised approaches (Fürstenau and Lapata, 2012), and combining PropBank roles to propose a cross-sentence inference technique (Kshirsagar et al., 2015). The inference can be integrated with existing trained supervised learning pipelines, which can provide a score for role assignments for a given span.

3 Approach

Processes are complex events with many participating entities and inter-related sub-events. In this work, we aim for a relatively simple macro-level role-based knowledge about processes. Our task is to find classes of entities that are likely to fill key roles within a process namely, the *undergoer*, *enabler*, *result*, and *action*[1] (different verbs denoting the main action when the process is occurring, e.g., "dry"). We select these roles based on an initial analysis of grade science questions that involve recognizing instances of processes from their descriptions. Table 2 shows some examples of the target knowledge roles.

[1]For simplicity, we abuse the notion of a role to also include the main action as a role.

We develop a scalable pipeline for gathering such role-based process knowledge. The input to our system is the name of a process, e.g., "evaporate". Then we use a set of query patterns to find sentences that describe the process. A semantic role classifier then identifies the target roles in these sentences. The output is a list of typical fillers for the four process roles.

This setting presents a unique opportunity, where the goal is to perform semantic role labeling on a set of closely related sentences, sentences that describe the same process. This allows us to design a joint inference method that can promote expectations of consistency amongst the extracted role fillers.

There is no large scale training data that can be readily used for this task. Because we target process-specific and not verb-specific semantic roles, existing ProbBank (Kingsbury and Palmer, 2003) trained SRL systems cannot be used directly. Frame-semantic parsers trained on FrameNet data (Baker et al., 1998) are also not directly usable because FrameNet lacks coverage for many of the processes discussed in the science domain. Therefore, we create a process dataset that covers a relatively small number of processes, but demonstrate that the role extraction generalizes to previously unseen processes as well.

3.1 Cross-Sentence Inference

Given a set of sentences about a process, we want to extract role fillers that are globally consistent i.e., we want role assignments that are compatible. Our approach is based on two observations: First, any given role is likely to have similar fillers for a particular process. For instance, the undergoers of the evaporation process are likely to be similar – they are usually liquids. Second, similar arguments are

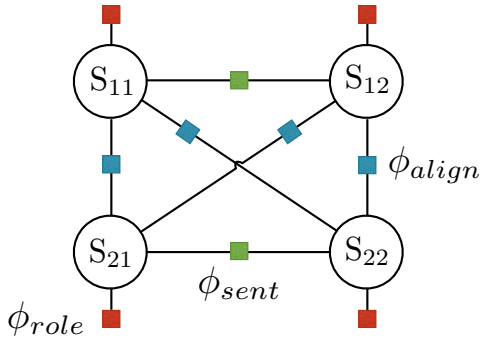

Figure 1: A factor graph representation of cross sentence inference. S_{11} and S_{12} denote role assignments for arguments a_{11} and a_{12} in one sentence, and S_{21} and S_{22} denote for arguments a_{21} and a_{22} in another. The ϕ_{role} factors score each role assignment to the arguments, and the ϕ_{align} factors score the compatibility of the connected arguments. ϕ_{sent} factors encode sentence level constraints.

unlikely to fill different roles for the same process. In evaporation, for example, it is highly unlikely that *water* is an undergoer in one sentence but is a result in another. These role-specific selectional preferences vary for each process and can be learned if there are enough example role fillers for each process during training (Zapirain et al., 2009; Zapirain et al., 2013). Since, we wish to handle processes for which we have no training data, we approximate this by modeling whether two arguments should receive the same role given their similarity and their context similarity.

Figure 1 illustrates the cross sentence inference problem using a factor graph. The S_{ij} random variables denote the role label assignment for the j^{th} argument in sentence i. Each assignment to an argument S_{ij} is scored by a combination of the role classifier's score (factor ϕ_{role}), and its pairwise compatibility with the assignments to other arguments (factor ϕ_{align}). The factors ϕ_{sent} capture two basic within sentence constraints.

3.2 Inference using ILP

We formulate the cross sentence inference task using an Integer Linear Program shown in Figure 2. The ILP seeks an assignment that maximizes a combination of individual role assignment scores and their global compatibility, which is measured as the similarity of fillers for the same role minus similarity of

$$\arg\max_{\mathbf{z}} \sum_k \sum_{i,j} z_{ijk} \Bigg(\lambda \underbrace{\phi_{role}(a_{ij}, k)}_{\text{Role classifier score}} + (1-\lambda) \underbrace{\Big[\Delta(a_{ij}, k) - \nabla(a_{ij}, k) \Big]}_{\text{Global compatibility}} \Bigg)$$

where compatibility with same roles is:

$$\Delta(a_{ij}, k) = \frac{1}{\tilde{N}_k} \sum_{l,m} z_{lmk} \phi_{align}(a_{ij}, a_{lm})$$

and compatibility with other roles is:

$$\nabla(a_{ij}) = \frac{2}{\tilde{N}_{k'}} \sum_{l,m} \sum_{n \neq k} z_{lmn} \underbrace{\phi_{align}(a_{ij}, a_{lm})}_{\text{Penalty when role n} \neq \text{k}}$$

subject to:

$$\sum_k z_{ijk} \leq 1 \qquad \forall\ a_{ij} \in \text{sentence}_i$$

$$\sum_j z_{ijk} \leq 1 \qquad \forall\ a_{ij} \in \text{sentence}_i, k \in \text{R}$$

$\tilde{N}_k$: Approximate number of arguments with role k

$\tilde{N}_{k'}$: Approximate number of arguments with role $n \neq k$

Figure 2: An Integer Linear Program formulation of the Cross-sentence Inference.

fillers of different roles.

The decision variables z_{ijk} denote role assignments to arguments. When z_{ijk} is set it denotes that argument j in sentence i (a_{ij}) has been assigned role k. The objective function uses three components to assign scores to an assignment.

1. Classifier Score $\phi_{role}(a_{ij}, k)$ – This is the score of a sentence-level role classifier for assigning role k to argument a_{ij}.
2. Within Role Compatibility $\Delta(a_{ij}, k)$ – This is a measure of argument a_{ij}'s compatibility with other arguments which have also been assigned the same role k. We measure compatibility using a notion of alignment. An argument is said to align with another if they are similar to each other in some respect (either lexically or semantically). As we show later, we develop an alignment cclassifier which predicts an alignment score ϕ_{align} for each pair of arguments. The compatibility is defined as a normalized sum of the alignment scores for argument a_{ij} paired with

other arguments that have also been assigned the role k. Without some normalization roles with many arguments will receive higher compatibility scores.To avoid this, we normalize by $(1/\tilde{N}_k)$, where $\tilde{N}_k$ refers to the number of arguments that the role classifier originally labeled with role k, an approximation to the number of arguments that are currently assigned role k by the ILP.

3. Across Role Incompatibility $\nabla(a_{ij}, k)$ – This is a measure of how well a_{ij} aligns with the other arguments that are assigned a different role ($n \neq k$). For good assignments this quantity should be low. Therefore we add this as a penalty to the objective. As with Δ, we use an approximation for normalization $(1/\tilde{N}_{k'})$, which is the product of other roles and the number of arguments in other sentences that can receive these roles. Because $\tilde{N}_{k'}$ is typically higher, we boost this score by 2 to balance against Δ.

Last, we use two sets of hard constraints to enforce the standard within-sentence expectations for roles: 1) A single argument can receive only one role label, and 2) A sentence cannot have more than one argument with the same label, except for the NONE role.

We use an off-the-shelf solver in Gurobi (www.gurobi.com) to find an approximate solution to the resulting optimization problem.

3.3 Role Classifier (Φ_{role})

The role classifier provides a score for each role label for a given argument. Although existing SRL and frame semantic parsers do not directly produce the role information we need (Section 2), we build on them by using their outputs for building a process role classifier.

Before we can assign role labels, we first need to generate candidate arguments. Using EasySRL (Lewis et al., 2015), a state-of-the-art SRL system, we generate the candidate argument spans for each predicate (verbs) in the sentence. Then, using a linear SVM classifier (Fan et al., 2008), we score the candidate arguments and the predicates for our four roles and a special NONE role to indicate the argument is not one of the four. The classifier is trained with a set of annotated examples (see Section 4) with the following sets of features.

i) Lexical and Syntactic – We use a small set of standard SRL features such as lexical and syntactic contexts of arguments (e.g., head word, its POS tag) and predicate-argument path features (e.g, dependency paths). We also add features that are specific to the nature of the process sentences. In particular, we encode syntactic relationships of arguments with respect to the process name mention in the sentence. We use Stanford CoreNLP toolkit (Manning et al., 2014) to obtain POS tags, and dependency parses to build these features.

ii) PropBank roles – While they do not have a 1-to-1 correspondence with process roles, we use the EasySRL roles coupled with the specific predicate as a feature to provide useful evidence towards the process role.

iii) Framenet Frames – We use the frames evoked by the words in the sentence to allow better feature sharing among related processes. For instance, the contexts of undergoers in evaporation and condensation are likely to be similar as they are both state changes which evoke the same `Undergo_Change` frame in FrameNet.

iv) Query patterns – We use query patterns to find sentences that are likely to contain the target roles of interest. The query pattern that retrieved a sentence can help bias the classifier towards roles that are likely to be expressed in it.

3.4 Alignment Classifier (Φ_{align})

Our goal with alignment is to identify arguments that should receive similar role labels. One way to do this argument alignment is to use techniques developed for phrase level entailment or similarity which often use resources such as WordNet and distributional embeddings such as word2vec (Mikolov et al., 2013) vectors. It turns out that this simple entailment or argument similarity, by itself, is not enough in many cases for our task[2]. Moreover, the enabler, and the result roles are often long phrases whose text-based similarity is not reliable. A more robust approach is necessary. Lexical and syntactic similarity of arguments and the context in which they are embedded can provide valuable additional information. Table 3 shows a complete list of features we use to train the alignment classifier.

[2]We used an approach that combined WordNet-based phrase similarity method, and Word2Vec vector similarity, where the vectors were learned from a general news domain.

Lexical
Entailment score of arguments. Word2vec similarity of argument vectors. Word2Vec similarity of head nodes of arguments. Word2Vec similarity of parent of the head nodes. Word2Vec similarity of verbs of argument sentences. Jaccard similarity of children of the head node.
Syntactic
Similarities of frames to right and left of arguments. Jaccard similarity of POS tags of argument. POS tag of head nodes match (boolean). POS tag of head node parents match (boolean). Similarity of dep. path from arg to process name. Similarity of POS tags on arg to process name path. Similarity of POS tags of arg's children. Similarity of the dependencies of the arg's head.
Sentence
Query patterns match argument sentences (boolean).

Table 3: Alignment Classifier Features. Similarities of sets were calculated using Jaccard co-efficient.

Fortunately, learning this classifier does not require any additional training data. The original data with annotated semantic role labels can be easily transformed to generate supervision for this classifier. For any given process, we consider all pairs of arguments in different sentences (i.e., (a_{ij}, a_{lm}) : $i \neq l$) and label them as aligned if they are labeled with the same role, or unaligned otherwise.

4 Evaluation

Our goal is to generate knowledge about processes discussed in grade-level science exams. Since existing semantic resources such as FrameNet do not provide adequate coverage for these, we created a dataset of process sentences annotated with the four process roles: undergoer, enabler, action, and result.

4.1 Dataset

This dataset consists of 1205 role fillers extracted from 537 sentences retrieved from the web. We first compiled the target processes from a list of process-oriented questions found in two collections: (i) New York Regents science exams (Clark, 2015), and (ii) helpteaching.com, a Web-based collection of practice questions. Then, we identified 127 process questions from which we obtained a set of 180 unique target processes. For each target process, we queried the web using Google to find definition-style sentences, which describe the target process. For each process we discarded some noisy sentences through a combination of automatic and manual filtering.

Query Patterns
⟨name⟩ is the process of ⟨x⟩
⟨name⟩ is the process by which ⟨x⟩
⟨name⟩ {occurs when} ⟨x⟩
⟨name⟩ { helps to | causes } ⟨x⟩

Table 4: Example query patterns used to find process description sentences.

Table 4 shows some examples of the 14 query patterns that we used to find process descriptions. Because these patterns are not process-specific, they work for unseen processes as well.

To find role fillers from these sentences, we first processed each sentence using EasySRL (Lewis et al., 2015) to generate candidate arguments. Some of the query patterns can be used to generate additional arguments. For example, in the pattern "⟨name⟩ is the process of ⟨x⟩" if ⟨x⟩ is a noun then it is likely to be an undergoer, and thus can be a good candidate. [3]. Then two annotators annotated the candidate arguments with the target roles if one were applicable and marked them as NONE otherwise. Disagreements were resolved by a third annotator. The annotations spanned a random subset of 54 target processes. The role label distribution is shown below:

Role	No. of instance
Undergoer	77
Enabler	154
Action	315
Result	194
NONE	465

Table 5: Role distribution

We conducted five fold cross validation experiments to test role extraction. To ensure that we are testing the generalization of the approach to unseen

[3]These patterns are ambiguous and are not adequate by themselves for accurately extracting the roles. We use them as features.

processes, we generated the folds such that the processes in the test fold were unseen during training. We compared the basic role classifier described in Section 3.3, the *within sentence* and the *cross sentence* inference models. We tune the ILP parameter λ for cross sentence inference based on a coarse-grained sweep on the training folds.

We also compared with a simple baseline that learned a mapping from PropBank roles produced by EasySRL system to the process roles by using the roles and the verb as features. We also add the FrameNet frames invoked by the lexical unit in the sentence. Note this is essentially a subset of the features we use in our role classifier. As a second baseline, we compare with a (nearly) out-of-the-box application of SEMAFOR (Das et al., 2010), a FrameNet based frame-semantic parser. We modified SEMAFOR to override the frame identification step since the process frame information is already associated with the test sentences.

4.2 Cross-Sentence Inference Results

Table 6 compares performance of the different methods. The learned role mapping of shallow semantic roles performs better than SEMAFOR but worse than the simple role classifier. SEMAFOR uses a large set of features which help it scale for a diverse set of frames in FrameNet. However, many of these many not be well suited for the process sentences in our relatively smaller dataset. Therefore, we use our custom role classifier as a strong baseline to demonstrate within and cross sentence gains. Enforcing sentence-level consistency through joint inference, shown as (+within sent.), improves over the baseline which does not use any consistency. It gains precision (by nearly 8 points), while loosing recall in the trade-off (by about 4.7 points) to yield an overall gain in F1 by 1.05 points. Enforcing cross sentence consistency, shown as (+cross sent.) provides additional gains beyond within sentence inference by another 2.38 points in F1 [4]. Table 7 shows how the gains are distributed across different roles. Cross sentence inference provides improvements for all roles, with the biggest for undergoers (nearly 4 points).

Method	Prec.	Rec.	F1
Role mapping	56.62	59.60	58.07
SEMAFOR	40.72	50.54	45.10
Role class. (ϕ_{role})	78.48	**78.62**	78.55
+ within sent.	86.25	73.91	79.60
+ cross sent.	**89.84**	75.36	**81.97**††

Table 6: Process role inference performance. †† indicates significant improvement over Role + within sentence system.

Method	Und.	Ena.	Act.	Res.
Role Class.	65.38	73.84	83.58	77.30
+ within	66.01	73.11	86.70	76.11
+ cross	**70.00**	**74.31**	**89.30**	**78.00**

Table 7: Performance (F1) across all roles.

Figure 3 shows the precision/recall plots for the basic role classifier and within and cross sentence inference. Both inference models trade recall for gains in precision. Cross sentence yields higher precision at most recall levels, for a smaller overall loss in recall compared to within sentence (1.6 versus 4.9).

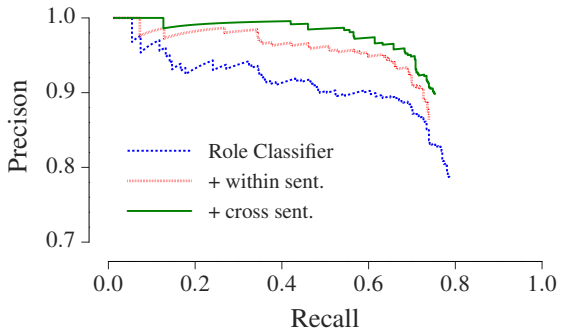

Figure 3: Precision/Recall trade-offs for process role inference. y-axis is truncated at 0.7 to better visualize the differences.

4.3 Ablations

Table 8 shows the utility of various components of cross sentence inference. Using argument entailment alone turns out to be ineffective and only produces a minor improvement (0.16 in F1). However, the alignment classifier scores are much more effective and yield about 2.37 points gain in F1. Both within and across role compatibilities, Δ and ∇, yield statistically significant improvements[5] over

[4] The single parameter in ILP turned out to be stable across the folds and obtained this best value at $\lambda = 0.8$.

[5] Significance measured using approximate randomization test

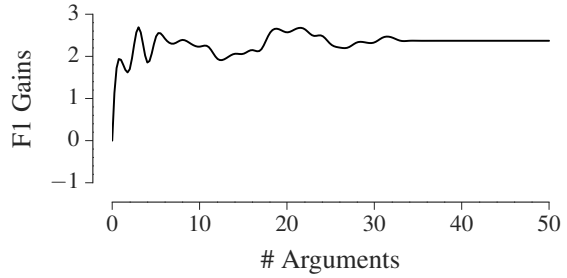

Figure 4: Cross sentence gains in F1 when varying the number of most similar arguments used to assess compatibilities.

within sentence inference. Combining these complementary compatibilities provides the best gains.

Method	Prec.	Rec.	F1
within sent.	86.25	73.91	79.60
+ Entailment			
cross sent. w/ Δ	85.13	72.64	78.39
cross sent. w/ ∇	85.98	73.36	79.17
cross sent. w/ $\Delta + \nabla$	86.62	73.91	79.76
+ Alignment Classifier			
cross sent. w/ Δ	89.07	75.36	81.64††
cross sent. w/ ∇	88.72	75.54	81.60††
cross sent. w/ $\Delta + \nabla$	**89.84**	75.36	**81.97**††

Table 8: Performance impact of inference components. †† indicates significant improvement over within sentence.

We also studied the effect of varying the number of arguments that ILP uses to measure the compatibility of role assignments. Specifically, we allow inference to use just the top k alignments from the alignment classifier. Figure 4 shows the main trend. Using just the top similar argument already yields a 1 point gain in F1. Using more arguments tends to increase gains in general but with some fluctuations. Finding an assignment that respects all compatibilities across many argument pairs can be difficult. As seen in the figure, at some of the shorter span lengths we see a slightly larger gain ($+0.3$) compared to using all spans. This hints at benefits of a more flexible formulation that makes joint decisions on alignment and role label assignments.

Table 9 shows an ablation of the alignment classifier features. Entailment of arguments is the most informative feature for argument alignment. Adding lexical and syntactic context compatibilities adds significant boosts in precision and recall. Knowing that the arguments are retrieved by the same query pattern (sentence feature) only provides minor improvements. Even though the overall classification performance is far from perfect, cross sentence can benefit from alignment as long as it provides a higher score for argument pairs that should align compared to those that should not.

Feature	P	R	F1
Entailment score only	39.55	14.59	21.32
+Lexical	50.75	26.02	34.40
+Syntactic	62.31	31.47	41.82
+Sentence	62.33	31.41	41.53

Table 9: Performance of different feature groups for alignment.

4.3.1 Error Analysis

We conduct an error analysis over a random set of 50 errors observed for cross sentence inference. In addition to issues from noisy web sentences and nested arguments from bad candidate extraction, we find the following main types of errors:

- Dissimilar role fillers (27.5 %) – In some processes, the fillers for the *result* role have high levels of variability that makes alignment error prone. For the process camouflage, for instance, the *result* roles include 'disorientation', 'protect from predator', 'remain undetected' etc.
- Bad role classifier scores (37.5%) – For some instances the role classifier assign high scores to incorrect labels, effectively preventing the ILP from flipping to the correct role. For example, the argument that follows "causes" tends to be a result in many cases but not always, leading to high scoring errors. For example, in the sentence with "...when heat from the sun causes water on earth's ...", the role classifier incorrectly assigns 'water' to a result role with high confidence.
- Improper Weighting (7.5%)– Sometimes the ILP does not improve upon a bad top choice from the role classifier. In some of these cases, rather than the fixed lambda, a different weighted combination of role and alignment classifier scores

would have helped the ILP to flip. For example, the argument 'under autumn conditions' from the sentence 'hibernation occurs when the insects are maintained under autumn conditions.' has a good role score and is similar to other correctly labeled enablers such as 'cold , winter conditions' but yet is unable to improve.

The rest (27.5 %) are due to noisy web sentences, incorrect argument extraction and errors outside the scope of cross sentence inference.

5 Conclusions

Simple role-based knowledge is essential for recognizing and reasoning about situations involving processes. In this work we developed a cross sentence inference method for automatically acquiring such role-based knowledge for new processes. The main idea is to enforce compatibility among roles extracted from sentences belonging to a single process. We find that the compatibility can be effectively assessed using an alignment classifier built without any additional supervision. Empirical evaluation on a process dataset shows that cross sentence inference using an Integer Linear Program helps improve the accuracy of process knowledge extraction.

Abstract

Entity linking is the task of identifying mentions of entities in text, and linking them to entries in a knowledge base. This task is especially difficult in microblogs, as there is little additional text to provide disambiguating context; rather, authors rely on an implicit common ground of shared knowledge with their readers. In this paper, we attempt to capture some of this implicit context by exploiting the social network structure in microblogs. We build on the theory of *homophily*, which implies that socially linked individuals share interests, and are therefore likely to mention the same sorts of entities. We implement this idea by encoding authors, mentions, and entities in a continuous vector space, which is constructed so that socially-connected authors have similar vector representations. These vectors are incorporated into a neural structured prediction model, which captures structural constraints that are inherent in the entity linking task. Together, these design decisions yield F1 improvements of 1%-5% on benchmark datasets, as compared to the previous state-of-the-art.

1 Introduction

Entity linking on short texts (e.g., Twitter messages) is of increasing interest, as it is an essential step for many downstream applications, such as market research (Asur and Huberman, 2010), topic detection and tracking (Mathioudakis and Koudas, 2010), and question answering (Yih et al., 2015). Tweet entity linking is a particularly difficult problem, because the short context around an entity mention is often insufficient for entity disambiguation. For example, as shown in Figure 1, the entity mention 'Giants' in tweet t_1 can refer to the NFL football team *New York Giants* or the MLB baseball team *San Francisco Giants*. In this example, it is impossible to disambiguate between these entities solely based on the individual text message.

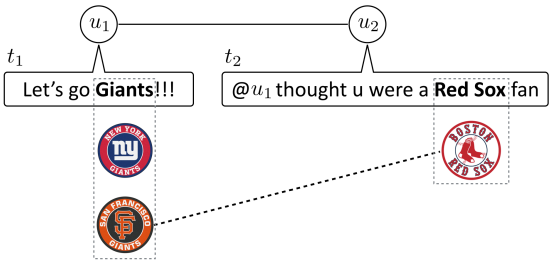

Figure 1: Illustration on leveraging social relations for entity disambiguation. Socially connected users u_1 and u_2 tend to talk about similar entities (baseball in the example).

We propose to overcome the difficulty and improve the entity disambiguation capability of the entity linking system by employing social network structures. The sociological theory of *homophily* asserts that socially connected individuals are more likely to have similar behaviors or share similar interests (McPherson et al., 2001). This property has been used to improve many natural language processing tasks such as sentiment analysis (Tan et al., 2011; Yang and Eisenstein, 2015), topic classification (Hovy, 2015) and user attribute inference (Li et al., 2015). We assume Twitter users will have similar interests in real world entities to their near neighbors — an assumption of *entity homophily* — which

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1452–1461,
Austin, Texas, November 1-5, 2016.

is demonstrated in Figure 1. The social relation between users u_1 and u_2 may lead to more coherent topics in tweets t_1 and t_2. Therefore, by successfully linking the less ambiguous mention 'Red Sox' in tweet t_2 to the *Boston Red Sox* baseball team, the tweet entity linking system will be more confident on linking 'Giants' to the *San Francisco Giants* football team in tweet t_1.

To exploit social information, we adopt the recent advance on embedding information networks (Tang et al., 2015), which induces low-dimensional representations for author nodes based on the network structure. By learning the semantic interactions between the author embeddings and the pre-trained Freebase entity embeddings, the entity linking system can incorporate more disambiguating context from the social network. We also consider low-dimensional representations of mentions, another source of related information for entity linking, with the intuition that semantically related mentions can refer to similar entities. Previously proposed approaches (Guo et al., 2013a; Yang and Chang, 2015) are based on hand-crafted features and off-the-shelf machine learning algorithms. Our preliminary study suggests that simply augmenting the traditional surface features with the distributed representations barely improves the performance of these entity linking systems. Therefore, we propose NTEL, a **N**eural model for **T**weet **E**ntity **L**inking, to leverage the distributed representations of authors, mentions, and entities. NTEL can not only make efficient use of statistical surface features built from a knowledge base, but also learn the interactions between these distributed representations.

Our contributions are summarized as follows:

- We present a novel model for entity linking that exploits distributed representations of users, mentions, and entities.
- We combine this distributed model with a feed-forward neural network that learns non-linear combinations of surface features.
- We perform message-level inference using a dynamic program to avoid overlapping mentions. The architecture is trained with loss-augmented decoding, a large margin learning technique for structured prediction.

Data	# Tweet	# Entity	Date
NEEL-train	2,340	2,202	Jul. - Aug. 2011
NEEL-test	1,164	687	Jul. - Aug. 2011
TACL	500	300	Dec. 2012

Table 1: Statistics of data sets.

- The complete system, NTEL, outperforms the previous state-of-the-art (Yang and Chang, 2015) by 3% average F1 on two benchmark datasets.

2 Data

Two publicly available datasets for tweet entity linking are adopted in the work. NEEL is originally collected and annotated for the Named Entity Extraction & Linking Challenge (Cano et al., 2014), and TACL is first used and released by Fang and Chang (2014). The datasets are then cleaned and unified by Yang and Chang (2015). The statistics of the datasets are presented in Table 1.

3 Testing Entity Homophily

The hypothesis of *entity homophily*, as presented in the introduction, is that socially connected individuals are more likely to mention similar entities than disconnected individuals. We now test the hypothesis on real data before we start building our entity linking systems.

Twitter social networks We test the assumption on the users in the NEEL-train dataset. We construct three author social networks based on the follower, mention and retweet relations between the 1,317 authors in the NEEL-train dataset, which we refer as FOLLOWER, MENTION and RETWEET. Specifically, we use the Twitter API to crawl the friends of the NEEL users (individuals that they follow) and the mention/retweet links are induced from their most recent 3,200 tweets.[1] We exploit bi-directed links to create the undirected networks, as bi-directed links result in stronger social network ties than directed links (Kwak et al., 2010; Wu et al., 2011). The numbers of social relations for the networks are 1,604, 379 and 342 respectively.

[1] We are able to obtain at most 3,200 tweets for each Twitter user, due to the Twitter API limits.

Network	$sim(i \leftrightarrow j)$	$sim(i \not\leftrightarrow j)$
FOLLOWER	0.128	0.025
MENTION	0.121	0.025
RETWEET	0.173	0.025

Table 2: The average entity-driven similarity results for the networks.

Metrics We propose to use the *entity-driven similarity* between authors to test the hypothesis of entity homophily. For a user u_i, we employ a Twitter NER system (Ritter et al., 2011) to detect entity mentions in the timeline, which we use to construct a user entity vector $\mathbf{u}_i^{(ent)}$, so that $u_{i,j}^{(ent)} = 1$ iff user i has mentioned entity j.[2] The entity-driven similarity between two users u_i and u_j is defined as the cosine similarity score between the vectors $\mathbf{u}_i^{(ent)}$ and $\mathbf{u}_j^{(ent)}$. We evaluate the three networks by calculating the average entity-driven similarity of the connected user pairs and that of the disconnected user pairs, which we name as $sim(i \leftrightarrow j)$ and $sim(i \not\leftrightarrow j)$.

Results The entity-driven similarity results of these networks are presented in Table 2. As shown, $sim(i \leftrightarrow j)$ is substantially higher than $sim(i \not\leftrightarrow j)$ on all three social networks, indicating that socially connected individuals clearly tend to mention more similar entities than disconnected individuals. Note that $sim(i \not\leftrightarrow j)$ is approximately equal to the same base rate defined by the average entity-driven similarity of all pairs of users, because the vast majority of user pairs are disconnected, no matter how to define the network. Among the three networks, RETWEET offers slightly higher $sim(i \leftrightarrow j)$ than FOLLOWER and MENTION. The results verify our hypothesis of entity homophily, which forms the basis for this research. Note that all social relation data was acquired in March 2016; by this time, the authorship information of 22.1% of the tweets in the NEEL-train dataset was no longer available, because the tweets or user accounts had been deleted.

4 Method

In this section, we present, NTEL, a novel neural based tweet entity linking framework that is able to leverage social information. We first formally define the task of tweet entity linking. Assume we are given an entity database (e.g., Wikipedia or Freebase), and a lexicon that maps a surface form into a set of entity candidates. For each input tweet, we consider any n-grams of the tweet that match the lexicon as mention candidates.[3] The entity linking system maps every mention candidate (e.g., 'Red Sox') in the message to an entity (e.g., *Boston Red Sox*) or to **Nil** (i.e., not an entity). There are two main challenges in the problem. First, a mention candidate can often potentially link to multiple entities according to the lexicon. Second, as shown in Figure 2, many mention candidates overlap with each other. Therefore, the entity linking system is required to disambiguate entities and produce non-overlapping entity assignments with respect to the mention candidates in the tweet.

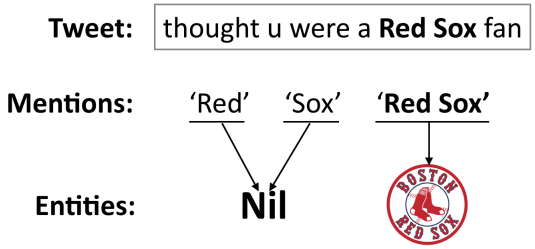

Figure 2: Illustration of the non-overlapping structure for the task of tweet entity linking. In order to link 'Red Sox' to a real entity, 'Red' and 'Sox' should be linked to **Nil**.

We formalize this task as a structured learning problem. Let $\mathbf{x}$ be the tweet, u be the author, and $\mathbf{y} = \{y_t\}_{t=1}^{T}$ be the entity assignments of the T mention candidates in the tweet. The overall scoring function $s(\mathbf{x}, \mathbf{y}, u)$ can be decomposed as follows,

$$s(\mathbf{x}, \mathbf{y}, u) = \sum_{t=1}^{T} g(\mathbf{x}, y_t, u, t), \qquad (1)$$

where $g(\mathbf{x}, y_t, u, t)$ is the scoring function for the t-th mention candidate choosing entity y_t. Note that the system needs to produce non-overlapping entity assignments, which will be resolved in the inference algorithm.

The overview of NTEL is illustrated in Figure 3. We further break down $g(\mathbf{x}, y_t, u, t)$ into two scoring

[2] We assume each name corresponds to a single entity for this metric, so this metric only approximates entity homophily.

[3] We adopted the same entity database and lexicon as those used by Yang and Chang (2015).

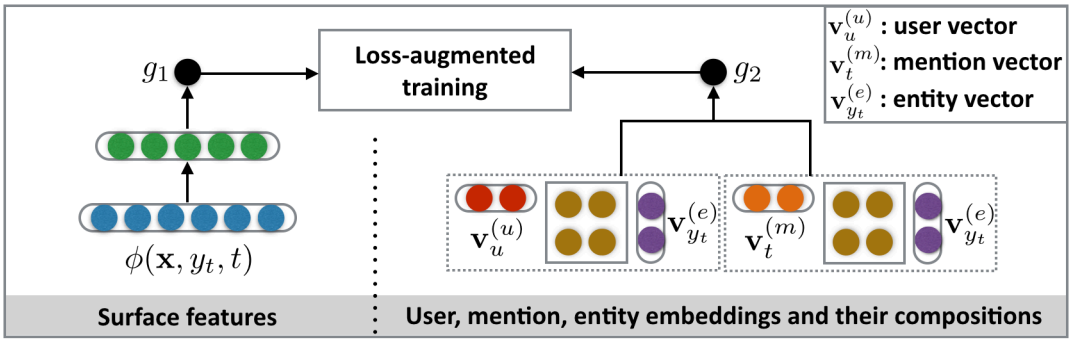

Figure 3: The proposed neural network approach for tweet entity linking. A composition model based on bilinear functions is used to learn the semantic interactions of user, mention, and entity.

functions:

$$g(\mathbf{x}, y_t, u, t; \Theta_1, \Theta_2) = g_1(\mathbf{x}, y_t, t; \Theta_1) + g_2(\mathbf{x}, y_t, u, t; \Theta_2), \quad (2)$$

where g_1 is the scoring function for our basic surface features, and g_2 is the scoring function for modeling user, mention, entity representations and their compositions. Θ_1 and Θ_2 are model parameters that will be detailed below. We choose to use a multilayer perceptron (MLP) to model $g_1(\mathbf{x}, y_t, t; \Theta_1)$, and we employ simple yet efficient bilinear functions to learn the compositions of user, mention, and entity representations $g_2(\mathbf{x}, y_t, u, t; \Theta_2)$. Finally, we present a training algorithm based on loss-augmented decoding and a non-overlapping inference algorithm.

4.1 Modeling Surface Features

We include the 37 features used by Yang and Chang (2015) as our surface feature set. These features are extracted from various sources, including a named entity recognizer, an entity type recognizer, and some statistics of the Wikipedia pages.

We exploit a multilayer perceptron (MLP) to transform the surface features to a real-valued score. The output of the MLP is formalized as follows,

$$g_1(\mathbf{x}, y_t, t; \Theta_1) = \boldsymbol{\beta}^\top \mathbf{h} + b$$
$$\mathbf{h} = \tanh(\mathbf{W}\phi(\mathbf{x}, y_t, t) + \mathbf{b}), \quad (3)$$

where $\phi(\mathbf{x}, y_t, t)$ is the feature function, $\mathbf{W}$ is an $M \times D$ matrix, the weights $\mathbf{b}$ are bias terms, and $\mathbf{h}$ is the output of the hidden layer of the MLP. $\boldsymbol{\beta}$ is an M dimensional vector of weights for the output score, and b is the bias term. The parameters of the MLP are $\Theta_1 = \{\mathbf{W}, \mathbf{b}, \boldsymbol{\beta}, b\}$. Yang and Chang (2015) argue that non-linearity is the key for obtaining good results on the task, as linear models are not expressive enough to capture the high-order relationships between the dense features. They propose a tree-based non-linear model for the task. The MLP forms simple non-linear mappings between the input features and the output score, whose parameters will be jointly learnt with other components in NTEL.

4.2 Modeling User, Mention, and Entity

To leverage the social network structure, we first train low-dimensional embeddings for the authors using the social relations. The mention and entity representations are given by word embeddings learnt with a large Twitter corpus and pre-trained Freebase entity embeddings respectively. We will denote the user, word, entity embedding matrices as:

$$\mathbf{E}^{(u)} = \{\mathbf{v}_u^{(u)}\} \quad \mathbf{E}^{(w)} = \{\mathbf{v}_w^{(w)}\} \quad \mathbf{E}^{(e)} = \{\mathbf{v}_e^{(e)}\},$$

where $\mathbf{E}^{(u)}, \mathbf{E}^{(w)}, \mathbf{E}^{(e)}$ are $V^{(u)} \times D^{(u)}, V^{(w)} \times D^{(w)}, V^{(e)} \times D^{(e)}$ matrices, and $\mathbf{v}_u^{(u)}$, $\mathbf{v}_w^{(w)}$, $\mathbf{v}_e^{(e)}$ are $D^{(u)}$, $D^{(w)}$, $D^{(e)}$ dimensional embedding vectors respectively. $V^{(u)}, V^{(w)}, V^{(e)}$ are the vocabulary sizes for users, words, and entities. Finally, we present a composition model for learning semantic interactions between user, mention, and entity.

User embeddings We obtain low-dimensional Twitter author embeddings $\mathbf{E}^{(u)}$ using *LINE* — the recently proposed model for embedding information networks (Tang et al., 2015). Specifically, we train *LINE* with the second-order proximity, which assumes that Twitter users sharing many neighbors are

close to each other in the embedding space. According to the original paper, the second-order proximity yields slightly better performances than the first-order proximity, which assumes connecting users are close to each other, on a variety of downstream tasks.

Mention embeddings The representation of a mention is the average of embeddings of words it contains. As each mention is typically one to three words, the simple representations often perform surprisingly well (Socher et al., 2013). We adopt the structured skip-gram model (Ling et al., 2015) to learn the word embeddings $\mathbf{E}^{(w)}$ on a Twitter corpus with 52 million tweets (Owoputi et al., 2013). The mention vector of the t-th mention candidate can be written as:

$$\mathbf{v}_t^{(m)} = \frac{1}{|\mathbf{x}_t^{(w)}|} \sum_{w \in \mathbf{x}_t^{(w)}} \mathbf{v}_w^{(w)}, \quad (4)$$

where $\mathbf{x}_t^{(w)}$ is the set of words in the mention.

Entity embeddings We use the pre-trained Freebase entity embeddings released by Google to represent entity candidates, which we refer as $\mathbf{E}^{(e)}$.[4] The embeddings are trained with the skip-gram model (Mikolov et al., 2013) on 100 billion words from various news articles. The entity embeddings can also be learnt from Wikipedia hyperlinks or Freebase entity relations, which we leave as future work.

Compositions of user, mention, and entity The distributed representations of users, mentions, and entities offer additional information that is useful for improving entity disambiguation capability. In particular, we explore the information by making two assumptions: socially connected users are interested in similar entities (entity homophily), and semantically related mentions are likely to be linked to similar entities.

We utilize a simple composition model that takes the form of the summation of two bilinear scoring functions, each of which explicitly leverages one of the assumptions. Given the author representation $\mathbf{v}_u^{(u)}$, the mention representation $\mathbf{v}_t^{(m)}$, and the entity representation $\mathbf{v}_{y_t}^{(e)}$, the output of the model can be written as:

$$\begin{aligned} g_2(\mathbf{x}, y_t, u, t; \Theta_2) =& {\mathbf{v}_u^{(u)}}^\top \mathbf{W}^{(u,e)} \mathbf{v}_{y_t}^{(e)} \\ &+ {\mathbf{v}_t^{(m)}}^\top \mathbf{W}^{(m,e)} \mathbf{v}_{y_t}^{(e)}, \end{aligned} \quad (5)$$

where $\mathbf{W}^{(u,e)}$ and $\mathbf{W}^{(m,e)}$ are $D^{(u)} \times D^{(e)}$ and $D^{(w)} \times D^{(e)}$ bilinear transformation matrices. Similar bilinear formulation has been used in the literature of knowledge base completion and inference (Socher et al., 2013; Yang et al., 2014). The parameters of the composition model are $\Theta_2 = \{\mathbf{W}^{(u,e)}, \mathbf{W}^{(m,e)}, \mathbf{E}^{(u)}, \mathbf{E}^{(w)}, \mathbf{E}^{(e)}\}$.

4.3 Non-overlapping Inference

The non-overlapping constraint for entity assignments requires inference method that is different from the standard Viterbi algorithm for a linear chain. We now present a variant of the Viterbi algorithm for the non-overlapping structure. Given the overall scoring function $g(\mathbf{x}, y_t, u, t)$ for the t-th mention candidate choosing an entity y_t, we sort the mention candidates by their end indices and define the Viterbi recursion by

$$\hat{y}_t = \underset{y_t \in \mathcal{Y}_{\mathbf{x}_t}, y_t \neq \textbf{Nil}}{\arg\max}\ g(\mathbf{x}, y_t, u, t) \quad (6)$$

$$a(1) = \max(g(\mathbf{x}, \textbf{Nil}, u, 1), g(\mathbf{x}, \hat{y_1}, u, 1)) \quad (7)$$

$$a(t) = \max\left(\psi_t(\textbf{Nil}), \psi_t(\hat{y}_t)\right) \quad (8)$$

$$\psi_t(\textbf{Nil}) = g(\mathbf{x}, \textbf{Nil}, u, t) + a(t-1) \quad (9)$$

$$\begin{aligned} \psi_t(\hat{y}_t) =& g(\mathbf{x}, \hat{y}_t, u, t) + \sum_{prev(t) < t' < t} g(\mathbf{x}, \textbf{Nil}, u, t') \\ &+ a(prev(t)) \end{aligned} \quad (10)$$

where $\mathcal{Y}_{\mathbf{x}_t}$ is set of entity candidates for the t-th mention candidate, and $prev(t)$ is a function that points out the previous non-overlapping mention candidate for the t-th mention candidate. We exclude any second-order features between entities. Therefore, for each mention candidate, we only need to decide whether it can take the highest scored entity candidate $\hat{y}_t$ or the special **Nil** entity based on whether it is overlapped with other mention candidates.

[4] Available at https://code.google.com/archive/p/word2vec/

4.4 Loss-augmented Training

The parameters need to be learnt during training are $\Theta = [\Theta_1, \{\mathbf{W}^{(u,e)}, \mathbf{W}^{(m,e)}\}]$.[5] We train NTEL by minimizing the following loss function for each training tweet:

$$L(\Theta) = \max_{\mathbf{y} \in \mathcal{Y}_\mathbf{x}} (\Delta(\mathbf{y}, \mathbf{y}^*) + s(\mathbf{x}, \mathbf{y}, u)) - s(\mathbf{x}, \mathbf{y}^*, u), \quad (11)$$

where $\mathbf{y}^*$ is the gold structure, $\mathcal{Y}_\mathbf{x}$ represents the set of valid output structures for $\mathbf{x}$, and $\Delta(\mathbf{y}, \mathbf{y}^*)$ is the weighted hamming distance between the gold structure $\mathbf{y}^*$ and the valid structure $\mathbf{y}$. The hamming loss is decomposable on the mention candidates, which enables efficient inferences. We set the hamming loss weight to 0.2 after a preliminary search. Note that the number of parameters in our composition model is large. Thus, we include an L2 regularizer on these parameters, which is omitted from Equation 11 for brevity. The evaluation of the loss function corresponds to the loss-augmented inference problem:

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y} \in \mathcal{Y}_\mathbf{x}} (\Delta(\mathbf{y}, \mathbf{y}^*) + s(\mathbf{x}, \mathbf{y}, u)), \quad (12)$$

which can be solved by the above non-overlapping inference algorithm. We employ vanilla SGD algorithm to optimize all the parameters. The numbers of training epochs are determined by early stopping (at most 1000 epochs). Training takes 6-8 hours on 4 threads.

5 Experiments

In this section, we evaluate NTEL on the NEEL and TACL datasets as described in § 2, focusing on investigating whether social information can improve the task. We also compare NTEL with the previous state-of-the-art system.

5.1 Social Network Expansion

We utilize Twitter follower, mention, and retweet social networks to train user embeddings. We were able to identify 2,312 authors for the tweets of the two datasets in March 2016. We then used the Twitter API to crawl their friend links and timelines, from which we can induce the networks. We find the numbers of social connections (bidirectional links) between these users are relatively small. In order to learn better user embeddings, we expand the set of author nodes by including nodes that will do the most to densify the author networks. For the follower network, we add additional individuals who are followed by at least twenty authors in the original set. For the mention or retweet networks, we add all users who have mentioned or retweeted by at least ten authors in the original set. The statistics of the resulting networks are presented in Table 3.

Network	# Author	# Relation
FOLLOWER+	8,772	286,800
MENTION+	6,119	57,045
RETWEET+	7,404	59,313

Table 3: Statistics of author social networks used for training user embeddings.

5.2 Experimental Settings

Following Yang and Chang (2015), we train all the models with the NEEL-train dataset and evaluate different systems on the NEEL-test and TACL datasets. In addition, 800 tweets from the NEEL-train dataset are sampled as our development set to perform parameter tuning. Note that Yang and Chang (2015) also attempt to optimize F1 scores by balancing precision and recall scores on the development set; we do not fine tune our F1 in this way, so that we can apply a single trained system across different test sets.

Metrics We follow prior work (Guo et al., 2013a; Yang and Chang, 2015) and perform the standard evaluation for an end-to-end entity linking system, computing precision, recall, and F1 score according to the entity references and the system outputs. An output entity is considered as correct if it matches the gold entity and the mention boundary overlaps with the gold mention boundary. More details about the metrics are described by Carmel et al. (2014).

Competitive systems Our first baseline system, NTEL-nonstruct, ignores the structure information and makes the entity assignment decision for each mention candidate individually. For NTEL, we start with a baseline system using the surface features, and then incorporate the two bilinear functions

[5] We fixed the pre-trained embedding matrices during loss-augmented training.

(user-entity and mention-entity) described in Equation 5 incrementally. Our main evaluation uses the RETWEET+ network, since the retweet network had the greatest entity homophily; an additional evaluation compares across network types.

Parameter tuning We tune all the hyper-parameters on the development set, and then re-train the models on the full training data with the best parameters. We choose the number of hidden units for the MLP from $\{20, 30, 40, 50\}$, and the regularization penalty for our composition model from $\{0.001, 0.005, 0.01, 0.05, 0.1\}$. The sizes of user embeddings and word embeddings are selected from $\{50, 100\}$ and $\{200, 400, 600\}$ respectively. The pre-trained Freebase entity embedding size is 1000. The learning rate for the SGD algorithm is set as 0.01. During training, we check the performance on the development set regularly to perform early stopping.

5.3 Results

Table 4 summarizes the empirical findings for our approach and S-MART (Yang and Chang, 2015) on the tweet entity linking task. For the systems with user-entity bilinear function, we report results obtained from embeddings trained on RETWEET+ in Table 4, and other results are available in Table 5. The best hyper-parameters are: the number of hidden units for the MLP is 40, the L2 regularization penalty for the composition parameters is 0.005, and the user embedding size is 100. For the word embedding size, we find 600 offers marginal improvements over 400 but requires longer training time. Thus, we choose 400 as the size of word embeddings.

As presented in Table 4, NTEL-nonstruct performs 2.7% F1 worse than the NTEL baseline on the two test sets, which indicates the non-overlapping inference improves system performance on the task. With structured inference but without embeddings, NTEL performs roughly the same as S-MART, showing that a feedforward neural network offers similar expressivity to the regression trees employed by Yang and Chang (2015).

Performance improves substantially with the incorporation of low-dimensional author, mention, and entity representations. As shown in Table 4, by learning the interactions between mention and entity representations, NTEL with mention-entity bilinear function outperforms the NTEL baseline system by 1.8% F1 on average. Specifically, the bilinear function results in considerable performance gains in recalls, with small compromise in precisions on the datasets.

Social information helps to increase about 1% F1 on top of both the NTEL baseline system and the NTEL system with mention-entity bilinear composition. In contrast to the mention-entity composition model, which mainly focuses on improving the baseline system on recall scores, the user-entity composition model increases around 2.5% recalls, without much sacrifice in precisions.

Our best system achieves the state-of-the-art results on the NEEL-test dataset and the TACL dataset, outperforming S-MART by 0.9% and 5.4% F1 scores respectively. To establish the statistical significance of the results, we obtain 100 bootstrap samples for each test set, and compute the F1 score on each sample for each algorithm. Two-tail paired t-test is then applied to determine if the F1 scores of two algorithms are significantly different. NTEL significantly outperforms S-MART on the NEEL-test dataset and the TACL dataset under $p < 0.01$ level, with t-statistics equal to 11.5 and 33.6 respectively.

As shown in Table 5, MENTION+ and RETWEET+ perform slightly better than FOLLOWER+. Puniyani et al. (2010) show that the mention network has stronger linguistic properties than the follower network, as it gives better correlations on each author's distribution over latent topics as induced by latent Dirichlet allocation (Blei et al., 2003). Our results suggest that the properties hold with respect to the authors' interests on real world entities.

5.4 Error Analysis & Discussion

We examine the outputs of different systems, focusing on investigating what errors are corrected by the two bilinear functions. The results reveal that the mention-entity composition improves the system ability to tackle mentions that are abbreviations such as 'WSJ' (*The Wall Street Journal*) and 'SJSU' (*San Jose State University*), which leads to higher recall scores. The mention-entity model also helps to eliminate errors that incorrectly link non-entities to popular entities. For example, the NTEL baseline

System	user -entity	mention -entity	NEEL-test			TACL			Avg. F1

Table 5: Comparison of different social networks with our full model. The best results are in **bold**.

system links 'sec' in the tweet 'I'm a be in Miami for sec to hit da radio!' to *Southeastern Conference*, which is corrected by the mention-entity composition model. The word semantic information encoded in the mention representations alleviates the biased entity information given by the surface features.

The user-entity composition model is good at handling highly ambiguous mentions. For example, our full model successfully disambiguates entities for mentions such as 'Sox' (*Boston Red Sox* vs. *Chicago White Sox*), 'Sanders' (*Bernie Sanders* vs. *Barry Sanders*), and 'Memphis' (*Memphis Grizzlies* vs. *Memphis, Tennessee*), which are mistakenly linked to the other entities or **Nil** by the mention-entity model. Another example is that the social network information helps the system correctly link 'Kim' to *Lil' Kim* instead of *Kim Kardashian*, despite that the latter entity's wikipedia page is considerably more popular.

6 Related Work

Tweet entity linking Previous work on entity linking mainly focuses on well-written documents (Bunescu and Pasca, 2006; Cucerzan, 2007; Milne and Witten, 2008), where entity disambiguation is usually performed by maximizing the global topical coherence between entities. However, these approaches often yield unsatisfactory performance on Twitter messages, due to the short and noisy nature of the tweets. To tackle this problem, collective tweet entity linking methods that leverage enriched context and metadata information have been proposed (Huang et al., 2014). Guo et al. (2013b) search for textually similar tweets for a target tweet, and encourage these Twitter messages to contain similar entities through label propagation. Shen et al. (2013) employ Twitter user account information to improve entity linking, based on the intuition that all tweets posted by the same user share an underlying topic distribution. Fang and Chang (2014) demonstrate that spatial and temporal signals are critical for the task, and they advance the performance by associating entity prior distributions with different timestamps and locations. Our work overcomes the difficulty by leveraging social relations — socially connected individuals are assumed to share similar interests on entities. As the Twitter post information is often sparse for some users, our assumption enables the utilization of more relevant information that helps to improve the task.

NLP with social relations Most previous work on incorporating social relations for NLP problems focuses on Twitter sentiment analysis, where the existence of social relations between users is considered as a clue that the sentiment polarities of messages from the users should be similar. Speriosu et al. (2011) construct a heterogeneous network with tweets, users, and n-grams as nodes, and the sentiment label distributions associated with the nodes

are refined by performing label propagation over social relations. Tan et al. (2011) and Hu et al. (2013) leverage social relations for sentiment analysis by exploiting a factor graph model and the graph Laplacian technique respectively, so that the tweets belonging to social connected users share similar label distributions. We work on entity linking in Twitter messages, where the label space is much larger than that of sentiment classification. The social relations can be more relevant in our problem, as it is challenging to obtain the entity prior distribution for each individual.

7 Conclusion

We present a neural based structured learning architecture for tweet entity linking, leveraging the tendency of socially linked individuals to share similar interests on named entities — the phenomenon of *entity homophily*. By modeling the compositions of vector representations of author, entity, and mention, our approach is able to exploit the social network as a source of contextual information. This vector-compositional model is combined with nonlinear feature combinations of surface features, via a feedforward neural network. To avoid predicting overlapping entity mentions, we employ a structured prediction algorithm, and train the system with loss-augmented decoding.

Social networks arise in other settings besides microblogs, such as webpages and academic research articles; exploiting these networks is a possible direction for future work. We would also like to investigate other metadata attributes that are relevant to the task, such as spatial and temporal signals.

Carnegie Mellon University

Abstract

Named Entity Recognition is a well established information extraction task with many state of the art systems existing for a variety of languages. Most systems rely on language specific resources, large annotated corpora, gazetteers and feature engineering to perform well monolingually. In this paper, we introduce an attentional neural model which only uses language universal phonological character representations with word embeddings to achieve state of the art performance in a monolingual setting using supervision and which can quickly adapt to a new language with minimal or no data. We demonstrate that phonological character representations facilitate cross-lingual transfer, outperform orthographic representations and incorporating both attention and phonological features improves statistical efficiency of the model in 0-shot and low data transfer settings with no task specific feature engineering in the source or target language.

1 Introduction

Named Entity Recognition (NER) (Nadeau and Sekine, 2007; Marrero et al., 2013) is an information extraction task that deals with finding and classifying entities in text into a fixed set of types of interest. It is challenging for a variety of reasons. Named Entities (NEs) can be arbitrarily synthesized (eg. people's/organization's names). NEs are often not subject to uniform cross-linguistic spelling conventions: compare *France* (English) and *Frantsiya* (Uzbek). NEs occur rarely in data which makes generalization difficult. Skewed class statistics necessitate measures to prevent models from merely favoring a majority class.

Named entities must also be annotated in context (eg. "[New York Times]$_{\text{ORG}}$" vs. "[New York]$_{\text{LOC}}$"). Lexical ambiguity (Turkey—country vs. bird), semantic ambiguity ("I work at the [New York Times]$_{\text{ORG}}$" vs. "I read the New York Times") and sparsity induced by morphology add complexity.

Despite the challenges mentioned above, competent monolingual systems that rely on having sufficient annotated data, knowledge and resources available for engineering features have been developed. A more challenging task is to design a model that retains competence in monolingual scenarios and can easily be transferred to a low resource language with minimum overhead in terms of data annotation requirements and feature engineering. This transfer setting introduces additional challenges such as varying character usage conventions across languages with same script, differing scripts, lack of NE transliteration, varying morphology, different lexicons and mutual non-intelligibility to name a few.

We propose the following changes over prior work (Lample et al., 2016) to address the challenges of the low-resource transfer setting. We use:

1. Language universal phonological character representations instead of orthographic ones.

2. Attention over characters of a word while labeling it with an NE category.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1462–1472,
Austin, Texas, November 1-5, 2016.

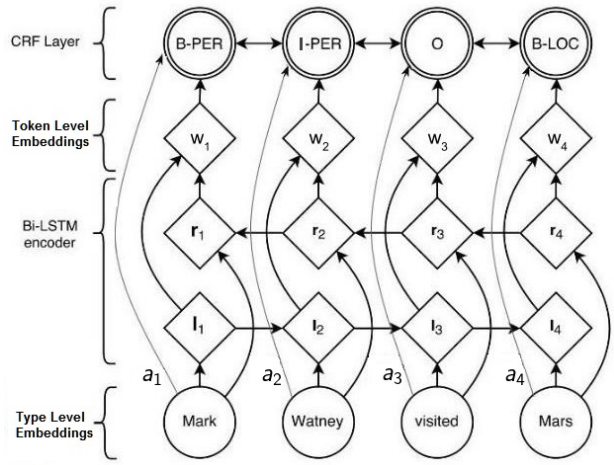

Figure 1: Attentional LSTM-CRF architecture. l_i denotes the encoding of a word and its left context (forward LSTM) while r_i includes only right context (backward LSTM). Inputs to word LSTMs are obtained using character LSTMs and word-embeddings. a_i denotes an attentional context vector concatenated with l_i and r_i.

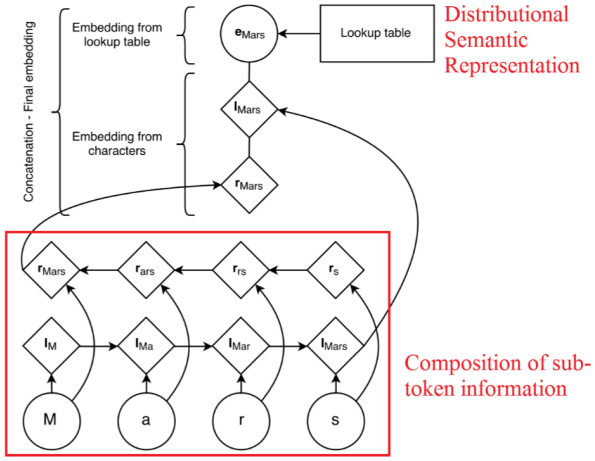

Figure 2: Type level word representations - l denotes a word prefix encoding (by forward char LSTM) while r denotes a word suffix encoding (by backward char LSTM).

We show that using phonological character representations instead does not negatively impact performance on two languages: Spanish and Turkish. We then show that using global phonological representations enables model transfer from one or more source languages to a target language with no extra effort, even when the languages use different scripts. We demonstrate that while attention over characters of words has marginal utility in monolingual and high resource settings, it greatly improves the statistical efficiency of the model in 0-shot and low resource transfer settings. We do require a mapping from a language's script to phonological feature space which is script specific and not task specific. This presents little or no overhead due to existence of tools like PanPhon (Littell et al., 2016).

2 Our Approach

Figure 1 provides a high level overview of our model. We model the words of a sentence at the type level and the token level. At the type level (ignorant of sentential context), we use bidirectional character LSTMs as in figure 2 to compose characters of a word to obtain its word representation and concatenate this with a word embedding that captures distributional semantics. This can memorize entities or capture morphological and suffixal clues that can help at a discriminative task like NER. We compose type level word representations with bidirectional LSTMs to obtain token level (cognizant of sentential context) representations. Using token level word representations along with an attentional context vector for each word based on the sequence of characters it contains, we generate score functions used by a Conditional Random Field (CRF) for inference. To facilitate transfer across languages with different scripts, we use Epitran [1] and PanPhon (Littell et al., 2016).

Epitran is a straightforward orthography-to-IPA (International Phonetic Alphabet [language universal]) system including a collection of preprocessors and grapheme-to-phoneme mappings for a variety of language-script pairs. It converts a word from its native script into a sequence of IPA characters, each of which approximately corresponds to a phoneme. PanPhon is a database of IPA-to-phonological feature vector mappings and a library for querying, manipulating, and exploiting this database. It consumes the output of Epitran and produces feature vectors (21 dimensions) of phonological characteristics such as whether a phoneme is articulated with (accompanied by) vibration of the vocal folds (voiced), with the tongue in a high, low, back, or front position, with the lips rounded or unrounded, with tongue tip or blade (coronal), etc. Figure 3 depicts the sequence of operations applied to the same NE

[1] https://github.com/dmort27/epitran

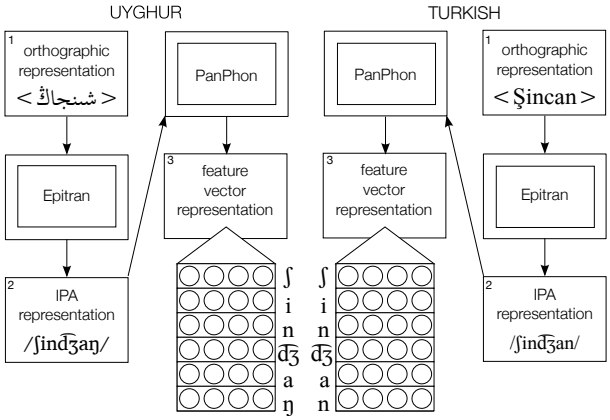

Figure 3: Use of Epitran and PanPhon to enable transfer across orthographies

in Uyghur (Perso-Arabic script) and Turkish (Latin script), thus making the equivalence across scripts apparent. We concatenate the feature vectors from PanPhon and 1-hot encodings of the corresponding IPA characters and use these as inputs to the character bi-LSTMs.

This shift to IPA space is motivated by prior work (Tsvetkov et al., 2015; Tsvetkov and Dyer, 2015) which demonstrated the value of projecting orthographic surface forms of words into a phonological space for detecting loan words, transliteration and cognates even in language pairs that exhibit significant typological, morphological and phonological differences. Our underlying assumption is that named entities are likely to be transliterated or retain pronunciation patterns across languages. Additionally, phenomena such as vowel harmony manifest explicitly in IPA representation and can potentially be helpful for NER. Foreign named entities for example, need not obey vowel harmony rules prevalent in languages like Turkish. A powerful sequence model such as a LSTM could be tolerant to the noise created by lexical aberrations, lack of spelling conventions, vowel raising etc. when given a phonological representation of an NE in different languages.

Our second proposed change is to incorporate attention over the sequence of IPA segments in a word when predicting scores for its possible labels. Attention is an unsupervised alternative to convolution or feature engineering to capture helpful localized phenomena like capitalization of first letter, presence of case markers, special characters, helpful morphological suffixes etc. or the conjunction of multiple such phenomena. Such features have been the mainstay of most prior work for NER. Most of these features are subtle and occur at the type level, whereas the CRF performs inference at the token level. We show (empirically) that attention makes the CRF more sensitive to such useful type level phenomena during inference and improves the statistical efficiency of the model in certain scenarios. Having described our intuitions, we now provide mathematical details of our model.

2.1 Model Description

2.1.1 LSTM

Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) belongs to a special breed of neural networks called Recurrent Neural Networks (RNNs) which are capable of processing sequential input of unbounded and arbitrary length. This makes them suitable for a sequence labeling task. LSTMs incorporate gating functions at each time step to allow the network to forget, remember and update contextual memory and mitigate problems like vanishing gradient. We use the following implementation:

$$
\begin{aligned}
i_t =& \sigma\left(W_{xi}x_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i\right) \\
c_t =& (1 - i_t) \odot c_{t-1} + \\
& i_t \odot \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \\
o_t =& \sigma\left(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_t + b_o\right) \\
h_t =& o_t \odot \tanh(c_t)
\end{aligned}
$$

where $\odot$ indicates element-wise product and σ indicates element-wise sigmoid function.

In practice we use bi-directional LSTMs (each with its own parameters) to mitigate cases where the LSTM may be biased towards the last few inputs it reads. This is done both at the word-level and the character level. Let the hidden state at time step **t** of the forward LSTM be denoted by $\overrightarrow{h_t}$ and the corresponding state of the backward LSTM be denoted by $\overleftarrow{h_t}$. At the character level, for a word with L characters, we only take the final hidden states in each direction i.e. $[\overrightarrow{h_L}; \overleftarrow{h_0}]$ and concatenate them to get a representation of the word that comprises these characters. At the word level, we concatenate corresponding forward and backward LSTM states for each word X_t to get $[\overrightarrow{h_t}; \overleftarrow{h_t}]$ which is the token

level representation for the t^{th} word in a sentence X. We use this to generate un-normalized energy/score functions for the CRF layer.

2.2 Attention

Let $w_t = [\overrightarrow{h_t}; \overleftarrow{h_t}]$ indicate the concatenated word bi-LSTM output (of dimension d_1) at step t corresponding to the t^{th} word (X_t) in the input sequence X. Let M_t be the matrix containing the concatenated bi-directional character LSTM outputs for each character of X_t. It has dimensions (l_t, d_2) where d_2 is the dimension of the concatenated bi-directional character LSTM hidden states and l_t is the number of characters in X_t. Let m_t^i denote the i^{th} row of M_t. Let P be a parameter matrix of dimension (d_1, d_2) and *p* be a bias vector of length d_2. We follow (Bahdanau et al., 2014) in the formulation of attention context vector a_t:

$$w'_t = \tanh(w_t \cdot P + p)$$
$$\alpha_i = \frac{\exp(w'_t \cdot m_t^i)}{\sum_{j=1}^{l_t} \exp(w'_t \cdot m_t^j)}$$
$$a_t = \sum_{i=1}^{l_t} (\alpha_i * m_t^i)$$

The attentional context vector a_t is then appended to w_t to obtain concatenated vector u_t = $[a_t; w_t]$. We apply a linear transform U (matrix of dimension $(d_1 + d_2, k)$ where *k* is the number of unique NER tags). This gives us:

$$e_t = u_t \cdot U \tag{1}$$

where e_t is a vector of un-normalized energy/score functions indicating the compatibility between word X_t and each of the *k* possible NER labels it can be given. Note that each word has a separate attention context vector obtained using the character LSTM hidden states generated by its constituent characters.

2.3 Conditional Random Field

Unlike Hidden Markov Models, CRFs do not enforce any independence assumptions among observed data and directly model the likelihood of a labeling hypothesis discriminatively. They also model adjacency compatibility between NER tags which can capture strong constraints like an 'I-label' tag not following an O tag without a 'B-label' tag in between them (see section 2.6). In our model, the CRF is parametrized as follows:

For a word sequence X = $(x_1, x_2, ...x_N)$, let **E** be a matrix of dimension (k,N) where k is the number of unique NER tags and N is the sequence length. The t^{th} column is the vector e_t obtained in equation 1. Let **T** be the square transition matrix of size (k+2, k+2) which captures transition score between the k NER tags, the start and the end symbols. Let Y = $(y_1, y_2, ...y_N)$ be the label sequence associated with the input word sequence, each y_i being an index into the ordered set of unique NER tags. Let y_0 be the start symbol and y_{N+1} be the end symbol. The score of this sequence is evaluated as:

$$S(X, Y) = \sum_{i=1}^{N} E_{y_i, i} + \sum_{j=0}^{N} T_{y_j, y_{j+1}}$$

Let $\mathcal{Y}_\mathcal{X}$ indicate the exponential space of all possible labelings of this sequence X. The partition function associated with this CRF is then evaluated as:

$$Z = \sum_{Y \in \mathcal{Y}_\mathcal{X}} e^{S(X,Y)}$$

The probability of a specific labeling $Y \in \mathcal{Y}_\mathcal{X}$:

$$P(Y|X) = \frac{e^{S(X,Y)}}{Z}$$

The training objective is to maximize conditional log probability of the correct labeling sequence Y^*:

$$log(P(Y^*|X)) = S(X, Y^*) - log\,(Z) \tag{2}$$

The decoding criteria for an input sequence X is:

$$Y^* = \underset{Y \in \mathcal{Y}_\mathcal{X}}{\arg\max}\, S(X, Y) \tag{3}$$

Normally, evaluating the partition function over the exponential space of all possible labelings would be intractable. However, as described in (Lafferty et al., 2001), this can be done efficiently for linear chain CRFs using the forward backward algorithm.

2.4 Word Representations

The inputs to our model are in the form of type level word representations (figure 2). Motivated by the distributional hypothesis (Harris, 1954; Firth, 1957)

we use word embeddings as inputs. In the monolingual scenario, we use structured skipgram word embeddings (Ling et al., 2015a). For the transfer scenario, embeddings can optionally be trained using techniques like multi CCA described in (Ammar et al., 2016). By learning a linear transformation from a shared vector space between languages, the model may acquire some transfer capability to the target language.

We use character bi-LSTMs to handle the Out Of Vocabulary (OOV) problem as in (Ling et al., 2015b). However, just as a distributional hypothesis exists for words, prior work (Tsvetkov and Dyer, 2015; Tsvetkov et al., 2015) suggests phonological character representations capture inherent similarities between characters that are not apparent from orthogonal one-hot orthographic character representations and can serve as a language universal surrogate for character representations. This is also useful for multi-lingual named entity recognition as explained in section 2. Therefore we make use of Epitran and PanPhon as in figure 3 to obtain both 1-hot IPA character encodings and phonological feature vectors capturing similarity between IPA characters. These form the inputs to the character bi-LSTMs. The mapping from orthographic character segments to IPA is sometimes many to one (ambiguous) and unarticulated characters (like periods in NE abbreviations) and capitalization information is lost by default. Given the importance of such orthographic features for NER and the ambiguity introduced, a drop in performance may be expected by using phonological character representations.

2.5 Training

Our model parametrization is similar to (Lample et al., 2016). The weights to be trained include the the CRF transition matrix **T**, the projection parameters are used to generate matrix **E** (P and U), the LSTM parameters and word and character embedding matrices. The objective is to maximize the log probability of the correct labeling sequence as given in equation 2. This objective is fully differentiable and standard back-propagation is used to learn weights. We use Stochastic Gradient Descent with a learning rate of 0.05 and gradients clipped at 5.0 providing best performance. Using Adadelta or Adam leads to faster convergence but slightly worse performance. Word level LSTMs use a hidden layer size of 100, orthographic character LSTMs (if used) used a hidden layer of size 25 while phonological character LSTMs used a hidden layer of size 15 due to the smaller phonetic alphabet. Tuning these did not have a major effect on performance. Dropout of 0.5 is applied after concatenation of the word embeddings and character LSTM outputs. Best dropout value was chosen through ablation studies. For Spanish, we use word embeddings pre-trained on the Spanish Gigaword version 3. For transfer experiments, we use multilingual word embeddings trained using multi CCA described in (Ammar et al., 2016).

2.6 Entity Types and Tagging Schemes

In all of the datasets in table 1, 4 entity types are annotated:

1. **Persons (PER)**
   Real/fictional, living/dead people. Aliases and family names are also annotated. E.g. Barack Obama, the [Kennedys], Puff Daddy etc.
2. **Locations (LOC)**
   Geographical locations without a dedicated population and government. E.g. Nile river, Sahara desert, Mt. Everest, Asia etc.
3. **Geo-Political Entities (GPE)**
   Geographical regions with corresponding population and government. Mentions can be nominal (e.g. India, E.U., Britain etc.) or adjectival (e.g. [British] army, [French] government etc.).
4. **Organizations (ORG)**
   Names of entities with organization and managerial structure. E.g. Democratic Party, Google, JetBlue, etc.

A BIO tagging scheme is used for all annotations. All non-entity tokens are annotated as 'O'. The first token of an entity span is annotated as 'B-label' and all remaining tokens in the entity span are annotated as 'I-label'.

3 Experiments

We conduct four different experiments:

1. CoNLL 2002 Spanish NER (Sang., 2002) task. This demonstrates the monolingual competence of phonological character representations vs. orthographic representations.

2. Turkish NER using the Linguistic Data Consortium's LDC2014E115 BOLT Turkish Language Pack [2]. This demonstrates the utility of phonological character representations and attention in a morphologically rich, low resource language. We compare against a state-of-the-art monolingual model (Lample et al., 2016) that uses orthographic character LSTMs.
3. Transfer Experiments from Uzbek to Turkish using LDC2014E112 BOLT [3] data pack for Uzbek and LDC2014E115 BOLT data pack for Turkish. These two languages have similar syntax and word order (Dryer, 2013) but vary significantly in morphology, vowel harmony and phonology, can use different scripts (Uzbek-Latin/Cyrilic, Turkish-Latin) and are not mutually intelligible.
4. Transfer Experiments from Uzbek and Turkish into Uyghur using LDC2014E112 and LDC2014E115 BOLT data pack for Uzbek and Turkish respectively and Uyghur data provided as part of DARPA LORELEI[4]. These languages all have different scripts, lexicons, morphology and phonology. Results are reported by NIST [5] on an unseen test set.

3.1 Results

Tables 2 and 3 report results from monolingual experiments in Spanish. In table 3, we report the performance of our best model against other state-of-the-art models for the Spanish CoNLL 2002 NER task (Sang., 2002). Our model performs marginally better than other benchmarks with the optimal configuration of hyper-parameters and using pre-trained word embeddings. Table 2 report ablation study results, which reveal that using pre-trained word embeddings without using character LSTMs yields a very strong baseline that already out-performs various previous benchmarks. Using character LSTMs that compose orthographic character representations yields a +0.91 improvement in F1 score and a further

+0.12 F1 with attention. Using phonological character representations instead yields an improvement of +0.47 F1 and a further +0.8 F1 with attention. Thus, phonological representations benefit more from attention applied over them to beat out orthographic representations in that scenario. Using sparse features indicating the character category (alphabet vs. number vs. punctuation/non-phonetic) and capitalization in conjunction with with phonological character representations and word embeddings with attention over phonological characters yields the best configuration that slightly outperforms the best published models so far. Given that many previous benchmarks used features that rely heavily on orthography, this is an encouraging result since one would expect to lose some performance by using more abstract phonological representations as explained in section 2.4.

Tables 4 and 5 highlight results from monolingual experiments on Turkish. This dataset is much more challenging since the annotated training courpus is significantly smaller than the CoNLL 2002 shared task dataset and because Turkish is an agglutinative language exhibiting sparsity inducing morphology which leads to huge vocabulary size. As a competitive baseline, we train the LSTM CRF described in (Lample et al., 2016) due to its documented ability to obtain state-of-the-art monolingual results for many languages with minimal feature engineering. Our best model from the Turkish ablation study outperforms this baseline. We also see a stark contrast between the ablation study results for Turkish compared to Spanish. Firstly, word embeddings alone perform rather poorly due to the challenges of reliably estimating them for a large vocabulary given a small dataset. Character composed representations of words provide a significant performance boost (+17.27 F1 for the best model). Secondly, usage of sparse character features (like capitalization) seems to hurt performance in all but the last model in table 4. Thirdly, phonological and orthographic character representations are complementary in the case of Turkish, unlike Spanish. This is not too surprising since Turkish exhibits phonological phenomena like vowel harmony. Lack of vowel harmony in a word could give-away a foreign word or a named entity for example. Results show that attention is helpful as well. We would also like to point out that the only models in the ablation studies eligible for transfer are those that do not use orthographic character representations. Among these, the model that uses phonological representation with attention and word vectors performs the best and also outperforms the baseline system.

Our next experiments on model transfer are arguably the most interesting. Tables 7 and 8 document single source (Uzbek to Turkish) transfer results. We find that using sparse character category and capitalization features in conjunction with attention and phonological features yields the best 0-shot transfer performance (no training labels in the target language). Specifically, attention provides +6 F1 in 0-shot and 5% labeled-target language data scenarios. It is interesting to note that using multilingual word embeddings for the source and target languages alone accounts for very poor transfer. We also find that with as little as 20% of the data, we approach the performance of a monolingual target model that was trained on all the data. We also notice that the transfer models retain a consistent advantage over a monolingually trained target language model across all data availability scenarios. Lastly, we note that while attention provides a significant improvement in 0-shot and 5% data availability scenarios, a model without attention (or sparse features like capitalization) eventually does better with more data. This indicates that the model is competent enough to leverage transfer via phonology alone. This could also possibly be because attention patterns from Uzbek could bring in a bias that is eventually sub-optimal for Turkish due to dif-

ferent morphology and phonology. In future work, we shall perform more insightful error analysis to explain these trends.

Table 6 documents NIST evaluation results on an unseen Uyghur test set (with gold annotations) for the best transfer model configuration jointly trained on Turkish and Uzbek gold annotations and Uyghur training annotations produced by a non-speaker linguist (non-gold). Since Uyghur lacks helpful type-level orthographic features such as capitalization, our transfer model in table 6 does not use any sparse features or attention but benefits from transfer via the phonological character representations we've proposed. Despite the noisy supervision provided in the target language, transferring from Turkish and Uzbek provides a +14.1 F1 improvement over a state of the art monolingual model trained on the same Uyghur annotations. It is worth pointing out that this transfer was achieved across 3 languages each with different scripts, morphology, phonology and lexicons.

4 Prior Work

NER is a well-studied sequence-labeling problem for which many different approaches have been proposed. Early works had a monolingual focus and relied heavily on feature engineering. Approaches include maximum entropy models (Chieu and Ng, 2003), hierarchically smoothed tries (Cucerzan and Yarowsky, 1999), decision trees (Carreras et al., 2002) and models incorporating syntactic, semantic and world knowledge (Wakao et al., 1996). Each of these models brings in a bias of its own. Florian et al. (2003) successfully tried ensembling multiple classifiers and improved performance.

Since NER is a sequence labeling problem, there are local dependencies both among NE labels associated with words and among the words themselves, that could aid the labeling process. To explicitly deal with these sequential characteristics, Hidden Markov Models (HMMs) and Conditional Random Fields (CRFs) became very popular. (Klein et al., 2003; Florian et al., 2003; McCallum and Li, 2003; Ratinov and Roth, 2009; Chandra et al., 1981; Lin and Wu, 2009; Lample et al., 2016; Yang et al., 2016; Ma and Hovy, 2016). CRFs eventually became more popular because they are discriminative models that directly model the required posterior probability of a labeling sequence using parametrized functions of features. They do not model the probability of the observed sentence itself, avoid Markovian independence assumptions made by HMMs and avoid the label bias problem.

Most of the work cited so far makes use of hand engineered features. The following approaches minimize the use of features while still maintaining a monolingual focus. Collobert et al. (2011), Turian et al. (2010), and Ando and Zhang (2005) use unsupervised features in conjunction with engineered features capturing capitalization, character categories and gazetteer matches. Collobert et al. (2011) use a Convolutional Neural Network (CNN) over the sequence of word embeddings. Huang et al. (2015) instead use bi-directional LSTMs over the sequence of words, along with spelling and orthographic features.

The most recent work eliminates feature engineering altogether and combines CRFs with LSTMs

which can model long sequences while remembering appropriate past context. Lample et al. (2016) proposed an architecture that uses both character and word level LSTMs to produce score functions for CRF inference conditioned on global context. Ma and Hovy (2016) replace the character LSTMs of Lample et al. (2016) with a CNN instead. Yang et al. (2016) follow a very similar architecture to Lample et al. (2016), replacing the LSTMs with Gated Recurrent Units (Cho et al., 2014). However, Yang et al. (2016) also tackle multi task and multi-lingual joint training scenarios.

Most of the models cited so far are monolingual either because they use hand crafted features and language specific resources or because of deep-seated assumptions. For example a change in orthography, lexicon, script, word order or addition of complex morphology makes transfer impossible. This is the central challenge that we tackle. There has been much less work catering to this scenario. Kim et al. (2012) use weak annotations from Wikipedia metadata and parallel data for multi lingual NER. Yang et al. (2016) addresses the use case of multilingual joint training, which assumes there is sufficient data available in all languages. Nothman et al. (2013) also operate under the assumption of availability of Wikipedia data.

To the best of our knowledge, a scenario involving transfer of a model trained in one (or more) source language(s) to another language with little or no labeled data, different script, different morphology, different lexicon, lack of transliteration, non-mutual intelligibility etc. has not been addressed recently.

5 Conclusion

In this paper, we presented two improvements over a state-of-the-art monolingual model to address Named Entity Recognition in transfer settings. The first seeks to reconcile various dimensions of variability between languages such as varying script, orthographic conventions, phonological phenomena etc. by representing words as sequences of IPA (International Phonetic Alphabet) segments consistent across all languages, rather than sequences of characters specific to a particular language. Secondly, we exploit the one-to-one mapping between input sequence words and output labels and advocate for the use of attention over the character/IPA sequence of a word when predicting its label. We show empirically that these two improvements 1) achieve at least state-of-the-art performance on a monolingual NER task in Spanish, 2) handle complex morphology in languages such as Turkish, Uzbek and Uyghur better than state of the art, 3) provide 0-shot performance in a transfer scenario to a related new language, well above that possible using multilingual word embeddings alone, and 4) are capable of generalizing to a new language with much less training data than a monolingually trained model. Moreover, all of this is achieved without any extra feature engineering specific to the task or language, apart from mapping characters in that language to IPA. We believe these results to be encouraging and look forward to replicating these results on more language pairs in different language families and further automating the process of obtaining phonological character representations.

Abstract

The goal of language modeling techniques is to capture the statistical and structural properties of natural languages from training corpora. This task typically involves the learning of short range dependencies, which generally model the syntactic properties of a language and/or long range dependencies, which are semantic in nature. We propose in this paper a new multi-span architecture, which separately models the short and long context information while it dynamically merges them to perform the language modeling task. This is done through a novel recurrent Long-Short Range Context (LSRC) network, which explicitly models the local (short) and global (long) context using two separate hidden states that evolve in time. This new architecture is an adaptation of the Long-Short Term Memory network (LSTM) to take into account the linguistic properties. Extensive experiments conducted on the Penn Treebank (PTB) and the Large Text Compression Benchmark (LTCB) corpus showed a significant reduction of the perplexity when compared to state-of-the-art language modeling techniques.

1 Introduction

A high quality Language Model (LM) is considered to be an integral component of many systems for speech and language technology applications, such as machine translation (Brown et al., 1990), speech recognition (Katz, 1987), etc. The goal of an LM is to identify and predict probable sequences of predefined linguistic units, which are typically words. These predictions are typically guided by the semantic and syntactic properties encoded by the LM.

In order to capture these properties, classical LMs were typically developed as fixed (short) context techniques such as, the word count-based methods (Rosenfeld, 2000; Kneser and Ney, 1995), commonly known as N-gram language models, as well as the Feedforward Neural Networks (FFNN) (Bengio et al., 2003), which were introduced as an alternative to overcome the exponential growth of parameters required for larger context sizes in N-gram models.

In order to overcome the short context constraint and capture long range dependencies known to be present in language, Bellegarda (1998a) proposed to use Latent Semantic Analysis (LSA) to capture the global context, and then combine it with the standard N-gram models, which capture the local context. In a similar but more recent approach, Mikolov and Zweig (2012) showed that Recurrent Neural Network (RNN)-based LM performance can be significantly improved using an additional global topic information obtained using Latent Dirichlet Allocation (LDA). In fact, although recurrent architectures theoretically allow the context to indefinitely cycle in the network, Hai Son et al. (2012) have shown that, in practice, this information changes quickly in the classical RNN (Mikolov et al., 2010) structure, and that it is experimentally equivalent to an 8-gram FFNN. Another alternative to model linguistic dependencies, Long-Short Term Memory (LSTM) (Sundermeyer et al., 2012), addresses some learning issues from the original RNN by controlling the longevity of context information in the net-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1473–1481,
Austin, Texas, November 1-5, 2016.

work. This architecture, however, does not particularly model long/short context but rather uses a single state to model the global linguistic context.

Motivated by the works in (Bellegarda, 1998a; Mikolov and Zweig, 2012), this paper proposes a novel neural architecture which explicitly models 1) the local (short) context information, generally syntactic, as well as 2) the global (long) context, which is semantic in nature, using two separate recurrent hidden states. These states evolve in parallel within a long-short range context network. In doing so, the proposed architecture is particularly adapted to model natural languages that manifest local-global context information in their linguistic properties.

We proceed as follows. Section 2 presents a brief overview of short vs long range context language modeling techniques. Section 3 introduces the novel architecture, Long-Short Range Context (LSRC), which explicitly models these two dependencies. Then, Section 4 evaluates the proposed network in comparison to different state-of-the-art language models on the PTB and the LTCB corpus. Finally, we conclude in Section 5.

2 Short vs Long Context Language Models

The goal of a language model is to estimate the probability distribution $p(w_1^T)$ of word sequences $w_1^T = w_1, \cdots, w_T$. Using the chain rule, this distribution can be expressed as

$$p(w_1^T) = \prod_{t=1}^{T} p(w_t|w_1^{t-1}) \quad (1)$$

This probability is generally approximated under different simplifying assumptions, which are typically derived based on different linguistic observations. All these assumptions, however, aim at modeling the optimal context information, be it syntactic and/or semantic, to perform the word prediction. The resulting models can be broadly classified into two main categories: long and short range context models. The rest of this section presents a brief overview of these categories with a particular focus on Neural Network (NN)-based models.

2.1 Short Range Context

This category includes models that approximate (1) based on the Markov dependence assumption of order $N-1$. That is, the prediction of the current word depends only on the last $N-1$ words in the history. In this case, (1) becomes

$$p(w_1^T) \approx \prod_{t=1}^{T} p(w_t|w_{t-N+1}^{t-1}) \quad (2)$$

The most popular methods that subscribe in this category are the N-gram models (Rosenfeld, 2000; Kneser and Ney, 1995) as well as the FFNN model (Bengio et al., 2003), which estimates each of the terms involved in this product, i.e, $p(w_t|w_{t-N+1}^{t-1})$ in a single bottom-up evaluation of the network.

Although these methods perform well and are easy to learn, the natural languages that they try to encode, however, are not generated under a Markov model due to their dynamic nature and the long range dependencies they manifest. Alleviating this assumption led to an extensive research to develop more suitable modeling techniques.

2.2 Long Range Context

Conventionally, N-gram related LMs have not been built to capture long linguistic dependencies, although significant word triggering information is still available for large contexts. To illustrate such triggering correlations spread over a large context, we use correlation defined over a distance d, given by $c_d(w_1, w_2) = \frac{P_d(w_1,w_2)}{P(w_1)P(w_2)}$. A value greater than 1 shows that it is more likely that the word w_1 follows w_2 at a distance d than expected without the occurrence of w_2. In Figure 1, we show the variation of this correlation for pronouns with the distance d. It can be observed that seeing another "he" about twenty words after having seen a first "he" is much more likely. A similar observation can be made for the word "she". It is, however, surprising that seeing "he" after "he" is three times more likely than seeing "she" after "she", so "he" is much more predictive. In the cases of cross-word triggering of "he" $\rightarrow$ "she" and "she" $\rightarrow$ "he", we find that the correlation is suppressed in comparison to the same word triggering for distances larger than three. In summary, Figure 1 demonstrates that word triggering information exists at large distances, even up to one thousand words. These conclusions were confirmed by similar correlation experiments that we conducted

for different types of words and triggering relations.

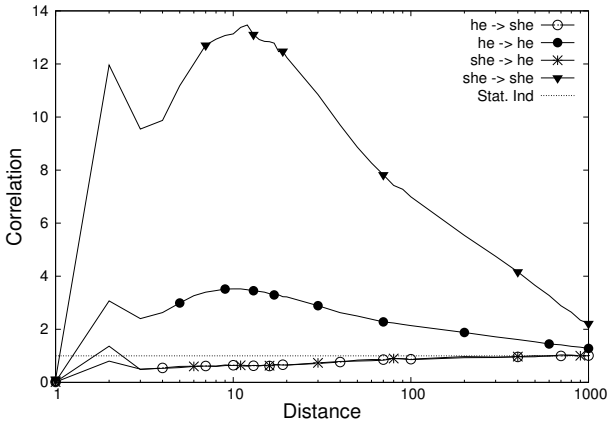

Figure 1: Variation of word triggering correlations for pronouns over large distances.

In order to model this long-term correlation and overcome the restrictive Markov assumption, recurrent language models have been proposed to approximate (1) according to

$$p(w_1^T) \approx \prod_{t=1}^{T} p(w_t|w_{t-1}, h_{t-1}) = \prod_{t=1}^{T} p(w_t|h_t) \quad (3)$$

In NN-based recurrent models, h_t is a context vector which represents the complete history, and modeled as a hidden state that evolves within the network.

2.2.1 Elman-Type RNN-based LM

The classical RNN (Mikolov et al., 2010) estimates each of the product terms in (3) according to

$$H_t = f\left(X_{t-1} + V \cdot H_{t-1}\right) \quad (4)$$
$$P_t = g\left(W \cdot H_t\right) \quad (5)$$

where X_{t-1} is a continuous representation (i.e, embedding) of the word w_{t-1}, V encodes the recurrent connection weights and W is the hidden-to-output connection weights. These parameters define the network and are learned during training. Moreover, $f(\cdot)$ is an activation function, whereas $g(\cdot)$ is the softmax function. Figure (2) shows an example of the standard RNN architecture.

Theoretically, the recurrent connections of an RNN allow the context to indefinitely cycle in the network and thus, modeling long context. In practice, however, Hai Son et al. (2012) have shown that this information changes quickly over time, and that it is experimentally equivalent to an 8-gram FFNN. This observation was confirmed by the experiments that we report in this paper.

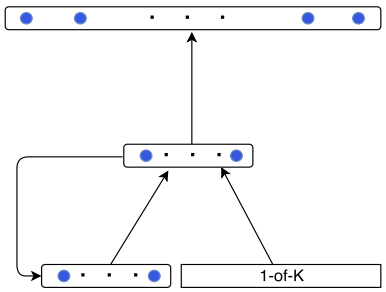

Figure 2: Elman RNN architecture.

2.2.2 Long-Short Term Memory Network

In order to alleviate the rapidly changing context issue in standard RNNs and control the longevity of the dependencies modeling in the network, the LSTM architecture (Sundermeyer et al., 2012) introduces an internal memory state C_t, which explicitly controls the amount of information, to forget or to add to the network, before estimating the current hidden state. Formally, this is done according to

$$\{i, f, o\}_t = \sigma\left(U^{i,f,o} \cdot X_{t-1} + V^{i,f,o} \cdot H_{t-1}\right) \quad (6)$$
$$\tilde{C}_t = f\left(U^c \cdot X_{t-1} + V^c \cdot H_{t-1}\right) \quad (7)$$
$$C_t = f_t \odot C_{t-1} + i_t \odot \tilde{C}_t \quad (8)$$
$$H_t = o_t \odot f\left(C_t\right) \quad (9)$$
$$P_t = g\left(W \cdot H_t\right) \quad (10)$$

where $\odot$ is the element-wise multiplication operator, $\tilde{C}_t$ is the memory candidate, whereas i_t, f_t and o_t are the input, forget and output gates of the network, respectively. Figure 3 illustrates the recurrent module of an LSTM network. Learning of an LSTM model requires the training of the network parameters $U^{i,f,o,c}$, $V^{i,f,o,c}$ and W.

Although LSTM models have been shown to outperform classical RNN in modeling long range dependencies, they do not explicitly model long/short context but rather use a single state to encode the global linguistic context.

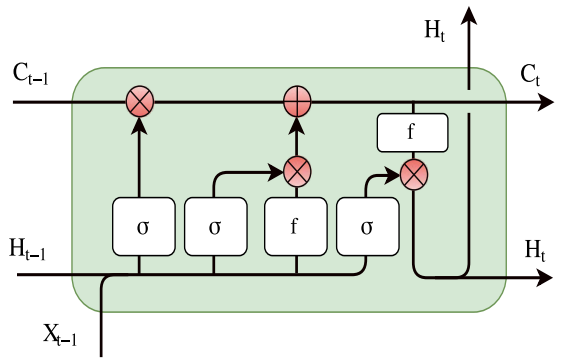

Figure 3: Block diagram of the recurrent module of an LSTM network.

3 Multi-Span Language Models

The attempts to learn and combine short and long range dependencies in language modeling led to what is known as multi-span LMs (Bellegarda, 1998a). The goal of these models is to learn the various constraints, both local and global, that are present in a language. This is typically done using two different models, which separately learn the local and global context, and then combine their resulting linguistic information to perform the word prediction. For instance, Bellegarda (1998b) proposed to use Latent Semantics Analysis (LSA) to capture the global context, and then combine it with the standard N-gram models, which capture the local context, whereas Mikolov and Zweig (2012) proposed to model the global topic information using Latent Dirichlet Allocation (LDA), which is then combined with an RNN-based LM. This idea is not particular to language modeling but has been also used in other Natural Language Processing (NLP) tasks, e.g., Anastasakos et al. (2014) proposed to use a local/global model to perform a spoken language understanding task.

3.1 Long-Short Range Context Network

Following the line of thoughts in (Bellegarda, 1998b; Mikolov and Zweig, 2012), we propose a new multi-span model, which takes advantage of the LSTM ability to model long range context while, simultaneously, learning and integrating the short context through an additional recurrent, local state. In doing so, the resulting Long-Short Range Context (LSRC) network is able to separately model the short/long context while it dynamically combines them to perform the next word prediction task. Formally, this new model is defined as

$$H_t^l = f\left(X_{t-1} + U_l^c \cdot H_{t-1}^l\right) \quad (11)$$

$$\{i,f,o\}_t = \sigma\left(V_l^{i,f,o} \cdot H_t^l + V_g^{i,f,o} \cdot H_{t-1}^g\right) \quad (12)$$

$$\tilde{C}_t = f\left(V_l^c \cdot H_t^l + V_g^c \cdot H_{t-1}^g\right) \quad (13)$$

$$C_t = f_t \odot C_{t-1} + i_t \odot \tilde{C}_t \quad (14)$$

$$H_t^g = o_t \odot f\left(C_t\right) \quad (15)$$

$$P_t = g\left(W \cdot H_t^g\right) \quad (16)$$

Learning of an LSRC model requires the training of the local parameters $V_l^{i,f,o,c}$ and U_l^c, the global parameters $V_g^{i,f,o,c}$ and the hidden-to-output connection weights W. This can be done using the standard Back-Propagation Through Time (BPTT) algorithm, which is typically used to train recurrent networks.

The proposed approach uses two hidden states, namely, H_t^l and H_t^g to model short and long range context, respectively. More particularly, the local state H_t^l evolves according to (11) which is nothing but a simple recurrent model as it is defined in (4). In doing so, H_t^l is expected to have a similar behavior to RNN, which has been shown to capture local/short context (up to 10 words), whereas the global state H_t^g follows the LSTM model, which is known to capture longer dependencies (see example in Figure 5). The main difference here, however, is the dependence of the network modules (gates and memory candidate) on the previous local state H_t^l instead of the last seen word X_{t-1}. This model is based on the assumption that the local context carries more linguistic information, and is therefore, more suitable to combine with the global context and update LSTM, compared to the last seen word. Figure 4 illustrates the recurrent module of an LSRC network. It is worth mentioning that this model was not particularly developed to separately learn syntactic and semantic information. This may come, however, as a result of the inherent local and global nature of these two types of linguistic properties.

3.2 Context Range Estimation

For many NLP applications, capturing the global context information can be a crucial component to develop successful systems. This is mainly due to

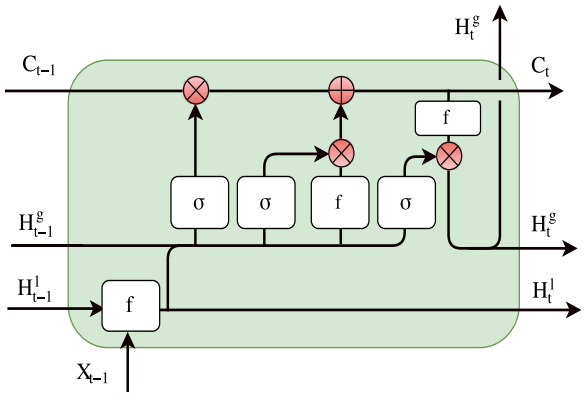

Figure 4: Block diagram of the recurrent module of an LSRC network.

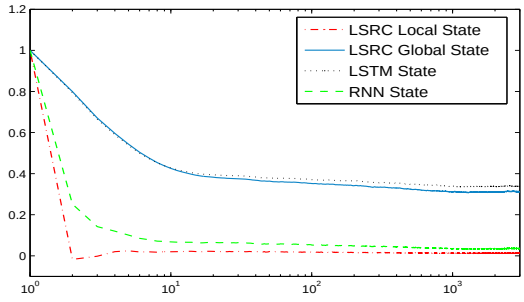

Figure 5: Temporal correlation of the proposed network in comparison to LSTM and RNN.

the inherent nature of languages, where a single idea or topic can span over few sentences, paragraphs or a complete document. LSA-like approaches take advantage of this property, and aim at extracting some hidden "concepts" that best explain the data in a low-dimension "semantic space". To some extent, the hidden layer of LSRC/LSTM can be seen as a vector in a similar space. The information stored in this vector, however, changes continuously based on the processed words. Moreover, interpreting its content is generally difficult. As an alternative, measuring the temporal correlation of this hidden vector can be used as an indicator of the ability of the network to model short and long context dependencies. Formally, the temporal correlation of a hidden state H over a distance d is given by

$$c_d = \frac{1}{D}\sum_{t=1}^{t=D} SM(H_t, H_{t+d}) \qquad (17)$$

where D is the test data size in words and SM is a similarity measure such as the *cosine similarity*. This measure allows us to evaluate how fast does the information stored in the hidden state change over time.

In Figure 5, we show the variation of this temporal correlation for the local and global states of the proposed LSRC network in comparison to RNN and LSTM for various values of the distance d (up to 3000). This figure was obtained on the test set of the Penn Treebank (PTB) corpus, described in Section (4). The main conclusion we can draw from this figure is the ability of the LSRC local and global states (trained jointly) to behave in a similar fashion to RNN and LSTM states (trained separately), respectively. We can also conclude that the LSRC global state and LSTM are able to capture long range correlations, whereas the context changes rapidly over time in RNN and LSRC local state.

4 Experiments and Results

4.1 Experimental Setup

We evaluated the proposed architecture on two different benchmark tasks. The first set of experiments was conducted on the commonly used Penn Treebank (PTB) corpus using the same experimental setup adopted in (Mikolov et al., 2011) and (Zhang et al., 2015). Namely, sections 0-20 are used for training while sections 21-22 and 23-24 are used for validation an testing, respectively. The vocabulary was limited to the most 10k frequent words while the remaining words were mapped to the token <unk>.

In order to evaluate how the proposed approach performs on large corpora in comparison to other methods, we run a second set of experiments on the Large Text Compression Benchmark (LTCB) (Mahoney, 2011). This corpus is based on the enwik9 dataset which contains the first 10^9 bytes of enwiki-20060303-pages-articles.xml. We adopted the same training-test-validation data split as well as the the same data processing[1] which were used in (Zhang et al., 2015). The vocabulary is limited to the most 80k

[1]All the data processing steps described here for PTB and LTCB were performed using the FOFE toolkit in (Zhang et al., 2015), which is available at `https://wiki.eecs.yorku.ca/lab/MLL/_media/projects:fofe:fofe-code.zip`

frequent words with all remaining words replaced by <unk>. Details about the sizes of these two corpora can be found in Table 1.

Corpus	Train	Dev	Test
PTB	930K	74K	82K
LTCB	133M	7.8M	7.9M

Table 1: Corpus size in number of words.

Similarly to the RNN LM toolkit[2] (Mikolov et al., 2011), we have used a single end sentence tag between each two consecutive sentences, whereas the begin sentence tag was not included[3].

4.2 Baseline Models

The proposed LSRC architecture is compared to different LM approaches that model short or long range context. These include the commonly used N-gram Kneser-Ney (KN) (Kneser and Ney, 1995) model with and without cache (Kuhn and De Mori, 1990), as well as different feedforward and recurrent neural architectures. For short (fixed) size context models, we compare our method to 1) the FFNN-based LM (Bengio et al., 2003), as well as 2) the Fixed-size Ordinally Forgetting Encoding (FOFE) approach, which is implemented in (Zhang et al., 2015) as a sentence-based model. For these short size context models, we report the results of different history window sizes (1, 2 and 4). The 1^{st}, 2^{nd} and 4^{th}-order FOFE results were either reported in (Zhang et al., 2015) or obtained using the freely available FOFE toolkit [1].
