For recurrent models that were designed to capture long term context, we compared the proposed approach to 3) the full RNN (without classes) (Mikolov et al., 2011), 4) to a deep RNN (D-RNN)[4] (Pascanu et al., 2013), which investigates different approaches to construct mutli-layer RNNs, and finally 5) to the LSTM model (Sundermeyer et al., 2012), which explicitly regulates the amount of information that propagates in the network. The recurrent models results are reported for different numbers of hidden layers (1 or 2). In order to investigate the impact of deep models on the LSRC architecture, we added a single hidden, non-recurrent layer (of size 400 for PTB and 600 for the LTCB experiments) to the LSRC model (D-LSRC). This was sufficient to improve the performance with a negligible increase in the number of model parameters.

4.3 PTB Experiments

For the PTB experiments, the FFNN and FOFE models use a word embedding size of 200, whereas the hidden layer(s) size is fixed at 400, with all hidden units using the Rectified Linear Unit (ReLu) i.e., $f(x) = max(0, x)$ as activation function. We also use the same learning setup adopted in (Zhang et al., 2015). Namely, we use the stochastic gradient descent algorithm with a mini-batch size of 200, the learning rate is initialized to 0.4, the momentum is set to 0.9, the weight decay is fixed at 4×10^{-5}, whereas the training is done in epochs. The weights initialization follows the normalized initialization proposed in (Glorot and Bengio, 2010). Similarly to (Mikolov et al., 2010), the learning rate is halved when no significant improvement of the validation data log-likelihood is observed. Then, we continue with seven more epochs while halving the learning rate after each epoch.

Regarding the recurrent models, we use $f = tanh(\cdot)$ as activation function for all recurrent layers, whereas "$f = sigmoid(\cdot)$" is used for the input, forget and output gates of LSTM and LSRC. The additional non-recurrent layer in D-LSRC, however, uses the ReLu activation function. The word embedding size was set to 200 for LSTM and LSRC whereas it is the same as the hidden layer size for RNN (result of the RNN equation 4). In order to illustrate the effectiveness of the LSRC model, we also report the results when the embedding size is fixed at 100, LSRC(100). The training uses the BPTT algorithm for 5 time steps. Similarly to short context models, the mini-batch was set to 200. The learning rate, however, was set to 1.0 and the weight decay to 5×10^{-5}. The use of momentum did not lead to any additional improvement. Moreover, the data is processed sequentially without any sentence independence assumption. Thus, the recurrent mod-

[2]The RNN LM toolkit is available at `http://www.rnnlm.org/`

[3]This explains the difference in the corpus size compared to the one reported in (Zhang et al., 2015).

[4]The deep RNN results were obtained using L_p and maxout units, dropout regularization and gradient control techniques, which are known to significantly improve the performance. None of these techniques, however, were used in our experiments.

els will be able to capture long range dependencies that exist beyond the sentence boundary.

In order to compare the model sizes, we also report the Number of Parameters (NoP) to train for each of the models above.

Table 2: LMs performance on the PTB test set.

Table 2 shows the perplexity evaluation on the PTB test set. As a first observation, we can clearly see that the proposed approach outperforms all other models for all configurations, in particular, RNN and LSTM. This observation includes other models that were reported in the literature, such as random forest LM (Xu and Jelinek, 2007), structured LM (Filimonov and Harper, 2009) and syntactic neural network LM (Emami and Jelinek, 2004). More particularly, we can conclude that LSRC, with an embedding size of 100, achieves a better performance than all other models while reducing the number of parameters by $\approx 29\%$ and $\approx 17\%$ compared to RNN and LSTM, respectively. Increasing the embedding size to 200, which is used by the other models, improves significantly the performance with a resulting NoP comparable to LSTM. The significance of the improvements obtained here over LSTM were confirmed through a statistical significance t-test, which led to p-values $\leq 10^{-10}$ for a significance level of 5% and 0.01%, respectively.

The results of the deep models in Table 2 also show that adding a single non-recurrent hidden layer to LSRC can significantly improve the performance. In fact, the additional layer bridges the gap between the LSRC models with an embedding size of 100 and 200, respectively. The resulting architectures outperform the other deep recurrent models with a significant reduction of the number of parameters (for the embedding size 100), and without usage of dropout regularization, L_p and maxout units or gradient control techniques compared to the deep RNN[4](D-RNN).

We can conclude from these experiments that the explicit modeling of short and long range dependencies using two separate hidden states improves the performance while significantly reducing the number of parameters.

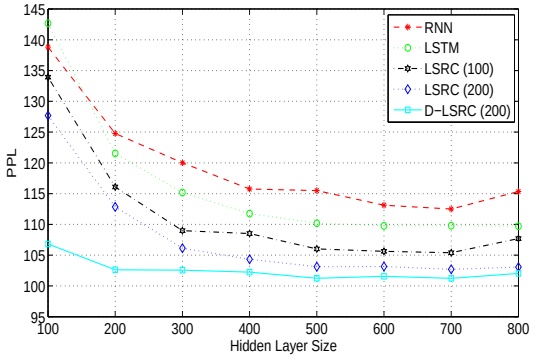

Figure 6: Perplexity of the different NN-based LMs with different hidden layer sizes on the PTB test set.

In order to show the consistency of the LSRC improvement over the other recurrent models, we report the variation of the models performance with respect to the hidden layer size in Figure 6. This figure shows that increasing the LSTM or RNN hidden layer size could not achieve a similar performance to the one obtained using LSRC with a small layer size (e.g., 300). It is also worth mentioning that this observation holds when comparing a 2-recurrent layers LSTM to LSRC with an additional non-recurrent layer.

4.4 LTCB Experiments

The LTCB experiments use the same PTB setup with minor modifications. The results shown in Table 3 follow the same experimental setup proposed in (Zhang et al., 2015). More precisely, these results were obtained without use of momentum or weight decay (due to the long training time required for this corpus), the mini-batch size was set to 400, the learning rate was set to 0.4 and the BPTT step was fixed at 5. The FFNN and FOFE architectures use 2 hidden layers of size 600, whereas RNN, LSTM and LSRC have a single hidden layer of size 600. Moreover, the word embedding size was set to 200 for all models except RNN, which was set to 600. We also report results for an LSTM with 2 recurrent layers as well as for LSRC with an additional non-recurrent layer. The recurrent layers are marked with an "R" in Table 3.

	model			NoP
Context Size M=N-1	1	2	4	4
KN	239	156	132	—
KN+cache	188	127	109	—
FFNN [M*200]-600-600-80k	235	150	114	64.84M
FOFE [M*200]-600-600-80k	112	107	100	64.84M
RNN [600]-R600-80k	85			96.36M
LSTM [200]-R600-80k	66			65.92M
LSTM [200]-R600-R600-80k	61			68.80M
LSRC [200]-R600-80k	63			65.96M
LSRC [200]-R600-600-80k	59			66.32M

Table 3: LMs performance on the LTCB test set.

The results shown in Table 3 generally confirm the conclusions we drew from the PTB experiments above. In particular, we can see that the proposed LSRC model largely outperforms all other models. In particular, LSRC clearly outperforms LSTM with a negligible increase in the number of parameters (resulting from the additional $200 \times 200 = 0.04M$ local connection weights U_l^c) for the single layer results. We can also see that this improvement is maintained for deep models (2 hidden layers), where the LSRC model achieves a slightly better performance while reducing the number of parameters by $\approx 2.5M$ and speeding up the training time by $\approx 20\%$ compared to deep LSTM.

The PTB and LTCB results clearly highlight the importance of recurrent models to capture long range dependencies for LM tasks. The training of these models, however, requires large amounts of data to significantly outperform short context models. This can be seen in the performance of RNN and LSTM in the PTB and LTCB tables above. We can also conclude from these results that the explicit modeling of long and short context in a multi-span model can lead to a significant improvement over state-of-the are models.

5 Conclusion and Future Work

We investigated in this paper the importance, followed by the ability, of standard neural networks to encode long and short range dependencies for language modeling tasks. We also showed that these models were not particularly designed to, explicitly and separately, capture these two linguistic information. As an alternative solution, we proposed a novel long-short range context network, which takes advantage of the LSTM ability to capture long range dependencies, and combines it with a classical RNN network, which typically encodes a much shorter range of context. In doing so, this network is able to encode the short and long range linguistic dependencies using two separate network states that evolve in time. Experiments conducted on the PTB and the large LTCB corpus have shown that the proposed approach significantly outperforms different state-of-the are neural network architectures, including LSTM and RNN, even when smaller architectures are used. This work, however, did not investigate the nature of the long and short context encoded by this network or its possible applications for other NLP tasks. This is part of our future work.

Abstract

To enable language-based communication and collaboration with cognitive robots, this paper presents an approach where an agent can learn task models jointly from language instruction and visual demonstration using an And-Or Graph (AoG) representation. The learned AoG captures a hierarchical task structure where linguistic labels (for language communication) are grounded to corresponding state changes from the physical environment (for perception and action). Our empirical results on a cloth-folding domain have shown that, although state detection through visual processing is full of uncertainties and error prone, by a tight integration with language the agent is able to learn an effective AoG for task representation. The learned AoG can be further applied to infer and interpret on-going actions from new visual demonstration using linguistic labels at different levels of granularity.

1 Introduction

Given tremendous advances in robotics, computer vision, and natural language processing, a new generation of cognitive robots have emerged that aim to collaborate with humans in joint tasks. To facilitate natural and efficient communication with these physical agents, natural language processing will need to go beyond traditional symbolic representations, but rather ground language to sensors (e.g., visual perception) and actuators (e.g., lower-level control systems) of physical agents. The internal task representation will need to capture both higher-level concepts (for language communication) and lower-level visual features (for perception and action).

To address this need, we have developed an approach on learning *procedural tasks* jointly from language instruction and visual demonstration. In particular, we use And-Or Graph (AoG), which has been used in many computer vision tasks and robotic applications (Zhao and Zhu, 2013; Li et al., 2016; Xiong et al., 2016), to represent a hierarchical task model that not only captures symbolic concepts (extracted from language instructions) but also the corresponding visual state changes from the physical environment (detected by computer vision algorithms).

Different from previous works that ground language to perception (Liu et al., 2012; Matuszek et al., 2012; Kollar et al., 2013; Yu and Siskind, 2013; Yang et al., 2016), a key innovation in our framework is that language is no longer grounded just to perceived objects in the environment, but is further grounded to a hierarchical structure of *state changes* where the states are perceived from the environment during visual demonstration. The state of environment is an important notion in robotic systems as the change of states drives planning for lower-level robotic actions. Thus, connecting language concepts to state changes, our learned AoG provides a unified representation that integrates language and vision to not only support language-based communication but also facilitate robot action planning and execution in the future.

More specifically, within this AoG framework, we have developed and evaluated our algorithms in the

* The first two authors contributed equally to this paper.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1482–1492,
Austin, Texas, November 1-5, 2016.

context of learning a *cloth-folding* task. Although cloth-folding appears simple and intuitive for humans, it represents significant challenges for both vision and robotics systems. Furthermore, although symbolic language processing in this domain is easy due to limited use of vocabulary, grounded language understanding is particularly challenging. A simple phrase (e.g., "fold in half") could have different grounded meanings (e.g., lower-level representation) given different contexts. Thus, this cloth-folding domain is a good starting point to focus on grounding language to task structures.

Our empirical results have shown that, although state detection from the physical world can be extremely noisy, our learning algorithm that tightly incorporates language is capable of acquiring an effective and meaningful task model to compensate the uncertainties in visual processing. Once the AoG for the task is learned, it can be applied by our inference algorithm, for example, to infer on-going actions from new visual demonstration and generate linguistic labels at different levels of granularity to facilitate human-agent communication.

2 Related Work

Recent years have seen an increasing amount of work on grounding language to visual perception (Liu et al., 2012; Matuszek et al., 2012; Yu and Siskind, 2013; Kollar et al., 2013; Naim et al., 2015; Yang et al., 2016; Gao et al., 2016). Furthermore, the robotics community made significant efforts to utilize novel grounding techniques to facilitate task execution given natural language instructions (Chen et al., 2010; Kollar et al., 2010; Tellex et al., 2011; Misra et al., 2014) and task learning from demonstration (Saunders et al., 2006; Chernova and Veloso, 2008).

Research on Learning from Demonstration (LfD) employed various approaches to model the tasks (Argall et al., 2009), such as state-to-action mapping (Chernova and Veloso, 2009), predicate calculus (Hofmann et al., 2016), and Hierarchical Task Networks (Nejati et al., 2006; Hogg et al., 2009). However, aspiring to enable human robot communication, the framework developed in this paper focuses on task representation using language grounded to a structure of state changes detected from the physical world. As demonstrated in recent work (She et al., 2014a; Misra et al., 2015; She and Chai, 2016), explicitly modeling change of states is an important step towards interacting with robots in the physical world.

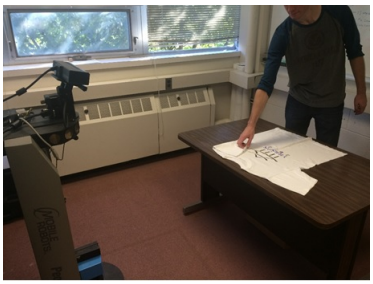

Figure 1: The setting of our situated task learning where a human teacher teaches the robot how to fold a T-shirt through both task demonstrations and language instructions.

Additionally, there has also been an increasing amount of work that learns new tasks either using methods like supervised learning on large corpus of data (Branavan et al., 2010; Branavan et al., 2012; Tellex et al., 2014; Misra et al., 2014), or by learning from humans through dialogue (Cantrell et al., 2012; Mohan et al., 2013; Kirk and Laird, 2013; She et al., 2014b; Mohseni-Kabir et al., 2015). In this paper, we focus on jointly learning new tasks through visual demonstration and language instruction. The learned task model is explicitly represented by an AoG, a hierarchical structure consisting of both linguistic labels and corresponding changes of states from the physical world. This rich task model will facilitate not only language-based communication, but also lower-level action planning and execution.

3 Task and Data

In this paper, we use cloth-folding (e.g., teaching a robot how to fold a T-shirt) as the task to demonstrate and evaluate our joint task learning approach. As mentioned earlier, cloth-folding, although simple for humans, represents a challenging task for the robotics community due to the complex state and action space.

Figure 1 illustrates the setting for our situated task learning. A human teacher can teach a robot how to fold a T-shirt through simultaneous verbal instructions and visual demonstrations. A Microsoft Kinect2 camera is mounted on the robot to record

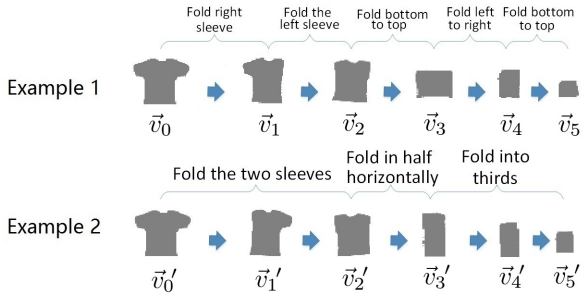

Figure 2: Examples of our parallel data where language instructions are paired with a sequence of visual states detected from the video.

the human's visual demonstration, and the human's corresponding verbal instructions are recorded by Kinect2's embedded microphone array.

A recorded video of task demonstration and its corresponding verbal instruction become one training example for our task learning system. Figure 2 shows two examples of such "parallel data". The visual demonstration is processed into a sequence of visual states, where each state is a numeric vector ($\vec{v}_i$) capturing the visual features of the T-shirt at a particular time (see later Section 5.1 for details). The recorded verbal instructions are then aligned with the sequence of visual states based on the timing information.

During teaching the task, we specifically requested the demonstrator to describe and do each step at roughly the same time. This greatly simplified the alignment problem. Since our ultimate goal is to enable humans to teach the robot through natural language dialogue and demonstration, our hypothesis is that the alignment issue can be alleviated by certain dialogue mechanism (e.g., ask to repeat the action, ask for step-by-step aligned instructions, etc.). As it is human's best interest that the robot gets the clearest instructions, we also anticipate during dialogue human teachers will be collaborative and provide mostly aligned instructions. Certainly, these hypotheses will need to be validated in the dialogue setting in our future work.

In our collected data, each *change of state*, i.e., a transition between two visual states, is caused by one or more physical actions. Some language descriptions align with only a single-step change of state. For instance, "*fold right sleeve*" is aligned with the change ($\vec{v}_0 \rightarrow \vec{v}_1$) and "*fold left sleeve*" is aligned with ($\vec{v}_1 \rightarrow \vec{v}_2$) in Example 1. This kind of single-step change of state is considered as a **primitive action**. Other language descriptions are aligned with a sequence of multiple state changes. For instance, "*fold the two sleeves*" in Example 2 is aligned with two consecutive changes: ($\vec{v}_0', \vec{v}_1', \vec{v}_2'$). This kind of sequence of state changes is considered as a **complex action**, which can be decomposed into partially ordered primitive actions. A complex action can also be concisely represented by the change from the initial state to the end state in the sequence, such as ($\vec{v}_0' \rightarrow \vec{v}_2'$) in Example 2.

These parallel data are used to train and test our learning and inference algorithms presented later.

4 And-Or Graph Representation

We use AoG as the formal model of a procedural task. Figure 3 shows an example AoG for the cloth-folding task. It is a hierarchical structure that explicitly captures the compositionality and reconfigurability of a procedural task. The terminal nodes capture state changes associated with primitive actions of this task, and non-terminal nodes capture state changes associated with complex actions which are further composed by lower-level actions.

In addition to state changes, the learned AoG is also labeled with linguistic information (e.g., verb frames) capturing the causes of the corresponding state changes. The state changes are also considered as grounded meanings of these verb frames. For example, Figure 3 shows two "*fold the t-shirt*" labels at the top layer. Note that although symbolically, these two phrases have the same meaning (e.g., same verb frames), their grounded meanings are different as they correspond to different changes of state. Being able to represent differences or ambiguities in grounded meanings is crucial to connect language to perception and action.

Formally, an AoG is defined as a 5-tuple $\mathcal{G} = (S, \Sigma, N, R, \Theta)$, where

- S is a root node (or a start symbol) representing a complete task.
- Σ is a set of terminal nodes, each of which represents a change of state associated with a primitive action.
- $N = N^{AND} \cup N^{OR}$ is a set of non-terminal nodes, which is divided into two disjoint sub-

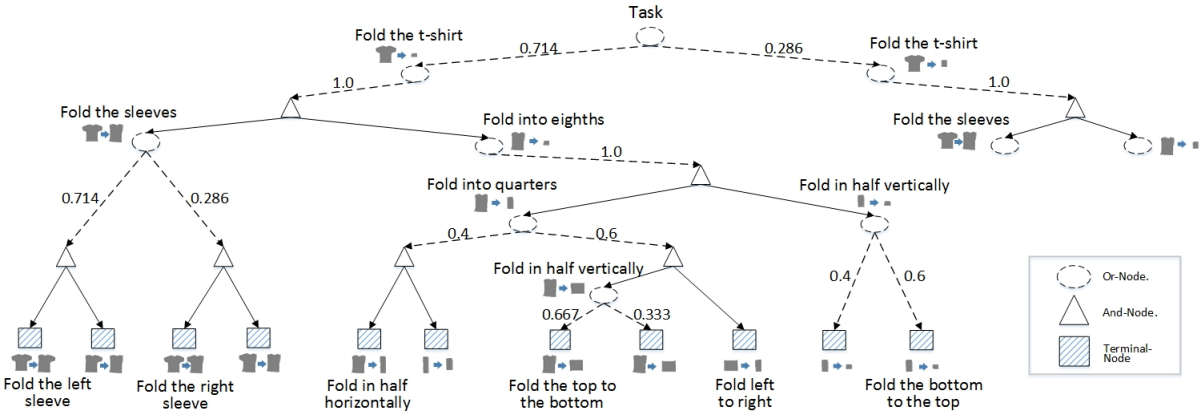

Figure 3: An example of the learned AoG

sets of And-nodes and Or-nodes.

- R is a "child-parent" relation (many-to-one mapping), i.e., $R(n^{ch}) = n^{pa}$ (meaning n^{pa} is the parent node of n^{ch}), where $n^{ch} \in \Sigma \cup N$ and $n^{pa} \in N \cup \{S\}$.
- Θ is a set of conditional probabilities $p(n^{ch}|n^{pa})$, where $n^{pa} \in N^{OR}$, $n^{ch} \in \{n \mid R(n) = n^{pa}\}$. Namely, for each Or-node, Θ defines a probability distribution over the set of all its children nodes.

In essence, our AoG model is equivalent to Probabilistic Context-Free Grammar (PCFG). An AoG can be converted into a PCFG:

- Each And-node and its children form a production rule

$$n^{AND} \rightarrow n_1^{ch} \wedge n_2^{ch} \wedge \dots$$

that represents the decomposition of a complex action into sequentially ordered sub-actions.

- Each Or-node and its children form a production rule

$$n^{OR} \rightarrow n_1^{ch} \mid n_2^{ch} \mid \dots$$

that represents all the alternative ways of accomplishing an action. Each alternative also comes with a probability as specified in Θ.

5 Method

5.1 Vision and Language Processing

The input data to our AoG learning algorithm consist of co-occurring visual demonstrations and language instructions as described in Section 3. Based on the RGB-D information provided by the Kinect2 sensor, we developed a vision processing system to keep track of human's actions and statuses of the T-shirt object.

To learn a meaningful task structure, the most important visual information are those key statuses that the object goes through. Therefore, our vision system processes each visual demonstration into a sequence of *states*. Each state $\vec{v}$ is a multi-dimensional numeric vector that encodes the geometric information of the detected T-shirt, such as its smallest bounding rectangle and largest inscribed contour-fitting rectangle. These key states are detected by tracking the human's folding actions. Namely, whenever a folding action is detected[1], we append the new state caused by the action to the sequence of observed states, till the end of the demonstration.

The verbal instructions given by the demonstrators were mainly verb phrases such as "fold *which-part*", "fold to *which-position*", or "fold *in-what-manner*". A semantic parser[2] is applied to parse each instruction text into a canonical verb-frame representation, such as

$$FOLD: \quad [PART: left\ sleeve] \\ [POSITION: middle].$$

Through the vision and language processing, each task demonstration becomes two parallel sequences, i.e., a sequence of extracted visual states and a sequence of parsed language instructions. The align-

[1]The vision system keeps track of human's hands, and detects a folding action as a gripping action followed by moving and releasing the hand(s).

[2]We use the CMU's Phoenix parser: http://wiki.speech.cs.cmu.edu/olympus/index.php/Phoenix

ment between these two sequences is also extracted from their co-occurrence timing information. Thus, an instance of a task demonstration is formally represented as a 3-tuple $x = (D, L, \Delta)$, where $D = \{\vec{v}_1, \vec{v}_2, \ldots, \vec{v}_M\}$ is the sequence of visual states, $L = \{l_1, l_2, \ldots, l_K\}$ is the sequence of linguistic verb-frames, and $\Delta(k) = (i, j)$ is an "alignment function" specifying the correspondence between a linguistic verb-frame l_k and a single or a sub-sequence of visual state(s) $\{\vec{v}_i, \ldots, \vec{v}_j\}$ $(i \leq j)$.

Then, given a dataset $\mathcal{X}$ of such task demonstrations, our AoG learning algorithm learns an AoG $\mathcal{G}$ as defined in Section 4. The next section describes our learning algorithm in detail.

5.2 AoG Learning Algorithm

Learning an AoG $\mathcal{G} = (S, \Sigma, N, R, \Theta)$ is carried out in two stages. Firstly, we learn a set of terminal nodes Σ to represent the primitive actions (i.e., the actions that can be preformed in a single step). This is done through clustering the observed visual states. Secondly, the hierarchical structure (i.e., N and R) and parameters Θ of the AoG is learned using an iterative grammar induction algorithm.

5.2.1 Learning Terminal Nodes

A terminal node in the AoG represents a primitive action, which causes the object to directly change from one state to another. Thus we represent a terminal node as a 2-tuple of states (or a "change of state"). Since the visual states detected by computer vision are numeric vectors with continuous values, we first apply a clustering algorithm to form a finite set of discrete state representations. Each cluster then represents a unique situation that one can encounter in a task. Since when learning a new task we usually do not know how many unique situations exist, here we employ a greedy clustering algorithm (Ng and Cardie, 2002), which does not assume a fixed number of clusters.

As the greedy clustering algorithm relies on the pairwise similarities of all the visual states, we also train an SVM classifier on a separate dataset of 22 T-shirt folding videos and use its classification output to measure the similarity between two visual states. The SVM classifier takes two numeric vectors as an input, and predicts whether these two vectors represent the same status of a T-shirt. We then apply this SVM classifier on each pair of detected visual states in our new dataset (i.e., the dataset for learning the AoG), and use the SVM's output class label (1 or -1) multiplies its classification confidence score as the similarity measurement between two visual states.

After clustering all the observed visual states in the data, we then replace each numeric vector state representation with the cluster "ID" it belongs to. Thus each visual demonstration now becomes a sequence of symbolic values, denoted as $D' = \{s_1, s_2, \ldots, s_M\}$. And we further transform it into an equivalent *change of state* sequence $C = \{(s_1, s_2), (s_2, s_3), \ldots, (s_{M-1}, s_M)\}$, in which each change of state essentially represents a primitive action in this task. These change of state pairs then form the set of terminal nodes Σ.

5.2.2 Learning the Structure and Parameters

With the sequences of numeric vector states replaced by the "symbolic" change of state sequences in the first stage, we can further learn the structure and parameters of an AoG. Namely, to learn N, R, and Θ that maximize the posterior probability:

$$\begin{aligned} & \arg\max_{N,R,\Theta} P(N, R, \Theta | \mathcal{X}, \Sigma) \\ = & \arg\max_{N,R,\Theta} P(N, R | \mathcal{X}, \Sigma)\, P(\Theta | \mathcal{X}, \Sigma, N, R). \end{aligned}$$

Following the iterative grammar induction paradigm (Tu et al., 2013; Xiong et al., 2016), we employ an iterative procedure that alternatively solves $\arg\max_{N,R} P(N, R | \mathcal{X}, \Sigma)$ and $\arg\max_{\Theta} P(\Theta | \mathcal{X}, \Sigma, N, R)$.

To solve the first term, we use greedy or beam search with a heuristic function similar to (Solan et al., 2005). To solve the second term, we estimate the probability of each branch of an Or-node by computing the frequency of that branch, which is essentially a maximum likelihood estimation similar to (Pei et al., 2013).

In detail, the learning procedure first initializes empty N, R, and Θ, then iterates through the following two steps until no further update can be made.

Step (1): search for new And-nodes.

This step searches for new And-node candidates from $\Sigma \cup N$, and update N and R with the top-ranked candidates. Specifically, we denote an And-node candidate to be searched as $A = (s_l \rightarrow s_m \rightarrow s_r)$.

Here s_l is the initial state of an existing node, whose end state is s_m. And s_r is the end state of another existing node, whose initial state is s_m. Thus an And-node candidate always has two child nodes, and represents a pattern of sub-sequences which starts from state s_l, ends at s_r, and has s_m occurred somewhere in the middle.

Using the above notation, the heuristic function for ranking And-node candidates is defined as

$$h(A) = (1 - \lambda)P_{state}(A) + \lambda P_{label}(A)$$

where $P_{state}(A)$ captures the prevalence of a particular And-node candidate based on the observed state change sequences:

$$P_{state}(A) = \frac{P_R(A) + P_L(A)}{2}$$

and $P_R(A)$ is the ratio between the number of times $(s_l \rightarrow s_m \rightarrow s_r)$ appears and the number of times $(s_l \rightarrow s_m)$ appears, and $P_L(A)$ is the ratio between the number of times $(s_l \rightarrow s_m \rightarrow s_r)$ appears and the number of times $(s_m \rightarrow s_r)$ appears.

The component $P_{label}(A)$ captures the prevalence of linguistic labels associated with the sequential state change patterns. It is computed as the ratio between the number of times $(s_l \rightarrow s_m \rightarrow s_r)$ co-occurs with a linguistic instruction[3] and the total number of times $(s_l \rightarrow s_m \rightarrow s_r)$ appears.

We specially define two AoG learning settings based on the role that language plays:

- *Tight* language integration: incorporate heuristics on linguistic labels (i.e., $\lambda = 0.5$). In this setting, the learned AoG prefers And-nodes that not only happen frequently, but also can be described by a linguistic label.
- *Loose* language integration: without incorporating the heuristics on linguistic labels ($\lambda = 0$). Each And-node is learned only based on the frequency of its state change pattern. The learned node can still acquire a linguistic label if there happen to be a co-occurring one, but the chance is lower than the "tight" setting.

Step (2): search for new Or-nodes or new branches of existing Or-nodes, then update Θ.

Once new And-nodes are added by the previous step, the next step is to search for Or-nodes that can be created or updated. An Or-node in the AoG essentially represents the set of all And-nodes that share the same initial and end states, denoted as $(s_l \rightarrow s_r)$ here (s_l and s_r are the common initial and end states, respectively). Suppose $(s_l \rightarrow s'_m \rightarrow s_r)$ is a newly added And-node, it is then assigned as a child of the Or-node $(s_l \rightarrow s_r)$. To further update Θ, the branching probability is computes as the ratio between the number of times $(s_l \rightarrow s'_m \rightarrow s_r)$ appears and the number of times $(s_l \rightarrow s_r)$ appears.

5.3 Inference Using AoG

Once a task AoG is learned, it can be applied to interpret and explain new visual demonstrations using linguistic labels. Due to the noises and uncertainties from computer vision processing, one key challenge in interpreting the visual demonstration is to reliably identify the different states of the T-shirt.

To tackle this issue, we formulate a joint inference problem. Namely, given a task demonstration video, we first process it into a sequence of numeric vector states $D = \{\vec{v}_1, \vec{v}_2, \ldots, \vec{v}_M\}$ as described in Section 5.1. Then the goal of inference is to find the most-likely parse tree T and a sequence of "symbolic states" $D' = \{s_1, s_2, \ldots, s_M\}$ based on the AoG $\mathcal{G}$ and the input D:

$$(T^*, D'^*) = \arg\max_{T, D'} P(T, D' \mid \mathcal{G}, D)$$

We apply a chart parsing algorithm (Klein and Manning, 2001) to efficiently solve this problem. Furthermore, to accommodate the ambiguities in mapping a numeric vector state $\vec{v}_m$ to a symbolic state, we take into consideration the top-k hypotheses measured by the similarity between $\vec{v}_m$ and a symbolic state s_k.[4] For each state mapping hypothesis, we add a completed edge between indices m and $m + 1$ in the chart, with s_k as its symbol and a probability p based on the similarity between $\vec{v}_m$ and s_k. Based on the given AoG, the chart parsing algorithm then uses Dynamic Programming to search the best parse tree that maximizes the joint probability of $P(T, D'|\mathcal{G}, D)$.

Figure 4 illustrates the input and output of our inference algorithm. As illustrated by this example,

[3] Such information is encoded in the Δ function as mentioned in Section 5.1.

[4] A symbolic state is represented by a cluster of numeric vector states learned from the training data.

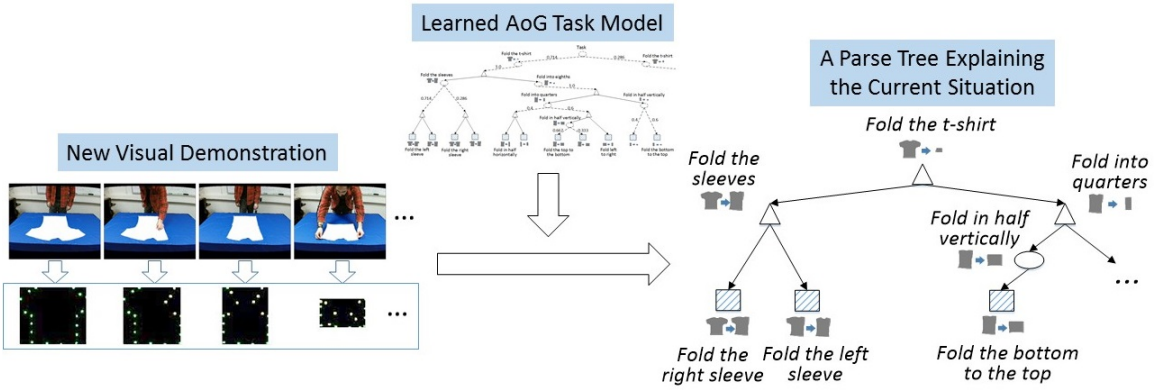

Figure 4: An illustration of the input and output of our AoG-based inference algorithm.

the parse tree represents a hierarchical structure underlying the observed task procedure, and the linguistic labels associated with the nodes can be used to describe the primitive and complex actions involved in the procedure.

6 Evaluation

Using the setting as described in Section 3, we collected 45 T-shirt folding demonstrations from 6 people to evaluate our AoG learning and inference methods. More specifically, we conducted a 5-fold cross validation. In each fold, 36 demonstrations were used for training to learn a task AoG. Then the remaining 9 demonstrations were used for testing, in which the learned AoG is further applied to process each of the testing visual demonstrations.

Motivated by earlier work on plan/activity recognition using CFG-based models (Carberry, 1990; Pynadath and Wellman, 2000), we use an extrinsic task that automatically assigns linguistic labels to new demonstrations to evaluate the quality of the learned AoG and the effectiveness of the inference algorithm. This involves three steps: (1) parse the video using the learned AoG; (2) identify linguistic labels associated with terminal or nonterminal nodes in the parse tree; and (3) compare the identified linguistic labels with the manually annotated labels.

We conduct the evaluation at two levels:

- **Primitive actions:** use linguistic labels associated with terminal nodes to describe the primitive actions in each video. This level provides detailed descriptions on how the observed task procedure is performed step-by-step.
- **Complex actions:** use linguistic labels associated with nonterminal nodes to describe complex actions. This provides a high-level "summary" of the detailed low-level actions.

The capability to recognize fine-grained primitive actions as well as high-level complex actions in a task procedure and to communicate those in language is important for many real-world AI applications such as human-robot collaboration (Mohseni-Kabir et al., 2015) and visual question answering (Tu et al., 2014).

6.1 Primitive Actions

We first compare the performance of interpreting primitive actions using the learned AoG with a baseline. The baseline applies a memory-based (or similarity-base) approach. Given a testing video, it extracts all the different visual states and maps each state to the nearest cluster learned from the training data (see Section 5.2.1). It then pairs each two consecutive states as a change of state instance, and uses the linguistic label corresponding to the identical change of state found in the training data as the label of a primitive action.

We measure the primitive action recognition performance in terms of the *normalized Minimal Edit Distance (MED)*. Namely, for each testing demonstration we calculate the MED between the ground-truth sequence of primitive action labels and the automatically generated sequence of labels, and divide the MED value by the length of the ground-truth sequence to produce a normalized score (a smaller score indicates better performance in recognizing the primitive actions).

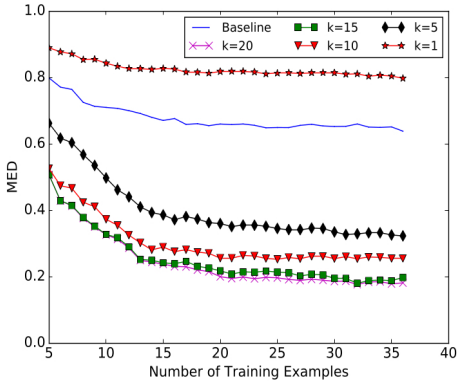

Figure 5: Performance of interpreting primitive actions. Different number of state mapping hypotheses (k) are used in the inference algorithm. The x-axis is the number of training examples used for learning the AoG.

The performances of the baseline and our AoG-based approach are shown in Figure 5. For the AoG-based approach, Figure 5 also shows the performances of incorporating different number of state mapping hypotheses (i.e., $k = 1, 5, 10, 15, 20$) into the inference algorithm (Section 5.3). Here we only report the performance of using AoG learned with the *tight* language integration (see Section 5.2.2), since there is no difference in performance between the tight and loose language integration settings in recognizing primitive actions[5].

As Figure 5 shows, the baseline performance is rather weak (i.e., high MED scores). This is largely due to the noise in state clustering and mapping from vision. After manually inspecting the collected demonstration videos, we found 18 unique statuses associated with folding a T-shirt. However the computer vision based clustering on average produces more than 30 clusters when all the 36 training examples are used. This makes it difficult to directly match the state changes as in the baseline. For our AoG-based method, when the inference algorithm only takes the single best state mapping hypothesis into consideration (i.e., $k = 1$), it yields a very weak performance because the observed state change sequence often cannot be parsed using the learned AoG.

However, the performance of the AoG-based method is significantly improved when multiple state mapping hypotheses are incorporated into the inference process. When the top-5 ($k = 5$) state mapping hypotheses are incorporated into the AoG-based inference, its MED score has already outperformed the baseline by a 0.3 gap ($p < 0.001$ using the Wilcoxon signed-rank test). When $k = 20$, the MED score has dropped by more than 0.6 compared to $k = 1$ ($p < 0.001$).

These results indicate that our AoG-based method is capable of learning useful task structure from small data. When multiple hypotheses of visual state mapping are incorporated, the learned AoG can compensate the uncertainties in vision processing and identify highly reliable primitive actions from unseen demonstrations.

6.2 Complex Actions

We further evaluate the performance of interpreting complex actions using the learned AoG. The baseline for comparison is similar to the one used in the previous section. It first converts a test video into a sequence of "symbolic" states by mapping each detected visual state to its nearest cluster. It then enumerates all the possible segments that consist of more than two consecutive states and search for the identical segments in the training data. If a matching segment is found, then the corresponding linguistic label (if any) is used as the label for a complex action. Since complex actions correspond to nonterminal nodes in the parse tree generated by AoG-based inference, and some of them may have linguistic labels while others may not. We use *precision*, *recall*, and *F-score* to measure how well the generated linguistic labels match the manually segmented and annotated complex actions in testing videos.

Figure 6 shows the F-scores of recognizing complex actions using the AoG learned from the *loose* and the *tight* language integration, respectively. In this figure, results are based on $k = 20$ state mapping hypotheses incorporated into the inference algorithm. As shown here, performances from both settings are significantly better than the baseline ($p < 0.001$). The AoG learned based on the tight integration with language yields significantly better performance than the loose integration (over 0.2 gain on F-score, $p < 0.001$).

This result indicates that the tight integration of

[5]Because the linguistic labels generated for primitive actions are all from terminal nodes, and the two different AoG learning settings only affect nonterminal nodes.

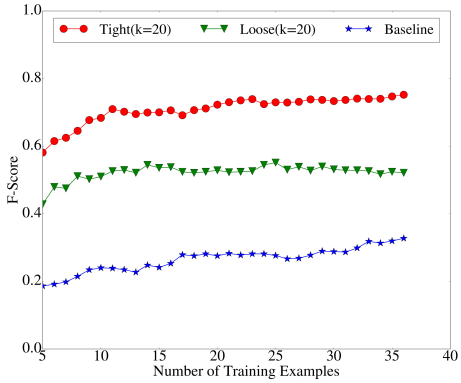

Figure 6: Performances (F-score) of recognizing complex actions. The lowest curve shows the performance from the baseline. Two other curves represent the performance using the AoG learned from the *loose* integration and the *tight* integration with language respectively (where $k = 20$ is used in inference).

language during AoG learning favors And-node patterns that are more likely to be described by natural language (or more consistent with human conceptualization of the task structure)[6]. Such an AoG representation can lead to recognition of video segments that can be better explained or summarized by human language. This capability of learning explicit and language-oriented task representations is important to link language and vision for enabling situated human-agent communication/collaboration.

Table 6.2 further shows the results from different numbers of state mapping hypotheses that are incorporated into the inference algorithm. As shown here, the trend of performance improvement with the increase in k is again observed. When multiple state mapping hypotheses are incorporated in inference, the learned AoG is capable of compensating uncertainties in vision processing and producing better parses for unseen visual demonstrations.

7 Conclusion and Future Work

This paper presents an approach on task learning where an agent can learn a grounded task model from human demonstrations and language instructions. A key innovation of this work is grounding language to a perceived structure of state changes based on AoG representation. Once the task model is acquired, it can be used as a basis to support collaboration and communication between humans and agents/robots. Using cloth-folding as an example, our empirical results have demonstrated that tightly integrating language with vision can effectively produce task structures in AoG that can generalize well to new demonstrations.

Although we have only made an initial attempt on a small task, our approach can be naturally extended to more complex tasks such like assembling and cooking. Both the AoG representation and the task learning approach are general and applicable to different domains. What needs to be adapted is the representation of the visual states and computer vision algorithms to detect these states for a specific task.

Grounding language to a structure of perceived state changes will provide an important stepping stone towards integrating language, perception, and action for human-robot communication and collaboration. Currently, our algorithms learn the task structures based on offline parallel data. Our future work will explore incremental learning through human-agent dialogue to acquire grounded task structures.

Table 1: Performance of recognizing complex actions using the AoG learned from the loose and tight integration of language as described in Section 5.2. Different (k) number of state mapping hypotheses are used in the inference algorithm.

		k=1	k=5	k=10	k=15	k=20
Precision	Loose	0.34	0.76	0.79	0.84	0.84
	Tight	0.34	0.8	0.86	0.89	0.9
Recall	Loose	0.12	0.33	0.35	0.38	0.38
	Tight	0.12	0.51	0.59	0.64	0.65
F-Score	Loose	0.17	0.46	0.49	0.52	0.52
	Tight	0.18	0.63	0.70	0.74	0.75

Acknowledgments

The authors are grateful to Sarah Fillwock and James Finch for their help on data collection and processing, to Mun Wai Lee for his helpful discussions, and to anonymous reviewers for their valuable comments and suggestions. This work was supported in part by N66001-15-C-4035 from the DARPA SIMPLEX program, and IIS-1208390 and IIS-1617682 from the National Science Foundation.

[6]By further investigating the learned AoG under the two different settings, we found that the nonterminal nodes learned from the tight language integration setting is more likely to acquire a linguistic label (33%) than the nonterminal nodes learned from the loose setting (18%).

Abstract

We present an approach to simultaneously perform semantic segmentation and prepositional phrase attachment resolution for captioned images. Some ambiguities in language cannot be resolved without simultaneously reasoning about an associated image. If we consider the sentence "I shot an elephant in my pajamas", looking at language alone (and not using common sense), it is unclear if it is the person or the elephant wearing the pajamas or both. Our approach produces a diverse set of plausible hypotheses for both semantic segmentation and prepositional phrase attachment resolution that are then jointly reranked to select the most consistent pair. We show that our semantic segmentation and prepositional phrase attachment resolution modules have complementary strengths, and that joint reasoning produces more accurate results than any module operating in isolation. Multiple hypotheses are also shown to be crucial to improved multiple-module reasoning. Our vision and language approach significantly outperforms the Stanford Parser (De Marneffe et al., 2006) by 17.91% (28.69% relative) and 12.83% (25.28% relative) in two different experiments. We also make small improvements over DeepLab-CRF (Chen et al., 2015).

1 Introduction

Perception and intelligence problems are hard. Whether we are interested in understanding an image or a sentence, our algorithms must operate under tremendous levels of ambiguity. When a human reads the sentence "I eat sushi with tuna", it is clear that the preposition phrase "with tuna" modifies "sushi" and not the act of eating, but this may be ambiguous to a machine. This problem of determining whether a prepositional phrase ("with tuna") modifies a noun phrase ("sushi") or verb phrase ("eating") is formally known as Prepositional Phrase Attachment Resolution (PPAR) (Ratnaparkhi et al., 1994). Consider the captioned scene shown in Fig-

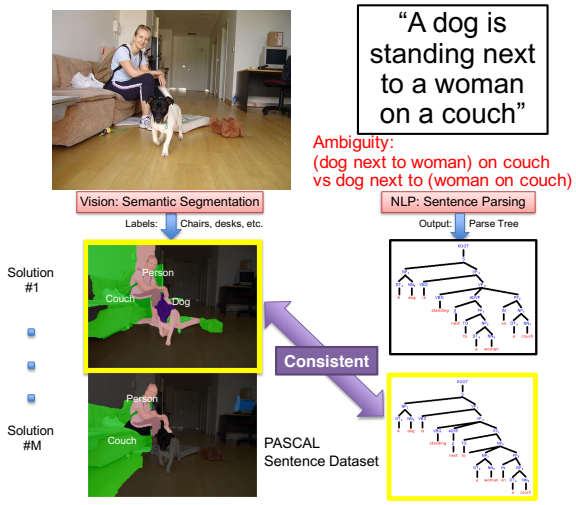

Figure 1: Overview of our approach. We propose a model for simultaneous 2D semantic segmentation and prepositional phrase attachment resolution by reasoning about sentence parses. The language and vision modules each produce M diverse hypotheses, and the goal is to select a pair of consistent hypotheses. In this example the ambiguity to be resolved from the image caption is whether the dog is standing on or next to the couch. Both modules benefit by selecting a pair of compatible hypotheses.

* Denotes equal contribution

Austin, Texas, November 1-5, 2016.

ure 1. The caption "A dog is standing next to a woman on a couch" exhibits a PP attachment ambiguity – "(dog next to woman) on couch" vs "dog next to (woman on couch)". It is clear that having access to image segmentations can help resolve this ambiguity, and having access to the correct PP attachment can help image segmentation.

There are two main roadblocks that keep us from writing a single unified model (say a graphical model) to perform both tasks: (1) Inaccurate Models – empirical studies (Meltzer et al., 2005, Szeliski et al., 2008, Kappes et al., 2013) have repeatedly found that models are often inaccurate and miscalibrated – their "most-likely" beliefs are placed on solutions far from the ground-truth. (2) Search Space Explosion – jointly reasoning about multiple modalities is difficult due to the combinatorial explosion of search space ($\{$exponentially-many segmentations$\}$ $\times$ $\{$exponentially-many sentence-parses$\}$).

Proposed Approach and Contributions. In this paper, we address the problem of simultaneous object segmentation (also called semantic segmentation) and PPAR in captioned scenes. To the best of our knowledge this is the first paper to do so.

Our main thesis is that a set of diverse plausible hypotheses can serve as a concise interpretable summary of uncertainty in vision and language 'modules' (What does the semantic segmentation module see in the world? What does the PPAR module describe?) and form the basis for tractable joint reasoning (How do we reconcile what the semantic segmentation module sees in the world with how the PPAR module describes it?).

Given our two modules with M hypotheses each, how can we integrate beliefs across the segmentation and sentence parse modules to pick the best pair of hypotheses? Our key focus is *consistency* – correct hypotheses from different modules will be correct in a consistent way, but incorrect hypotheses will be incorrect in incompatible ways. Specifically, we develop a MEDIATOR model that scores pairs for consistency and searches over all M^2 pairs to pick the highest scoring one. We demonstrate our approach on three datasets – ABSTRACT-50S (Vedantam et al., 2014), PASCAL-50S, and PASCAL-Context-50S (Mottaghi et al., 2014). We show that our vision+language approach significantly outperforms the Stanford Parser (De Marneffe et al., 2006) by 20.66% (36.42% relative) for ABSTRACT-50S, 17.91% (28.69% relative) for PASCAL-50S, and by 12.83% (25.28% relative) for PASCAL-Context-50S. We also make small but consistent improvements over DeepLab-CRF (Chen et al., 2015).

2 Related Work

Most works at the intersection of vision and NLP tend to be 'pipeline' systems, where vision tasks take 1-best inputs from NLP (*e.g.*, sentence parsings) without trying to improve NLP performance and vice-versa. For instance, Fidler et al. (2013) use prepositions to improve object segmentation and scene classification, but only consider the most-likely parse of the sentence and do not resolve ambiguities in text. Analogously, Yatskar et al. (2014) investigate the role of object, attribute, and action classification annotations for generating human-like descriptions. While they achieve impressive results at generating descriptions, they assume perfect vision modules to generate sentences. Our work uses current (still imperfect) vision and NLP modules to reason about images and provided captions, and simultaneously improve both vision and language modules. Similar to our philosophy, an earlier work by Barnard and Johnson (2005) used images to help disambiguate word senses (*e.g.* piggy banks vs snow banks). In a more recent work, Gella et al. (2016) studied the problem of reasoning about an image and a verb, where they attempt to pick the correct sense of the verb that describes the action depicted in the image. Berzak et al. (2015) resolve linguistic ambiguities in sentences coupled with videos that represent different interpretations of the sentences. Perhaps the work closest to us is Kong et al. (2014), who leverage information from an RGBD image and its sentential description to improve 3D semantic parsing and resolve ambiguities related to coreference resolution in the sentences (*e.g.*, what "it" refers to). We focus on a different kind of ambiguity – the Prepositional Phrase (PP) attachment resolution. In the classification of parsing ambiguities, coreference resolution is considered a discourse ambiguity (Poesio and Artstein, 2005) (arising out of two different words across sentences for the same object), while PP attachment is considered a syntactic ambiguity (arising out of multiple valid sentence

structures) and is typically considered much more difficult to resolve (Bach, 2016, Davis, 2016).

A number of recent works have studied problems at the intersection of vision and language, such as Visual Question Answering (Antol et al., 2015, Geman et al., 2014, Malinowski et al., 2015), Visual Madlibs (Yu et al., 2015), and image captioning (Vinyals et al., 2015, Fang et al., 2015). Our work falls in this domain with a key difference that we produce *both* vision and NLP outputs.

Our work also has similarities with works on 'spatial relation learning' (Malinowski and Fritz, 2014, Lan et al., 2012), *i.e*. learning a visual representation for noun-preposition-noun triplets ("car on road"). While our approach can certainly utilize such spatial relation classifiers if available, the focus of our work is different. Our goal is to improve semantic segmentation and PPAR by jointly reranking segmentation-parsing solution pairs. Our approach implicitly learns spatial relationships for prepositions ("on", "above") but these are simply emergent latent representations that help our reranker pick out the most consistent pair of solutions.

Our work utilizes a line of work (Batra et al., 2012, Batra, 2012, Prasad et al., 2014) on producing diverse plausible solutions from probabilistic models, which has been successfully applied to a number of problem domains (Guzman-Rivera et al., 2013, Yadollahpour et al., 2013, Gimpel et al., 2013, Premachandran et al., 2014, Sun et al., 2015, Ahmed et al., 2015).

3 Approach

In order to emphasize the generality of our approach, and to show that our approach is compatible with a wide class of implementations of semantic segmentation and PPAR modules, we present our approach with the modules abstracted as "black boxes" that satisfy a few general requirements and minimal assumptions. In Section 4, we describe each of the modules in detail, making concrete their respective features, and other details.

3.1 What is a Module?

The goal of a module is to take input variables $\mathbf{x} \in \mathcal{X}$ (images or sentences), and predict output variables $\mathbf{y} \in \mathcal{Y}$ (semantic segmentation) and $\mathbf{z} \in \mathcal{Z}$ (prepositional attachment expressed in sentence parse). The two requirements on a module are that it needs to be able to produce *scores* $S(\mathbf{y}|\mathbf{x})$ for potential solutions and a list of *plausible hypotheses* $\mathbf{Y} = \{\mathbf{y}^1, \mathbf{y}^2, \ldots, \mathbf{y}^M\}$.

Multiple Hypotheses. In order to be useful, the set $\mathbf{Y}$ of hypotheses must provide an accurate summary of the score landscape. Thus, the hypotheses should be plausible (*i.e*., high-scoring) and mutually non-redundant (*i.e*., diverse). Our approach (described next) is applicable to any choice of diverse hypothesis generators. In our experiments, we use the k-best algorithm of Huang and Chiang (2005) for the sentence parsing module and the DivMBest algorithm (Batra et al., 2012) for the semantic segmentation module. Once we instantiate the modules in Section 4, we describe the diverse solution generation in more detail.

3.2 Joint Reasoning Across Multiple Modules

We now show how to intergrate information from both segmentation and PPAR modules. Recall that our key focus is *consistency* – correct hypotheses from different modules will be correct in a consistent way, but incorrect hypotheses will be incorrect in incompatible ways. Thus, our goal is to search for a pair (semantic segmentation, sentence parsing) that is mutually consistent.

Let $\mathbf{Y} = \{\mathbf{y}^1, \ldots, \mathbf{y}^M\}$ denote the M semantic segmentation hypotheses and $\mathbf{Z} = \{\mathbf{z}^1, \ldots, \mathbf{z}^M\}$ denote the M PPAR hypotheses.

MEDIATOR Model. We develop a "mediator" model that identifies high-scoring hypotheses across modules in agreement with each other. Concretely, we can express the MEDIATOR model as a factor graph where each node corresponds to a module (semantic segmentation and PPAR). Working with such a factor graph is typically completely intractable because each node $\mathbf{y}, \mathbf{z}$ has exponentially-many states (image segmentations, sentence parsing). As illustrated in Figure 2, in this factor-graph view, the hypothesis sets $\mathbf{Y}, \mathbf{Z}$ can be considered 'delta-approximations' for reducing the size of the output spaces.

Unary factors $S(\cdot)$ capture the score/likelihood of each hypothesis provided by the corresponding module for the image/sentence at hand. Pairwise factors $C(\cdot, \cdot)$ represent consistency factors. Impor-

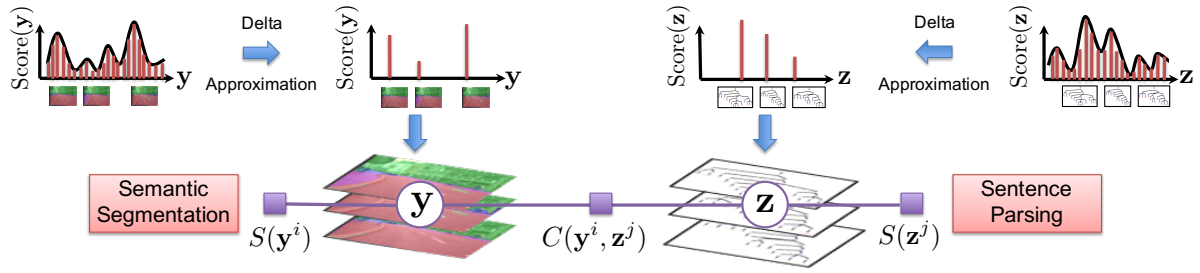

Figure 2: Illustrative inter-module factor graph. Each node takes exponentially-many or infinitely-many states and we use a 'delta approximation' to limit support.

tantly, since we have restricted each module variables to just M states, we are free to capture *arbitrary domain-specific high-order relationships* for consistency, without any optimization concerns. In fact, as we describe in our experiments, these consistency factors may be designed to exploit domain knowledge in fairly sophisticated ways.

Consistency Inference. We perform exhaustive inference over all possible tuples.

$$\underset{i,j\in\{1,\ldots,M\}}{\operatorname{argmax}} \Big\{\mathcal{M}(\mathbf{y}^i,\mathbf{z}^j) = S(\mathbf{y}^i) + S(\mathbf{z}^j) + C(\mathbf{y}^i,\mathbf{z}^j)\Big\}. \tag{1}$$

Notice that the search space with M hypotheses each is M^2. In our experiments, we allow each module to take a different value for M, and typically use around 10 solutions for each module, leading to a mere 100 pairs, which is easily enumerable. We found that even with such a small set, at least one of the solutions in the set tends to be *highly accurate*, meaning that the hypothesis sets have relatively high recall. This shows the power of using a small set of diverse hypotheses. For a large M, we can exploit a number of standard ideas from the graphical models literature (*e.g.* dual decomposition or belief propagation). In fact, this is one reason we show the factor in Figure 2; there is a natural decomposition of the problem into modules.

Training MEDIATOR. We can express the MEDIATOR score as $\mathcal{M}(\mathbf{y}^i,\mathbf{z}^j) = \mathbf{w}^\intercal\boldsymbol{\phi}(\mathbf{x},\mathbf{y}^i,\mathbf{z}^j)$, as a linear function of *score and consistency features* $\boldsymbol{\phi}(\mathbf{x},\mathbf{y}^i,\mathbf{z}^j) = [\phi_S(\mathbf{y}^i);\phi_S(\mathbf{z}^j);\phi_C(\mathbf{y}^i,\mathbf{z}^j)]$, where $\phi_S(\cdot)$ are the single-module (semantic segmentation and PPAR module) score features, and $\phi_C(\cdot,\cdot)$ are the inter-module consistency features. We describe these features in detail in the experiments. We learn these consistency weights $\mathbf{w}$ from a dataset annotated with ground-truth for the two modules $\mathbf{y},\mathbf{z}$. Let $\{\mathbf{y}^*,\mathbf{z}^*\}$ denote the `oracle` pair, composed of the most accurate solutions in the hypothesis sets. We learn the MEDIATOR parameters in a discriminative learning fashion by solving the following Structured SVM problem:

$$\min_{\mathbf{w},\xi_{ij}} \quad \frac{1}{2}\mathbf{w}^\intercal\mathbf{w} + C\sum_{ij}\xi_{ij} \tag{2a}$$

$$s.t. \quad \underbrace{\mathbf{w}^\intercal\boldsymbol{\phi}(\mathbf{x},\mathbf{y}^*,\mathbf{z}^*)}_{\text{Score of } \texttt{oracle} \text{ tuple}} - \underbrace{\mathbf{w}^\intercal\boldsymbol{\phi}(\mathbf{x},\mathbf{y}^i,\mathbf{z}^j)}_{\text{Score of any other tuple}}$$

$$\geq \underbrace{1}_{\text{Margin}} - \underbrace{\frac{\xi_{ij}}{\mathcal{L}(\mathbf{y}^i,\mathbf{z}^j)}}_{\text{Slack scaled by loss}} \qquad \forall i,j \in \{1,\ldots,M\}. \tag{2b}$$

Intuitively, we can see that the constraint (2b) tries to maximize the (soft) margin between the score of the `oracle` pair and all other pairs in the hypothesis sets. Importantly, the slack (or violation in the margin) is scaled by the loss of the tuple. Thus, if there are other good pairs not too much worse than the `oracle`, the margin for such tuples will not be tightly enforced. On the other hand, the margin between the `oracle` and bad tuples will be very strictly enforced.

This learning procedure requires us to define the loss function $\mathcal{L}(\mathbf{y}^i,\mathbf{z}^j)$, *i.e.*, the cost of predicting a tuple (semantic segmentation, sentence parsing). We use a weighted average of individual losses:

$$\mathcal{L}(\mathbf{y}^i,\mathbf{z}^j) = \alpha\ell(\mathbf{y}^{gt},\mathbf{y}^i) + (1-\alpha)\ell(\mathbf{z}^{gt},\mathbf{z}^j) \tag{3}$$

The standard measure for evaluating semantic segmentation is average Jaccard Index (or Intersection-over-Union) (Everingham et al., 2010), while for evaluating sentence parses w.r.t. their prepositional phrase attachment, we use the fraction of prepositions correctly attached. In our experiments, we report results with such a convex combination of module loss functions (for different values of α).

4 Experiments

We now describe the setup of our experiments, provide implementation details of the modules, and describe the consistency features.

Datasets. Access to rich annotated image + caption datasets is crucial for performing quantitative evaluations. Since this is the first paper to study the problem of joint segmentation and PPAR, no standard datasets for this task exist so we had to curate our own annotations for PPAR on three image caption datasets – ABSTRACT-50S (Vedantam et al., 2014), PASCAL-50S (Vedantam et al., 2014) (expands the UIUC PASCAL sentence dataset (Rashtchian et al., 2010) from 5 captions per image to 50), and PASCAL-Context-50S (Mottaghi et al., 2014) (which uses the PASCAL Context image annotations and the same sentences as PASCAL-50S). Our annotations are publicly available on the authors' webpages. To curate the PASCAL-Context-50S PPAR annotations, we first select all sentences that have preposition phrase attachment ambiguities. We then plotted the distribution of prepositions in these sentences. The top 7 prepositions are used, as there is a large drop in the frequencies beyond these. The 7 prepositions are: "on", "with", "next to", "in front of", "by", "near", and "down". We then further sampled sentences to ensure uniform distribution across prepositions. We perform a similar filtering for PASCAL-50S and ABSTRACT-50S (using the top-6 prepositions for ABSTRACT-50S). Details are in the supplement. We consider a preposition ambiguous if there are at least two parsings where one of the two objects in the preposition dependency is the same across the two parsings while the other object is different (*e.g.* (dog on couch) and (woman on couch)). To summarize the statistics of all three datasets:

1. **ABSTRACT-50S** (Vedantam et al., 2014): 25,000 sentences (50 per image) with 500 images from abstract scenes made from clipart. Filtering for captions containing the top-6 prepositions resulted in 399 sentences describing 201 unique images. These 6 prepositions are: "with", 'next to", "on top of", "in front of", "behind", and "under". Overall, there are 502 total prepositions, 406 ambiguous prepositions, 80.88% ambiguity rate and 60 sentences with multiple ambiguous prepositions.
2. **PASCAL-50S** (Vedantam et al., 2014): 50,000 sentences (50 per image) for the images in the UIUC PASCAL sentence dataset (Rashtchian et al., 2010). Filtering for the top-7 prepositions resulted in a total of 30 unique images, and 100 image-caption pairs, where ground-truth PPAR were carefully annotated by two vision + NLP graduate students. Overall, there are 213 total prepositions, 147 ambiguous prepositions, 69.01% ambiguity rate and 35 sentences with multiple ambiguous prepositions.
3. **PASCAL-Context-50S** (Mottaghi et al., 2014): We use images and captions from PASCAL-50S, but with PASCAL Context segmentation annotations (60 categories instead of 21). This makes the vision task more challenging. Filtering this dataset for the top-7 prepositions resulted in a total of 966 unique images and 1,822 image-caption pairs. Ground truth annotations for the PPAR were collected using Amazon Mechanical Turk. Workers were shown an image and a prepositional attachment (extracted from the corresponding parsing of the caption) as a phrase ("woman on couch"), and asked if it was correct. A screenshot of our interface is available in the supplement. Overall, there are 2,540 total prepositions, 2,147 ambiguous prepositions, 84.53% ambiguity rate and 283 sentences with multiple ambiguous prepositions.

Setup. *Single Module:* We first show that visual features help PPAR by using the ABSTRACT-50S dataset, which contains clipart scenes where the extent and position of all the objects in the scene is known. This allows us to consider a scenario with a perfect vision system.

Multiple Modules: In this experiment we use imperfect language and vision modules, and show improvements on the PASCAL-50S and PASCAL-Context-50S datasets.

Module 1: Semantic Segmentation (SS) $\mathbf{y}$. We use DeepLab-CRF (Chen et al., 2015) and DivMBest (Batra et al., 2012) to produce M diverse segmentations of the images. To evaluate we use image-level class-averaged Jaccard Index.

Module 2: PP Attachment Resolution (PPAR)

z. We use a recent version (v3.3.1; released 2014) of the PCFG Stanford parser module (De Marneffe et al., 2006, Huang and Chiang, 2005) to produce M parsings of the sentence. In addition to the parse trees, the module can also output *dependencies*, which make syntactical relationships more explicit. Dependencies come in the form *dependency_type(*$word_1$*,* $word_2$*)*, such as the preposition dependency *prep_on(woman-8, couch-11)* (the number indicates the word position in sentence). To evaluate, we count the percentage of preposition attachments that the parse gets correct.

Baselines:

- INDEP. In our experiments, we compare our proposed approach (MEDIATOR) to the highest scoring solution predicted independently from each module. For semantic segmentation this is the output of DeepLab-CRF (Chen et al., 2015) and for the PPAR module this is the 1-best output of the Stanford Parser (De Marneffe et al., 2006, Huang and Chiang, 2005). Since our hypothesis lists are generated by greedy M-Best algorithms, this corresponds to predicting the $(\mathbf{y}^1, \mathbf{z}^1)$ tuple. This comparison establishes the importance of joint reasoning. To the best of our knowledge, there is no existing (or even natural) joint model to compare to.
- DOMAIN ADAPTATION. We learn a reranker on the parses. Note that domain adaptation is only needed for PPAR since the Stanford parser is trained on Penn Treebank (Wall Street Journal text) and not on text about images (such as image captions). Such domain adaptation is not necessary for semantic segmentation. This is a competitive single-module baseline. Specifically, we use the *same* parse-based features as our approach, and learn a reranker over the M_z parse trees ($M_z = 10$).

Our approach (MEDIATOR) significantly outperforms both baselines. The improvements over INDEP show that joint reasoning produces more accurate results than any module (vision or language) operating in isolation. The improvements over DOMAIN ADAPTATION establish the source of improvements is indeed vision, and not the reranking step. Simply adapting the parse from its original training domain (Wall Street Journal) to our domain (image captions) is not enough.

Ablative Study. Ours-CASCADE: This ablation studies the importance of multiple hypothesis. For each module (say $\mathbf{y}$), we feed the single-best output of the other module $\mathbf{z}^1$ as input. Each module learns its own weight $\mathbf{w}$ using *exactly the same* consistency features and learning algorithm as MEDIATOR and predicts one of the plausible hypotheses $\hat{\mathbf{y}}^{\text{CASCADE}} = \text{argmax}_{\mathbf{y}\in\mathbf{Y}}\, \mathbf{w}^\intercal \boldsymbol{\phi}(\mathbf{x}, \mathbf{y}, \mathbf{z}^1)$. This ablation of our system is similar to (Heitz et al., 2008) and helps us in disentangling the benefits of multiple hypothesis and joint reasoning.

Finally, we note that Ours-CASCADE can be viewed as special cases of MEDIATOR. Let MEDIATOR-$(M_\mathbf{y}, M_\mathbf{z})$ denote our approach run with $M_\mathbf{y}$ hypotheses for the first module and $M_\mathbf{z}$ for the second. Then INDEP corresponds to MEDIATOR-$(1, 1)$ and CASCADE corresponds to predicting the $\mathbf{y}$ solution from MEDIATOR-$(M_\mathbf{y}, 1)$ and the $\mathbf{z}$ solution from MEDIATOR-$(1, M_\mathbf{z})$. To get an upper-bound on our approach, we report `oracle`, the accuracy of the most accurate tuple in 10×10 tuples.

In the main paper, our results are presented where MEDIATOR was trained with equally weighted loss ($\alpha = 0.5$), but we provide additional results for varying values of α in the supplement.

MEDIATOR and Consistency Features. Recall that we have two types of features – (1) score features $\phi_S(y^i)$ and $\phi_S(z^j)$, which try to capture how likely solutions y^i and z^j are respectively, and (2) consistency features $\phi_C(y^i, z^j)$, which capture how consistent the PP attachments in z^j are with the segmentation in y^i. For each ($object_1$, *preposition*, $object_2$) in z^j, we compute 6 features between $object_1$ and $object_2$ segmentations in y^i. Since the humans writing the captions may use multiple synonymous words (*e.g.* dog, puppy) for the same visual entity, we use word2vec (Mikolov et al., 2013) similarities to map the nouns in the sentences to the corresponding dataset categories.

- **Semantic Segmentation Score Features ($\phi_S(y^i)$) (2-dim)**: We use ranks and solution scores from DeepLab-CRF (Chen et al., 2015).
- **PPAR Score Features ($\phi_S(z^i)$) (9-dim)**: We use ranks and the log probability of parses from (De Marneffe et al., 2006), and 7 binary indicators for PASCAL (6 for ABSTRACT-50S) denoting which prepositions are present in the parse.

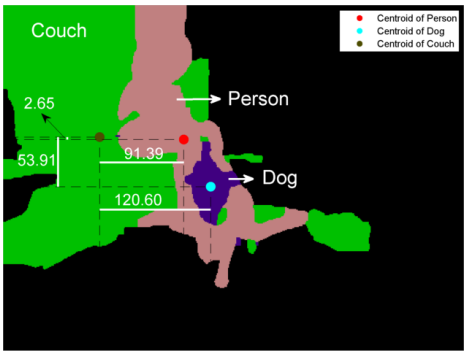

Figure 3: Example on PASCAL-50S ("A dog is standing next to a woman on a couch."). The ambiguity in this sentence "(dog next to woman) on couch" vs "dog next to (woman on couch)". We calculate the horizontal and vertical distances between the segmentation centers of "person" and "couch" and between the segmentation centers of "dog" and "couch". We see that the "dog" is much further below the couch (53.91) than the woman (2.65). So, if the MEDIATOR model learned that "on" means the first object is above the second object, we would expect it to choose the "person on couch" preposition parsing.

- **Inter-Module Consistency Features (56-dim)**: For each of the 7 prepositions, 8 features are calculated:
  - One feature is the Euclidean distance between the center of the segmentation masks of the two objects connected by the preposition. These two objects in the segmentation correspond to the categories with which the soft similarity of the two objects in the sentence is highest among all PASCAL categories.
  - Four features capture $\max\{0,$ (normalized -directional-distance)$\}$, where directional-distance measures above/below/left/right displacements between the two objects in the segmentation, and normalization involves dividing by height/width.
  - One feature is the ratio of sizes between object$_1$ and object$_2$ in the segmentation.
  - Two features capture the word2vec similarity between the two objects in PPAR (say 'puppy' and 'kitty') with their most similar PASCAL category (say 'dog' and 'cat'), where these features are 0 if the categories are not present in segmentation.

A visual illustration for some of these features for PASCAL can be seen in Figure 3. In the case where an object parsed from z^j is not present in the segmentation y^i, the distance features are set to 0. The ratio of areas features (area of smaller object / area of larger object) are also set to 0 assuming that the smaller object is missing. In the case where an object has two or more connected components in the segmentation, the distances are computed w.r.t. the centroid of the segmentation and the area is computed as the number of pixels in the union of the instance segmentation masks. We also calculate 20 features for PASCAL-50S and 59 features for PASCAL-Context-50S that capture that consistency between y^i and z^j, in terms of presence/absence of PASCAL categories. For each noun in PPAR we compute its word2vec similarity with all PASCAL categories. For each of the PASCAL categories, the feature is the sum of similarities (with the PASCAL category) over all nouns if the category is present in segmentation, and is -1 times the sum of similarities over all nouns otherwise. This feature set was not used for ABSTRACT-50S, since these features were intended to help improve the accuracy of the semantic segmentation module. For ABSTRACT-50S, we only use the 5 distance features, resulting in a 30-dim feature vector.

4.1 Single-Module Results

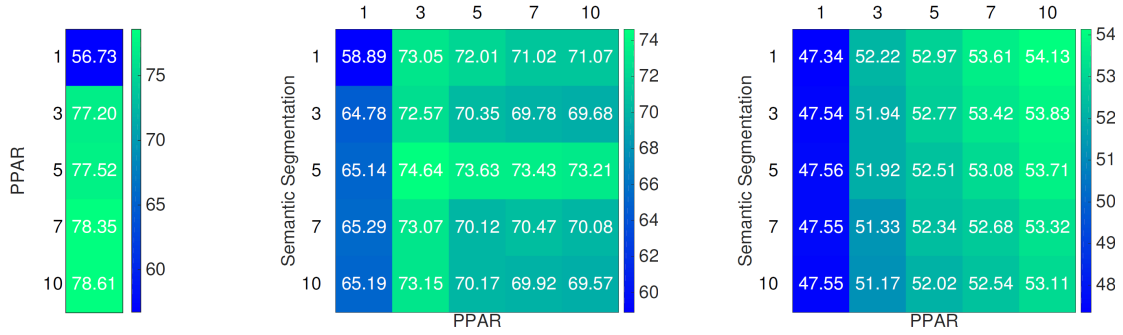
We performed a 10-fold cross-validation on the ABSTRACT-50S dataset to pick M (=10) and the weight on the hinge-loss for MEDIATOR (C). The results are presented in Table 1. Our approach significantly outpeforms 1-best outputs of the Stanford Parser (De Marneffe et al., 2006) by 20.66% (36.42% relative). This shows a need for diverse hypotheses and reasoning about visual features when picking a sentence parse. `oracle` denotes the best achievable performance using these 10 hypotheses.

Module	Stanford Parser	Domain Adaptation	Ours	`oracle`
PPAR	56.73	57.23	**77.39**	97.53

Table 1: Results on our subset of ABSTRACT-50S.

4.2 Multiple-Module Results

We performed 10-fold cross-val for our results of PASCAL-50S and PASCAL-Context-50S, with 8



(a) ABSTRACT-50S (b) PASCAL-50S (c) PASCAL-Context-50S

Figure 4: (a) Validation accuracies for different values of M on ABSTRACT-50S, (b) for different values of $M_{\mathbf{y}}, M_{\mathbf{z}}$ on PASCAL-50S, (c) for different values of $M_{\mathbf{y}}, M_{\mathbf{z}}$ on PASCAL-Context-50S.

	PASCAL-50S			PASCAL-Context-50S		
	Instance-Level Jaccard Index	PPAR Acc.	Average	Instance-Level Jaccard Index	PPAR Acc.	Average
DeepLab-CRF	66.83	-	-	**43.94**	-	-
Stanford Parser	-	62.42	-	-	50.75	-
Average	-	-	64.63	-	-	47.345
Domain Adaptation	-	72.08	-	-	58.32	-
Ours CASCADE	67.56	75.00	71.28	**43.94**	**63.58**	**53.76**
Ours MEDIATOR	**67.58**	**80.33**	**73.96**	**43.94**	**63.58**	**53.76**
`oracle`	69.96	96.50	83.23	49.21	75.75	62.48

Table 2: Results on our subset of the PASCAL-50S and PASCAL-Context-50S datasets. We are able to significantly outperform the Stanford Parser and make small improvements over DeepLab-CRF for PASCAL-50S.

`train` folds, 1 `val` fold, and 1 `test` fold, where the `val` fold was used to pick $M_{\mathbf{y}}$, $M_{\mathbf{z}}$, and C. Figure 4 shows the average combined accuracy on `val`, which was found to be maximal at $M_{\mathbf{y}} = 5, M_{\mathbf{z}} = 3$ for PASCAL-50S, and $M_{\mathbf{y}} = 1, M_{\mathbf{z}} = 10$ for PASCAL-Context-50S, which are used at test time.

We present our results in Table 2. Our approach significantly outperforms the Stanford Parser (De Marneffe et al., 2006) by 17.91% (28.69% relative) for PASCAL-50S, and 12.83% (25.28% relative) for PASCAL-Context-50S. We also make small improvements over DeepLab-CRF (Chen et al., 2015) in the case of PASCAL-50S. To measure statistical significance of our results, we performed paired t-tests between MEDIATOR and INDEP. For both modules (and average), the null hypothesis (that the accuracies of our approach and baseline come from the same distribution) can be successfully rejected at p-value 0.05. For sake of completeness, we also compared MEDIATOR with our ablated system (CASCADE) and found statistically significant differences only in PPAR.

These results demonstrate a need for each module to produce a diverse set of plausible hypotheses for our MEDIATOR model to reason about. In the case of PASCAL-Context-50S, MEDIATOR performs identical to CASCADE since $M_{\mathbf{y}}$ is chosen as 1 (which is the CASCADE setting) in cross-validation. Recall that MEDIATOR is a larger model class than CASCADE (in fact, CASCADE is a special case of MEDIATOR with $M_y = 1$). It is interesting to see that the large model class does not hurt, and MEDIATOR gracefully reduces to a smaller capacity model (CASCADE) if the amount of data is not enough to warrant the extra capacity. We hypothesize that in the presence of more training data, cross-validation may pick a different setting of $M_{\mathbf{y}}$ and $M_{\mathbf{z}}$, resulting in full utilization of the model capacity. Also note that our domain adaptation baseline achieved an accuracy higher than MAP/Stanford-Parser, but significantly lower than our approach for both PASCAL-50S and PASCAL-Context-50S. We also performed this for our single-module experiment and picked M_z (=10) with cross-validation,

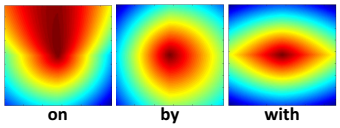


Figure 5: Visualizations for 3 different prepositions (red = high scores, blue = low scores). We can see that our model has implicitly learned spatial arrangements unlike other spatial relation learning (SRL) works.

Feature set	PASCAL-50S		PASCAL-Context-50S

Drop category presence	67.48	79.25	61.19

Table 3: Ablation study of different feature combinations. Only PPAR Acc. is shown for PASCAL-Context-50S because $M_y = 1$.

which resulted in an accuracy of 57.23%. Again, this is higher than MAP/Stanford-Parser (56.73%), but significantly lower than our approach (77.39%). Clearly, domain adaptation alone is not sufficient. We also see that `oracle` performance is fairly high, suggesting that when there is ambiguity and room for improvement, MEDIATOR is able to rerank effectively.

Ablation Study for Features. Table 3 displays results of an ablation study on PASCAL-50S and PASCAL-Context-50S to show the importance of the different features. In each row, we retain the module score features and drop a single set of consistency features. We can see all consistency features contribute to the performance of MEDIATOR.

Visualizing Prepositions. Figure 5 shows a visualization for what our MEDIATOR model has implicitly learned about 3 prepositions ("on", "by", "with"). These visualizations show the score obtained by taking the dot product of distance features (Euclidean and directional) between $object_1$ and $object_2$ connected by the preposition with the corresponding learned weights of the model, considering $object_2$ to be at the center of the visualization. Notice that these were learned without explicit training for spatial learning as in spatial relation learning (SRL) works (Malinowski and Fritz, 2014, Lan et al., 2012). These were simply recovered as an intermediate step towards reranking SS + PPAR hypotheses. Also note that SRL cannot handle multiple segmentation hypotheses, which our work shows are important (Table 2 CASCADE). In addition, our approach is more general.

5 Discussions and Conclusion

We presented an approach to the simultaneous reasoning about prepositional phrase attachment resolution of captions and semantic segmentation in images that integrates beliefs across the modules to pick the best pair of a diverse set of hypotheses. Our full model (MEDIATOR) significantly improves the accuracy of PPAR over the Stanford Parser by 17.91% for PASCAL-50S and by 12.83% for PASCAL-Context-50S, and achieves a small improvement on semantic segmentation over DeepLab-CRF for PASCAL-50S. These results demonstrate a need for information exchange between the modules, as well as a need for a diverse set of hypotheses to concisely capture the uncertainties of each module. Large gains in PPAR validate our intuition that vision is very helpful for dealing with ambiguity in language. Furthermore, we see even larger gains are possible from the oracle accuracies.

While we have demonstrated our approach on a task involving simultaneous reasoning about language and vision, our approach is general and can be used for other applications. Overall, we hope our approach will be useful in a number of settings.

CHARAGRAM: Embedding Words and Sentences via Character n-grams

Abstract

We present CHARAGRAM embeddings, a simple approach for learning character-based compositional models to embed textual sequences. A word or sentence is represented using a character n-gram count vector, followed by a single nonlinear transformation to yield a low-dimensional embedding. We use three tasks for evaluation: word similarity, sentence similarity, and part-of-speech tagging. We demonstrate that CHARAGRAM embeddings outperform more complex architectures based on character-level recurrent and convolutional neural networks, achieving new state-of-the-art performance on several similarity tasks.[1]

1 Introduction

Representing textual sequences such as words and sentences is a fundamental component of natural language understanding systems. Many functional architectures have been proposed to model compositionality in word sequences, ranging from simple averaging (Mitchell and Lapata, 2010; Iyyer et al., 2015) to functions with rich recursive structure (Socher et al., 2011; Zhu et al., 2015; Tai et al., 2015; Bowman et al., 2016). Most work uses words as the smallest units in the compositional architecture, often using pretrained word embeddings or learning them specifically for the task of interest (Tai et al., 2015; He et al., 2015).

Some prior work has found benefit from using character-based compositional models that encode arbitrary character sequences into vectors. Examples include recurrent neural networks (RNNs) and convolutional neural networks (CNNs) on character sequences, showing improvements for several NLP tasks (Ling et al., 2015a; Kim et al., 2015; Ballesteros et al., 2015; dos Santos and Guimarães, 2015). By sharing subword information across words, character models have the potential to better represent rare words and morphological variants.

Our approach, CHARAGRAM, uses a much simpler functional architecture. We represent a character sequence by a vector containing counts of character n-grams, inspired by Huang et al. (2013). This vector is embedded into a low-dimensional space using a single nonlinear transformation. This can be interpreted as learning embeddings of character n-grams, which are learned so as to produce effective sequence embeddings when a summation is performed over the character n-grams in the sequence.

We consider three evaluations: word similarity, sentence similarity, and part-of-speech tagging. On multiple word similarity datasets, CHARAGRAM outperforms RNNs and CNNs, achieving state-of-the-art performance on SimLex-999 (Hill et al., 2015). When evaluated on a large suite of sentence-level semantic textual similarity tasks, CHARAGRAM embeddings again outperform the RNN and CNN architectures as well as the PARAGRAM-PHRASE embeddings of Wieting et al. (2016). We also consider English part-of-speech (POS) tagging using the bidirectional long short-term memory tagger of Ling et al. (2015a). The three architectures reach similar performance, though CHARAGRAM converges fastest to high accuracy.

[1] Trained models and code are available at http://ttic.uchicago.edu/~wieting.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1504–1515,
Austin, Texas, November 1-5, 2016.

We perform extensive analysis of our CHARAGRAM embeddings. We find large gains in performance on rare words, showing the empirical benefit of subword modeling. We also compare performance across different character n-gram vocabulary sizes, finding that the semantic tasks benefit far more from large vocabularies than the syntactic task. However, even for challenging semantic similarity tasks, we still see strong performance with only a few thousand character n-grams.

Nearest neighbors show that CHARAGRAM embeddings simultaneously address differences due to spelling variation, morphology, and word choice. Inspection of embeddings of particular character n-grams reveals etymological links; e.g., *die* is close to *mort*. We release our resources to the community in the hope that CHARAGRAM can provide a strong baseline for subword-aware text representation.

2 Related Work

We first review work on using subword information in word embedding models. The simplest approaches append subword features to word embeddings, letting the model learn how to use the subword information for particular tasks. Some added knowledge-based morphological features to word representations (Alexandrescu and Kirchhoff, 2006; El-Desoky Mousa et al., 2013). Others learned embeddings jointly for subword units and words, defining simple compositional architectures (often based on addition) to create word embeddings from subword embeddings (Lazaridou et al., 2013; Botha and Blunsom, 2014; Qiu et al., 2014; Chen et al., 2015).

A recent trend is to use richer functional architectures to convert character sequences into word embeddings. Luong et al. (2013) used recursive models to compose morphs into word embeddings, using unsupervised morphological analysis. Ling et al. (2015a) used a bidirectional long short-term memory (LSTM) RNN on characters to embed arbitrary word types, showing strong performance for language modeling and POS tagging. Ballesteros et al. (2015) used this model to represent words for dependency parsing. Several have used character-level RNN architectures for machine translation, whether for representing source or target words (Ling et al., 2015b; Luong and Manning, 2016), or for generating entire translations character-by-character (Chung et al., 2016).

Sutskever et al. (2011) and Graves (2013) used character-level RNNs for language modeling. Others trained character-level RNN language models to provide features for NLP tasks, including tokenization and segmentation (Chrupała, 2013; Evang et al., 2013), and text normalization (Chrupała, 2014).

CNNs with character n-gram filters have been used to embed arbitrary word types for several tasks, including language modeling (Kim et al., 2015), part-of-speech tagging (dos Santos and Zadrozny, 2014), named entity recognition (dos Santos and Guimarães, 2015), text classification (Zhang et al., 2015), and machine translation (Costa-Jussà and Fonollosa, 2016). Combinations of CNNs and RNNs on characters have also been explored (Józefowicz et al., 2016).

Most closely-related to our approach is the DSSM (instantiated variously as "deep semantic similarity model" or "deep structured semantic model") developed by Huang et al. (2013). For an information retrieval task, they represented words using feature vectors containing counts of character n-grams. Sperr et al. (2013) used a very similar technique to represent words in neural language models for machine translation. Our CHARAGRAM embeddings are based on this same idea. We show this strategy to be extremely effective when applied to both words and sentences, outperforming character LSTMs like those used by Ling et al. (2015a) and character CNNs like those from Kim et al. (2015).

3 Models

We now describe models that embed textual sequences using their characters, including our CHARAGRAM model and the baselines that we compare to. We denote a character-based textual sequence by $x = \langle x_1, x_2, ..., x_m \rangle$, which includes space characters between words as well as special start-of-sequence and end-of-sequence characters. We use x_i^j to denote the subsequence of characters from position i to position j inclusive, i.e., $x_i^j = \langle x_i, x_{i+1}, ..., x_j \rangle$, and we define $x_i^i = x_i$.

Our CHARAGRAM model embeds a character sequence x by adding the vectors of its character n-

grams followed by an elementwise nonlinearity:

$$g_{\text{CHAR}}(x) = h\left(\boldsymbol{b} + \sum_{i=1}^{m+1} \sum_{j=1+i-k}^{i} \mathbb{I}\left[x_j^i \in V\right] W^{x_j^i}\right) \quad (1)$$

where h is a nonlinear function, $\boldsymbol{b} \in \mathbb{R}^d$ is a bias vector, k is the maximum length of any character n-gram, $\mathbb{I}[p]$ is an indicator function that returns 1 if p is true and 0 otherwise, V is the set of character n-grams included in the model, and $W^{x_j^i} \in \mathbb{R}^d$ is the vector for character n-gram x_j^i.

The set V is used to restrict the model to a predetermined set (vocabulary) of character n-grams. Below, we compare several choices for V. The number of parameters in the model is $d + d|V|$. This model is based on the letter n-gram hashing technique developed by Huang et al. (2013). One can also view Eq. (1) (as they did) as first populating a vector of length $|V|$ with counts of character n-grams followed by a nonlinear transformation.

We compare the CHARAGRAM model to two other models. First we consider LSTM architectures (Hochreiter and Schmidhuber, 1997) over the character sequence x, using the version from Gers et al. (2003). We use a forward LSTM over the characters in x, then take the final LSTM hidden vector as the representation of x. Below we refer to this model as "charLSTM."

We also compare to convolutional neural network (CNN) architectures, which we refer to below as "charCNN." We use the architecture from Kim (2014) with a single convolutional layer followed by an optional fully-connected layer. We use filters of varying lengths of character n-grams, using two primary configurations of filter sets, one of which is identical to that used by Kim et al. (2015). Each filter operates over the entire sequence of character n-grams in x and we use max pooling for each filter. We tune over the choice of nonlinearity for both the convolutional filters and for the optional fully-connected layer. We give more details below about filter sets, n-gram lengths, and nonlinearities.

We note that using character n-gram convolutional filters is similar to our use of character n-grams in the CHARAGRAM model. The difference is that, in the CHARAGRAM model, the n-gram must match exactly for its vector to affect the representation, while in the CNN each filter will affect the representation of all sequences (depending on the nonlinearity being used). So the CHARAGRAM model is able to learn precise vectors for particular character n-grams with specific meanings, while there is pressure for the CNN filters to capture multiple similar patterns that recur in the data. Our qualitative analysis shows the specificity of the learned character n-gram vectors learned by the CHARAGRAM model.

4 Experiments

We perform three sets of experiments. The goal of the first two (Section 4.1) is to produce embeddings for textual sequences such that the embeddings for paraphrases have high cosine similarity. Our third evaluation (Section 4.2) is a classification task, and follows the setup of the English part-of-speech tagging experiment from Ling et al. (2015a).

4.1 Word and Sentence Similarity

We compare the ability of our models to capture semantic similarity for both words and sentences. We train on noisy paraphrase pairs from the Paraphrase Database (PPDB; Ganitkevitch et al., 2013) with an L_2 regularized contrastive loss objective function, following the training procedure of Wieting et al. (2015) and Wieting et al. (2016). More details are provided in the supplementary material.

4.1.1 Datasets

For word similarity, we focus on two of the most commonly used datasets for evaluating semantic similarity of word embeddings: WordSim-353 (WS353) (Finkelstein et al., 2001) and SimLex-999 (SL999) (Hill et al., 2015). We also evaluate our best model on the Stanford Rare Word Similarity Dataset (Luong et al., 2013).

For sentence similarity, we evaluate on a diverse set of 22 textual similarity datasets, including all datasets from every SemEval semantic textual similarity (STS) task from 2012 to 2015. We also evaluate on the SemEval 2015 Twitter task (Xu et al., 2015) and the SemEval 2014 SICK Semantic Relatedness task (Marelli et al., 2014). Given two sentences, the aim of the STS tasks is to predict their similarity on a 0-5 scale, where 0 indicates the sentences are on different topics and 5 indicates that they are completely equivalent.

Each STS task consists of 4-6 datasets covering a wide variety of domains, including newswire, tweets, glosses, machine translation outputs, web forums, news headlines, image and video captions, among others. Most submissions for these tasks use supervised models that are trained and tuned on provided training data or similar datasets from older tasks. Further details are provided in the official task descriptions (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015).

4.1.2 Preliminaries

For training data, we use pairs from PPDB. For word similarity experiments, we train on word pairs and for sentence similarity, we train on phrase pairs. PPDB comes in different sizes (S, M, L, XL, XXL, and XXXL), where each larger size subsumes all smaller ones. The pairs in PPDB are sorted by a confidence measure and so the smaller sets contain higher precision paraphrases. PPDB is derived automatically from naturally-occurring bilingual text, and versions of PPDB have been released for many languages without the need for any manual annotation (Ganitkevitch and Callison-Burch, 2014).

Before training the CHARAGRAM model, we need to populate V, the vocabulary of character n-grams included in the model. We obtain these from the training data used for the final models in each setting, which is either the lexical or phrasal section of PPDB XXL. We tune over whether to include the full sets of character n-grams in these datasets or only those that appear more than once.

When extracting n-grams, we include spaces and add an extra space before and after each word or phrase in the training and evaluation data to ensure that the beginning and end of each word is represented. We note that strong performance can be obtained using far fewer character n-grams; we explore the effects of varying the number of n-grams and the n-gram orders in Section 4.4.

We used Adam (Kingma and Ba, 2014) with a learning rate of 0.001 to learn the parameters in the following experiments.

4.1.3 Word Embedding Experiments

Training and Tuning For hyperparameter tuning, we used one epoch on the lexical section of PPDB XXL, which consists of 770,007 word pairs. We used either WS353 or SL999 for model selection (reported below). We then took the selected hyperparameters and trained for 50 epochs to ensure that all models had a chance to converge.

Model	Tuned on	WS353	SL999
charCNN	SL999	26.31	30.64
	WS353	33.19	16.73
charLSTM	SL999	48.27	54.54
	WS353	51.43	48.83
CHARAGRAM	SL999	53.87	**63.33**
	WS353	**58.35**	60.00
inter-annotator agreement	-	75.6	78

Table 1: Word similarity results (Spearman's $\rho \times 100$). The inter-annotator agreement is the average Spearman's ρ between a single annotator and the average of all others.

Full details of our tuning procedure are provided in the supplementary material. In short, we tuned all models thoroughly, tuning the activation functions for CHARAGRAM and charCNN, as well as the regularization strength, mini-batch size, and sampling type for all models. For charCNN, we experimented with two filter sets: one uses 175 filters for each n-gram size $\in \{2, 3, 4\}$, and the other uses the set of filters from Kim et al. (2015), consisting of 25 filters of size 1, 50 of size 2, 75 of size 3, 100 of size 4, 125 of size 5, and 150 of size 6. We also experimented with using dropout (Srivastava et al., 2014) on the inputs to the final layer of charCNN in place of L_2 regularization, as well as removing the last feedforward layer. Neither variation significantly improved performance on our suite of tasks for word or sentence similarity. However, using more filters does improve performance, apparently linearly with the square of the number of filters.

Architecture Comparison The results are shown in Table 1. The CHARAGRAM model outperforms both the charLSTM and charCNN models, and also outperforms recent strong results on SL999.

We also found that the charCNN and charLSTM models take far more epochs to converge than the CHARAGRAM model. We noted this trend across experiments and explore it further in Section 4.3.

Comparison to Prior Work We found that performance of CHARAGRAM on word similarity tasks can be improved by using more character n-grams. This is explored in Section 4.4. Our best result from these experiments was obtained with the largest

Model	SL999
Hill et al. (2014)	52
Schwartz et al. (2015)	56
Faruqui and Dyer (2015)	58
Wieting et al. (2015)	66.7
CHARAGRAM (large)	**70.6**

Table 2: Spearman's $\rho \times 100$ on SL999. CHARAGRAM (large) refers to the CHARAGRAM model described in Section 4.4. This model contains 173,881 character n-grams, more than the 100,283 in the CHARAGRAM model used in Table 1.

model we considered, which contains 173,881 n-gram embeddings. When using WS353 for model selection and training for 25 epochs, this model achieves 70.6 on SL999. To our knowledge, this is the best result reported on SL999 in this setting; Table 2 shows comparable recent results. Note that a higher SL999 number is reported by Mrkšić et al. (2016), but the setting is not comparable to ours as they started with embeddings tuned on SL999.

Lastly, we evaluated our model on the Stanford Rare Word Similarity Dataset (Luong et al., 2013), using SL999 for model selection. We obtained a Spearman's ρ of 47.1, which outperforms the 41.8 result from Soricut and Och (2015) and is competitive with the 47.8 reported by Pennington et al. (2014), which used a 42B-token corpus for training.

4.1.4 Sentence Embedding Experiments

Training and Tuning We did initial training of our models using one pass through PPDB XL, which consists of 3,033,753 unique phrase pairs. Following Wieting et al. (2016), we use the annotated phrase pairs developed by Pavlick et al. (2015) as our validation set, using Spearman's ρ to rank the models. We then take the highest performing models and train on the 9,123,575 unique phrase pairs in the phrasal section of PPDB XXL for 10 epochs.

For all experiments, we fix the mini-batch size to 100, the margin δ to 0.4, and use MAX sampling (see supplementary material). For CHARAGRAM, V contains all 122,610 character n-grams ($n \in \{2, 3, 4\}$) in the PPDB XXL phrasal section. Other tuning settings are the same as Section 4.1.3.

For another baseline, we train the PARAGRAM-PHRASE model of Wieting et al. (2016), tuning its regularization strength over $\{10^{-5}, 10^{-6}, 10^{-7}, 10^{-8}\}$. The PARAGRAM-PHRASE model simply uses word averaging as its composition function, but outperforms many more complex models.

In this section, we refer to our model as CHARAGRAM-PHRASE because the input is a character sequence containing multiple words rather than only a single word as in Section 4.1.3. Since the vocabulary V is defined by the training data sequences, the CHARAGRAM-PHRASE model includes character n-grams that span multiple words, permitting it to capture some aspects of word order and word co-occurrence, which the PARAGRAM-PHRASE model is unable to do.

We encountered difficulties training the charLSTM and charCNN models for this task. We tried several strategies to improve their chance at convergence, including clipping gradients, increasing training data, and experimenting with different optimizers and learning rates. We found success by using the original (confidence-based) ordering of the PPDB phrase pairs for the initial epoch of learning, then shuffling them for subsequent epochs. This is similar to curriculum learning (Bengio et al., 2009). The higher-confidence phrase pairs tend to be shorter and have many overlapping words, possibly making them easier to learn from.

Results An abbreviated version of the sentence similarity results is shown in Table 3; the supplementary material contains the full results. For comparison, we report performance for the median (50%), third quartile (75%), and top-performing (Max) systems from the shared tasks. We observe strong performance for the CHARAGRAM-PHRASE model. It always does better than the charCNN and charLSTM models, and outperforms the PARAGRAM-PHRASE model on 15 of the 22 tasks. Furthermore, CHARAGRAM-PHRASE matches or exceeds the top-performing task-tuned systems on 5 tasks, and is within 0.003 on 2 more. The charLSTM and charCNN models are significantly worse, with the charCNN being the better of the two and beating PARAGRAM-PHRASE on 4 of the tasks.

We emphasize that there are many other models that could be compared to, such as an LSTM over word embeddings. This and many other models were explored by Wieting et al. (2016). Their PARAGRAM-PHRASE model, which simply learns word embeddings within an averaging composition

Dataset	50%	75%	Max	charCNN	charLSTM	PARAGRAM-PHRASE	CHARAGRAM-PHRASE
STS 2012 Average	54.5	59.5	70.3	56.5	40.1	58.5	**66.1**

Model	Accuracy (%)
charCNN	97.02
charLSTM	96.90
CHARAGRAM	96.99
CHARAGRAM (2-layer)	**97.10**

Table 4: Results on part-of-speech tagging.

function, was among their best-performing models. We used this model in our experiments as a strongly-performing representative of their results.

Lastly, we note other recent work that considers a similar transfer learning setting. The FastSent model (Hill et al., 2016) uses the 2014 STS task in its evaluation and reports an average Pearson's r of 61.3. On the same data, the C-PHRASE model (Pham et al., 2015) has an average Pearson's r of 65.7.[2] Both results are lower than the 74.7 achieved by CHARAGRAM-PHRASE on this dataset.

4.2 POS Tagging Experiments

We now consider part-of-speech (POS) tagging, since it has been used as a testbed for evaluating architectures for character-level word representations. It also differs from semantic similarity, allowing us to evaluate our architectures on a syntactic task. We replicate the POS tagging experimental setup of Ling et al. (2015a). Their model uses a bidirectional LSTM over character embeddings to represent words. They then use the resulting word representations in another bidirectional LSTM that predicts the tag for each word. We replace their character bidirectional LSTM with our three architectures: charCNN, charLSTM, and CHARAGRAM.

We use the Wall Street Journal portion of the Penn Treebank, using Sections 1-18 for training, 19-21 for tuning, and 22-24 for testing. We set the dimensionality of the character embeddings to 50 and that of the (induced) word representations to 150. For optimization, we use stochastic gradient descent with a mini-batch size of 100 sentences. The learning rate and momentum are set to 0.2 and 0.95 respectively. We train the models for 50 epochs, again to ensure that all models have an opportunity to converge.

The other settings for our models are mostly the same as for the word and sentence experiments (Section 4.1). We again use character n-grams with $n \in \{2, 3, 4\}$, tuning over whether to include all 54,893 in the training data or only those that occur more than once. However, there are two minor differences from the previous sections. First, we add a single binary feature to indicate if the token contains a capital letter. Second, our tuning considers rectified linear units as the activation function for the CHARAGRAM and charCNN architectures.[3]

The results are shown in Table 4. Performance is similar across models. We found that adding a second fully-connected 150 dimensional layer to the CHARAGRAM model improved results slightly.[4]

4.3 Convergence

One observation we made during our experiments was that different models converged at significantly different rates. Figure 1 plots the performance of the word similarity and tagging tasks as a function of training epoch. For word similarity, we plot the oracle Spearman's ρ on SL999, while for tagging we plot accuracy on the tuning set. We evaluate every quarter epoch (approximately every 194,252 word pairs) for word similarity and every epoch for tag-

[2]Both the results for FastSent and C-PHRASE were computed from Table 4 in (Hill et al., 2016).

[3]We did not consider ReLU for the similarity experiments because the final embeddings are used directly to compute cosine similarities, which led to poor performance when restricting the embeddings to be non-negative.

[4]We also tried adding a second (300 dimensional) layer for the word and sentence similarity models and found it to hurt performance.

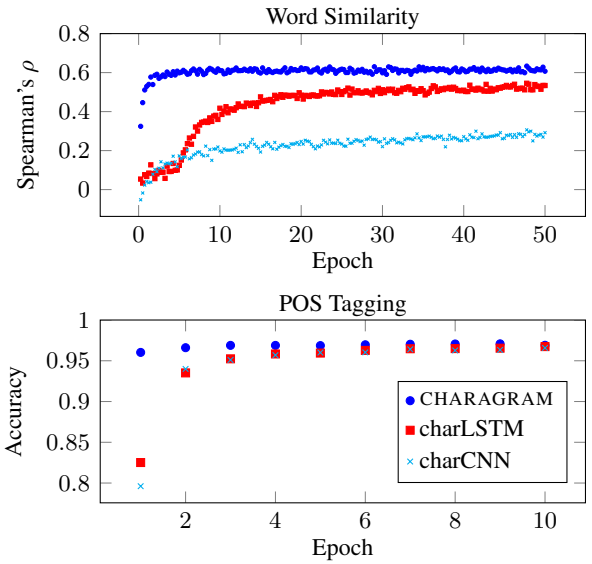

Figure 1: Plots of performance versus training epoch for word similarity and POS tagging.

ging. We only show the first 10 epochs of training in the tagging plot.

The plots show that the CHARAGRAM model converges quickly to high performance. The charCNN and charLSTM models take many more epochs to converge. Even with tagging, which uses a very high learning rate, CHARAGRAM converges significantly faster than the others. For word similarity, it appears that charCNN and charLSTM are still slowly improving at the end of 50 epochs. This suggests the possibility that these models could eventually surpass CHARAGRAM with more epochs. However, due to the large training sets available from PPDB and the computational requirements of these architectures, we were unable to explore the regime of training for many epochs. We conjecture that slow convergence could also be the reason for the inferior performance of LSTMs for similarity tasks as reported by Wieting et al. (2016).

4.4 Model Size Experiments

The default setting for our CHARAGRAM and CHARAGRAM-PHRASE models is to use all character bigram, trigrams, and 4-grams that occur in the training data at least C times, tuning C over the set $\{1, 2\}$. This results in a large number of parameters, which could be seen as an unfair advantage over the comparatively smaller charCNN and charLSTM similarity models, which have up to 881,025 and 763,200 parameters respectively (including 134 character embeddings for each).

Task	# n-grams	2	2,3	2,3,4	2,3,4,5	2,3,4,5,6
POS Tagging	100	95.52	96.09	96.15	96.13	96.16
	1,000	96.72	96.86	96.97	97.02	97.03
	50,000	96.81	97.00	97.02	97.04	**97.09**
Word Similarity	100	6.2	7.0	7.7	9.1	8.8
	1,000	15.2	33.0	38.7	43.2	43.9
	50,000	14.4	52.4	67.8	69.2	**69.5**
Sentence Similarity	100	40.2	33.8	32.5	31.2	29.8
	1,000	50.1	60.3	58.6	56.6	55.6
	50,000	45.7	64.7	**66.6**	63.0	61.3

Table 5: Results of using different numbers and different combinations of character n-grams.

However, for a given sequence, very few parameters in the CHARAGRAM model are actually used. For charCNN and charLSTM, by contrast, all parameters are used except character embeddings for characters not present in the sequence. For a 100-character sequence, the 300-dimensional CHARAGRAM model uses approximately 90,000 parameters, about one-tenth of those used by charCNN and charLSTM for the same sequence.

We performed a series of experiments to investigate how the CHARAGRAM and CHARAGRAM-PHRASE models perform with different numbers and lengths of character n-grams. For a given k, we took the k most frequent character n-grams for each value of n in use. We experimented with k values in $\{100, 1000, 50000\}$. If there were fewer than k unique character n-grams for a given n, we used all of them. For these experiments, we did very little tuning, setting the regularization strength to 0 and only tuning the activation function. For word similarity, we report performance on SL999 after 5 training epochs on the lexical section of PPDB XXL. For sentence similarity, we report the average Pearson's r over all 22 datasets after 5 training epochs on the phrasal section of PPDB XL. For tagging, we report accuracy on the tuning set after 50 training epochs.

The results are shown in Table 5. When using extremely small models with only 100 n-grams of each order, we still see relatively strong performance on tagging. However, the similarity tasks require far more n-grams to yield strong performance. Using 1000 n-grams clearly outperforms 100, and 50,000 n-grams performs best. We also found that models converged more quickly on tagging than on the similarity tasks. We suspect this is due to differences in task complexity. In tagging, the model does not

need to learn all facets of each word's semantics; it only needs to map a word to its syntactic categories. Therefore, simple surface-level features like affixes can help tremendously. However, learning representations that reflect detailed differences in word meaning is a more fine-grained endeavor and this is presumably why larger models are needed and convergence is slower.

5 Analysis

5.1 Quantitative Analysis

One of our primary motivations for character-based models is to address the issue of out-of-vocabulary (OOV) words, which were found to be one of the main sources of error for the PARAGRAM-PHRASE model from Wieting et al. (2016). They reported a negative correlation (Pearson's r of -0.45) between OOV rate and performance. We took the 12,108 sentence pairs in all 20 SemEval STS tasks and binned them by the total number of unknown words in the pairs.[5] We computed Pearson's r over each bin. The results are shown in Table 6.

Number of Unknown Words	N	PARAGRAM-PHRASE	CHARAGRAM-PHRASE
0	11,292	71.4	**73.8**
1	534	68.8	**78.8**
2	194	66.4	**72.8**
≥ 1	816	68.6	**77.9**
≥ 0	12,108	71.0	**74.0**

Table 6: Performance (Pearson's $r \times 100$) as a function of the number of unknown words in the sentence pairs over all 20 SemEval STS datasets. N is the number of sentence pairs.

The CHARAGRAM-PHRASE model has better performance for each number of unknown words. The PARAGRAM-PHRASE model degrades when more unknown words are present, presumably because it is forced to use the same unknown word embedding for all unknown words. The CHARAGRAM-PHRASE model has no notion of unknown words, as it can embed any character sequence.

We next investigated the sensitivity of the two models to length, as measured by the maximum of the lengths of the two sentences in a pair. We binned all of the 12,108 sentence pairs in the 20 SemEval STS tasks by length and then again found the Pearson's r for both the PARAGRAM-PHRASE and CHARAGRAM-PHRASE models. The results are shown in Table 7.

Max Length	N	PARAGRAM-PHRASE	CHARAGRAM-PHRASE
≤ 4	71	67.9	**72.9**
5	216	71.1	**71.9**
6	572	67.0	**69.7**
7	1,097	71.5	**74.0**
8	1,356	74.2	**74.5**
9	1,266	71.7	**72.7**
10	1,010	70.7	**74.2**
11-15	3,143	71.8	**73.7**
16-20	1,559	73.0	**75.1**
≥ 21	1,818	74.5	**75.4**

Table 7: Performance (Pearson's $r \times 100$) as a function of the maximum number of tokens in the sentence pairs over all 20 SemEval STS datasets. N is the number of sentence pairs.

Both models are robust to sentence length, achieving the highest correlations on the longest sentences. We also find that CHARAGRAM-PHRASE outperforms PARAGRAM-PHRASE at all sentence lengths.

5.2 Qualitative Analysis

Bigram	CHARAGRAM-PHRASE	PARAGRAM-PHRASE
not capable	incapable, unable, incapacity	not, capable, stalled
not able	unable, incapable, incapacity	not, able, stalled
not possible	impossible impracticable unable	not, stalled, possible
not sufficient	insufficient, sufficient, inadequate	not, sufficient, stalled
not easy	easy, difficult, tough	not, stalled, easy

Table 8: Nearest neighboring words of selected bigrams under CHARAGRAM-PHRASE and PARAGRAM-PHRASE embeddings.

Aside from OOVs, the PARAGRAM-PHRASE model lacks the ability to model word order or cooccurrence, since it simply averages the words in the sequence. We were interested to see whether CHARAGRAM-PHRASE could handle negation, since it does model limited information about word order (via character n-grams that span multiple words). We made a list of "not" bigrams that could be represented by a single word, then embedded each bigram using both models and did a nearest-neighbor search over a working vocabulary.[6] The results, in Table 8, show how the CHARAGRAM-PHRASE embeddings model negation. In all cases but one, the near-

[5] Unknown words were defined as those not present in the 1.7 million unique (case-insensitive) tokens that comprise the vocabulary for the GloVe embeddings available at `http://nlp.stanford.edu/projects/glove/`. The PARAGRAM-SL999 embeddings, used to initialize the PARAGRAM-PHRASE model, use this same vocabulary.

[6] This has all words in PPDB-XXL, our evaluations, and two other datasets: SST (Socher et al., 2013) and SNLI (Bowman et al., 2015), resulting in 93,217 unique (up-to-casing) tokens.

Word	Nearest Neighbors
vehicals	vehical, vehicles, vehicels, vehicular, cars, vehicle, automobiles, car
serious-looking	serious, grave, acute, serious-minded, seriousness, gravity, serious-faced
near-impossible	impossible, hard/impossible, audacious-impossible, impractical, unable
growths	growth, grow, growing, increases, grows, increase, rise, growls, rising
litered	liter, litering, lited, liters, literate, literature, literary, literal, lite, obliterated
journeying	journey, journeys, voyage, trip, roadtrip, travel, tourney, voyages, road-trip
babyyyyyy	babyyyyyyy, baby, babys, babe, baby.i, babydoll, babycake, darling
adirty	dirty, dirtyyyyyy, filthy, down-and-dirty, dirtying, dirties, ugly, dirty-blonde
refunding	refunds, refunded, refund, repayment, reimbursement, rebate, repay reimbursements, reimburse, repaying, repayments, rebates, rebating, reimburses
professors	professor, professorships, professorship, teachers, professorial, teacher prof., teaches, lecturers, teachings, instructors, headteachers, teacher-student
huge	enormous, tremendous, large, big, vast, overwhelming, immense, giant formidable, considerable, massive, huger, large-scale, great, daunting

Table 9: Nearest neighbors of CHARAGRAM-PHRASE embeddings. Above the double horizontal line are nearest neighbors of words that were not in our training data, and below it are nearest neighbors of words that were in our training data.

est neighbor is a paraphrase for the bigram and the next neighbors are mostly paraphrases as well. The PARAGRAM-PHRASE model, unsurprisingly, is incapable of modeling negation. In all cases, the nearest neighbor is *not*, as it carries much more weight than the word it modifies. The remaining nearest neighbors are either the modified word or *stalled*.

We did two additional nearest neighbor explorations with our CHARAGRAM-PHRASE model. First, we collected nearest neighbors for words that were not in the training data (i.e., PPDB XXL), but were in our working vocabulary. These are shown in the upper part of Table 9. In the second, we collected nearest neighbors of words that were in our training data, shown in the lower part of Table 9.

Several kinds of similarity are being captured simultaneously. One kind is similarity in terms of spelling variation, including misspellings (*vehicals*, *vehicels*) and repetition for emphasis (*babyyyyyyy*). Another kind is similarity in terms of morphological variants of a shared root (e.g., *journeying* and *journey*). We also find many synonym relationships without significant amounts of overlapping characters (e.g., *vehicles*, *cars*, *automobiles*). Words in the training data, which tend to be more commonly used, do tend to have higher precision in their nearest neighbors (e.g., neighbors of *huge*). We see occasional mistakes for words that share many characters but are not paraphrases (e.g., *litered*, a likely misspelling of *littered*).

Lastly, since our model learns embeddings for character n-grams, we show an analysis of character n-gram nearest neighbors in Table 10. They appear to be grouped into themes, such as death (row 1), food (row 2), and speed (row 3), but have different granularities. The n-grams in the last row appear in paraphrases of *2*, whereas the second-to-last row shows n-grams in words related to language.

n-gram	Nearest Neighbors
die	_dy, _die, dead,_dyi, rlif, mort, ecea, rpse, d_aw
foo	_foo,_eat, meal, alim, trit, feed, grai,_din, nutr, toe
pee	peed, hast, spee, fast, mpo_, pace, _vel, loci, ccel
aiv	waiv, aive, boli, epea, ncel, abol, lift, bort, bol
ngu	ngue, uist, ongu, tong, abic, gual, fren, ocab, ingu
_2	2_, _02, _02_,_tw,_dua,_xx,_ii_, xx, o_14, d_2

Table 10: Nearest neighbors of character n-gram embeddings from trained CHARAGRAM-PHRASE model. The underscore indicates a space, which signals the beginning or end of a word.

6 Conclusion

We performed a careful empirical comparison of character-based compositional architectures on three NLP tasks. We found a consistent trend: the simplest architecture converges fastest to high performance. These results, coupled with those from Wieting et al. (2016), suggest that practitioners should begin with simple architectures rather than moving immediately to RNNs and CNNs. We release our code and trained models so they can be used by the NLP community for general-purpose, character-based text representation.

Length bias in Encoder Decoder Models and a Case for Global Conditioning

Abstract

Encoder-decoder networks are popular for modeling sequences probabilistically in many applications. These models use the power of the Long Short-Term Memory (LSTM) architecture to capture the *full dependence* among variables, unlike earlier models like CRFs that typically assumed conditional independence among non-adjacent variables. However in practice encoder-decoder models exhibit a bias towards short sequences that surprisingly gets worse with increasing beam size.

In this paper we show that such phenomenon is due to a discrepancy between the full sequence margin and the per-element margin enforced by the locally conditioned training objective of a encoder-decoder model. The discrepancy more adversely impacts long sequences, explaining the bias towards predicting short sequences.

For the case where the predicted sequences come from a closed set, we show that a globally conditioned model alleviates the above problems of encoder-decoder models. From a practical point of view, our proposed model also eliminates the need for a beam-search during inference, which reduces to an efficient dot-product based search in a vector-space.

1 Introduction

In this paper we investigate the use of neural networks for modeling the conditional distribution $\Pr(\mathbf{y}|\mathbf{x})$ over sequences $\mathbf{y}$ of discrete tokens in response to a complex input $\mathbf{x}$, which can be another sequence or an image. Such models have applications in machine translation (Bahdanau et al., 2014; Sutskever et al., 2014), image captioning (Vinyals et al., 2015), response generation in emails (Kannan et al., 2016), and conversations (Khaitan, 2016; Vinyals and Le, 2015; Li et al., 2015).

The most popular neural network for probabilistic modeling of sequences in the above applications is the encoder-decoder (ED) network (Sutskever et al., 2014). A ED network first encodes an input $\mathbf{x}$ into a vector which is then used to initialize a recurrent neural network (RNN) for decoding the output $\mathbf{y}$. The decoder RNN factorizes $\Pr(\mathbf{y}|\mathbf{x})$ using the chain rule as $\prod_j \Pr(y_j|y_1, \ldots, y_{j-1}, \mathbf{x})$ where $y_1, \ldots, y_n$ denote the tokens in $\mathbf{y}$. This factorization does not entail any conditional independence assumption among the $\{y_j\}$ variables. This is unlike earlier sequence models like CRFs (Lafferty et al., 2001) and MeMMs (McCallum et al., 2000) that typically assume that a token is independent of all other tokens given its adjacent tokens. Modern-day RNNs like LSTMs promise to capture non-adjacent and long-term dependencies by summarizing the set of previous tokens in a continuous, high-dimensional state vector. Within the limits of parameter capacity allocated to the model, the ED, by virtue of exactly factorizing the token sequence, is consistent.

However, when we created and deployed an ED model for a chat suggestion task we observed several counter-intuitive patterns in its predicted outputs. Even after training the model over billions of examples, the predictions were systematically biased towards short sequences. Such bias has also been seen in translation (Cho et al., 2014). Another curious

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1516–1525,
Austin, Texas, November 1-5, 2016.

phenomenon was that the accuracy of the predictions sometimes dropped with increasing beam-size, more than could be explained by statistical variations of a well-calibrated model (Ranzato et al., 2016).

In this paper we expose a margin discrepancy in the training loss of encoder-decoder models to explain the above problems in its predictions. We show that the training loss of ED network often underestimates the margin of separating a correct sequence from an incorrect shorter sequence. The discrepancy gets more severe as the length of the correct sequence increases. That is, even after the training loss converges to a small value, full inference on the training data can incur errors causing the model to be underfitted for long sequences in spite of low training cost. We call this the length bias problem.

We propose an alternative model that avoids the margin discrepancy by globally conditioning the $P(\mathbf{y}|\mathbf{x})$ distribution. Our model is applicable in the many practical tasks where the space of allowed outputs is closed. For example, the responses generated by the smart reply feature of Inbox is restricted to lie within a hand-screened whitelist of responses $\mathcal{W} \subset \mathcal{Y}$ (Kannan et al., 2016), and the same holds for a recent conversation assistant feature of Google's Allo (Khaitan, 2016). Our model uses a second RNN encoder to represent the output as another fixed length vector. We show that our proposed encoder-encoder model produces better calibrated whole sequence probabilities and alleviates the length-bias problem of ED models on two conversation tasks. A second advantage of our model is that inference is significantly faster than ED models and is guaranteed to find the globally optimal solution. In contrast, inference in ED models requires an expensive beam-search which is both slow and is not guaranteed to find the optimal sequence.

2 Length Bias in Encoder-Decoder Models

In this section we analyze the widely used encoder-decoder neural network for modeling $\Pr(\mathbf{y}|\mathbf{x})$ over the space of discrete output sequences. We use $y_1, \ldots, y_n$ to denote the tokens in a sequence $\mathbf{y}$. Each y_i is a discrete symbol from a finite dictionary V of size m. Typically, m is large. The length n of a sequence is allowed to vary from sequence to sequence even for the same input $\mathbf{x}$. A special token EOS $\in V$ is used to mark the end of a sequence. We use $\mathcal{Y}$ to denote the space of such valid sequences and θ to denote the parameters of the model.

2.1 The encoder-decoder network

The Encoder-Decoder (ED) network represents $\Pr(\mathbf{y}|\mathbf{x}, \theta)$ by applying chain rule to exactly factorize it as $\prod_{t=1}^{n} \Pr(y_t|y_1, \ldots, y_{t-1}, \mathbf{x}, \theta)$. First, an encoder with parameters $\theta_x \subset \theta$ is used to transform $\mathbf{x}$ into a d-dimensional real-vector $\mathbf{v}_x$. The network used for the encoder depends on the form of $\mathbf{x}$ — for example, when $\mathbf{x}$ is also a sequence, the encoder could be a RNN. The decoder then computes each $\Pr(y_t|y_1, \ldots, y_{t-1}, \mathbf{v}_x, \theta)$ as

$$\Pr(y_t|y_1, \ldots, y_{t-1}, \mathbf{v}_x, \theta) = P(y_t|\mathbf{s}_t, \theta), \qquad (1)$$

where $\mathbf{s}_t$ is a state vector implemented using a recurrent neural network as

$$\mathbf{s}_t = \begin{cases} \mathbf{v}_x & \text{if } t = 0, \\ \text{RNN}(\mathbf{s}_{t-1}, \theta_{E,y_{t-1}}, \theta_R) & \text{otherwise.} \end{cases} \qquad (2)$$

where RNN() is typically a stack of LSTM cells that captures long-term dependencies, $\theta_{E,y} \subset \theta$ are parameters denoting the embedding for token y, and $\theta_R \subset \theta$ are the parameters of the RNN. The function $\Pr(y|\mathbf{s}, \theta_y)$ that outputs the distribution over the m tokens is a softmax:

$$\Pr(y|\mathbf{s}, \theta) = \frac{e^{\mathbf{s}\theta_{S,y}}}{e^{\mathbf{s}\theta_{S,1}} + \ldots + e^{\mathbf{s}\theta_{S,m}}}, \qquad (3)$$

where $\theta_{S,y} \subset \theta$ denotes the parameters for token y in the final softmax.

2.2 The Origin of Length Bias

The ED network builds a single probability distribution over sequences of arbitrary length. For an input $\mathbf{x}$, the network needs to choose the highest probability $\mathbf{y}$ among valid candidate sequences of widely different lengths. Unlike in applications like entity-tagging and parsing where the length of the output is determined based on the input, in applications like response generation valid outputs can be of widely varying length. Therefore, $\Pr(\mathbf{y}|\mathbf{x}, \theta)$ should be well-calibrated over all sequence lengths. Indeed under infinite data and model capacity the ED model is consistent and will represent all sequence lengths faithfully. In practice when training data is

finite, we show that the ED model is biased against long sequences. Other researchers (Cho et al., 2014) have reported this bias but we are not aware of any analysis like ours explaining the reasons of this bias.

Claim 2.1. *The training loss of the ED model underestimates the margin of separating long sequences from short ones.*

Proof. Let $\mathbf{x}$ be an input for which a correct output $\mathbf{y}^+$ is of length ℓ and an incorrect output $\mathbf{y}^-$ is of length 1. Ideally, the training loss should put a positive margin between $\mathbf{y}^+$ and $\mathbf{y}^-$ which is $\log \Pr(\mathbf{y}^+|\mathbf{x}) - \log \Pr(\mathbf{y}^-|\mathbf{x})$. Let us investigate if the maximum likelihood training objective of the ED model achieves that. We can write this objective as:

$$\max_{\theta} \log \Pr(y_1^+|\mathbf{x},\theta) + \sum_{j=2}^{\ell} \log \Pr(y_j^+|y_{1\ldots j-1}^+, \mathbf{x}, \theta). \tag{4}$$

Only the first term in the above objective is involved in enforcing a margin between $\mathbf{y}^+$ and $\mathbf{y}^-$ because $\log \Pr(y_1^+|\mathbf{x})$ is maximized when $\log \Pr(y_1^-|\mathbf{x})$ is correspondingly minimized. Let $m_L(\theta) = \log \Pr(y_1^+|\mathbf{x},\theta) - \log \Pr(y_1^-|\mathbf{x},\theta)$, the local margin from the first position and $m_R(\theta) = \sum_{j=2}^{\ell} \log \Pr(y_j^+|\mathbf{y}_{1\ldots j-1}^+, \mathbf{x}, \theta)$. It is easy to see that our desired margin between $\mathbf{y}^+$ and $\mathbf{y}^-$ is $\log \Pr(\mathbf{y}^+|\mathbf{x}) - \log \Pr(\mathbf{y}^-|\mathbf{x}) = m_L + m_R$. Let $m_g = m_L + m_R$. Assuming two possible labels for the first position ($m = 2$) [1], the training objective in Equation 4 can now be rewritten in terms of the margins as:

$$\min_{\theta} \log(1 + e^{-m_L(\theta)}) - m_R(\theta)$$

We next argue that this objective is not aligned with our ideal goal of making the global margin $m_L + m_R$ positive.

First, note that m_R is a log probability which under finite parameters will be non-zero. Second, even though m_L can take any arbitrary finite value, the training objective drops rapidly when m_L is positive. When training objective is regularized and training data is finite, the model parameters θ cannot take very large values and the trainer will converge at a small positive value of m_L. Finally, we show that the value of m_R decreases with increasing sequence length. For each position j in the sequence, we add to m_R log-probability of y_j^+. The maximum value of $\log \Pr(y_j^+|\mathbf{y}_{1\ldots j-1}^+, \mathbf{x}, \theta)$ is $\log(1-\epsilon)$ where ϵ is non-zero and decreasing with the magnitude of the parameters θ. In general, $\log \Pr(y_j^+|\mathbf{y}_{1\ldots j-1}^+, \mathbf{x}, \theta)$ can be a much smaller negative value when the input $\mathbf{x}$ has multiple correct responses as is common in conversation tasks. For example, an input like $\mathbf{x}$ ='How are you?', has many possible correct outputs: $\mathbf{y} \in$ {'I am good', 'I am great', 'I am fine, how about you?', etc}. Let f_j denote the relative frequency of output y_j^+ among all correct responses with prefix $\mathbf{y}_{1\ldots j-1}^+$. The value of m_R will be upper bounded as

$$m_R \leq \sum_{j=2}^{\ell} \log \min(1-\epsilon, f_j)$$

This term is negative always and increases in magnitude as sequence length increases and the set of positive outpus have high entropy. In this situation, when combined with regularization, our desired margin m_g may not remain positive even though m_L is positive. In summary, the core issue here is that since the ED loss is optimized and regularized on the local problem it does not control for the global, task relevant margin. □

This mismatch between the local margin optimized during training and the global margin explains the length bias observed by us and others (Cho et al., 2014). During inference a shorter sequence for which m_R is smaller wins over larger sequences.

This mismatch also explains why increasing beam size leads to a drop in accuracy sometimes (Ranzato et al., 2016)[2]. When beam size is large, we are more likely to dig out short sequences that have otherwise been separated by the local margin. We show empirically in Section 4.3 that for long sequences larger beam size hurts accuracy whereas for small sequences the effect is the opposite.

2.3 Proposed fixes to the ED models

Many ad hoc approaches have been used to alleviate length bias directly or indirectly. Some resort to nor-

[1] For $m > 2$, the objective will be upper bounded by $\min_\theta \log(1 + (m-1)e^{-m_L(\theta)}) - m_R(\theta)$. The argument that follows remains largely unchanged

[2] Figure 6 in the paper shows a drop in BLEU score by 0.5 as the beam size is increased from 3 to 10.

malizing the probability by the full sequence length (Cho et al., 2014; Graves, 2013) whereas (Abadie et al., 2014) proposes segmenting longer sentences into shorter phrases. (Cho et al., 2014) conjectures that the length bias of ED models could be because of limited representation power of the encoder network. Later more powerful encoders based on attention achieved greater accuracy (Bahdanau et al., 2014) on long sequences. Attention can be viewed as a mechanism of improving the capacity of the local models, thereby making the local margin m_L more definitive. But attention is not effective for all tasks — for example, (Vinyals and Le, 2015) report that attention was not useful for conversation.

Recently (Bengio et al., 2015; Ranzato et al., 2016) propose another modification to the ED training objective where the true token y_{j-1} in the training term $\log \Pr(y_j|y_1, \ldots, y_{j-1})$ is replaced by a sample or top-k modes from the posterior at position $j-1$ via a careful schedule. Incidently, this fix also helps to indirectly alleviate the length bias problem. The sampling causes incorrect tokens to be used as previous history for producing a correct token. If earlier the incorrect token was followed by a low-entropy EOS token, now that state should also admit the correct token causing a decrease in the probability of EOS, and therefore the short sequence.

In the next section we propose our more direct fix to the margin discrepancy problem.

3 Globally Conditioned Encoder-Encoder Models

We represent $\Pr(\mathbf{y}|\mathbf{x}, \theta)$ as a globally conditioned model $\frac{e^{s(\mathbf{y}|\mathbf{x},\theta)}}{Z(\mathbf{x},\theta)}$ where $s(\mathbf{y}|\mathbf{x}, \theta)$ denotes a score for output $\mathbf{y}$ and $Z(\mathbf{x}, \theta)$ denotes the shared normalizer. We show in Section 3.3 why such global conditioning solves the margin discrepancy problem of the ED model. The intractable partition function in global conditioning introduces several new challenges during training and inference. In this section we discuss how we designed our network to address them.

Our model assumes that during inference the output has to be selected from a given whitelist of responses $\mathcal{W} \subset \mathcal{Y}$. In spite of this restriction, the problem does not reduce to multi-class classification because of two important reasons. First, during training we wish to tap all available input-output pairs including the significantly more abundant outputs that do not come from the whitelist. Second, the whitelist could be very large and treating each output sequence as an atomic class can limit generalization achievable by modeling at the level of tokens in the sequence.

3.1 Modeling $s(\mathbf{y}|\mathbf{x}, \theta)$

We use a second encoder to convert $\mathbf{y}$ into a vector $\mathbf{v}_y$ of the same size as the vector $\mathbf{v}_x$ obtained by encoding $\mathbf{x}$ as in a ED network. The parameters used to encode $\mathbf{v}_x$ and $\mathbf{v}_y$ are disjoint. As we are only interested in a fixed dimensional output, unlike in ED networks, we have complete freedom in choosing the type of network to use for this second encoder. For our experiments, we have chosen to use an RNN with LSTM cells. Experimenting with other network architectures, such as bidirectional RNNs remains an interesting avenue for future work. The score $s(\mathbf{y}|\mathbf{x}, \theta)$ is the dot-product between $\mathbf{v}_y$ and $\mathbf{v}_x$. Thus our model is

$$\Pr(\mathbf{y}|\mathbf{x}) = \frac{e^{\mathbf{v}_x^T \mathbf{v}_y}}{\sum_{\mathbf{y}' \in \mathcal{Y}} e^{\mathbf{v}_x^T \mathbf{v}_{y'}}}. \quad (5)$$

3.2 Training and Inference

During training we use maximum likelihood to estimate θ given a large set of valid input-output pairs $\{(\mathbf{x}^1, \mathbf{y}^1), \ldots, (\mathbf{x}^N, \mathbf{y}^N)\}$ where each $\mathbf{y}^i$ belongs to $\mathcal{Y}$ which in general is much larger than $\mathcal{W}$. Our main challenge during training is that $\mathcal{Y}$ is intractably large for computing Z. We decompose Z as

$$Z = e^{s(\mathbf{y}|\mathbf{x},\theta)} + \sum_{\mathbf{y}' \in \mathcal{Y} \setminus \mathbf{y}} e^{s(\mathbf{y}'|\mathbf{x},\theta)}, \quad (6)$$

and then resort to estimating the last term using importance sampling. Constructing a high quality proposal distribution over $\mathcal{Y} \setminus \mathbf{y}$ is difficult in its own right, so in practice, we make the following approximations. We extract the most common T sequences across a data set into a pool of negative examples. We estimate the empirical prior probability of the sequences in that pool, $Q(\mathbf{y})$, and then draw k samples from this distribution. We take care to remove the true sequence from this distribution so as to remove the need to estimate its prior probability.

During inference, given an input $\mathbf{x}$ we need to find $\text{argmax}_{\mathbf{y} \in \mathcal{W}} s(\mathbf{y}|\mathbf{x}, \theta)$. This task can be performed

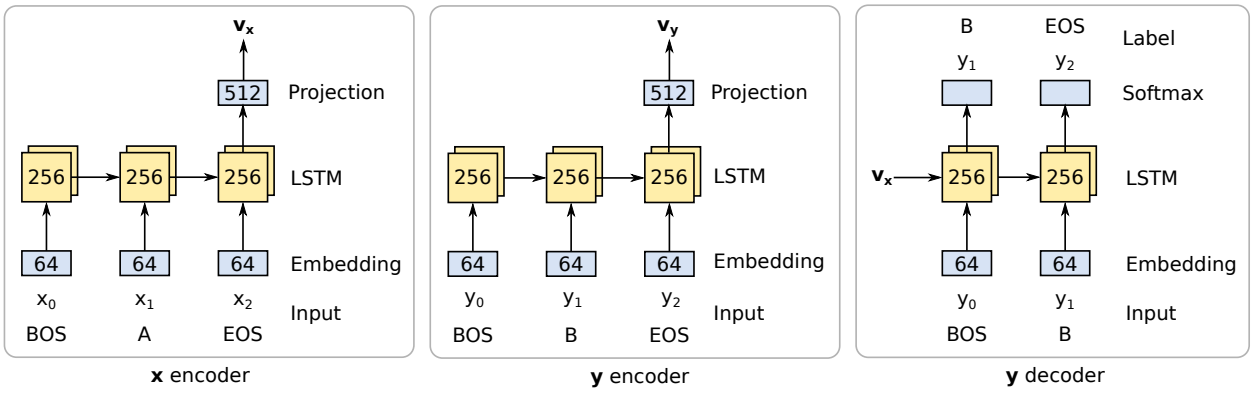

Figure 1: Neural network architectures used in our experiments. The context encoder network is used for both encoder-encoder and encoder-decoder models to encode the context sequence ('A') into a $\mathbf{v}_x$. For the encoder-encoder model, label sequence ('B') are encoded into $\mathbf{v}_y$ by the label encoder network. For the encoder-decoder network, the label sequence is decomposed using the chain rule by the decoder network.

efficiently in our network because the vectors $\mathbf{v}_y$ for the sequences $\mathbf{y}$ in the whitelist $\mathcal{W}$ can be pre-computed. Given an input $\mathbf{x}$, we compute $\mathbf{v}_x$ and take dot-product with the pre-computed vectors to find the highest scoring response. This gives us the optimal response. When $\mathcal{W}$ is very large, we can obtain an approximate solution by indexing the vectors $\mathbf{v}_y$ of $\mathcal{W}$ using recent methods specifically designed for dot-product based retrieval (Guo et al., 2016).

3.3 Margin

It is well-known that the maximum likelihood training objective of a globally normalized model is margin maximizing (Rosset et al., 2003). We illustrate this property using our set up from Claim 2.1 where a correct output $\mathbf{y}^+$ is of length ℓ and an incorrect output $\mathbf{y}^-$ is of length 1 with two possible labels for each position ($m = 2$).

The globally conditioned model learns a parameter per possible sequence and assigns the probability to each sequence using a softmax over those parameters. Additionally, we place a Gaussian prior on the parameters with a precision c. The loss for a positive example becomes:

$$\mathcal{L}_G(\mathbf{y}^+) = -\log \frac{e^{-\theta_{\mathbf{y}^+}}}{\sum_{\mathbf{y}'} e^{-\theta_{\mathbf{y}'}}} + \frac{c}{2} \sum_{\mathbf{y}'} \theta^2_{\mathbf{y}'},$$

where the sums are taken over all possible sequences.

We also train an ED model on this task. It also learns a parameter for every possible sequence, but assigns probability to each sequence using the chain rule. We also place the same Gaussian prior as above on the parameters. Let $\mathbf{y}_j$ denote the first j tokens $\{y_1, \ldots, y_j\}$ of sequence $\mathbf{y}$. The loss for a positive example for this model is then:

$$\mathcal{L}_L(\mathbf{y}^+) = -\sum_{j=1}^{\ell} \left(\log \frac{e^{-\theta_{\mathbf{y}^+_j}}}{\sum_{\mathbf{y}'_j} e^{-\theta_{\mathbf{y}'_j}}} + \frac{c}{2} \sum_{\mathbf{y}'_j} \theta^2_{\mathbf{y}'_j} \right),$$

where the inner sums are taken over all sequences of length j.

We train both models on synthetic sequences generated using the following rule. The first token is chosen to be '1' probability 0.6. If '1' is chosen, it means that this is a positive example and the remaining $\ell - 1$ tokens are chosen to be '1' with probability $0.9^{\frac{1}{\ell-1}}$. If a '0' is chosen as the first token, then that is a negative example, and the sequence generation does not go further. This means that there are $2^{\ell-1}$ unique positive sequences of length ℓ and one negative sequence of length 1. The remaining possible sequences do not occur in the training or testing data. By construction the unbiased margin between the most probable correct example and the incorrect example is length independent and positive. We sample 10000 such sequences and train both models using

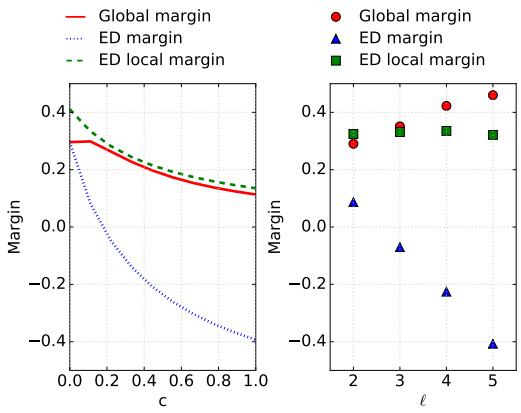

Figure 2: Comparing final margins of ED model with a globally conditioned model on example dataset of Section 3.3 as a function of regularization constant c and message length ℓ.

Adagrad (Duchi et al., 2011) for 1000 epochs with a learning rate of 0.1, effectively to convergence.

Figure 2 shows the margin for both models (between the most likely correct sequence and the incorrect sequence) and the local margin for the ED model at the end of training. On the left panel, we used sequences with $\ell = 2$ and varied the regularization constant c. When c is zero, both models learn the same global margin, but as it is increased the margin for the ED model decreases and becomes negative at $c > 0.2$, despite the local margin remaining positive and high. On the right panel we used $c = 0.1$ and varied ℓ. The ED model becomes unable to separate the sequences with length above 2 with this regularization constant setting.

4 Experiments

4.1 Datasets and Tasks

We contrast the quality of the ED and encoder-encoder models on two conversational datasets: Open Subtitles and Reddit Comments.

4.1.1 Open Subtitles Dataset

The Open Subtitles dataset consists of transcriptions of spoken dialog in movies and television shows (Lison and Tiedemann, 2016). We restrict our modeling only to the English subtitles, of which results in 319 million utternaces. Each utterance is tokenized into word and punctuation tokens, with the start and end marked by the BOS and EOS tokens. We randomly split out 90% of the utterances into the training set, placing the rest into the validation set. As the speaker information is not present in this data set, we treat each utterance as a label sequence, with the preceding utterances as context.

4.1.2 Reddit Comments Dataset

The Reddit Comments dataset is constructed from publicly available user comments on submissions on the Reddit website. Each submission is associated with a list of directed comment trees. In total, there are 41 million submissions and 501 million comments. We tokenize the individual comments in the same way as we have done with the utternaces in the Open Subtitles dataset. We randomly split 90% of the submissions and the associated comments into the training set, and the rest into the validation set. We use each comment (except the ones with no parent comments) as a label sequence, with the context sequence composed of its ancestor comments.

4.1.3 Whitelist and Vocabulary

From each dataset, we derived a dictionary of 20 thousand most commonly used tokens. Additionally, each dictionary contained the unknown token (UNK), BOS and EOS tokens. Tokens in the datasets which were not present in their associated vocabularies were replaced by the UNK token.

From each data set, we extracted 10 million most common label sequences that also contained at most 100 tokens. This set of sequences was used as the negative sample pool for the encoder-encoder models. For evaluation we created a whitelist $\mathcal{W}$ out of the 100 thousand most common sequences. We removed any sequence from this set that contained any UNK tokens to simplify inference.

4.1.4 Sequence Prediction Task

To evaluate the quality of these models, we task them to predict the true label sequence given its context. Due to the computational expense, we sub-sample the validation data sets to around 1 million context-label pairs. We additionally restrict the context-label pairs such that the label sequence is present in the evaluation set of common messages. We use recall@K as a measure of accuracy of the model predictions. It is defined as the fraction of test pairs where the correct label is within K most

probable predictions according to the model. For encoder-encoder models we use an exhaustive search over the evaluation set of common messages. For ED models we use a beam search with width ranging from 1 to 15 over a token prefix trie constructed from the sequences in $\mathcal{W}$.

4.2 Model Structure and Training Procedure

The context encoder, label encoder and decoder are implemented using LSTM recurrent networks (Hochreiter and Schmidhuber, 1997) with peephole connections (Sak et al., 2014). The context and label token sequences were mapped to embedding vectors using a lookup table that is trained jointly with the rest of the model parameters. The recurrent nets were unrolled in time up to 100 time-steps, with label sequences of greater length discarded and context sequences of greater length truncated.

The decoder in the ED model is trained by using the true label sequence prefix as input, and a shifted label sequence as output (Sutskever et al., 2014). The partition function in the softmax over tokens is estimated using importance sampling with a unigram distribution over tokens as the proposal distribution (Jean et al., 2014). We sample 512 negative examples from $Q(\mathbf{y})$ to estimate the partition function for the encoder-encoder model. See Figure 1 for connectivity and network size details.

All models were trained using Adagrad (Duchi et al., 2011) with an initial base learning rate of 0.1 which we exponentially decayed with a decade of 15 million steps. For stability, we clip the L2 norm of the gradients to a maximum magnitude of 1 as described in (Pascanu et al., 2012). All models are trained for 30 million steps with a mini-batch size of 64. The models are trained in a distributed manner on CPUs and NVidia GPUs using TensorFlow (Abadi et al., 2015).

4.3 Results

We first demonstrate the discrepancy between the local and global margin in the ED models as discussed in Section 3.3. We used a beam size of 15 to get the top prediction from our trained ED models on the test data and focussed on the subset for which the top prediction was incorrect. We measured local and global margin between the top predicted sequence ($\mathbf{y}^-$) and the correct test sequence ($\mathbf{y}^+$) as follows: Global margin is the difference in their full sequence log probability. Local margin is the difference in the local token probability of the smallest position j where $y_j^- \neq y_j^+$, that is local margin is $\Pr(y_j^+|\mathbf{y}^+_{1\ldots j-1}, \mathbf{x}, \theta) - \Pr(y_j^-|\mathbf{y}^+_{1\ldots j-1}, \mathbf{x}, \theta)$. Note the training loss of ED models directly compares only the local margin.

Global margin is much smaller than local margin In Figure 3 we show the local and global margin as a 2D histogram with color luminosity denoting frequency. We observe that the global margin values are much smaller than the local margins. The prominent spine is for $(\mathbf{y}^+, \mathbf{y}^-)$ pairs differing only in a single position making the local and global margins equal. Most of the mass is below the spine. For a significant fraction of cases (27% for Reddit, and 21% for Subtitles), the local margin is positive while the global margin is negative. That is, the ED loss for these sequences is small even though the log-probability of the correct sequence is much smaller than the log-probability of the predicted wrong sequence.

Beam search is not the bottleneck An interesting side observation from the plots in Figure 3 is that more than 98% of the wrong predictions have a negative margin, that is, the score of the correct sequence is indeed lower than the score of the wrong prediction. Improving the beam-width beyond 15 is not likely to improve these models since only in 1.9% and 1.7% of the cases is the correct score higher than the score of the wrong prediction.

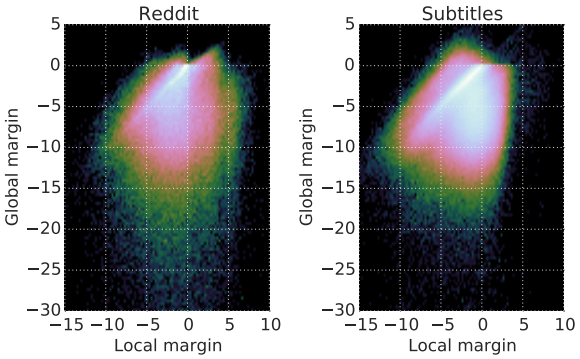

Figure 3: Local margin versus global margin for incorrectly predicted sequences. The color luminosity is proportional to frequency.

Margin discrepancy is higher for longer sequences In Figure 4 we show that this discrepancy is significantly more pronounced for longer sequences. In the figure we show the fraction of wrongly predicted sequences with a positive local margin. We find that as sequence length increases, we have more cases where the local margin is positive yet the global margin is negative. For example, for the Reddit dataset half of the wrongly predicted sequences have a positive local margin indicating that the training loss was low for these sequences even though they were not adequately separated.

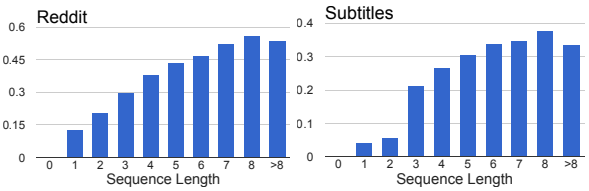

Figure 4: Fraction of incorrect predictions with positive local margin.

Increasing beam size drops accuracy for long sequences Next we show why this discrepancy leads to non-monotonic accuracies with increasing beam-size. As beam size increases, the predicted sequence has higher probability and the accuracy is expected to increase if the trained probabilities are well-calibrated. In Figure 5 we plot the number of correct predictions (on a log scale) against the length of the correct sequence for beam sizes of 1, 5, 10, and 15. For small sequence lengths, we indeed observe that increasing the beam size produces more accurate results. For longer sequences (length > 4) we observe a drop in accuracy with increasing the beam width beyond 1 for Reddit and beyond 5 for Subtitles.

Globally conditioned models are more accurate than ED models We next compare the ED model with our globally conditioned encoder-encoder (EE) model. In Figure 6 we show the recall@K values for K=1, 3 and 5 for the two datasets for increasing length of correct sequence. We find the EE model is largely better that the ED model. The most interesting difference is that for sequences of length greater than 8, the ED model has a recall@5 of zero for both datasets. In contrast, the EE model manages

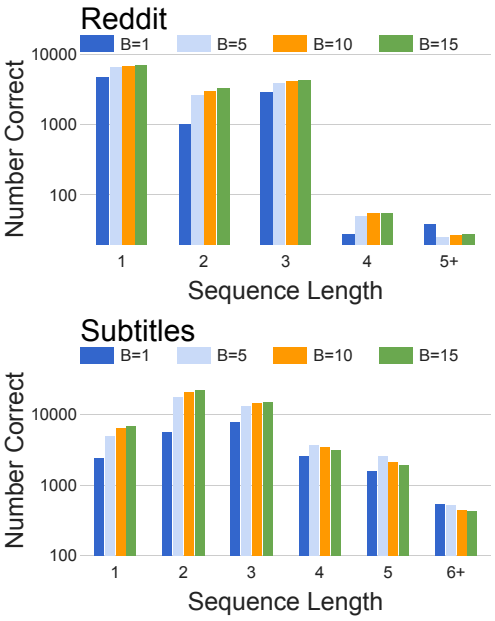

Figure 5: Effect of beam width on the number of correct predictions broken down by sequence length.

to achieve significant recall even at large sequence lengths.

Length normalization of ED models A common modification to the ED decoding procedure used to promote longer message is normalization of the prediction log-probability by its length raised to some power f (Cho et al., 2014; Graves, 2013). We experimented with two settings, $f = 0.5$ and 1.0. Our experiments show that while this indeed promotes longer sequences, it does so at the expense of reducing the accuracy on the shorter sequences.

5 Related Work

In this paper we showed that encoder-decoder models suffer from length bias and proposed a fix using global conditioning. Global conditioning has been proposed for other RNN-based sequence prediction tasks in (Yao et al., 2014) and (Andor et al., 2016). The RNN models that these work attempt to fix capture only a weak form of dependency among variables, for example they assume $\mathbf{x}$ is seen incrementally and only adjacent labels in $\mathbf{y}$ are directly dependent. As proved in (2016) these models are subject to label bias since they cannot represent a distribution that a globally conditioned model can. Thus, their fix for global dependency is using a CRFs. Such

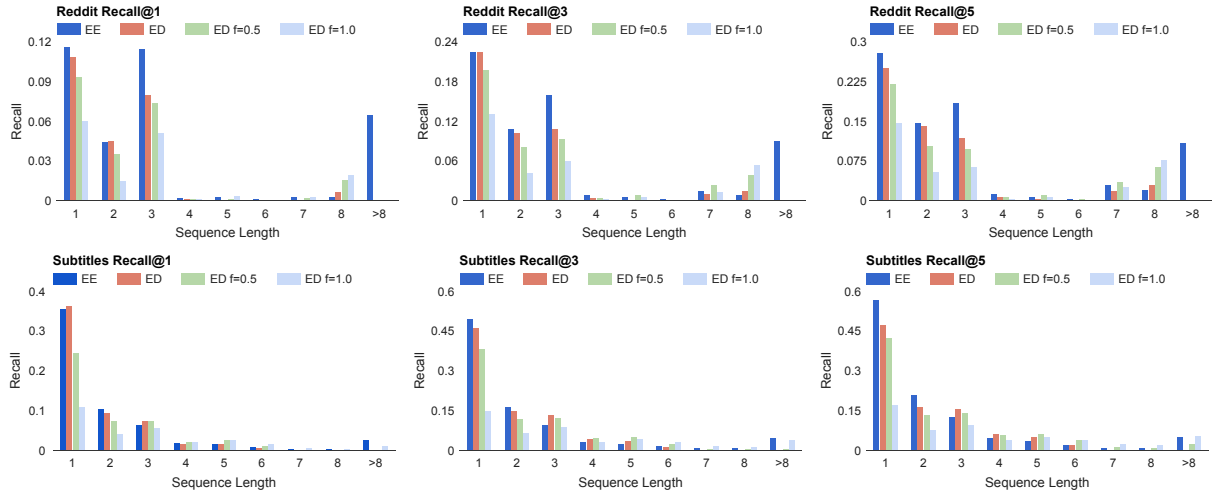

Figure 6: Comparing recall@1, 3, 5 for increasing length of correct sequence.

global conditioning will compromise a ED model which does not assume *any conditional independence* among variables. The label-bias proof of (2016) is not applicable to ED models because the proof rests on the entire input not being visible during output. Earlier illustrations of label bias of MeMMs in (Bottou, 1991; Lafferty et al., 2001) also require local observations. In contrast, the ED model transitions on the entire input and chain rule is an exact factorization of the distribution. Indeed one of the suggestions in (Bottou, 1991) to surmount label-bias is to use a fully connected network, which the ED model already does.

Our encoder-encoder network is reminiscent of the dual encoder network in (Lowe et al., 2015), also used for conversational response generation. A crucial difference is our use of importance sampling to correctly estimate the probability of a large set of candidate responses, which allows us to use the model as a standalone response generation system. Other differences include our model using separate sets of parameters for the two encoders, to reflect the assymetry of the prediction task. Lastly, we found it crucial for the model's quality to use multiple appropriately weighed negative examples for every positive example during training.

(Ranzato et al., 2016) also highlights limitations of the ED model and proposes to mix the ED loss with a sequence-level loss in a reinforcement learning framework under a carefully tuned schedule. Our method for global conditioning can capture sequence-level losses like BLEU score more easily, but may also benefit from a similar mixed loss function.

6 Conclusion

We have shown that encoder-decoder models in the regime of finite data and parameters suffer from a length-bias problem. We have proved that this arises due to the locally normalized models insufficiently separating correct sequences from incorrect ones, and have verified this empirically. We explained why this leads to the curious phenomenon of decreasing accuracy with increasing beam size for long sequences. Our proposed encoder-encoder architecture side steps this issue by operating in sequence probability space directly, yielding improved accuracy for longer sequences.

One weakness of our proposed architecture is that it cannot generate responses directly. An interesting future work is to explore if the ED model can be used to generate a candidate set of responses which are then re-ranked by our globally conditioned model. Another future area is to see if the techniques for making Bayesian networks discriminative can fix the length bias of encoder decoder networks (Peharz et al., 2013; Guo et al., 2012).

Does String-Based Neural MT Learn Source Syntax?

Xing Shi, Inkit Padhi, and Kevin Knight
Information Sciences Institute & Computer Science Department
University of Southern California
xingshi@isi.edu, ipadhi@usc.edu, knight@isi.edu

Abstract

We investigate whether a neural, encoder-decoder translation system learns syntactic information on the source side as a by-product of training. We propose two methods to detect whether the encoder has learned local and global source syntax. A fine-grained analysis of the syntactic structure learned by the encoder reveals which kinds of syntax are learned and which are missing.

1 Introduction

The sequence to sequence model (*seq2seq*) has been successfully applied to neural machine translation (NMT) (Sutskever et al., 2014; Cho et al., 2014) and can match or surpass MT state-of-art. Non-neural machine translation systems consist chiefly of phrase-based systems (Koehn et al., 2003) and syntax-based systems (Galley et al., 2004; Galley et al., 2006; DeNeefe et al., 2007; Liu et al., 2011; Cowan et al., 2006), the latter of which adds syntactic information to source side (tree-to-string), target side (string-to-tree) or both sides (tree-to-tree). As the seq2seq model first encodes the source sentence into a high-dimensional vector, then decodes into a target sentence, it is hard to understand and interpret what is going on inside such a procedure. Considering the evolution of non-neural translation systems, it is natural to ask:

1. Does the encoder learn syntactic information about the source sentence?
2. What kind of syntactic information is learned, and how much?
3. Is it useful to augment the encoder with additional syntactic information?

In this work, we focus on the first two questions and propose two methods:

- We create various syntactic labels of the source sentence and try to predict these syntactic labels with logistic regression, using the learned sentence encoding vectors (for sentence-level labels) or learned word-by-word hidden vectors (for word-level label). We find that the encoder captures both global and local syntactic information of the source sentence, and different information tends to be stored at different layers.
- We extract the whole constituency tree of source sentence from the NMT encoding vectors using a retrained linearized-tree decoder. A deep analysis on these parse trees indicates that much syntactic information is learned, while various types of syntactic information are still missing.

2 Example

As a simple example, we train an English-French NMT system on 110M tokens of bilingual data (English side). We then take 10K separate English sentences and label their *voice* as active or passive. We use the learned NMT encoder to convert these sentences into 10k corresponding 1000-dimension encoding vectors. We use 9000 sentences to train a logistic regression model to predict voice using the encoding cell states, and test on the other 1000 sentences. We achieve 92.8% accuracy (Table 2), far above the majority class baseline (82.8%). This means that in reducing the source sentence to a

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1526–1534,
Austin, Texas, November 1-5, 2016.

Model	Accuracy
Majority Class	82.8
English to French (E2F)	92.8
English to English (E2E)	82.7

fixed-length vector, the NMT system has decided to store the voice of English sentences in an easily accessible way.

When we carry out the same experiment on an English-English (auto-encoder) system, we find that English voice information is no longer easily accessed from the encoding vector. We can only predict it with 82.7% accuracy, no better than chance. Thus, in learning to reproduce input English sentences, the seq2seq model decides to use the fixed-length encoding vector for other purposes.

3 Related work

Interpreting Recurrent Neural Networks. The most popular method to visualize high-dimensional vectors, such as word embeddings, is to project them into two-dimensional space using *t-SNE* (van der Maaten and Hinton, 2008). Very few works try to interpret recurrent neural networks in NLP. Karpathy et al. (2016) use a character-level LSTM language model as a test-bed and find several activation cells that track long-distance dependencies, such as line lengths and quotes. They also conduct an error analysis of the predictions. Li et al. (2016) explore the syntactic behavior of an RNN-based sentiment analyzer, including the compositionality of negation, intensification, and concessive clauses, by plotting a 60-dimensional heat map of hidden unit values. They also introduce a first-order derivative based method to measure each unit's contribution to the final decision.

Verifying syntactic/semantic properties. Several works try to build a good distributional representation of sentences or paragraph (Socher et al., 2013; Kalchbrenner et al., 2014; Kim, 2014; Zhao et al., 2015; Le and Mikolov, 2014; Kiros et al., 2015). They implicitly verify the claimed syntactic/semantic properties of learned representations by applying them to downstream classification tasks such as sentiment analysis, sentence classification, semantic relatedness, paraphrase detection, image-sentence ranking, question-type classification, etc.

Novel contributions of our work include:

- We locate a subset of activation cells that are responsible for certain syntactic labels. We explore the concentration and layer distribution of different syntactic labels.
- We extract whole parse trees from NMT encoding vectors in order to analyze syntactic properties directly and thoroughly.
- Our methods are suitable for large scale models. The models in this work are 2-layer 1000-dimensional LSTM seq2seq models.

4 Datasets and models

We train two NMT models, English-French (E2F) and English-German (E2G). To answer whether these translation models' encoders to learn store syntactic information, and how much, we employ two benchmark models:

- An upper-bound model, in which the encoder learns quite a lot of syntactic information. For the upper bound, we train a neural parser that learns to "translate" an English sentence to its linearized constitutional tree (E2P), following Vinyals et al. (2015).
- An lower-bound model, in which the encoder learns much less syntactic information. For the lower bound, we train two sentence auto-encoders: one translates an English sentence to itself (E2E), while the other translates a permuted English sentence to itself (PE2PE). We already had an indication above (Section 2) that a copying model does not necessarily need to remember a sentence's syntactic structure.

Figure 1 shows sample inputs and outputs of the E2E, PE2PE, E2F, E2G, and E2P models.

We use English-French and English-German data from WMT2014 (Bojar et al., 2014). We take 4M English sentences from the English-German data to train E2E and PE2PE. For the neural parser (E2P), we construct the training corpus following the recipe of Vinyals et al. (2015). We collect 162K training sentences from publicly available treebanks, including Sections 0-22 of the Wall Street Journal Penn Treebank (Marcus et al., 1993), Ontonotes version 5

Model	Target Language	Input vocabulary size	Output vocabulary size	Train/Dev/Test Corpora Sizes (sentence pairs)	BLEU
E2E	English	200K	40K	4M/3000/2737	89.11
PE2PE	Permuted English	200K	40K	4M/3000/2737	88.84
E2F	French	200K	40K	4M/6003/3003	24.59

Figure 1: Sample inputs and outputs of the E2E, PE2PE, E2F, E2G, and E2P models.

(Pradhan and Xue, 2009) and the English Web Treebank (Petrov and McDonald, 2012). In addition to these gold treebanks, we take 4M English sentences from English-German data and 4M English sentences from English-French data, and we parse these 8M sentences with the Charniak-Johnson parser[1] (Charniak and Johnson, 2005). We call these 8,162K pairs the CJ corpus. We use WSJ Section 22 as our development set and section 23 as the test set, where we obtain an F1-score of 89.6, competitive with the previously-published 90.5 (Table 4).

Model Architecture. For all experiments[2], we use a two-layer encoder-decoder with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997). We use a minibatch of 128, a hidden state size of 1000, and a dropout rate of 0.2.

[1]The CJ parser is here https://github.com/BLLIP/bllip-parser and we used the pretrained model "WSJ+Gigaword-v2".

[2]We use the toolkit: https://github.com/isi-nlp/Zoph_RNN

Parser	WSJ 23 F1-score	# valid trees (out of 2416)
CJ Parser	92.1	2416
E2P	89.6	2362
(Vinyals et al., 2015)	90.5	unk

Table 3: Labeled F1-scores of different parsers on WSJ Section 23. The F1-score is calculated on valid trees only.

For auto-encoders and translation models, we train 8 epochs. The learning rate is initially set as 0.35 and starts to halve after 6 epochs. For E2P model, we train 15 epochs. The learning rate is initialized as 0.35 and starts to decay by 0.7 once the perplexity on a development set starts to increase. All parameters are re-scaled when the global norm is larger than 5. All models are non-attentional, because we want the encoding vector to summarize the whole source sentence. Table 4 shows the settings of each model and reports the BLEU scores.

5 Syntactic Label Prediction

5.1 Experimental Setup

In this section, we test whether different seq2seq systems learn to encode syntactic information about the source (English) sentence.

With 1000 hidden states, it is impractical to investigate each unit one by one or draw a heat map of the whole vector. Instead, we use the hidden states to predict syntactic labels of source sentences via logistic regression. For multi-class prediction, we use a one-vs-rest mechanism. Furthermore, to identify a subset of units responsible for certain syntactic labels, we use the recursive feature elimination (RFE) strategy: the logistic regression is first trained using

Label	Train	Test	Number of classes	Most frequent label
Voice	9000	1000	2	Active
Tense	9000	1000	2	Non-past
TSS	9000	1000	20	NP-VP
POS	87366	9317	45	NN
SPC	81292	8706	24	NP

Table 4: Corpus statistics for five syntactic labels.

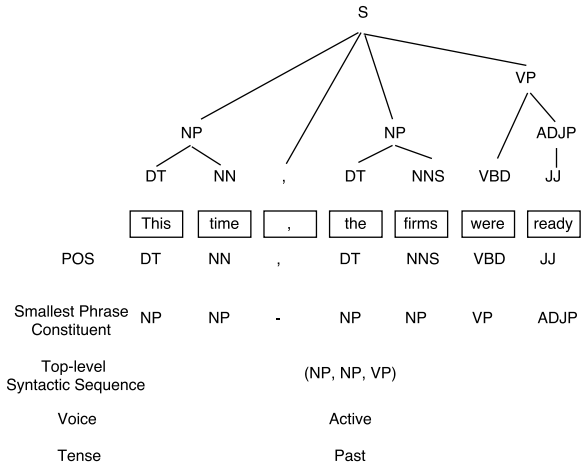

Figure 2: The five syntactic labels for sentence "This time , the firms were ready".

all 1000 hidden states, after which we recursively prune those units whose weights' absolute values are smallest.

We extract three sentence-level syntactic labels:

1. Voice: active or passive.
2. Tense: past or non-past.
3. TSS: Top level syntactic sequence of the constituent tree. We use the most frequent 19 sequences ("NP-VP", "PP-NP-VP", etc.) and label the remainder as "Other".

and two word-level syntactic labels:

1. POS: Part-of-speech tags for each word.
2. SPC: The smallest phrase constituent that above each word.

Both voice and tense labels are generated using rule-based systems based on the constituent tree of the sentence.

Figure 2 provides examples of our five syntactic labels. When predicting these syntactic labels using corresponding cell states, we split the dataset into training and test sets. Table 4 shows statistics of each labels.

For a source sentence s,

$$s = [w_1, ..., w_i, ..., w_n]$$

the two-layer encoder will generate an array of cell vectors c during encoding,

$$c = [(c_{1,0}, c_{1,1}), ..., (c_{i,0}, c_{i,1}), ..., (c_{n,0}, c_{n,1})]$$

We extract a sentence-level syntactic label L_s, and predict it using the encoding cell states that will be fed into the decoder:

$$L_s = g(c_{n,0}) \text{ or } L_s = g(c_{n,1})$$

where $g(\cdot)$ is the logistic regression.

Similarly, for extracting word-level syntactic labels:

$$L_w = [L_{w1}, ..., L_{wi}, ..., L_{wn}]$$

we predict each label L_{wi} using the cell states immediately after encoding the word w_i:

$$L_{wi} = g(c_{i,0}) \text{ or } L_{Wi} = g(c_{i,1})$$

5.2 Result Analysis

Test-set prediction accuracy is shown in Figure 3. For voice and tense, the prediction accuracy of two auto-encoders is almost same as the accuracy of majority class, indicating that their encoders do not learn to record this information. By contrast, both the neural parser and the NMT systems achieve approximately 95% accuracy. When predicting the top-level syntactic sequence (TSS) of the whole sentence, the Part-of-Speech tags (POS), and smallest phrase constituent (SPC) for each word, all five models achieve an accuracy higher than that of majority class, but there is still a large gap between the accuracy of NMT systems and auto-encoders. These observations indicate that the NMT encoder learns significant sentence-level syntactic information—it can distinguish voice and tense of the source sentence, and it knows the sentence's structure to some extent. At the word level, the NMT's encoder also tends to cluster together the words that have similar POS and SPC labels.

Different syntactic information tends to be stored at different layers in the NMT models. For word-level syntactic labels, POS and SPC, the accuracy of the lower layer's cell states ($C0$) is higher than that of the upper level ($C1$). For the sentence-level

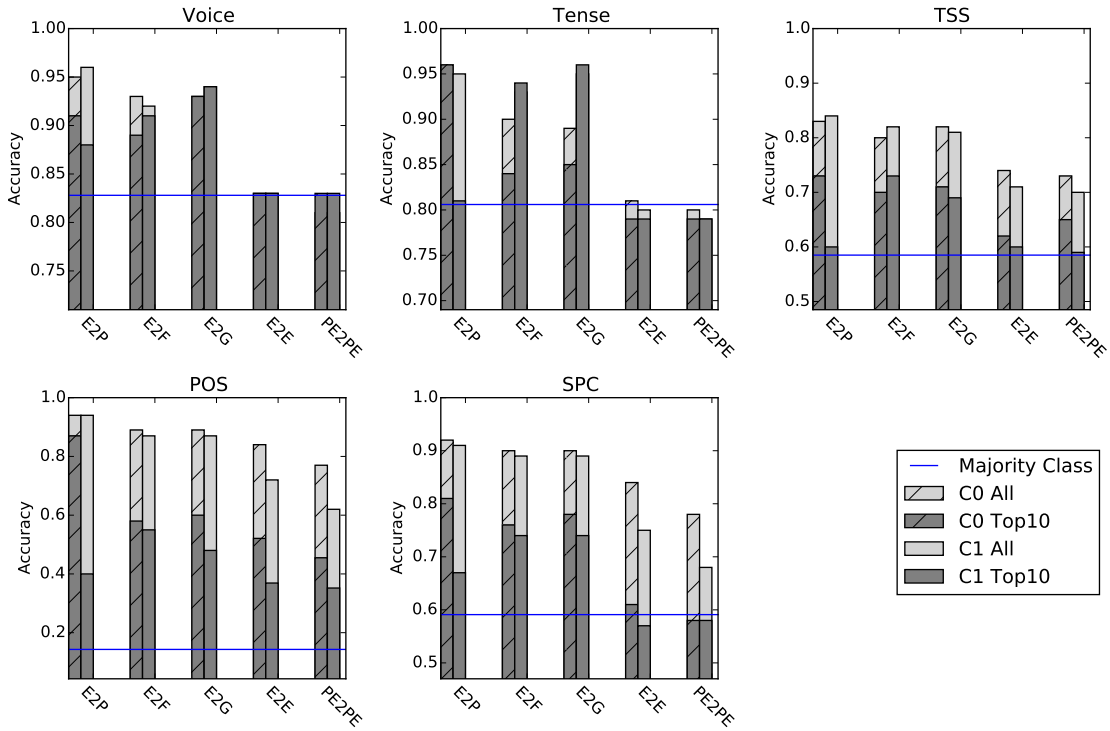

Figure 3: Prediction accuracy of five syntactic labels on test. Each syntactic label is predicted using both the lower-layer cell states (C0) and higher-layer cell states (C1). For each cell state, we predict each syntactic label using all 1000 units (All), as well as the top 10 units (Top10) selected by recursive feature elimination. The horizontal blue line is the majority class accuracy.

labels, especially tense, the accuracy of $C1$ is larger than $C0$. This suggests that the local features are somehow preserved in the lower layer whereas more global, abstract information tends to be stored in the upper layer.

For two-classes labels, such as voice and tense, the accuracy gap between all units and top-10 units is small. For other labels, where we use a one-versus-rest strategy, the gap between all units and top-10 units is large. However, when predicting POS, the gap of neural parser (E2P) on the lower layer ($C0$) is much smaller. This comparison indicates that a small subset of units explicitly takes charge of POS tags in the neural parser, whereas for NMT, the POS info is more distributed and implicit.

There are no large differences between encoders of E2F and E2G regarding syntactic information.

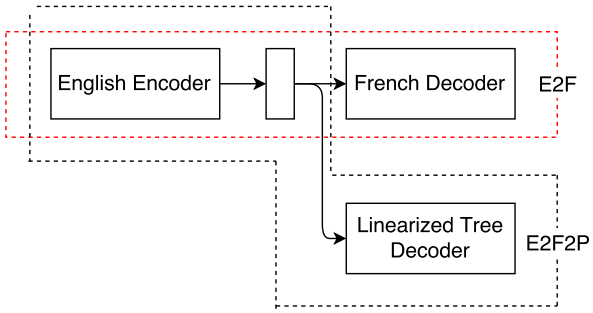

Figure 4: E2F and E2F2P share the same English encoder. When training E2F2P, we only update the parameters of linearized tree decoder, keeping the English encoder's parameters fixed.

6 Extract Syntactic Trees from Encoder

6.1 Experimental Setup

We now turn to whether NMT systems capture deeper syntactic structure as a by-product of learning to translate from English to another language. We do this by predicting full parse trees from the information stored in encoding vectors. Since this is a structured prediction problem, we can no longer use logistic regression. Instead, we extract a constituency parse tree from the encoding vector of a model E2X by using a new neural parser E2X2P with the following steps:

1. Take the E2X encoder as the encoder of the new model E2X2P.
2. Initialize the E2X2P decoder parameters with a uniform distribution.
3. Fine-tune the E2X2P decoder (while keeping its encoder parameters fixed), using the CJ corpus, the same corpus used to train $E2P$.

Figure 4 shows how we construct model E2F2P from model E2F. For fine-tuning, we use the same dropout rate and learning rate updating configuration for E2P as described in Section 4.

6.2 Evaluation

We train four new neural parsers using the encoders of the two auto-encoders and the two NMT models respectively. We use three tools to evaluate and analyze:

1. The EVALB tool[3] to calculate the labeled bracketing F1-score.
2. The zxx package[4] to calculate Tree edit distance (TED) (Zhang and Shasha, 1989).
3. The Berkeley Parser Analyser[5] (Kummerfeld et al., 2012) to analyze parsing error types.

The linearized parse trees generated by these neural parsers are not always well-formed. They can be split into the following categories:

- Malformed trees: The linearized sequence can not be converted back into a tree, due to missing or mismatched brackets.
- Well-formed trees: The sequence can be converted back into a tree. Tree edit distance can be calculated on this category.
  - Wrong length trees: The number of tree leaves does not match the number of source-sentence tokens.
  - Correct length trees: The number of tree leaves *does* match the number of source-sentence tokens.

Before we move to results, we emphasize the following points:

First, compared to the linear classifier used in Section 5, the retrained decoder for predicting a linearized parse tree is a highly non-linear method. The syntactic prediction/parsing performance will increase due to such non-linearity. Thus, we do not make conclusions based only on absolute performance values, but also on a comparison against the designed baseline models. An improvement over the lower bound models indicates that the encoder learns syntactic information, whereas a decline from the upper bound model shows that the encoder loses certain syntactic information.

Second, the NMT's encoder maps a plain English sentence into a high-dimensional vector, and our goal is to test whether the projected vectors form a more syntactically-related manifold in the high-dimensional space. In practice, one could also predict parse structure for the E2E in two steps: (1) use E2E's decoder to recover the original English sentence, and (2) parse that sentence with the CJ parser. But in this way, the manifold structure in the high-dimensional space is destroyed during the mapping.

6.2.1 Result Analysis

Table 5 reports perplexity on training and development sets, the labeled F1-score on WSJ Section 23, and the Tree Edit Distance (TED) of various systems.

Tree Edit Distance (TED) calculates the minimum-cost sequence of node edit operations (delete, insert, rename) between a gold tree and a test tree. When decoding with beam size 10, the four new neural parsers can generate well-formed trees for almost all the 2416 sentences in the WSJ section 23. This makes TED a robust metric to evaluate the overall performance of each parser. Table 5 reports the average TED per sentence. Trees extracted from E2E and PE2PE encoding vectors (via models E2E2P and PE2PE2P, respectively) get TED above 30, whereas the NMT systems get

Model	Perplexity on Train	Perplexity on WSJ 22	Labeled F1 on WSJ23	# EVALB-trees (out of 2416)	Average TED per sentence	# Well-formed trees (out of 2416)
PE2PE2P	1.83	1.92	46.64	818	34.43	2416
E2E2P	1.69	1.77	59.35	796	31.25	2416
E2G2P	1.39	1.41	80.34	974	17.11	2340
E2F2P	1.36	1.38	79.27	1093	17.77	2415
E2P	1.11	1.18	89.61	2362	11.50	2415

Table 5: Perplexity, labeled F1-score, and Tree Edit Distance (TED) of various systems. Labeled F1-scores are calculated on EVALB-trees only. Tree edit distances are calculated on the well-formed trees only. EVALB-trees are those whose number of leaves match the number of words in the source sentence, and are otherwise accepted by standard Treebank evaluation software.

approximately 17 TED.

Among the well-formed trees, around half have a mismatch between number of leaves and number of tokens in the source sentence. The labeled F1-score is reported over the rest of the sentences only. Though biased, this still reflects the overall performance: we achieve around 80 F1 with NMT encoding vectors, much higher than with the E2E and PE2PE encoding vectors (below 60).

6.2.2 Fine-grained Analysis

Besides answering whether the NMT encoders learn syntactic information, it is interesting to know what kind of syntactic information is extracted and what is not.

As Table 5 shows, different parsers generate different numbers of trees that are acceptable to Treebank evaluation software ("EVALB-trees"), having the correct number of leaves and so forth. We select the intersection set of different models' EVALB-trees. We get a total of 569 shared EVALB-trees. The average length of the corresponding sentence is 12.54 and the longest sentence has 40 tokens. The average length of all 2416 sentences in WSJ section 23 is 23.46, and the longest is 67. As we do not apply an attention model for these neural parsers, it is difficult to handle longer sentences. While the intersection set may be biased, it allows us to explore how different encoders decide to capture syntax on short sentences.

Table 6 shows the labeled F1-scores and Part-of-Speech tagging accuracy on the intersection set. The NMT encoder extraction achieves around 86 percent tagging accuracy, far beyond that of the auto-encoder based parser.

Model	Labeled F1	POS Tagging Accuracy
PE2PE2P	58.67	54.32
E2E2P	70.91	68.03
E2G2P	85.36	85.30
E2F2P	86.62	87.09
E2P	93.76	96.00

Table 6: Labeled F1-scores and POS tagging accuracy on the intersection set of EVALB-trees of different parsers. There are 569 trees in the intersection, and the average length of corresponding English sentence is 12.54.

Besides the tagging accuracy, we also utilize the Berkeley Parser Analyzer (Kummerfeld et al., 2012) to gain a more linguistic understanding of predicted parses. Like TED, the Berkeley Parser Analyzer is based on tree transformation. It repairs the parse tree via a sequence of sub-tree movements, node insertions and deletions. During this process, multiple bracket errors are fixed, and it associates this group of node errors with a linguistically meaningful error type.

The first column of Figure 5 shows the average number of bracket errors per sentence for model E2P on the intersection set. For other models, we report the ratio of each model to model E2P. Kummerfeld et al. (2013) and Kummerfeld et al. (2012) give descriptions of different error types. The NMT-based predicted parses introduce around twice the bracketing errors for the first 10 error types, whereas for "Sense Confusion", they bring more than 16 times bracket errors. "Sense confusion" is the case where the head word of a phrase receives the wrong POS,

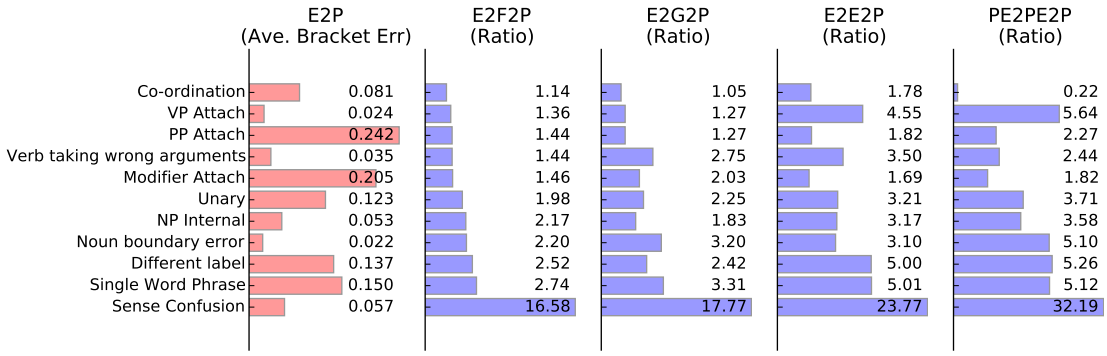

Figure 5: For model $E2P$ (the red bar), we show the average number of bracket errors per sentence due to the top 11 error types. For other models, we show the ratio of each model's average number of bracket errors to that of model $E2P$. Errors analyzed on the intersection set. The table is sorted based on the ratios of the $E2F2P$ model.

resulting in an attachment error. Figure 6 shows an example.

Even though we can predict 86 percent of parts-of-speech correctly from NMT encoding vectors, the other 14 percent introduce quite a few attachment errors. NMT sentence vectors encode a lot of syntax, but they still cannot grasp these subtle details.

7 Conclusion

We investigate whether NMT systems learn source-language syntax as a by-product of training on string pairs. We find that both local and global syntactic information about source sentences is captured by the encoder. Different types of syntax is stored in different layers, with different concentration degrees. We also carry out a fine-grained analysis of the constituency trees extracted from the encoder, highlighting what syntactic information is still missing.

Abstract

Neural Machine Translation (NMT) based on the encoder-decoder architecture has recently become a new paradigm. Researchers have proven that the target-side monolingual data can greatly enhance the decoder model of NMT. However, the source-side monolingual data is not fully explored although it should be useful to strengthen the encoder model of NMT, especially when the parallel corpus is far from sufficient. In this paper, we propose two approaches to make full use of the source-side monolingual data in NMT. The first approach employs the self-learning algorithm to generate the synthetic large-scale parallel data for NMT training. The second approach applies the multi-task learning framework using two NMTs to predict the translation and the reordered source-side monolingual sentences simultaneously. The extensive experiments demonstrate that the proposed methods obtain significant improvements over the strong attention-based NMT.

1 Introduction

Neural Machine Translation (NMT) following the encoder-decoder architecture proposed by (Kalchbrenner and Blunsom, 2013; Cho et al., 2014) has become the novel paradigm and obtained state-of-the-art translation quality for several language pairs, such as English-to-French and English-to-German (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015b; Sennrich et al., 2015). This end-to-end NMT typically consists of two recurrent neural networks. The encoder network maps the source sentence of variable length into the context vector representation; and the decoder network generates the target translation word by word starting from the context vector.

Currently, most NMT methods utilize only the sentence aligned parallel corpus for model training, which limits the capacity of the model. Recently, inspired by the successful application of target monolingual data in conventional statistical machine translation (SMT) (Koehn et al., 2007; Chiang, 2007), Gulcehre et al. (2015) and Sennrich et al. (2015) attempt to enhance the decoder network model of NMT by incorporating the target-side monolingual data so as to boost the translation fluency. They report promising improvements by using the target-side monolingual data. In contrast, the source-side monolingual data is not fully explored. Luong et al. (2015a) adopt a simple autoencoder or skip-thought method (Kiros et al., 2015) to exploit the source-side monolingual data, but no significant BLEU gains are reported. Note that, in parallel to our efforts, Cheng et al. (2016b) have explored the usage of both source and target monolingual data using a similar semi-supervised reconstruction method, in which two NMTs are employed. One translates the source-side monolingual data into target translations, and the other reconstructs the source-side monolingual data from the target translations.

In this work, we investigate the usage of the source-side large-scale monolingual data in NMT and aim at greatly enhancing its encoder network so that we can obtain high quality context vector representations. To achieve this goal, we propose two

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1535–1545,
Austin, Texas, November 1-5, 2016.

approaches. Inspired by (Ueffing et al., 2007; Wu et al., 2008) handling source-side monolingual corpus in SMT and (Sennrich et al., 2015) exploiting target-side monolingual data in NMT, the first approach adopts the self-learning algorithm to generate adequate synthetic parallel data for NMT training. In this method, we first build the baseline machine translation system with the available aligned sentence pairs, and then obtain more synthetic parallel data by translating the source-side monolingual sentences with the baseline system.

The proposed second approach applies the multi-task learning framework to predict the target translation and the reordered source-side sentences at the same time. The main idea behind is that we build two NMTs: one is trained on the aligned sentence pairs to predict the target sentence from the source sentence, while the other is trained on the source-side monolingual corpus to predict the reorderd source sentence from original source sentences[1]. It should be noted that the two NMTs share the same encoder network so that they can help each other to strengthen the encoder model.

In this paper, we make the following contributions:

- To fully investigate the source-side monolingual data in NMT, we propose and compare two methods. One attempts to enhance the encoder network of NMT by producing rich synthetic parallel corpus using a self-learning algorithm, and the other tries to perform machine translation and source sentence reordering simultaneously with a multi-task learning architecture.

- The extensive experiments on Chinese-to-English translation show that our proposed methods significantly outperform the strong NMT baseline augmented with the attention mechanism. We also find that the usage of the source-side monolingual data in NMT is more effective than that in SMT. Furthermore, we find that more monolingual data does not always improve the translation quality and only relevant monolingual data helps.

[1]We reorder all the source-side monolingual sentences so as to make them close to target language in word order.

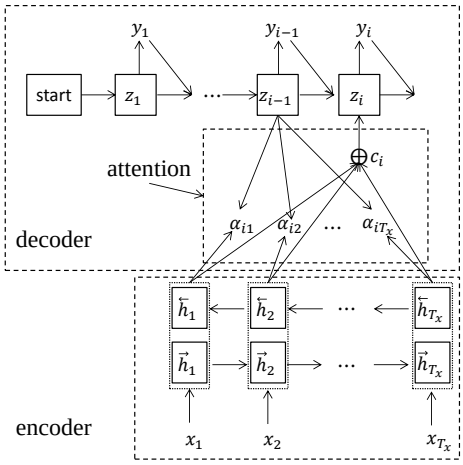

Figure 1: The encoder-decoder NMT with attention.

2 Neural Machine Translation

Our approach on using source-side monolingual corpora can be applied in any neural machine translation as long as it employs the encoder-decoder framework. Without loss of generality, we use the attention-based NMT proposed by (Bahdanau et al., 2014), which utilizes recurrent neural networks for both encoder and decoder as illustrated in Fig. 1.

The encoder-decoder NMT first encodes the source sentence $X = (x_1, x_2, \cdots, x_{T_x})$ into a sequence of context vectors $C = (\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_{T_x})$ whose size varies with respect to the source sentence length. Then, the encoder-decoder NMT decodes from the context vectors C and generates target translation $Y = (y_1, y_2, \cdots, y_{T_y})$ one word each time by maximizing the probability of $p(y_i|y_{<i}, C)$. Note that x_j (y_i) is word embedding corresponding to the j_{th} (i_{th}) word in the source (target) sentence. Next, we briefly review the encoder introducing how to obtain C and the decoder addressing how to calculate $p(y_i|y_{<i}, C)$.

Encoder: The context vectors C are generated by the encoder using a pair of recurrent neural networks (RNN) which consists of a forward RNN and a backward RNN. The forward RNN operates left-to-right over the source sentence from the first word, resulting in the forward context vectors $C_f = (\overrightarrow{h}_1, \overrightarrow{h}_2, \cdots, \overrightarrow{h}_{T_x})$, in which

$$\overrightarrow{h}_j = RNN(\overrightarrow{h}_{j-1}, x_j) \quad (1)$$

$\overleftarrow{h}_j$ can be calculated similarly.

RNN can be a Gated Recurrent Unit (GRU) (Cho et al., 2014) or a Long Short-Term Memory Unit (LSTM) (Hochreiter and Schmidhuber, 1997). At each position j of the source sentence, the context vector $\mathbf{h}_j$ is defined as the concatenation of the forward and backward context vectors.

Decoder: The conditional probability $p(y_i|y_{<i}, C)$ is computed in different ways according to the choice of the context C at time i. In (Cho et al., 2014), the authors choose $C = \mathbf{h}_{T_x}$, while Bahdanau et al. (2014) use different context c_i at different time step and the conditional probability will become:

$$p(y_i|y_{<i}, C) = p(y_i|y_{<i}, c_i) = g(y_{i-1}, z_i, c_i) \quad (2)$$

where z_i is the i_{th} hidden state of the decoder and is calculated conditioning on the previous hidden state z_{i-1}, previous output y_{i-1} and and the source context vector c_i at time i:

$$z_i = RNN(z_{i-1}, y_{i-1}, c_i) \quad (3)$$

In attention-based NMT, c_i is computed as the weighted sum of the source-side context vectors, just as illustrated in the top half of Fig. 1.

All the parameters of the encoder-decoder NMT are optimized to maximize the following conditional log-likelihood of the ***sentence aligned bilingual data***:

$$\mathcal{L}(\theta) = \frac{1}{N}\sum_{n=1}^{N}\sum_{i=1}^{T_y} logp(y_i^{(n)}|y_{<i}^{(n)}, X^{(n)}, \theta) \quad (4)$$

3 Incorporating Source-side Monolingual Data in NMT

We can see from the above objective function that all the network parameters are only optimized on the sentence aligned parallel corpus. It is well known that more related data of high quality leads to better and more robust network models. However, bilingual data is scarce in many languages (or domains). It becomes a key issue how to improve the encoder and decoder networks using other data besides the parallel sentence pairs. Gulcehre et al. (2015) and Sennrich et al. (2015) have tried to fine-tune the decoder neural network with target-side large-scale monolingual data and they report remarkable performance improvement with the enhanced decoder. In contrast, we believe that the encoder part of NMT can also be greatly strengthened with the source-side monolingual data.

To investigate fully the source-side monolingual data in improving the encoder network of NMT, we propose two approaches: the first one employs the self-learning algorithm to provide synthetic parallel data in which the target part is obtained through automatically translating the source-side monolingual data, which we refer to as *self-learning method*. The second one applies the multi-task learning framework that consists of two NMTs sharing the same encoder network to simultaneously train one NMT model on bilingual data and the other sentence reordering NMT model[2] on source-side monolingual data, which we refer to as *sentence reordering method*.

3.1 Self-learning Method

Given the sentence aligned bitext $\mathcal{D}_b = \{(X_b^{(n)}, Y_b^{(n)})\}_{n=1}^{N}$ in which N is not big enough, we have the source-side large-scale monolingual data $\mathcal{D}_{sm} = \{X_{sm}^{m}\}_{m=1}^{M}$ which is related to the bitext and $M \gg N$.

Our goal is to generate much more bilingual data using $\mathcal{D}_b$ and $\mathcal{D}_{sm}$. From the view of machine learning, we are equipped with some labelled data $\mathcal{D}_b$ and plenty of unlabelled data $\mathcal{D}_{sm}$, and we aim to obtain more labelled data for training better models. Self-learning is a simple but effective algorithm to tackle this issue. It first establishes a baseline with labelled data and then adopts the baseline to predict the labels of the unlabelled data. Finally, the unlabelled data together with the predicted labels become new labelled data.

In our scenario, the self-learning algorithm perform the following three steps . First, a baseline machine translation (MT) system (can use any translation model, SMT or NMT) is built with the given bilingual data $\mathcal{D}_b$. Second, the baseline MT sys-

[2]NMT is essentially a sequence-to-sequence prediction model. In most cases, the input sequence is different from the output sequence. In the sentence reordering NMT, we require that output sequence to be the reordered input sentences which are close to English word order.

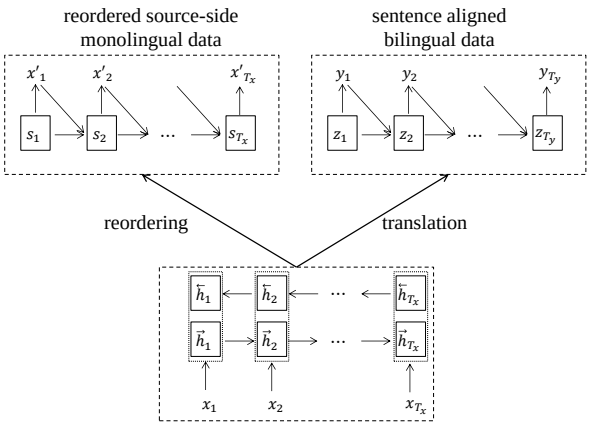

Figure 2: Multi-task learning framework to use source-side monolingual data in NMT, which includes a translation model and a sentence reordering model.

tem automatically translates the source-side monolingual sentences $\mathcal{D}_{sm}$ into target translations $\mathcal{D}_{tt} = \{(Y_{tt}^m)\}_{m=1}^M$, and further pairs $\mathcal{D}_{sm}$ with $\mathcal{D}_{tt}$ resulting in the synthetic parallel corpus $\mathcal{D}_{syn} = \{(X_{sm}^m, Y_{tt}^m)\}_{m=1}^M$. Third, the synthetic parallel corpus $\mathcal{D}_{syn}$ plus the original bitext $\mathcal{D}_b$ are combined together to train the new NMT model.

In principle, we can apply any MT system as the baseline to generate the synthetic bilingual data. In accordance with the translation model we focus on in this work, we employ NMT as the baseline MT system. Note that the synthetic target parts may negatively influence the decoder model of NMT. To address this problem, we can distinguish original bitext from the synthetic bilingual sentences during NMT training by freezing the parameters of the decoder network for the synthetic data.

It is worthy to discuss why self-learning algorithm can improve the encoder model of NMT. Even though we require $\mathcal{D}_{sm}$ to share the same source language vocabulary as $\mathcal{D}_b$ and no new word translations can be generated, the source-side monolingual data provides much more permutations of words in the vocabulary. Our RNN encoder network model will be optimized to well explain all of the word permutations. Thus, the encoder model of NMT can be enhanced for better generalization.

3.2 Sentence Reordering Method

The self-learning algorithm needs to translate first the large-scale source-side monolingual data. A natural question arises that whether can we improve the encoder model of NMT using just source-side monolingual corpora rather than the synthetic parallel data. Luong et al. (2015a) attempt to leverage source-side monolingual data in NMT using a simple autoencoder and skip-thought vectors. However, no promising results are reported. We believe that the reason lies in two aspects: 1) the large-scale monolingual data is not carefully selected; and 2) the adopted model is relatively simple. In this work, we propose to apply the multi-task learning method which designs a parameter sharing neural network framework to perform two tasks: machine translation and source sentence reordering. Fig.2 illustrates the overview of our framework for source-side monolingual data usage.

As shown in Fig. 2, our framework consists of two neural networks that shares the same encoder model but employs two different decoder models for machine translation and sentence reordering respectively. For the machine translation task trained on the sentence aligned parallel data $\mathcal{D}_b$, the network parameters are optimized to maximize the conditional probability of the target sentence $Y_b^{(n)}$ given a source sentence $X_b^{(n)}$, namely argmax$p(Y_b^{(n)}|X_b^{(n)})$.

As for the sentence reordering task trained on source-side monolingual data $\mathcal{D}_{sm}$, we regard it as a special machine translation task in which the target output is just the reordered source sentence, $Y_{sm}^{(m)} = X_{sm}^{'(m)}$. $X_{sm}^{'(m)}$ is obtained from $X_{sm}^{(m)}$ by using the pre-ordering rules proposed by (Wang et al., 2007), which can permutate the words of the source sentence so as to approximate the target language word order[3]. In this way, the sentence reordering NMT is more powerful than an autoencoder. Using the NMT paradigm, the shared encoder network is leveraged to learn the deep representation $C_{sm}^{(n)}$ of the source sentence $X_{sm}^{(n)}$, and the decoder network is employed to predict the reordered source sentence from the deep representation $C_{sm}^{(n)}$ (here $X_{sm}^{(n)} \in \mathcal{D}_{sm}$) by maximizing $p(X_{sm}^{'(n)}|X_{sm}^{(n)})$. Note that the above two

[3]The pre-ordering rules are obtained from the parsed source trees which heavily depend on the accuracy and efficiency of the parser. In fact, it takes us lots of time (even longer than synthetic parallel data generation) to parse all the source-side monolingual data. In the future, we attempt to design a more efficient pre-ordering method relying only on the bilingual training data.

tasks share the same encoder model to obtain the encoding of the source sentences. Accordingly, the overall objective function of this multi-task learning is the summation of log probabilities of machine translation and sentence reordering:

$$\mathcal{L}(\theta) = \frac{1}{N}\sum_{n=1}^{N}\sum_{i=1}^{T_y} logp(y_i^{(n)}|y_{<i}^{(n)}, X^{(n)}, \theta) + \frac{1}{M}\sum_{m=1}^{M}\sum_{i=1}^{T_X} logp(X_i^{'(m)}|X_{<i}^{'(m)}, X^{(m)}, \theta) \quad (5)$$

where $(\theta = \theta_{enc}, \theta_{dec_T}, \theta_{dec_R})$. θ_{enc} is the parameter collection of source language encoder network, θdec_T denotes the parameter set of the decoder network for translation, and θ_{dec_R} represents the parameters of the decoder network for sentence reordering.

Intuitively, the sentence reordering task is easier than the translation task. Furthermore, in this paper, we pay much more attention on the translation task compared to the sentence reordering task. Considering these, we distinguish these two tasks during the parameter optimization process. It is performed using an alternate iteration strategy. For each iteration, we first optimize the encoder-decoder network parameters in the reordering task for one epoch. The learnt encoder network parameters are employed to initialize the encoder model for the translation task. Then, we learn the encoder-decoder network parameters in the translation task for several epochs[4]. The new encoder parameters are then used to initialize the encoder model for the reordering task. We continue the iteration until the constraint (e.g. iteration number or no parameter change) is satisfied. The weakness is that this method is less efficient than the self-learning approach.

4 Experimental Settings

In this section we describe the data set used in our experiments, data preprocessing, the training and evaluation details, and all the translation methods we compare in experiments.

[4]We rune four epochs for the translation task in each iteration.

4.1 Dataset

We perform two tasks on Chinese-to-English translation: one for small data set and the other for large-scale data set. Our small training data includes 0.63M sentence pairs (after data cleaning) extracted from LDC corpora[5]. The large-scale data set contains about 2.1M sentence pairs including the small training data. For validation, we choose NIST 2003 (MT03) dataset. For testing, we use NIST 2004 (MT04), NIST 2005 (MT05) and NIST 2006 (MT06) datasets. As for the source-side monolingual data, we collect about 20M Chinese sentences from LDC and we retain the sentences in which more than 50% words should appear in the source-side portion of the bilingual training data, resulting in 6.5M monolingual sentences for small training data set (12M for large-scale training data set) ordered by the word hit rate.

4.2 Data Preprocessing

We apply word-level translation in experiments. The Chinese sentences are word segmented using Stanford Word Segmenter[6]. To pre-order the Chinese sentences using the syntax-based reordering method proposed by (Wang et al., 2007), we utilize the Berkeley parser (Petrov et al., 2006). The English sentences are tokenized using the tokenizer script from the Moses decoder[7]. To speed up the training procedure, we clean the training data and remove all the sentences of length over 50 words. We limit the vocabulary in both Chinese and English to the most 40K words and all the out-of-vocabulary words are replaced with *UNK*.

4.3 Training and Evaluation Details

Each NMT model is trained on GPU K40 using stochastic gradient decent algorithm AdaGrad (Duchi et al., 2011). We use mini batch size of 32. The word embedding dimension of source and target language is 500 and the size of hidden layer is set to 1024. The training time for each model ranges from 5 days to 10 days for small training data set and ranges from 8 days to 15 days for large training data

RNNSearch-Mono-Autoencoder (50%)	31.55	32.07	28.19	30.85
RNNSearch-Mono-Autoencoder (100%)	27.81	30.32	25.84	27.73

Table 1: Translation results (BLEU score) for different translation methods. For our methods exploring the source-side monolingual data, we investigate the performance change as we choose different scales of monolingual data (e.g. from top 25% to 100% according to the word coverage of the monolingual sentence in source language vocabulary of bilingual training corpus).

set[8]. We use case-insensitive 4-gram BLEU score as the evaluation metric (Papineni et al., 2002).

4.4 Translation Methods

In the experiments, we compare our method with conventional SMT model and a strong NMT model. We list all the translation methods as follows:

- **Moses**: It is the state-of-the-art phrase-based SMT system (Koehn et al., 2007). We use its default configuration and train a 4-gram language model on the target portion of the bilingual training data.
- **RNNSearch**: It is an attention-based NMT system (Bahdanau et al., 2014).
- **RNNSearch-Mono-SL**: It is our NMT system which makes use of the source-side large-scale monolingual data by applying the self-learning algorithm.
- **RNNSearch-Mono-MTL**: It is our NMT system that exploits the source-side monolingual data by using our multi-task learning framework which performs machine translation and sentence reordering at the same time.
- **RNNSearch-Mono-Autoencoder**: It also applies the multi-task learning framework in which a simple autoencoder is adopted on source-side monolingual data (Luong et al., 2015a).

[8]It needs another 5 to 10 days when adding millions of monolingual data.

5 Translation Results on Small Data

For translation quality evaluation, we attempt to figure out four questions: 1) Can the source-side monolingual data improve the neural machine translation? 2) Could the improved NMT outperform the state-of-the-art phrase-based SMT? 3) Whether it is true that the more the source-side monolingual data the better the translation quality? 4) Which MT model is more suitable to incorporate source-side monolingual data: SMT or NMT?

5.1 Effects of Source-side Monolingual Data in NMT

Table 1 reports the translation quality for different methods. Comparing the first two lines in Table 1, it is obvious that the NMT method *RNNSearch* performs much worse than the SMT model *Moses* on Chinese-to-English translation. The gap is as large as approximately 2.0 BLEU points (28.38 vs. 30.30). We speculate that the encoder-decoder network models of NMT are not well optimized due to insufficient bilingual training data.

The focus of this work is to figure out whether

the encoder model of NMT can be improved using source-side monolingual data and further boost the translation quality. The four lines (3-6 in Table 1) show the BLEU scores when applying self-learning algorithm to incorporate the source-side monolingual data. Clearly, *RNNSearch-Mono-SL* outperforms *RNNSearch* in most cases. The best performance is obtained if the top 50% monolingual data is used. The biggest improvement is up to 4.05 BLEU points (32.43 vs. 28.38 on MT03) and it also significantly outperforms *Moses*.

When employing our multi-task learning framework to incorporate source-side monolingual data, the translation quality can be further improved (Lines 7-10 in Table 1). For example, *RNNSearch-Mono-MTL* using the top 50% monolingual data can remarkably outperform the baseline *RNNSearch*, with an improvement up to 5.0 BLEU points (33.38 vs. 28.38 on MT03). Moreover, it also performs significantly better than the state-of-the-art phrase-based SMT *Moses* by the largest gains of 3.38 BLEU points (31.57 vs. 28.19 on MT05). The promising results demonstrate that source-side monolingual data can improve neural machine translation and our multi-task learning is more effective.

From the last two lines in Table 1, we can see that *RNNSearch-Mono-Autoencoder* can also improve the translation quality by more than 1.0 BLEU points when using the most related monolingual data. However, it underperforms *RNNSearch-Mono-MTL* by a large gap. It indicates that sentence reordering model is better than sentence reconstruction model for exploiting the source-side monolingual data.

Note that we sort the source-side monolingual data according to the word coverage [9] in the bilingual training data. Sentences in the front have more shared words with the source-side vocabulary of bilingual training data. We can clearly see from Table 1 that monolingual data cannot always improve NMT. By adding closely related corpus (25% to 50%), the methods can achieve better and better performance. However, when adding more unrelated monolingual data (75% to 100%) which shares fewer and fewer words in common with the bilingual data, the translation quality becomes worse and worse, and even worse than the baseline *RNNSearch*. Both self-learning algorithm *RNNSearch-Mono-SL* and multi-task learning framework *RNNSearch-Mono-MTL* have the same trend. This indicates that only closely related source-side monolingual data can lead to performance improvement.

[9] In current work, the simple word coverage is applied to indicate the similarity. In the future, we plan to use phrase embedding (Zhang et al., 2014) or sentence embedding (Zhang et al., 2015; Wang et al., 2016a; Wang et al., 2016b) to select the relevant monolingual data.

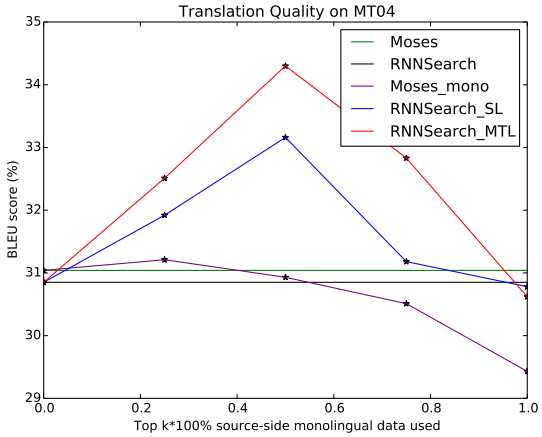

Figure 3: Effects of source-side monolingual data on MT04.

5.2 NMT vs. SMT on Using Source-side Monolingual Data

Although the proposed multi-task learning framework cannot fit SMT because of no shared deep information between the two tasks in SMT, self-learning algorithm can also be applied in SMT as done by (Ueffing et al., 2007; Wu et al., 2008). We may want to know whether NMT is more effective in using source-side monolingual data than SMT.

We apply the self-learning algorithm in SMT by incorporating top 25%, 50%, 75% and 100% synthetic sentence pairs to retrain baseline Moses. Fig. 3 shows the effect of source-side monolingual data in different methods on test set MT04. The figure reveals three similar phenomena. First, related monolingual data can boost the translation quality no matter whether NMT or SMT is used, but mixing more unrelated monolingual corpus will decrease the performance. Second, integrating closely related source-side monolingual data in NMT (*RNNSearch-SL* and *RNNSearch-MTL*) is much more effective than that in SMT (e.g. results for top 50%). It is because that SMT relies on the translation rules

Method	MT03	MT04	MT05	MT06
RNNSearch	35.18	36.20	33.21	32.86
RNNSearch-Mono-MTL (50%)	**36.32**	**37.51**	**35.08**	**34.26**
RNNSearch-Mono-MTL (100%)	35.75	36.74	34.23	33.52

Table 2: Translation results (BLEU score) for different translation methods in large-scale training data.

learnt from the bilingual training data and the synthetic parallel data is obtained by these rules, and thus the synthetic parallel data cannot generate much more information. In contrast, NMT provides a encoder-decoder mechanism and depends heavily on the source language semantic vector representations which facilitate the information sharing. Third, the translation quality changes much more dramatically in NMT methods than that in SMT. It indicates that the neural network models incline to be more affected by the quality of the training data.

6 Translation Results on Large-scale Data

A natural question arises that is the source-side monolingual data still very helpful when we have much more bilingual training data. We conduct the large-scale experiments using our proposed multi-task framework *RNNSearch-Mono-MTL*. Table 2 reports the results.

We can see from the table that closely related source-side monolingual data (the top 50%) can also boost the translation quality on all of the test sets. The performance improvement can be more than 1.0 BLEU points. Compared to the results on small training data, the gains from source-side monolingual data are much smaller. It is reasonable since large-scale training data can make the parameters of the encoder-decoder parameters much stable. We can also observe the similar phenomenon that adding more unrelated monolingual data leads to decreased translation quality.

7 Related Work

As a new paradigm for machine translation, the encoder-decoder based NMT has drawn more and more attention. Most of the existing methods mainly focus on designing better alignment mechanisms (attention model) for the decoder network (Cheng et al., 2016a; Luong et al., 2015b; Cohn et al., 2016; Feng et al., 2016; Tu et al., 2016; Mi et al., 2016a; Mi et al., 2016b), better objective functions for BLEU evaluation (Shen et al., 2016) and better strategies for handling unknown words (Luong et al., 2015c; Sennrich et al., 2015; Li et al., 2016) or large vocabularies (Jean et al., 2015; Mi et al., 2016c).

Our focus in this work is aiming to make full use of the source-side large-scale monolingual data in NMT, which is not fully explored before. The most related works lie in three aspects: 1) applying target-side monolingual data in NMT, 2) targeting knowledge sharing with multi-task NMT, and 3) using source-side monolingual data in conventional SMT and NMT.

Gulcehre et al. (2015) first investigate the target-side monolingual data in NMT. They propose shallow and deep fusion methods to enhance the decoder network by training a big language model on target-side large-scale monolingual data. Sennrich et al. (2015) further propose a new approach to use target-side monolingual data. They generate the synthetic bilingual data by translating the target monolingual sentences to source language sentences and retrain NMT with the mixture of original bilingual data and the synthetic parallel data. It is similar to our self-learning algorithm in which we concern the source-side monolingual data. Furthermore, their method requires to train an additional NMT from target language to source language, which may negatively influence the attention model in the decoder network.

Dong et al. (2015) propose a multi-task learning method for translating one source language into multiple target languages in NMT so that the encoder network can be shared when dealing with several sets of bilingual data. Zoph et al. (2016), Zoph and Knight (2016) and Firat et al. (2016) further deal with more complicated cases (e.g. multi-source languages). Note that all these methods require bilingual training corpus. Instead, we adapt the multi-task learning framework to better accommodate the source-side monolingual data.

Ueffing et al. (2007) and Wu et al. (2008) explore

the usage of source-side monolingual data in conventional SMT with a self-learning algorithm. Although we apply self-learning in this work, we use it to enhance the encoder network in NMT rather than generating more translation rules in SMT and we also adapt a multi-task learning framework to take full advantage of the source-side monolingual data. Luong et al. (2015a) also investigate the source-side monolingual data in the multi-task learning framework, in which a simple autoencoder or skip-thought vectors are employed to model the monolingual data. Our sentence reordering model is more powerful than simple autoencoder in encoder enhancement. Furthermore, they do not carefully prepare the monolingual data for which we show that only related monolingual data leads to big improvements.

In parallel to our work, Cheng et al. (2016b) propose a similar semi-supervised framework to handle both source and target language monolingual data. If source-side monolingual data is considered, a reconstruction framework including two NMTs is employed. One NMT translates the source-side monolingual data into target language translations, from which the other NMT attempts to reconstruct the original source-side monolingual data. In contrast to their approach, we propose a sentence reordering model rather than the sentence reconstruction model. Furthermore, we carefully investigate the relationship between the monolingual data quality and the translation performance improvement.

8 Conclusions and Future Work

In this paper, we propose a self-learning algorithm and a new multi-task learning framework to use source-side monolingual data so as to improve the encoder network of the encoder-decoder based NMT. The self-learning algorithm generates the synthetic parallel corpus and enlarge the bilingual training data to enhance the encoder model of NMT. The multi-task learning framework performs machine translation on bilingual data and sentence reordering on source-side monolingual data by sharing the same encoder network. The experiments show that our method can significantly outperform the strong attention-based NMT baseline, and the proposed multi-task learning framework performs better than the self-learning algorithm at the expense of low efficiency. Furthermore, the experiments also demonstrate that NMT is more effective for incorporating the source-side monolingual data than conventional SMT. We also observe that more monolingual data does not always improve the translation quality and only relevant data does help.

In the future, we would like to design smarter mechanisms to distinguish real data from synthetic data in self-learning algorithm, and attempt to propose better models for handling source-side monolingual data. We also plan to apply our methods in other languages, especially for low-resource languages.

Phrase-based Machine Translation is State-of-the-Art for Automatic Grammatical Error Correction

Marcin Junczys-Dowmunt and **Roman Grundkiewicz**
Adam Mickiewicz University in Poznań
ul. Umultowska 87, 61-614 Poznań, Poland

Abstract

In this work, we study parameter tuning towards the M^2 metric, the standard metric for automatic grammar error correction (GEC) tasks. After implementing M^2 as a scorer in the Moses tuning framework, we investigate interactions of dense and sparse features, different optimizers, and tuning strategies for the CoNLL-2014 shared task. We notice erratic behavior when optimizing sparse feature weights with M^2 and offer partial solutions. We find that a bare-bones phrase-based SMT setup with task-specific parameter-tuning outperforms all previously published results for the CoNLL-2014 test set by a large margin (46.37% M^2 over previously 41.75%, by an SMT system with neural features) while being trained on the same, publicly available data. Our newly introduced dense and sparse features widen that gap, and we improve the state-of-the-art to 49.49% M^2.

1 Introduction

Statistical machine translation (SMT), especially the phrase-based variant, is well established in the field of automatic grammatical error correction (GEC) and systems that are either pure SMT or incorporate SMT as system components occupied top positions in GEC shared tasks for different languages.

With the recent paradigm shift in machine translation towards neural translation models, neural encoder-decoder models are expected to appear in the field of GEC as well, and first published results (Xie et al., 2016) already look promising. As it is the case in classical bilingual machine translation research, these models should be compared against strong SMT baselines. Similarly, system combinations of SMT with classifier-based approaches (Rozovskaya and Roth, 2016) suffer from unnecessarily weak MT base systems which make it hard to assess how large the contribution of the classifier pipelines really is. In this work we provide these baselines.

During our experiments, we find that a bare-bones phrase-based system outperforms the best published results on the CoNLL-2014 test set by a significant margin only due to a task-specific parameter tuning when being trained on the same data as previous systems. When we further investigate the influence of well-known SMT-specific features and introduce new features adapted to the problem of GEC, our final systems outperform the best reported results by 8% M^2, moving the state-of-the-art results for the CoNLL-2014 test set from 41.75% M^2 to 49.49%.

The paper is organized as follows: section 2 describes previous work, the CoNLL-2014 shared tasks on GEC and follow-up papers. Our main contributions are presented in sections 3 and 4 where we investigate the interaction of parameter tuning towards the M^2 metric with task-specific dense and sparse features. Especially tuning for sparse features is more challenging than initially expected, but we describe optimizer hyper-parameters that make sparse feature tuning with M^2 feasible. Section 5 reports on the effects of adding a web-scale n-gram language model to our models.

Scripts and models used in this paper are available from `https://github.com/grammatical/baselines-emnlp2016` to facilitate reproducibility of our results.

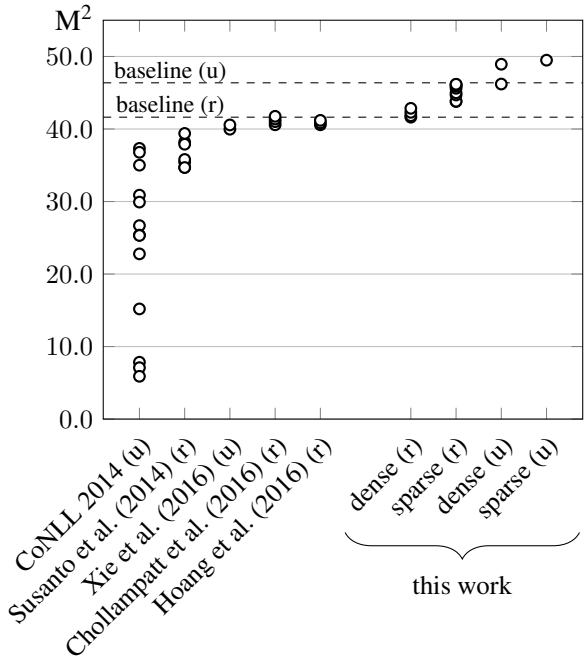

Figure 1: Comparison with previous work on the CoNLL-2014 task, trained on publicly available data. Dashed lines mark results for our baseline systems with restricted (r) and unrestricted (u) data.

2 Previous Work

While machine translation has been used for GEC in works as early as Brockett et al. (2006), we start our discussion with the CoNLL-2014 shared task (Ng et al., 2014) where for the first time an unrestricted set of errors had to be fully corrected. Previous work, most notably during the CoNLL shared-task 2013 (Ng et al., 2013), concentrated only on five selected errors types, but machine translation approaches (Yoshimoto et al., 2013; Yuan and Felice, 2013) were used as well.

The goal of the CoNLL-2014 shared task was to evaluate algorithms and systems for automatically correcting grammatical errors in essays written by second language learners of English. Grammatical errors of 28 types were targeted. Participating teams were given training data with manually annotated corrections of grammatical errors and were allowed to use additional publicly available data.

The corrected system outputs were evaluated blindly using the MaxMatch (M^2) metric (Dahlmeier and Ng, 2012). Thirteen system submissions took part in the shared task. Among the top-three positioned systems, two submissions — CAMB (Felice et al., 2014) and AMU (Junczys-Dowmunt and Grundkiewicz, 2014)[1] — were partially or fully based on SMT. The second system, CUUI (Rozovskaya et al., 2014), was a classifier-based approach, another popular paradigm in GEC.

After the shared task, Susanto et al. (2014) published work on GEC systems combinations. They combined the output from a classification-based system and a SMT-based system using MEMT (Heafield and Lavie, 2010), reporting new state-of-the-art results for the CoNLL-2014 test set.

Xie et al. (2016) presented a neural network-based approach to GEC. Their method relies on a character-level encoder-decoder recurrent neural network with an attention mechanism. They use data from the public Lang-8 corpus and combine their model with an n-gram language model trained on web-scale Common Crawl data.

More recent results are Chollampatt et al. (2016) and Hoang et al. (2016) which also rely on MT systems with new features (a feed-forward neural translation model) and n-best list re-ranking methods. However, most of the improvement over the CoNLL-2014 shared task of these works stems from using the parameter tuning tools we introduced in Junczys-Dowmunt and Grundkiewicz (2014).

In Figure 1 we give a graphical overview of the published results for the CoNLL-2014 test set in comparison to the results we will discuss in this work. Positions marked with (r) use only restricted data which corresponds to the data set used by Susanto et al. (2014). Positions with (u) make use of web-scale data, this corresponds to the resources used in Xie et al. (2016). We marked the participants of the CoNLL-2014 shared task as unrestricted as some participants made use of Common Crawl data or Google n-grams. The visible plateau for results

[1] Junczys-Dowmunt and Grundkiewicz (2014) is our own contribution and introduced many of the concepts discussed in this work, but seemingly to little effect during the task. Later analysis revealed that our submission had an incorrectly filtered language model that was missing many possible entries. Our original system without this deficiency would have achieved results around 44% M^2 already in 2014. This discovery triggered an intensive reanalysis of our shared task system with significantly new conclusions presented in this work. We apologize for supplying these results so late, as this seems to have halted progress in the field for nearly two years.

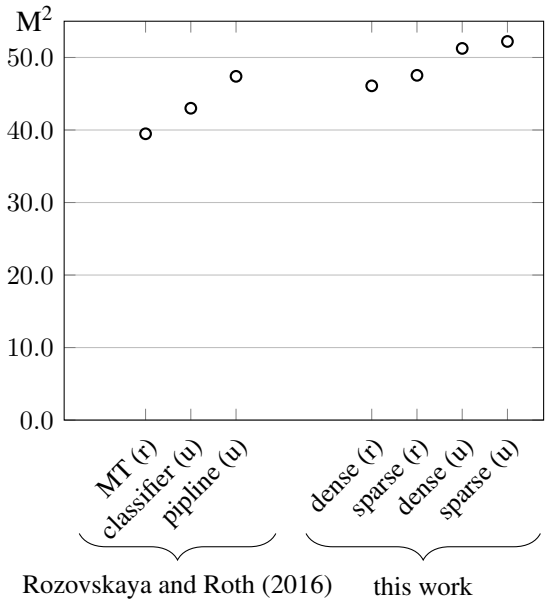

Figure 2: Comparison with Rozovskaya and Roth (2016) using the non-public Lang-8 data set. Here (r) means no web-scale monolingual resources, (u) includes Google 1T n-grams or CommonCrawl.

prior to this work seem to confirm our claims about missing strong baselines.

Rozovskaya and Roth (2016) introduce a SMT-classifier pipeline with state-of-the-art results. Unfortunately, these results are reported for a training set that is not publicly available (data crawled from the Lang-8 website)[2]. Figure 2 compares our results for this resource to Rozovskaya and Roth (2016). See Section 6 for details.

3 Dense feature optimization

Moses comes with tools that can tune parameter vectors according to different MT tuning metrics. Prior work used Moses with default settings: minimum error rate training (Och, 2003) towards BLEU (Papineni et al., 2002). BLEU was never designed for grammatical error correction; we find that directly optimizing for M^2 works far better.

[2]We shared this resource that has been crawled by us for use in Junczys-Dowmunt and Grundkiewicz (2014) privately with Rozovskaya and Roth (2016), but originally were not planning to report results for this resource in the future. We now provide a comparison to Rozovskaya and Roth (2016), but discourage any further use of this unofficial data due to reproducibility issues.

3.1 Tuning towards M^2

The M^2 metric (Dahlmeier and Ng, 2012) is an F-Score, based on the edits extracted from a Levenshtein distance matrix. For the CoNLL-2014 shared task, the β-parameter was set to 0.5, putting two times more weight on precision than on recall.

In Junczys-Dowmunt and Grundkiewicz (2014) we have shown that tuning with BLEU is counterproductive in a setting where M^2 is the evaluation metric. For inherently weak systems this can result in all correction attempts to be disabled, MERT then learns to disallow all changes since they lower the similarity to the reference as determined by BLEU. Systems with better training data, can be tuned with BLEU without suffering this "disabling" effect, but will reach non-optimal performance. However, Susanto et al. (2014) tune the feature weights of their two SMT-based systems with BLEU on the CoNLL-2013 test set and report state-of-the-art results.

Despite tuning with M^2, in Junczys-Dowmunt and Grundkiewicz (2014) we were not able to beat systems that did not tune for the task metric. We reinvestigated these ideas with radically better results, re-implemented the M^2 metric in C++ and added it as a scorer to the Moses parameter optimization framework. Due to this integration we can now tune parameter weights with MERT, PRO or Batch Mira. The inclusion of the latter two enables us to experiment with sparse features.

Based on Clark et al. (2011) concerning the effects of optimizer instability, we report results averaged over five tuning runs. Additionally, we compute parameter weight vector centroids as suggested by Cettolo et al. (2011). They showed that parameter vector centroids averaged over several tuning runs yield similar to or better than average results and reduce variance. We generally confirm this for M^2-based tuning.

3.2 Dense features

The standard features in SMT have been chosen to help guiding the translation process. In a GEC setting the most natural units seem to be minimal edit operations that can be either counted or modeled in context with varying degrees of generalization. That way, the decoder can be informed on several levels

source phrase	target phrase	LD	D	I	S
a short time .	short term only .	3	1	1	1
a situation	into a situation	1	0	1	0
a supermarket .	a supermarket .	0	0	0	0
a supermarket .	at a supermarket	2	1	1	0
able	unable	1	0	0	1

Table 1: Word-based Levenshtein distance (LD) feature and separated edit operations (D = deletions, I = insertions, S = substitutions)

of abstraction how the output differs from the input.[3] In this section we implement several features that try to capture these operation in isolation and in context.

3.2.1 Stateless features

Our stateless features are computed during translation option generation before decoding, modeling relations between source and target phrases. They are meant to extend the standard SMT-specific MLE-based phrase and word translation probabilities with meaningful phrase-level information about the correction process.

Levenshtein distance. In Junczys-Dowmunt and Grundkiewicz (2014) we use word-based Levenshtein distance between source and target as a translation model feature, Felice et al. (2014) independently experiment with a character-based version.

Edit operation counts. We further refine Levenshtein distance feature with edit operation counts. Based on the Levenshtein distance matrix, the numbers of deletions, insertions, and substitutions that transform the source phrase into the target phrase are computed, the sum of these counts is equal to the original Levenshtein distance (see Table 1).

3.2.2 Stateful features

Contrary to stateless features, stateful features can look at translation hypotheses outside their own span and take advantage of the constructed target context. The most typical stateful features are language models. In this section, we discuss LM-like features over edit operations.

[3]We believe this is important information that currently has not yet been mastered in neural encoder-decoder approaches.

Corpus	Sentences	Tokens
NUCLE	57.15 K	1.15 M
CoNLL-2013 Test Set	1.38 K	29.07 K
CoNLL-2014 Test Set	1.31 K	30.11 K
Lang-8	2.23 M	30.03 M
Lang-8 (non-public)	3.72 M	51.07 M
Wikipedia	213.08 M	3.37 G
CommonCrawl (u)	59.13 G	975.63 G

Table 2: Parallel (above line) and monolingual training data.

Operation Sequence Model. Durrani et al. (2013) introduce Operation Sequence Models in Moses. These models are Markov translation models that in our setting can be interpreted as Markov edition models. Translations between identical words are matches, translations that have different words on source and target sides are substitutions; insertions and deletions are interpreted in the same way as for SMT. Gaps, jumps, and other operations typical for OSMs do not appear as we disabled reordering.

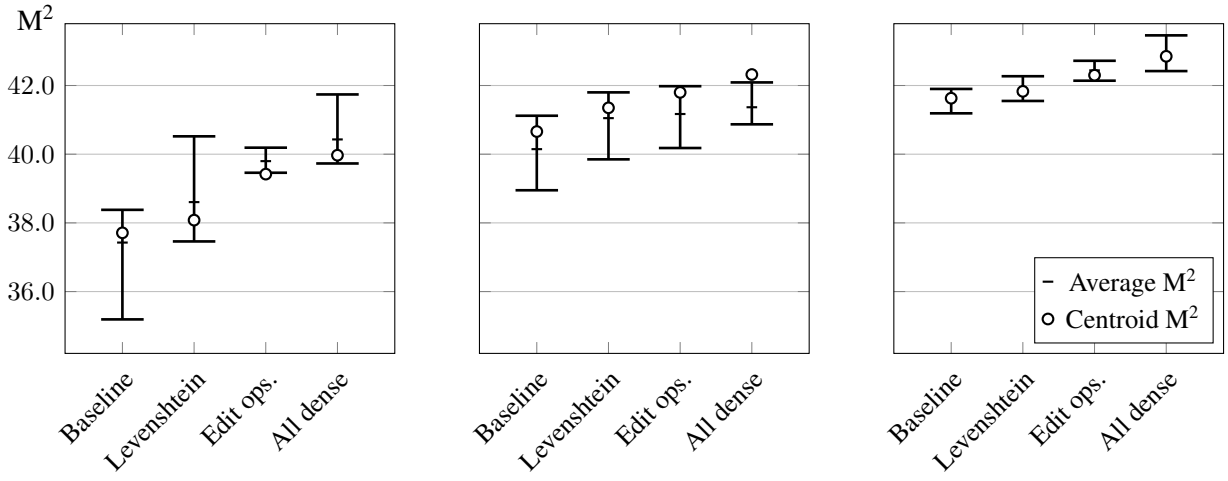
Word-class language model. The monolingual Wikipedia data has been used create a 9-gram word-class language model with 200 word-classes produced by word2vec (Mikolov et al., 2013). This features allows to capture possible long distance dependencies and semantical aspects.

3.3 Training and Test Data

The training data provided in both shared tasks is the NUS Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013). NUCLE consists of 1,414 essays written by Singaporean students who are non-native speakers of English. The essays cover topics, such as environmental pollution, health care, etc. The grammatical errors in these essays have been hand-corrected by professional English teachers and annotated with one of the 28 predefined error type.

Another 50 essays, collected and annotated similarly as NUCLE, were used in both CoNLL GEC shared tasks as blind test data. The CoNLL-2014 test set has been annotated by two human annotators, the CoNLL-2013 by one annotator. Many participants of CoNLL-2014 shared task used the test set from 2013 as development set for their systems.

As mentioned before, we report main results us-



(a) Optimized using BLEU on the CoNLL-2013 test set

(b) Optimized using M^2 on the CoNLL-2013 test set

(c) Optimized using M^2 on 4 folds of error-rate-adapted NUCLE

Figure 3: Results on the CoNLL-2014 test set for different optimization settings (5 runs for each system) and different feature sets, the "All dense" entry includes OSM, the word class language model, and edit operations). The small circle marks results for averaged weights vectors and is chosen as the final result.

ing similar training data as Susanto et al. (2014). We refer to this setting that as the "resticted-data setting" (r). Parallel data for translation model training is adapted from the above mentioned NUCLE corpus and the publicly available Lang-8 corpus (Mizumoto et al., 2012), this corpus is distinct from the non-public web-crawled data described in Section 6. Uncorrected sentences serve as source data, corrected counterparts as target data. For language modeling, the target language sentences of both parallel resources are used, additionally we extract all text from the English Wikipedia.

Phrase-based SMT makes it ease to scale up in terms of training data, especially in the case of n-gram language models. To demonstrate the ease of data integration we propose an "unrestricted setting" (u) based on the data used in Junczys-Dowmunt and Grundkiewicz (2014), one of the shared task submissions, and later in Xie et al. (2016). We use Common Crawl data made-available by Buck et al. (2014).

3.4 Experiments

Our system is based on the phrase-based part of the statistical machine translation system Moses (Koehn et al., 2007). Only plain text data is used for language model and translation model training. External linguistic knowledge is introduced during parameter tuning as the tuning metric relies on the error annotation present in NUCLE. The translation model is built with the standard Moses training script, word-alignment models are produced with MGIZA++ (Gao and Vogel, 2008), we restrict the word alignment training to 5 iterations of Model 1 and 5 iterations of the HMM-Model. No reordering models are used, the distortion limit is set to 0, effectively prohibiting any reordering. All systems use one 5-gram language model that has been estimated from the target side of the parallel data available for translation model training. Another 5-gram language model trained on Wikipedia in the restricted setting or on Common Crawl in the unrestricted case.

Systems are retuned when new features of any type are added. We first successfully reproduce results from Susanto et al. (2014) for BLEU-based tuning on the CoNLL-2013 test set as the development set (Fig. 3a) using similar training data. Repeated tuning places the scores reported by Susanto et al. (2014) for their SMT-ML combinations (37.90 – 39.39) within the range of possible values for a purely Moses-based system without any specific features (35.19 – 38.38) or with just the Levenshtein distance features (37.46 – 40.52). Since Susanto et al. (2014) do not report results for multiple tuning steps, the extend of influence of optimizer

instability on their experiments remains unclear. Even with BLEU-based tuning, we can see significant improvements when replacing Levenshtein distance with the finer-grained edit operations, and another performance jump with additional stateful features. The value range of the different tuning runs for the last feature set includes the currently best-performing system (Xie et al. (2016) with 40.56%), but the result for the averaged centroid are inferior.

Tuning directly with M^2 (Fig. 3b) and averaging weights across five iterations, yields between 40.66% M^2 for a vanilla Moses system and 42.32% for a system with all described dense features. Results seen to be more stable. Averaging weight vectors across runs to produce the final vector seems like a fair bet. Performance with the averaged weight vectors is either similar to or better than the average number for five runs.

3.5 Larger development sets

No less important than choosing the correct tuning metric is a good choice of the development set. Among MT researches, there is a number of more or less well known truths about suitable development sets for translation-focused settings: usually they consist of between 2000 and 3000 sentences, they should be a good representation of the testing data, sparse features require more sentences or more references, etc. Until now, we followed the seemingly obvious approach from Susanto et al. (2014) to tune on the CoNLL-2013 test set. The CoNLL-2013 test set consists of 1380 sentences, which might be barely enough for a translation-task, and it is unclear how to quantify it in the context of grammar correction. Furthermore, calculating the error rate in this set reveals that only 14.97% of the tokens are part of an erroneous fragment, for the rest, input and reference data are identical. Intuitively, this seems to be very little significant data for tuning an SMT system.

We therefore decide to take advantage of the entire NUCLE data as a development set which so far has only been used as translation model training data. NUCLE consist of more than 57,000 sentences, however, the error rate is significantly lower than in the previous development set, only 6.23%. We adapt the error rate by greedily removing sentences from NUCLE until an error rate of ca. 15% is reached, 23381 sentences and most error annotations remain. We further divide the data into four folds. Each folds serves as development set for parameter tuning, while the three remaining parts are treated as translation model training data. The full Lang-8 data is concatenated with is NUCLE training set, and four models are trained. Tuning is then performed four times and the resulting four parameter weight vectors are averaged into a single weight vector across folds. We repeat this procedure again five times which results in 20 separate tuning steps. Results on the CoNLL-2014 test set are obtained using the full translation model with a parameter vector average across five runs. The CoNLL-2013 test set is not being used for tuning and can serve as a second test set.

As can be seen in Fig. 3c, this procedure significantly improves performance, also for the barebones set-up (41.63%). The lower variance between iterations is an effect of averaging across folds.

It turns out that what was meant to be a strong baseline, is actually among the strongest systems reported for this task, outperformed only by the further improvements over this baseline presented in this work.

4 Sparse Features

We saw that introducing finer-grained edit operations improved performance. The natural evolution of that idea are features that describe specific correction operations with and without context. This can be accomplished with sparse features, but tuning sparse features according to the M^2 metric poses unexpected problems.

4.1 Optimizing for M^2 with PRO and Mira

The MERT tool included in Moses cannot handle parameter tuning with sparse feature weights and one of the other optimizers available in Moses has to be used. We first experimented with both, PRO (Hopkins and May, 2011) and Batch Mira (Cherry and Foster, 2012), for the dense features only, and found PRO and Batch Mira with standard settings to either severely underperform in comparison to MERT or to suffer from instability with regard to different test sets (Table 3).

Experiments with Mira hyper-parameters allowed to counter these effects. We first change the

Optimizer	2013	2014
MERT	33.50	42.85
PRO	33.68	40.34
Mira	29.19	34.13
-model-bg	31.06	43.88
-D 0.001	33.86	42.91

Table 3: Tuning with different optimizers with dense features only, results are given for the CoNLL-2013 and CoNLL-2014 test set

background BLEU approximation method in Batch Mira to use model-best hypotheses (`--model-bg`) which seems to produce more satisfactory results. Inspecting the tuning process, however, reveals problems with this setting, too. Figure 4 documents how instable the tuning process with Mira is across iterations. The best result is reached after only three iterations. In a setting with sparse features this would result in only a small set of weighted sparse features.

After consulting with one of the authors of Batch-Mira, we set the background corpus decay rate to 0.001 (`-D 0.001`), resulting in a sentence-level approximation of M^2. Mira's behavior seems to stabilize across iterations. At this point it is not quite clear why this is required. While PRO's behavior is more sane during tuning, results on the test sets are subpar. It seems that no comparable hyper-parameter settings exist for PRO.

4.2 Sparse edit operations

Our sparse edit operations are again based on the Levenshtein distance matrix and count specific edits that are annotated with the source and target tokens that took part in the edit. For the following erroneous/corrected sentence pair

```
Err: Then a new problem comes out .
Cor: Hence , a new problem surfaces .
```

we generate sparse features that model contextless edits (matches are omitted):

```
subst(Then,Hence)=1
insert(,)=1
subst(comes, surfaces)=1
del(out)=1
```

and sparse features with one-sided left or right or two-sided context:

```
<s>_subst(Then,Hence)=1
```

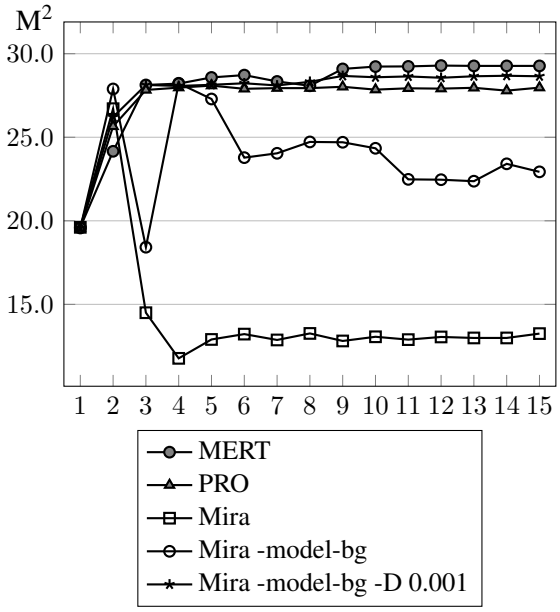


Figure 4: Results per iteration on development set (4-th NUCLE fold)

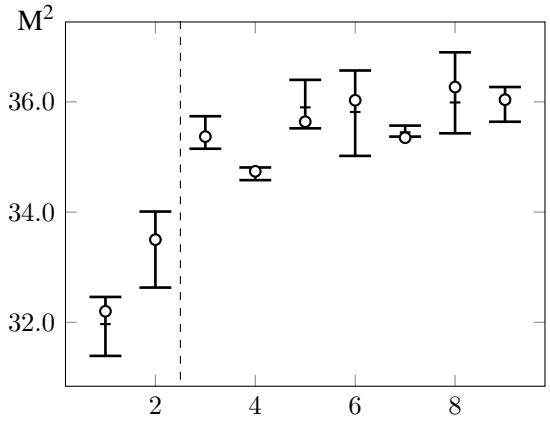
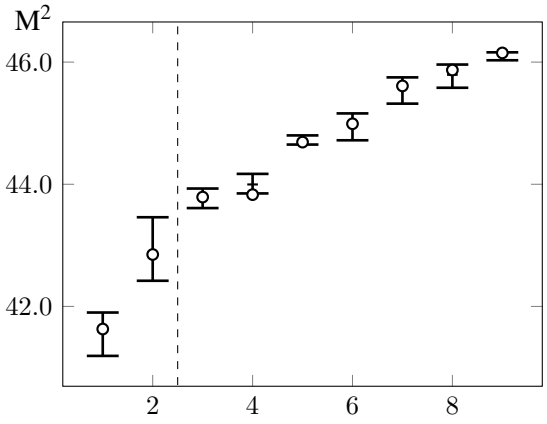
```
subst(Then,Hence)_a=1
Hence_insert(,)=1
insert(,)_a=1
problem_subst(comes, surfaces)=1
subst(comes, surfaces)_out=1
comes_del(out)=1
del(out)_.=1
<s>_subst(Then,Hence)_a=1
Hence_insert(,)_a=1
problem_subst(comes, surfaces)_out=1
comes_del(out)_.=1
```

All sparse feature types are added on-top of our best dense-features system. When using sparse features with context, the contextless features are included. The context annotation comes from the erroneous source sentence, not from the corrected target sentence. We further investigate different source factors: elements taking part in the edit operation or appearing in the context can either be word forms (factor 0) or word classes (factor 1). As before for dense features we average sparse feature weights across folds and multiple tuning runs.

Figure 5 summarizes the results for our sparse feature experiments. On both test sets we can see significant improvements when including edit-based sparse features, the performance increases even more when source context is added. The CoNLL-2013 test set contains annotations from only one annotator and is strongly biased towards high



(a) CoNLL-2014 test set



(b) CoNLL-2014 test set

Symbol	Description
E0	Edit operation on words, no context
E1	Edit operation on word classes, no context
E0C10	Edit operation on words with left/right context of maximum length 1 on words
E1C11	Edit operation on word classes with left/right context of maximum length 1 on word classes
E0C11	Edit operation on words with left/right context of maximum length 1 on word classes

Figure 5: Results on the CoNLL-2013 and CoNLL-2014 test set for different sparse features sets

precision which might explain the greater instability. It appears that sparse features with context where surface forms and word-classes are mixed allow for the best fine-tuning.

5 Adding a web-scale language model

Until now we restricted our experiments to data used by Susanto et al. (2014). However, systems from the CoNLL-2014 were free to use any publicly available data, for instance in Junczys-Dowmunt and Grundkiewicz (2014), we made use of an n-gram language model trained from Common Crawl. Xie et al. (2016) reach the best published result for the task (before this work) by integrating a similar n-gram language model with their neural approach.

We filter the English resources made available by Buck et al. (2014) with cross-entropy filtering (Moore and Lewis, 2010) using the corrected NUCLE corpus as seed data. We keep all sentence with a negative cross-entropy score and compute a 5-gram KenLM (Heafield, 2011) language model with heavy pruning. This step produces roughly 300G of compressed text and a manageable 21G binary model (available for download).

Table 4 summarizes the best results reported in this paper for the CoNLL-2014 test set (column 2014) before and after adding the Common Crawl n-gram language model. The vanilla Moses baseline with the Common Crawl model can be seen as a new simple baseline for unrestricted settings and is ahead of any previously published result. The combination of sparse features and web-scale monolingual data marks our best result, outperforming previously published results by 8% M^2 using similar training data. While our sparse features cause a respectable gain when used with the smaller language model, the web-scale language model seems to cancel out part of the effect.

Bryant and Ng (2015) extended the CoNLL-2014 test set with additional annotations from two to ten annotators. We report results for this valuable resource (column 2014-10) as well.[4] According to Bryant and Ng (2015), human annotators seem to reach on average 72.58% M^2 which can be seen as an upper-bound for the task. In this work, we made a large step towards this upper-bound.

[4]See Bryant and Ng (2015) for a re-assessment of the CoNLL-2014 systems with this extended test set.

System	2014 Prec.	2014 Recall	2014 M^2	2014-10 Prec.	2014-10 Recall	2014-10 M^2
Baseline	48.97	26.03	41.63	69.29	31.35	55.78

System	Prec.	Recall	M^2
R&R (np)	60.17	25.64	47.40
Best dense (np)	53.56	29.59	46.09
+CCLM	61.74	30.51	51.25
Best sparse (np)	58.57	27.11	47.54
+CCLM	63.52	30.49	52.21

Table 5: Previous best systems trained with non-public (np) error-corrected data for comparison with Rozovskaya and Roth (2016) denoted as R&R.

6 More error-corrected data

As mentioned before, Rozovskaya and Roth (2016) trained their systems on crawled data from the Lang-8 website that has been collect by us for our submission to the CoNLL-2014 shared task. Since this data has not been made officially available, we treat it as non-public. This makes it difficult to put their results in relation with previously published work, but we can at least provide a comparison for our systems. As our strongest MT-only systems trained on public data already outperform the pipelined approaches from Rozovskaya and Roth (2016), it is unsurprising that adding more error-corrected parallel data results in an even wider gap (Table 5). We can assume that this gap would persist if only public data had been used. Although these are the highest reported results for the CoNLL-2014 shared task so far, we think of them as unofficial results and refer to Table 4 as our final results in this work.

7 Conclusions

Despite the fact that statistical machine translation approaches are among the most popular methods in automatic grammatical error correction, few papers that report results for the CoNLL-2014 test set seem to have exploited its full potential. An important aspect when training SMT systems that one needs to tune parameters towards the task evaluation metric seems to have been under-explored.

We have shown that a pure SMT system actually outperforms the best reported results for any paradigm in GEC if correct parameter tuning is performed. With this tuning mechanism available, task-specific features have been explored that bring further significant improvements, putting phrase-based SMT ahead of other approaches by a large margin. None of the explored features require complicated pipelines or re-ranking mechanisms. Instead they are a natural part of the log-linear model in phrase-based SMT. It is therefore quite easy to reproduce our results and the presented systems may serve as new baselines for automatic grammatical error correction. Our systems and scripts have been made available for better reproducibility.

Acknowledgments

Abstract

Neural machine translation (NMT) often makes mistakes in translating low-frequency content words that are essential to understanding the meaning of the sentence. We propose a method to alleviate this problem by augmenting NMT systems with discrete translation lexicons that efficiently encode translations of these low-frequency words. We describe a method to calculate the lexicon probability of the next word in the translation candidate by using the attention vector of the NMT model to select which source word lexical probabilities the model should focus on. We test two methods to combine this probability with the standard NMT probability: (1) using it as a bias, and (2) linear interpolation. Experiments on two corpora show an improvement of 2.0-2.3 BLEU and 0.13-0.44 NIST score, and faster convergence time.[1]

1 Introduction

Neural machine translation (NMT, §2; Kalchbrenner and Blunsom (2013), Sutskever et al. (2014)) is a variant of statistical machine translation (SMT; Brown et al. (1993)), using neural networks. NMT has recently gained popularity due to its ability to model the translation process end-to-end using a single probabilistic model, and for its state-of-the-art performance on several language pairs (Luong et al., 2015a; Sennrich et al., 2016).

One feature of NMT systems is that they treat each word in the vocabulary as a vector of continuous-valued numbers. This is in contrast to more traditional SMT methods such as phrase-based machine translation (PBMT; Koehn et al. (2003)), which represent translations as discrete pairs of word strings in the source and target languages. The use of continuous representations is a major advantage, allowing NMT to share statistical power between similar words (e.g. "dog" and "cat") or contexts (e.g. "this is" and "that is"). However, this property also has a drawback in that NMT systems often mistranslate into words that seem natural in the context, but do not reflect the content of the source sentence. For example, Figure 1 is a sentence from our data where the NMT system mistakenly translated "Tunisia" into the word for "Norway." This variety of error is particularly serious because the content words that are often mistranslated by NMT are also the words that play a key role in determining the whole meaning of the sentence.

Input:	I come from Tunisia.

System:	ノルウェー の 出身です。
	Noruue- no shusshindesu.
	(I'm from Norway.)

Figure 1: An example of a mistake made by NMT on low-frequency content words.

In contrast, PBMT and other traditional SMT methods tend to rarely make this kind of mistake. This is because they base their translations on discrete phrase mappings, which ensure that source words will be translated into a target word that has

[1] Tools to replicate our experiments can be found at http://isw3.naist.jp/~philip-a/emnlp2016/index.html

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1557–1567,
Austin, Texas, November 1-5, 2016.

been observed as a translation at least once in the training data. In addition, because the discrete mappings are memorized explicitly, they can be learned efficiently from as little as a single instance (barring errors in word alignments). Thus we hypothesize that if we can incorporate a similar variety of information into NMT, this has the potential to alleviate problems with the previously mentioned fatal errors on low-frequency words.

In this paper, we propose a simple, yet effective method to incorporate discrete, probabilistic lexicons as an additional information source in NMT (§3). First we demonstrate how to transform lexical translation probabilities (§3.1) into a predictive probability for the next word by utilizing attention vectors from attentional NMT models (Bahdanau et al., 2015). We then describe methods to incorporate this probability into NMT, either through linear interpolation with the NMT probabilities (§3.2.2) or as the bias to the NMT predictive distribution (§3.2.1). We construct these lexicon probabilities by using traditional word alignment methods on the training data (§4.1), other external parallel data resources such as a handmade dictionary (§4.2), or using a hybrid between the two (§4.3).

We perform experiments (§5) on two English-Japanese translation corpora to evaluate the method's utility in improving translation accuracy and reducing the time required for training.

2 Neural Machine Translation

The goal of machine translation is to translate a sequence of source words $F = f_1^{|F|}$ into a sequence of target words $E = e_1^{|E|}$. These words belong to the source vocabulary V_f, and the target vocabulary V_e respectively. NMT performs this translation by calculating the conditional probability $p_m(e_i|F, e_1^{i-1})$ of the ith target word e_i based on the source F and the preceding target words e_1^{i-1}. This is done by encoding the context $\langle F, e_1^{i-1} \rangle$ a fixed-width vector $\boldsymbol{\eta}_i$, and calculating the probability as follows:

$$p_m(e_i|F, e_1^{i-1}) = \text{softmax}(W_s \boldsymbol{\eta}_i + \boldsymbol{b}_s), \quad (1)$$

where W_s and $\boldsymbol{b}_s$ are respectively weight matrix and bias vector parameters.

The exact variety of the NMT model depends on how we calculate $\boldsymbol{\eta}_i$ used as input. While there are many methods to perform this modeling, we opt to use attentional models (Bahdanau et al., 2015), which focus on particular words in the source sentence when calculating the probability of e_i. These models represent the current state of the art in NMT, and are also convenient for use in our proposed method. Specifically, we use the method of Luong et al. (2015a), which we describe briefly here and refer readers to the original paper for details.

First, an *encoder* converts the source sentence F into a matrix R where each column represents a single word in the input sentence as a continuous vector. This representation is generated using a bidirectional encoder

$$\overrightarrow{\boldsymbol{r}}_j = \text{enc}(\text{embed}(f_j), \overrightarrow{\boldsymbol{r}}_{j-1})$$
$$\overleftarrow{\boldsymbol{r}}_j = \text{enc}(\text{embed}(f_j), \overleftarrow{\boldsymbol{r}}_{j+1})$$
$$\boldsymbol{r}_j = [\overleftarrow{\boldsymbol{r}}_j; \overrightarrow{\boldsymbol{r}}_j].$$

Here the embed$(\cdot)$ function maps the words into a representation (Bengio et al., 2003), and enc$(\cdot)$ is a stacking long short term memory (LSTM) neural network (Hochreiter and Schmidhuber, 1997; Gers et al., 2000; Sutskever et al., 2014). Finally we concatenate the two vectors $\overrightarrow{\boldsymbol{r}}_j$ and $\overleftarrow{\boldsymbol{r}}_j$ into a bidirectional representation $\boldsymbol{r}_j$. These vectors are further concatenated into the matrix R where the jth column corresponds to $\boldsymbol{r}_j$.

Next, we generate the output one word at a time while referencing this encoded input sentence and tracking progress with a *decoder* LSTM. The decoder's hidden state $\boldsymbol{h}_i$ is a fixed-length continuous vector representing the previous target words e_1^{i-1}, initialized as $\boldsymbol{h}_0 = \boldsymbol{0}$. Based on this $\boldsymbol{h}_i$, we calculate a similarity vector $\boldsymbol{\alpha}_i$, with each element equal to

$$\alpha_{i,j} = \text{sim}(\boldsymbol{h}_i, \boldsymbol{r}_j). \quad (2)$$

sim$(\cdot)$ can be an arbitrary similarity function, which we set to the dot product, following Luong et al. (2015a). We then normalize this into an *attention* vector, which weights the amount of focus that we put on each word in the source sentence

$$\boldsymbol{a}_i = \text{softmax}(\boldsymbol{\alpha}_i). \quad (3)$$

This attention vector is then used to weight the encoded representation R to create a context vector $\boldsymbol{c}_i$ for the current time step

$$\boldsymbol{c} = R\boldsymbol{a}.$$

Finally, we create $\boldsymbol{\eta}_i$ by concatenating the previous hidden state $\boldsymbol{h}_{i-1}$ with the context vector, and performing an affine transform

$$\boldsymbol{\eta}_i = W_\eta[\boldsymbol{h}_{i-1}; \boldsymbol{c}_i] + b_\eta,$$

Once we have this representation of the current state, we can calculate $p_m(e_i|F, e_1^{i-1})$ according to Equation (1). The next word e_i is chosen according to this probability, and we update the hidden state by inputting the chosen word into the decoder LSTM

$$\boldsymbol{h}_i = \text{enc}(\text{embed}(e_i), \boldsymbol{h}_{i-1}). \quad (4)$$

If we define all the parameters in this model as θ, we can then train the model by minimizing the negative log-likelihood of the training data

$$\hat{\theta} = \operatorname*{argmin}_\theta \sum_{\langle F,\, E\rangle} \sum_i -\log(p_m(e_i|F, e_1^{i-1}; \theta)).$$

3 Integrating Lexicons into NMT

In §2 we described how traditional NMT models calculate the probability of the next target word $p_m(e_i|e_1^{i-1}, F)$. Our goal in this paper is to improve the accuracy of this probability estimate by incorporating information from discrete probabilistic lexicons. We assume that we have a lexicon that, given a source word f, assigns a probability $p_l(e|f)$ to target word e. For a source word f, this probability will generally be non-zero for a small number of translation candidates, and zero for the majority of words in V_E. In this section, we first describe how we incorporate these probabilities into NMT, and explain how we actually obtain the $p_l(e|f)$ probabilities in §4.

3.1 Converting Lexicon Probabilities into Conditioned Predictive Proabilities

First, we need to convert lexical probabilities $p_l(e|f)$ for the individual words in the source sentence F to a form that can be used together with $p_m(e_i|e_1^{i-1}, F)$. Given input sentence F, we can construct a matrix in which each column corresponds to a word in the input sentence, each row corresponds to a word in the V_E, and the entry corresponds to the appropriate lexical probability:

$$L_F = \begin{bmatrix} p_l(e=1|f_1) & \cdots & p_l(e=1|f_{|F|}) \\ \vdots & \ddots & \vdots \\ p_l(e=|V_e||f_1) & \cdots & p_l(e=|V_e||f_{|F|}) \end{bmatrix}.$$

This matrix can be precomputed during the encoding stage because it only requires information about the source sentence F.

Next we convert this matrix into a predictive probability over the next word: $p_l(e_i|F, e_1^{i-1})$. To do so we use the alignment probability $\boldsymbol{a}$ from Equation (3) to weight each column of the L_F matrix:

$$p_l(e_i|F, e_1^{i-1}) = L_F \boldsymbol{a}_i = \begin{bmatrix} p_l(e=1|f_1) & \cdots & p_{lex}(e=1|f_{|F|}) \\ \vdots & \ddots & \vdots \\ p_l(e=V_e|f_1) & \cdots & p_{lex}(e=V_e|f_{|F|}) \end{bmatrix} \begin{bmatrix} a_{i,1} \\ \vdots \\ a_{i,|F|} \end{bmatrix}.$$

This calculation is similar to the way how attentional models calculate the context vector $\boldsymbol{c}_i$, but over a vector representing the probabilities of the target vocabulary, instead of the distributed representations of the source words. The process of involving $\boldsymbol{a}_i$ is important because at every time step i, the lexical probability $p_l(e_i|e_1^{i-1}, F)$ will be influenced by different source words.

3.2 Combining Predictive Probabilities

After calculating the lexicon predictive probability $p_l(e_i|e_1^{i-1}, F)$, next we need to integrate this probability with the NMT model probability $p_m(e_i|e_1^{i-1}, F)$. To do so, we examine two methods: (1) adding it as a bias, and (2) linear interpolation.

3.2.1 Model Bias

In our first `bias` method, we use $p_l(\cdot)$ to bias the probability distribution calculated by the vanilla NMT model. Specifically, we add a small constant ϵ to $p_l(\cdot)$, take the logarithm, and add this adjusted log probability to the input of the softmax as follows:

$$p_b(e_i|F, e_1^{i-1}) = \text{softmax}(W_s\boldsymbol{\eta}_i + b_s + \log(p_l(e_i|F, e_1^{i-1}) + \epsilon)).$$

We take the logarithm of $p_l(\cdot)$ so that the values will still be in the probability domain after the softmax is calculated, and add the hyper-parameter ϵ to prevent zero probabilities from becoming $-\infty$ after taking the log. When ϵ is small, the model will be more heavily biased towards using the lexicon, and when ϵ is larger the lexicon probabilities will be given less weight. We use $\epsilon = 0.001$ for this paper.

3.2.2 Linear Interpolation

We also attempt to incorporate the two probabilities through linear interpolation between the standard NMT probability model probability $p_m(\cdot)$ and the lexicon probability $p_l(\cdot)$. We will call this the `linear` method, and define it as follows:

$$p_o(e_i|F,e_1^{i-1}) = \begin{bmatrix} p_l(e_i=1|F,e_1^{i-1}) & p_m(e=1|F,e_1^{i-1}) \\ \vdots & \vdots \\ p_l(e_i=|V_e||F,e_1^{i-1}) & p_m(e=|V_e||F,e_1^{i-1}) \end{bmatrix} \begin{bmatrix} \lambda \\ 1-\lambda \end{bmatrix},$$

where λ is an interpolation coefficient that is the result of the sigmoid function $\lambda = \text{sig}(x) = \frac{1}{1+e^{-x}}$. x is a learnable parameter, and the sigmoid function ensures that the final interpolation level falls between 0 and 1. We choose $x = 0$ ($\lambda = 0.5$) at the beginning of training.

This notation is partly inspired by Allamanis et al. (2016) and Gu et al. (2016) who use linear interpolation to merge a standard attentional model with a "copy" operator that copies a source word as-is into the target sentence. The main difference is that they use this to copy words into the output while our method uses it to influence the probabilities of all target words.

4 Constructing Lexicon Probabilities

In the previous section, we have defined some ways to use predictive probabilities $p_l(e_i|F,e_1^{i-1})$ based on word-to-word lexical probabilities $p_l(e|f)$. Next, we define three ways to construct these lexical probabilities using automatically learned lexicons, handmade lexicons, or a combination of both.

4.1 Automatically Learned Lexicons

In traditional SMT systems, lexical translation probabilities are generally learned directly from parallel data in an unsupervised fashion using a model such as the IBM models (Brown et al., 1993; Och and Ney, 2003). These models can be used to estimate the alignments and lexical translation probabilities $p_l(e|f)$ between the tokens of the two languages using the expectation maximization (EM) algorithm.

First in the expectation step, the algorithm estimates the expected count $c(e|f)$. In the maximization step, lexical probabilities are calculated by dividing the expected count by all possible counts:

$$p_{l,a}(e|f) = \frac{c(f,e)}{\sum_{\tilde{e}} c(f,\tilde{e})},$$

The IBM models vary in level of refinement, with Model 1 relying solely on these lexical probabilities, and latter IBM models (Models 2, 3, 4, 5) introducing more sophisticated models of fertility and relative alignment. Even though IBM models also occasionally have problems when dealing with the rare words (e.g. "garbage collecting" effects (Liang et al., 2006)), traditional SMT systems generally achieve better translation accuracies of low-frequency words than NMT systems (Sutskever et al., 2014), indicating that these problems are less prominent than they are in NMT.

Note that in many cases, NMT limits the target vocabulary (Jean et al., 2015) for training speed or memory constraints, resulting in rare words not being covered by the NMT vocabulary V_E. Accordingly, we allocate the remaining probability assigned by the lexicon to the unknown word symbol $\langle\text{unk}\rangle$:

$$p_{l,a}(e=\langle\text{unk}\rangle|f) = 1 - \sum_{i\in V_e} p_{l,a}(e=i|f). \quad (5)$$

4.2 Manual Lexicons

In addition, for many language pairs, broad-coverage handmade dictionaries exist, and it is desirable that we be able to use the information included in them as well. Unlike automatically learned lexicons, however, handmade dictionaries generally do not contain translation probabilities. To construct the probability $p_l(e|f)$, we define the set of translations K_f existing in the dictionary for particular source word f, and assume a uniform distribution over these words:

$$p_{l,m}(e|f) = \begin{cases} \frac{1}{|K_f|} & \text{if } e \in K_f \\ 0 & \text{otherwise} \end{cases}.$$

Following Equation (5), unknown source words will assign their probability mass to the $\langle\text{unk}\rangle$ tag.

4.3 Hybrid Lexicons

Handmade lexicons have broad coverage of words but their probabilities might not be as accurate as the

Table 1: Corpus details.

learned ones, particularly if the automatic lexicon is constructed on in-domain data. Thus, we also test a `hybrid` method where we use the handmade lexicons to complement the automatically learned lexicon.[2] [3] Specifically, inspired by phrase table fill-up used in PBMT systems (Bisazza et al., 2011), we use the probability of the automatically learned lexicons $p_{l,a}$ by default, and fall back to the handmade lexicons $p_{l,m}$ only for uncovered words:

$$p_{l,h}(e|f) = \begin{cases} p_{l,a}(e|f) & \text{if } f \text{ is covered} \\ p_{l,m}(e|f) & \text{otherwise} \end{cases} \quad (6)$$

5 Experiment & Result

In this section, we describe experiments we use to evaluate our proposed methods.

5.1 Settings

Dataset: We perform experiments on two widely-used tasks for the English-to-Japanese language pair: KFTT (Neubig, 2011) and BTEC (Kikui et al., 2003). KFTT is a collection of Wikipedia article about city of Kyoto and BTEC is a travel conversation corpus. BTEC is an easier translation task than KFTT, because KFTT covers a broader domain, has a larger vocabulary of rare words, and has relatively long sentences. The details of each corpus are depicted in Table 1.

We tokenize English according to the Penn Treebank standard (Marcus et al., 1993) and lowercase, and tokenize Japanese using KyTea (Neubig et al., 2011). We limit training sentence length up to 50 in both experiments and keep the test data at the original length. We replace words of frequency less than a threshold u in both languages with the $\langle$unk$\rangle$ symbol and exclude them from our vocabulary. We choose $u = 1$ for BTEC and $u = 3$ for KFTT, resulting in $|V_f| = 17.8$k, $|V_e| = 21.8$k for BTEC and $|V_f| = 48.2$k, $|V_e| = 49.1$k for KFTT.

NMT Systems: We build the described models using the Chainer[4] toolkit. The depth of the stacking LSTM is $d = 4$ and hidden node size $h = 800$. We concatenate the forward and backward encodings (resulting in a 1600 dimension vector) and then perform a linear transformation to 800 dimensions.

We train the system using the Adam (Kingma and Ba, 2014) optimization method with the default settings: $\alpha = 1\text{e}{-3}, \beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 1\text{e}{-8}$. Additionally, we add dropout (Srivastava et al., 2014) with drop rate $r = 0.2$ at the last layer of each stacking LSTM unit to prevent overfitting. We use a batch size of $B = 64$ and we run a total of $N = 14$ iterations for all data sets. All of the experiments are conducted on a single GeForce GTX TITAN X GPU with a 12 GB memory cache.

At test time, we use beam search with beam size $b = 5$. We follow Luong et al. (2015b) in replacing every unknown token at position i with the target token that maximizes the probability $p_{l,a}(e_i|f_j)$. We choose source word f_j according to the highest alignment score in Equation (3). This unknown word replacement is applied to both baseline and proposed systems. Finally, because NMT models tend to give higher probabilities to shorter sentences (Cho et al., 2014), we discount the probability of $\langle$EOS$\rangle$ token by 10% to correct for this bias.

Traditional SMT Systems: We also prepare two traditional SMT systems for comparison: a PBMT system (Koehn et al., 2003) using Moses[5] (Koehn et al., 2007), and a hierarchical phrase-based MT system (Chiang, 2007) using Travatar[6] (Neubig, 2013), Systems are built using the default settings, with models trained on the training data, and weights tuned on the development data.

Lexicons: We use a total of 3 lexicons for the

[2] Alternatively, we could imagine a method where we combined the training data and dictionary before training the word alignments to create the lexicon. We attempted this, and results were comparable to or worse than the fill-up method, so we use the fill-up method for the remainder of the paper.

[3] While most words in the V_f will be covered by the learned lexicon, many words (13% in experiments) are still left uncovered due to alignment failures or other factors.

Table 2: Accuracies for the baseline attentional NMT (attn) and the proposed bias-based method using the automatic (auto-bias) or hybrid (hyb-bias) dictionaries. Bold indicates a gain over the attn baseline, † indicates a significant increase at $p < 0.05$, and $*$ indicates $p < 0.10$. Traditional phrase-based (pbmt) and hierarchical phrase based (hiero) systems are shown for reference.

proposed method, and apply bias and linear method for all of them, totaling 6 experiments. The first lexicon (auto) is built on the training data using the automatically learned lexicon method of §4.1 separately for both the BTEC and KFTT experiments. Automatic alignment is performed using GIZA++ (Och and Ney, 2003). The second lexicon (man) is built using the popular English-Japanese dictionary Eijiro[7] with the manual lexicon method of §4.2. Eijiro contains 104K distinct word-to-word translation entries. The third lexicon (hyb) is built by combining the first and second lexicon with the hybrid method of §4.3.

Evaluation: We use standard single reference BLEU-4 (Papineni et al., 2002) to evaluate the translation performance. Additionally, we also use NIST (Doddington, 2002), which is a measure that puts a particular focus on low-frequency word strings, and thus is sensitive to the low-frequency words we are focusing on in this paper. We measure the statistical significant differences between systems using paired bootstrap resampling (Koehn, 2004) with 10,000 iterations and measure statistical significance at the $p < 0.05$ and $p < 0.10$ levels.

Additionally, we also calculate the recall of rare words from the references. We define "rare words" as words that appear less than eight times in the target training corpus or references, and measure the percentage of time they are recovered by each translation system.

5.2 Effect of Integrating Lexicons

In this section, we first a detailed examination of the utility of the proposed bias method when used with the auto or hyb lexicons, which empirically gave the best results, and perform a comparison among the other lexicon integration methods in the following section. Table 2 shows the results of these methods, along with the corresponding baselines.

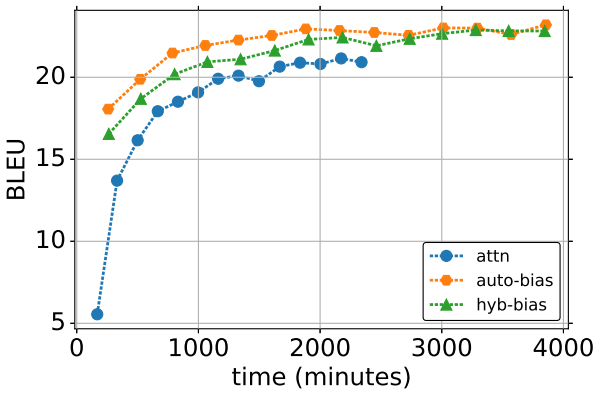

Figure 2: Training curves for the baseline attn and the proposed bias method.

First, compared to the baseline attn, our bias method achieved consistently higher scores on both test sets. In particular, the gains on the more difficult KFTT set are large, up to 2.3 BLEU, 0.44 NIST, and 30% Recall, demonstrating the utility of the proposed method in the face of more diverse content and fewer high-frequency words.

Compared to the traditional pbmt systems hiero, particularly on KFTT we can see that the proposed method allows the NMT system to exceed the traditional SMT methods in BLEU. This is despite the fact that we are not performing ensembling, which has proven to be essential to exceed traditional systems in several previous works (Sutskever

Table 3: Examples where the proposed auto-bias improved over the baseline system attn. Underlines indicate words were mistaken in the baseline output but correct in the proposed model's output.

et al., 2014; Luong et al., 2015a; Sennrich et al., 2016). Interestingly, despite gains in BLEU, the NMT methods still fall behind in NIST score on the KFTT data set, demonstrating that traditional SMT systems still tend to have a small advantage in translating lower-frequency words, despite the gains made by the proposed method.

In Table 3, we show some illustrative examples where the proposed method (auto-bias) was able to obtain a correct translation while the normal attentional model was not. The first example is a mistake in translating "extramarital affairs" into the Japanese equivalent of "soccer," entirely changing the main topic of the sentence. This is typical of the errors that we have observed NMT systems make (the mistake from Figure 1 is also from attn, and was fixed by our proposed method). The second example demonstrates how these mistakes can then affect the process of choosing the remaining words, propagating the error through the whole sentence.

Next, we examine the effect of the proposed method on the training time for each neural MT method, drawing training curves for the KFTT data in Figure 2. Here we can see that the proposed bias training methods achieve reasonable BLEU scores in the upper 10s even after the first iteration. In contrast, the baseline attn method has a BLEU score of around 5 after the first iteration, and takes significantly longer to approach values close to its maximal

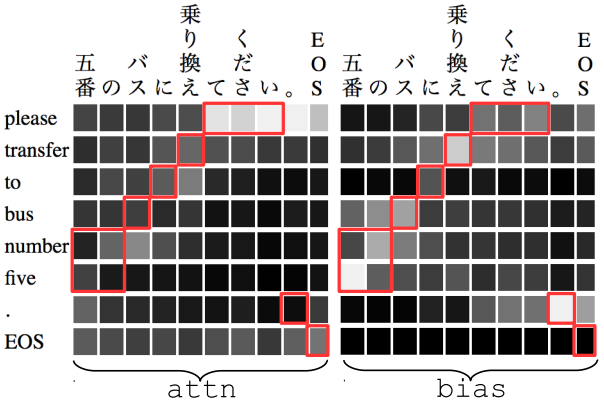

Figure 3: Attention matrices for baseline attn and proposed bias methods. Lighter colors indicate stronger attention between the words, and boxes surrounding words indicate the correct alignments.

accuracy. This shows that by incorporating lexical probabilities, we can effectively bootstrap the learning of the NMT system, allowing it to approach an appropriate answer in a more timely fashion.[8]

It is also interesting to examine the alignment vectors produced by the baseline and proposed meth-

[8]Note that these gains are despite the fact that one iteration of the proposed method takes a longer (167 minutes for attn vs. 275 minutes for auto-bias) due to the necessity to calculate and use the lexical probability matrix for each sentence. It also takes an additional 297 minutes to train the lexicon with GIZA++, but this can be greatly reduced with more efficient training methods (Dyer et al., 2013).

ods, a visualization of which we show in Figure 3. For this sentence, the outputs of both methods were both identical and correct, but we can see that the proposed method (right) placed sharper attention on the actual source word corresponding to content words in the target sentence. This trend of peakier attention distributions in the proposed method held throughout the corpus, with the per-word entropy of the attention vectors being 3.23 bits for auto-bias, compared with 3.81 bits for attn, indicating that the auto-bias method places more certainty in its attention decisions.

5.3 Comparison of Integration Methods

Finally, we perform a full comparison between the various methods for integrating lexicons into the translation process, with results shown in Table 4. In general the bias method improves accuracy for the auto and hyb lexicon, but is less effective for the man lexicon. This is likely due to the fact that the manual lexicon, despite having broad coverage, did not sufficiently cover target-domain words (coverage of unique words in the source vocabulary was 35.3% and 9.7% for BTEC and KFTT respectively).

Interestingly, the trend is reversed for the linear method, with it improving man systems, but causing decreases when using the auto and hyb lexicons. This indicates that the linear method is more suited for cases where the lexicon does not closely match the target domain, and plays a more complementary role. Compared to the log-linear modeling of bias, which strictly enforces constraints imposed by the lexicon distribution (Klakow, 1998), linear interpolation is intuitively more appropriate for integrating this type of complimentary information.

On the other hand, the performance of linear interpolation was generally lower than that of the bias method. One potential reason for this is the fact that we use a constant interpolation coefficient that was set fixed in every context. Gu et al. (2016) have recently developed methods to use the context information from the decoder to calculate the different interpolation coefficients for every decoding step, and it is possible that introducing these methods would improve our results.

6 Additional Experiments

To test whether the proposed method is useful on larger data sets, we also performed follow-up experiments on the larger Japanese-English ASPEC dataset (Nakazawa et al., 2016) that consist of 2 million training examples, 63 million tokens, and 81,000 vocabulary size. We gained an improvement in BLEU score from 20.82 using the attn baseline to 22.66 using the auto-bias proposed method. This experiment shows that our method scales to larger datasets.

7 Related Work

From the beginning of work on NMT, unknown words that do not exist in the system vocabulary have been focused on as a weakness of these systems. Early methods to handle these unknown words replaced them with appropriate words in the target vocabulary (Jean et al., 2015; Luong et al., 2015b) according to a lexicon similar to the one used in this work. In contrast to our work, these only handle unknown words and do not incorporate information from the lexicon in the learning procedure.

There have also been other approaches that incorporate models that learn when to copy words as-is into the target language (Allamanis et al., 2016; Gu et al., 2016; Gülçehre et al., 2016). These models

are similar to the `linear` approach of §3.2.2, but are only applicable to words that can be copied as-is into the target language. In fact, these models can be thought of as a subclass of the proposed approach that use a lexicon that assigns a all its probability to target words that are the same as the source. On the other hand, while we are simply using a static interpolation coefficient λ, these works generally have a more sophisticated method for choosing the interpolation between the standard and "copy" models. Incorporating these into our `linear` method is a promising avenue for future work.

In addition Mi et al. (2016) have also recently proposed a similar approach by limiting the number of vocabulary being predicted by each batch or sentence. This vocabulary is made by considering the original HMM alignments gathered from the training corpus. Basically, this method is a specific version of our bias method that gives some of the vocabulary a bias of negative infinity and all other vocabulary a uniform distribution. Our method improves over this by considering actual translation probabilities, and also considering the attention vector when deciding how to combine these probabilities.

Finally, there have been a number of recent works that improve accuracy of low-frequency words using character-based translation models (Ling et al., 2015; Costa-Jussà and Fonollosa, 2016; Chung et al., 2016). However, Luong and Manning (2016) have found that even when using character-based models, incorporating information about words allows for gains in translation accuracy, and it is likely that our lexicon-based method could result in improvements in these hybrid systems as well.

8 Conclusion & Future Work

In this paper, we have proposed a method to incorporate discrete probabilistic lexicons into NMT systems to solve the difficulties that NMT systems have demonstrated with low-frequency words. As a result, we achieved substantial increases in BLEU (2.0-2.3) and NIST (0.13-0.44) scores, and observed qualitative improvements in the translations of content words.

For future work, we are interested in conducting the experiments on larger-scale translation tasks. We also plan to do subjective evaluation, as we expect that improvements in content word translation are critical to subjective impressions of translation results. Finally, we are also interested in improvements to the `linear` method where λ is calculated based on the context, instead of using a fixed value.

Abstract

The encoder-decoder framework for neural machine translation (NMT) has been shown effective in large data scenarios, but is much less effective for low-resource languages. We present a transfer learning method that significantly improves BLEU scores across a range of low-resource languages. Our key idea is to first train a high-resource language pair (the *parent model*), then transfer some of the learned parameters to the low-resource pair (the *child model*) to initialize and constrain training. Using our transfer learning method we improve baseline NMT models by an average of 5.6 BLEU on four low-resource language pairs. Ensembling and unknown word replacement add another 2 BLEU which brings the NMT performance on low-resource machine translation close to a strong syntax based machine translation (SBMT) system, exceeding its performance on one language pair. Additionally, using the transfer learning model for re-scoring, we can improve the SBMT system by an average of 1.3 BLEU, improving the state-of-the-art on low-resource machine translation.

1 Introduction

Neural machine translation (NMT) (Sutskever et al., 2014) is a promising paradigm for extracting translation knowledge from parallel text. NMT systems have achieved competitive accuracy rates under large-data training conditions for language pairs such as English–French. However, neural methods are data-hungry and learn poorly from low-count events. This behavior makes vanilla NMT a poor choice for low-resource languages, where parallel data is scarce. Table 1 shows that for 4 low-resource languages, a standard string-to-tree statistical MT system (SBMT) (Galley et al., 2004; Galley et al., 2006) strongly outperforms NMT, even when NMT uses the state-of-the-art local attention plus feed-input techniques from Luong et al. (2015a).

Language	Train Size	Test Size	SBMT BLEU	NMT BLEU
Hausa	1.0m	11.3K	23.7	16.8
Turkish	1.4m	11.6K	20.4	11.4
Uzbek	1.8m	11.5K	17.9	10.7
Urdu	0.2m	11.4K	17.9	5.2

Table 1: NMT models with attention are outperformed by standard string-to-tree statistical MT (SBMT) when translating low-resource languages into English. Train/test bitext corpus sizes are English token counts. Single-reference, case-insensitive BLEU scores are given for held-out test corpora.

In this paper, we describe a method for substantially improving NMT results on these languages. Our key idea is to first train a high-resource language pair, then use the resulting trained network (the *parent model*) to initialize and constrain training for our low-resource language pair (the *child model*). We find that we can optimize our results by fixing certain parameters of the parent model and letting the rest be fine-tuned by the child model. We report NMT improvements from transfer learning of 5.6 BLEU on average, and we provide an analysis of why the method works. The final NMT system

Austin, Texas, November 1-5, 2016.

approaches strong SBMT baselines in all four language pairs, and exceeds SBMT performance in one of them. Furthermore, we show that NMT is an exceptional re-scorer of 'traditional' MT output; even NMT that on its own is worse than SBMT is consistently able to improve upon SBMT system output when incorporated as a re-scoring model.

We provide a brief description of our NMT model in Section 2. Section 3 gives some background on transfer learning and explains how we use it to improve machine translation performance. Our main experiments translating Hausa, Turkish, Uzbek, and Urdu into English with the help of a French–English parent model are presented in Section 4. Section 5 explores alternatives to our model to enhance understanding. We find that the choice of parent language pair affects performance, and provide an empirical upper bound on transfer performance using an artificial language. We experiment with English-only language models, copy models, and word-sorting models to show that what we transfer goes beyond monolingual information and that using a translation model trained on bilingual corpora as a parent is essential. We show the effects of freezing, fine-tuning, and smarter initialization of different components of the attention-based NMT system during transfer. We compare the learning curves of transfer and no-transfer models, showing that transfer solves an overfitting problem, not a search problem. We summarize our contributions in Section 6.

2 NMT Background

In the neural encoder-decoder framework for MT (Neco and Forcada, 1997; Castaño and Casacuberta, 1997; Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015a), we use a recurrent neural network (encoder) to convert a source sentence into a dense, fixed-length vector. We then use another recurrent network (decoder) to convert that vector to a target sentence. In this paper, we use a two-layer encoder-decoder system (Figure 1) with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997). The models were trained to optimize maximum likelihood (via a softmax layer) with back-propagation through time (Werbos, 1990). Additionally, we use an attention mechanism that allows the target decoder to look back at

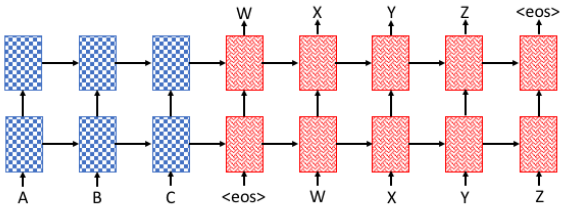

Figure 1: The encoder-decoder framework for neural machine translation (NMT) (Sutskever et al., 2014). Here, a source sentence C B A (presented in reverse order as A B C) is translated into a target sentence W X Y Z. At each step, an evolving real-valued vector summarizes the state of the encoder (blue, checkerboard) and decoder (red, lattice). Not shown here are the attention connections present in our model used by the decoder to access encoder states.

the source encoder, specifically the local attention model from Luong et al. (2015a). In our model we also use the feed-input input connection from Luong et al. (2015a) where at each timestep on the decoder we feed in the top layer's hidden state into the lowest layer of the next timestep.

3 Transfer Learning

Transfer learning uses knowledge from a learned task to improve the performance on a related task, typically reducing the amount of required training data (Torrey and Shavlik, 2009; Pan and Yang, 2010). In natural language processing, transfer learning methods have been successfully applied to speech recognition, document classification and sentiment analysis (Wang and Zheng, 2015). Deep learning models discover multiple levels of representation, some of which may be useful across tasks, which makes them particularly suited to transfer learning (Bengio, 2012). For example, Cireşan et al. (2012) use a convolutional neural network to recognize handwritten characters and show positive effects of transfer between models for Latin and Chinese characters. Ours is the first study to apply transfer learning to neural machine translation.

There has also been work on using data from multiple language pairs in NMT to improve performance. Recently, Dong et al. (2015) showed that sharing a source encoder for one language helps performance when using different target decoders

Decoder	Hausa	Turkish	Uzbek	Urdu
NMT	16.8	11.4	10.7	5.2
Xfer	21.3	17.0	14.4	13.8
Final	24.0	18.7	16.8	14.5
SBMT	23.7	20.4	17.9	17.9

Table 2: Our method significantly improves NMT results for the translation of low-resource languages into English. Results show test-set BLEU scores. The 'NMT' row shows results without transfer, and the 'Xfer' row shows results with transfer. The 'Final' row shows BLEU after we ensemble 8 models and use unknown word replacement.

Re-scorer	SBMT Decoder			
	Hausa	Turkish	Uzbek	Urdu
None	23.7	20.4	17.9	17.9
NMT	24.5	21.4	19.5	18.2
Xfer	**24.8**	**21.8**	**19.5**	**19.1**
LM	23.6	21.1	17.9	18.2

Table 3: Our transfer method applied to re-scoring output n-best lists from the SBMT system. The first row shows the SBMT performance with no re-scoring and the other 3 rows show the performance after re-scoring with the selected model. Note: the 'LM' row shows the results when an RNN LM trained on the large English corpus was used to re-score.

for different languages. In that paper the authors showed that using this framework improves performance for low-resource languages by incorporating a mix of low-resource and high-resource languages. Firat et al. (2016) used a similar approach, employing a separate encoder for each source language, a separate decoder for each target language, and a shared attention mechanism across all languages. They then trained these components jointly across multiple different language pairs to show improvements in a lower-resource setting.

There are a few key differences between our work and theirs. One is that we are working with truly small amounts of training data. Dong et al. (2015) used a training corpus of about 8m English words for the low-resource experiments, and Firat et al. (2016) used from 2m to 4m words, while we have at most 1.8m words, and as few as 0.2m. Additionally, the aforementioned previous work used the same domain for both low-resource and high-resource languages, while in our case the datasets come from vastly different domains, which makes the task much harder and more realistic. Our approach only requires using one additional high-resource language, while the other papers used many. Our approach also allows for easy training of new low-resource languages, while Dong et al. (2015) and Firat et al. (2016) do not specify how a new language should be added to their pipeline once the models are trained. Finally, Dong et al. (2015) observe an average BLEU gain on their low-resource experiments of +1.16, and Firat et al. (2016) obtain BLEU gains of +1.8, while we see a +5.6 BLEU gain.

The transfer learning approach we use is simple and effective. We first train an NMT model on a large corpus of parallel data (e.g., French–English). We call this the *parent model*. Next, we initialize an NMT model with the already-trained parent model. This new model is then trained on a very small parallel corpus (e.g., Uzbek–English). We call this the *child model*. Rather than starting from a random position, the child model is initialized with the weights from the parent model.

A justification for this approach is that in scenarios where we have limited training data, we need a strong prior distribution over models. The parent model trained on a large amount of bilingual data can be considered an anchor point, the peak of our prior distribution in model space. When we train the child model initialized with the parent model, we fix parameters likely to be useful across tasks so that they will not be changed during child model training. In the French–English to Uzbek–English example, as a result of the initialization, the English word embeddings from the parent model are copied, but the Uzbek words are initially mapped to random French embeddings. The parameters of the English embeddings are then frozen, while the Uzbek embeddings' parameters are allowed to be modified, i.e. *fine-tuned*, during training of the child model. Freezing certain transferred parameters and fine tuning others can be considered a hard approximation to a tight prior or strong regularization applied to some of the parameter space. We also experiment with ordinary L2 regularization, but find it does not significantly improve over the parameter freezing described above.

Our method results in large BLEU increases for a variety of low resource languages. In one of the

Language Pair	Role	Train Size	Dev Size	Test Size
Spanish–English	child	2.5m	58k	59k
French–English	parent	53m	58k	59k
German–English	parent	53m	58k	59k

Table 4: Data used for a low-resource Spanish–English task. Sizes are English-side token counts.

Parent	BLEU ↑	PPL ↓
none	16.4	15.9
French–English	**31.0**	**5.8**
German–English	29.8	6.2

Table 5: For a low-resource Spanish–English task, we experiment with several choices of parent model: none, French–English, and German–English. We hypothesize that French–English is best because French and Spanish are similar.

four language pairs our NMT system using transfer beats a strong SBMT baseline. Not only do these transfer models do well on their own, they also give large gains when used for re-scoring n-best lists ($n = 1000$) from the SBMT system. Section 4 details these results.

4 Experiments

To evaluate how well our transfer method works we apply it to a variety of low-resource languages, both stand-alone and for re-scoring a strong SBMT baseline. We report large BLEU increases across the board with our transfer method.

For all of our experiments with low-resource languages we use French as the parent source language and for child source languages we use Hausa, Turkish, Uzbek, and Urdu. The target language is always English. Table 1 shows parallel training data set sizes for the child languages, where the language with the most data has only 1.8m English tokens. For comparison, our parent French–English model uses a training set with 300 million English tokens and achieves 26 BLEU on the development set. Table 1 also shows the SBMT system scores along with the NMT baselines that do not use transfer. There is a large gap between the SBMT and NMT systems when our transfer method is not used.

The SBMT system used in this paper is a string-to-tree statistical machine translation system (Galley et al., 2006; Galley et al., 2004). In this system there are two count-based 5-gram language models. One is trained on the English side of the WMT 2015 English–French dataset and the other is trained on the English side of the low-resource bitext. Additionally, the SBMT models use thousands of sparsely-occurring, lexicalized syntactic features (Chiang et al., 2009).

For our NMT system, we use development sets for Hausa, Turkish, Uzbek, and Urdu to tune the learning rate, parameter initialization range, dropout rate, and hidden state size for all the experiments. For training we use a minibatch size of 128, hidden state size of 1000, a target vocabulary size of 15K, and a source vocabulary size of 30K. The child models are trained with a dropout probability of 0.5, as in Zaremba et al. (2014). The common parent model is trained with a dropout probability of 0.2. The learning rate used for both child and parent models is 0.5 with a decay rate of 0.9 when the development perplexity does not improve. The child models are all trained for 100 epochs. We re-scale the gradient when the gradient norm of all parameters is greater than 5. The initial parameter range is [-0.08, +0.08]. We also initialize our forget-gate biases to 1 as specified by Józefowicz et al. (2015) and Gers et al. (2000). For decoding we use a beam search of width 12.

4.1 Transfer Results

The results for our transfer learning method applied to the four languages above are in Table 2. The parent models were trained on the WMT 2015 (Bojar et al., 2015) French–English corpus for 5 epochs. Our baseline NMT systems ('NMT' row) all receive a large BLEU improvement when using the transfer method (the 'Xfer' row) with an average BLEU improvement of 5.6. Additionally, when we use unknown word replacement from Luong et al. (2015b) and ensemble together 8 models (the 'Final' row) we further improve upon our BLEU scores, bringing the average BLEU improvement to 7.5. Overall our method allows the NMT system to reach competitive scores and outperform the SBMT system in one of the four language pairs.

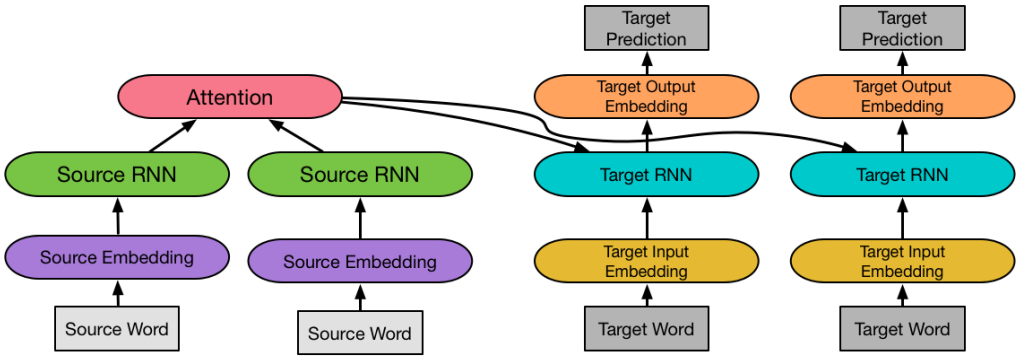

Figure 2: Our NMT model architecture, showing six blocks of parameters, in addition to source/target words and predictions. During transfer learning, we expect the source-language related blocks to change more than the target-language related blocks.

Language Pair	Parent	Train Size	BLEU ↑	PPL ↓
Uzbek–English	None	1.8m	10.7	22.4
	French–English	1.8m	**15.0 (+4.3)**	**13.9**
French′–English	None	1.8m	13.3	28.2
	French–English	1.8m	**20.0 (+6.7)**	**10.9**

Table 6: A better match between parent and child languages should improve transfer results. We devised a child language called French′, identical to French except for word spellings. We observe that French transfer learning helps French′ (13.3→20.0) more than it helps Uzbek (10.7→15.0).

4.2 Re-scoring Results

We also use the NMT model with transfer learning as a feature when re-scoring output n-best lists ($n = 1000$) from the SBMT system. Table 3 shows the results of re-scoring. We compare re-scoring with transfer NMT to re-scoring with baseline (i.e. non-transfer) NMT and to re-scoring with a neural language model. The neural language model is an LSTM RNN with 2 layers and 1000 hidden states. It has a target vocabulary of 100K and is trained using noise-contrastive estimation (Mnih and Teh, 2012; Vaswani et al., 2013; Baltescu and Blunsom, 2015; Williams et al., 2015). Additionally, it is trained using dropout with a dropout probability of 0.2 as suggested by Zaremba et al. (2014). Re-scoring with the transfer NMT model yields an improvement of 1.1–1.6 BLEU points above the strong SBMT system; we find that transfer NMT is a better re-scoring feature than baseline NMT or neural language models.

In the next section, we describe a number of additional experiments designed to help us understand the contribution of the various components of our transfer model.

5 Analysis

We analyze the effects of using different parent models, regularizing different parts of the child model, and trying different regularization techniques.

5.1 Different Parent Languages

In the above experiments we use French–English as the parent language pair. Here, we experiment with different parent languages. In this set of experiments we use Spanish–English as the child language pair. A description of the data used in this section is presented in Table 4.

Our experimental results are shown in Table 5, where we use French and German as parent languages. If we just train a model with no transfer on a small Spanish–English training set we get a BLEU score of 16.4. When using our transfer method we get Spanish–English BLEU scores of 31.0 and 29.8 via French and German parent languages, respectively. As expected, French is a better parent than German for Spanish, which could be the result of the parent language being more similar to the child language. We suspect using closely-related parent language pairs would improve overall quality.

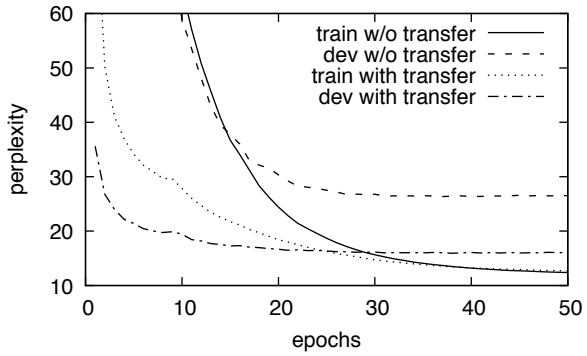

Figure 3: Uzbek–English learning curves for the NMT attention model with and without transfer learning. The training perplexity converges to a similar value in both cases. However, the development perplexity for the transfer model is significantly better.

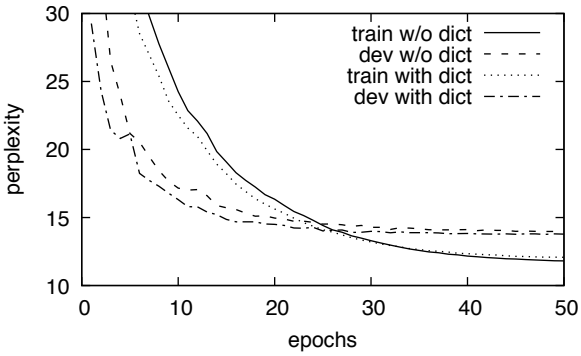

Figure 4: Uzbek–English learning curves for the transfer model with and without dictionary-based assignment of Uzbek word types to French word embeddings (from the parent model). Dictionary-based assignment enables faster improvement in early epochs. The model variants converge, showing that the unaided model is able to untangle the initial random Uzbek/French word-type mapping without help.

5.2 Effects of having Similar Parent Language

Next, we look at a best-case scenario in which the parent language is as similar as possible to the child language.

Here we devise a synthetic child language (called French′) which is exactly like French, except its vocabulary is shuffled randomly. (e.g., "internationale" is now "pomme," etc). This language, which looks unintelligible to human eyes, nevertheless has the same distributional and relational properties as actual French, i.e. the word that, prior to vocabulary reassignment, was 'roi' (king) is likely to share distributional characteristics, and hence embedding similarity, to the word that, prior to reassignment, was 'reine' (queen). French should be the ideal parent model for French′.

The results of this experiment are shown in Table 6. We get a 4.3 BLEU improvement with an unrelated parent (i.e. French–parent and Uzbek–child), but we get a 6.7 BLEU improvement with a 'closely related' parent (i.e. French–parent and French′–child). We conclude that the choice of parent model can have a strong impact on transfer models, and choosing better parents for our low-resource languages (if data for such parents can be obtained) could improve the final results.

5.3 Ablation Analysis

In all the above experiments, only the target input and output embeddings are fixed during training. In this section we analyze what happens when different parts of the model are fixed, in order to determine the scenario that yields optimal performance. Figure 2 shows a diagram of the components of a sequence-to-sequence model. Table 7 shows the effects of allowing various components of the child NMT model to be trained. We find that the optimal setting for transferring from French–English to Uzbek–English in terms of BLEU performance is to allow all of the components of the child model to be trained except for the input and output target embeddings.

Even though we use this setting for our main experiments, the optimum setting is likely to be language- and corpus-dependent. For Turkish, experiments show that freezing attention parameters as well gives slightly better results. For parent-child models with closely related languages we expect freezing, or strongly regularizing, more components of the model to give better results.

5.4 Learning Curve

In Figure 3 we plot learning curves for both a transfer and a non-transfer model on training and development sets. We see that the final training set perplexities for both the transfer and non-transfer model are very similar, but the development set perplexity for the transfer model is much better.

The fact that the two models start from and converge to very different points, yet have similar training set performances, indicates that our architecture

Source Embeddings	Source RNN	Target RNN	Attention	Target Input Embeddings	Target Output Embeddings	Dev BLEU ↑	Dev PPL ↓
🔒	🔒	🔒	🔒	🔒	🔒	0.0	112.6
🔓	🔒	🔒	🔒	🔒	🔒	7.7	24.7
🔓	🔓	🔒	🔒	🔒	🔒	11.8	17.0
🔓	🔓	🔓	🔒	🔒	🔒	14.2	14.5
🔓	🔓	🔓	🔓	🔒	🔒	**15.0**	13.9
🔓	🔓	🔓	🔓	🔓	🔒	14.7	**13.8**
🔓	🔓	🔓	🔓	🔓	🔓	13.7	14.4

Table 7: Starting with the parent French–English model (BLEU =24.4, PPL=6.2), we randomly assign Uzbek word types to French word embeddings, freeze various parameters of the neural network model (🔒), and allow Uzbek–English (child model) training to modify other parts (🔓). The table shows how Uzbek–English BLEU and perplexity vary as we allow more parameters to be re-trained.

and training algorithm are able to reach a good minimum of the training objective regardless of the initialization. However, the training objective seems to have a large basin of models with similar performance and not all of them generalize well to the development set. The transfer model, starting with and staying close to a point known to perform well on a related task, is guided to a final point in the weight space that generalizes to the development set much better.

5.5 Dictionary Initialization

Using the transfer method, we always initialize input language embeddings for the child model with randomly-assigned embeddings from the parent (which has a different input language). A smarter method might be to initialize child embeddings with similar parent embeddings, where similarity is measured by word-to-word t-table probabilities. To get these probabilities we compose Uzbek–English and English–French t-tables obtained from the Berkeley Aligner (Liang et al., 2006). We see from Figure 4 that this dictionary-based assignment results in faster improvement in the early part of the training. However the final performance is similar to our standard model, indicating that the training is able to untangle the dictionary permutation introduced by randomly-assigned embeddings.

5.6 Different Parent Models

In the above experiments, we use a parent model trained on a large French–English corpus. One might hypothesize that our gains come from exploiting the English half of the corpus as an additional language model resource. Therefore, we explore transfer learning for the child model with parent models that only use the English side of the French–English corpus. We consider the following parent models in our ablative transfer learning scenarios:

- A true translation model (French–English Parent)
- A word-for-word English copying model (English–English Parent)
- A model that unpermutes scrambled English (EngPerm–English Parent)
- (The parameters of) an RNN language model (LM Xfer)

Transfer Model	BLEU ↑	PPL ↓
None	10.7	22.4
French–English Parent	**14.4**	**14.3**
English–English Parent	5.3	55.8
EngPerm–English Parent	10.8	20.4
LM Xfer	12.9	16.3

Table 8: Transfer for Uzbek–English NMT with parent models trained only on English data. The English–English parent learns to copy English sentences, and the EngPerm–English learns to un-permute scrambled English sentences. The LM is a 2-layer LSTM RNN language model.

The results, in Table 8, show that transfer learning does not simply import an English language model, but makes use of translation parameters learned from the parent's large bilingual text.

6 Conclusion

Overall, our transfer method improves NMT scores on low-resource languages by a large margin and allows our transfer NMT system to come close to the performance of a very strong SBMT system, even exceeding its performance on Hausa–English. In addition, we consistently and significantly improve state-of-the-art SBMT systems on low-resource languages when the transfer NMT system is used for rescoring. Our experiments suggest that there is still room for improvement in selecting parent languages that are more similar to child languages, provided data for such parents can be found.

MixKMeans: Clustering Question-Answer Archives

Abstract

Community-driven Question Answering (CQA) systems that crowdsource experiential information in the form of questions and answers and have accumulated valuable reusable knowledge. Clustering of QA datasets from CQA systems provides a means of organizing the content to ease tasks such as manual curation and tagging. In this paper, we present a clustering method that exploits the two-part question-answer structure in QA datasets to improve clustering quality. Our method, *MixKMeans*, composes question and answer space similarities in a way that the space on which the match is higher is allowed to dominate. This construction is motivated by our observation that semantic similarity between question-answer data (QAs) could get localized in either space. We empirically evaluate our method on a variety of real-world labeled datasets. Our results indicate that our method significantly outperforms state-of-the-art clustering methods for the task of clustering question-answer archives.

1 Introduction

Community-based Question Answering (CQA) systems such as Yahoo! Answers[1], StackOverflow[2] and Baidu Zhidao[3] have become dependable sources of knowledge to solve common user problems. Unlike factoid question answering[4], CQA systems focus on crowdsourcing *how* and *why* questions and their answers. As is the case with any system where content is generated by web users, the generated content would be of varying quality, reliability, readability and abstraction. Thus, manual curation of such datasets is inevitable to weed out low quality and duplicate content to ensure user satisfaction. A natural way to aid manual curation of such broad-based CQA archives is to employ clustering so that semantically related QAs are grouped together; this would help organize the corpus in a way that experts engaged in manual curation be assigned specific clusters relating to areas of their expertise. Clustering also provides a platform to enable tagging the QA dataset; cluster topics could be used as tags, or other QAs in the same cluster could be tagged as being *related* to a QA. The fundamental difference between CQA archives and general text document collections is the existence of a two-part structure in QAs and the difference in lexical "character" between the question and answer parts. This *lexical chasm (i.e., gap)* (Berger et al., 2000) between question and answer parts has been a subject of much study, especially, in the context of improving QA retrieval. In this paper, we consider using the two-part structure in QAs for clustering CQA datasets.

Motivating Example: Table 1 lists four example QAs from the context of a CQA system focused on addressing myriad technical issues. These QAs have been tagged in the table with a manually identified root-cause to aid understanding; the root-cause is not part of the CQA data per se. $QA1$ and $QA2$ are seen to address related issues pertaining to routers, whereas $QA3$ and $QA4$ are focused on the same nar-

Austin, Texas, November 1-5, 2016.

row issue dealing with java libraries. Since $QA1$ and $QA2$ address different problems, they may not be expected to be part of the same cluster in fine-grained clusterings. On the other hand, the solutions suggested in $QA3$ and $QA4$ are distinct and different legitimate solutions to the *same* problem cause. Thus, from a semantics perspective, it is intuitive that $QA3$ and $QA4$ should be part of the same cluster in any clustering of the CQA dataset to aid actioning on them together; a human expert might decide to merge the question parts and tag one of the answers as an *alternative* answer. Let us now examine the lexical relatedness between the pairs as illustrated in Table 2. State-of-the-art text similarity measures that quantify word overlaps are likely to judge $QA1$ and $QA2$ to be having a *medium* similarity when either the question-part or the answer-part are considered. For the pair $(QA3, QA4)$, the question-part similarity would be judged to be *high* and the answer-part similarity as *low*. Thus, the high similarity between the root-causes of $QA3$ and $QA4$ manifest primarily in their question-parts. Analogously, we observed that some QAs involving the same root-cause lead to high answer-part similarity despite poor question-part similarity. This is especially true in cases involving suggestion of the same sequence of solution steps despite the question-part being divergent due to focusing on different symptoms of the same complex problem. From these observations, we posit that high similarities on *either* the question-space or answer-space is indicative of semantic relatedness. Any clustering method that uses a sum, average or weighted sum aggregation function to arrive at pair-wise similarities, such as a K-Means clustering that treats the collated QA as a single document, would intuitively be unable to heed to such differential manifestation of semantic similarities across the two parts.

Our Contributions: We address the problem of harnessing the two-part structure in QA pairs to improve clustering of CQA data. Based on our observations on CQA data such as those illustrated in the example, we propose a clustering approach, *MixK-Means*, that composes similarities (dissimilarities) in the question and answer spaces using a max (min) operator style aggregation. Through abundant empirical analysis on real-world CQA data, we illustrate that our method outperforms the state-of-the-art approaches for the task of CQA clustering.

2 Related Work

To enable position our work in the context of existing literature, we now summarize prior work along three related directions, viz., (1) processing of CQA datasets, (2) multi-modal data clustering, and (3) K-Means extensions.

Processing CQA Datasets: Most work on processing CQA data has been in the realm of retrieval, where the task addressed is to leverage CQA datasets to aid answering new questions. These start with a new question and find one of (i) related questions (Zhou et al., 2015), (ii) potentially usable answers (Shtok et al., 2012), or (iii) related QAs (Xue et al., 2008). Different methods differ in the technique employed to overcome the *lexical chasm*, with statistical translation models (Brown et al., 1993) that model word-level correlations between questions and answers being the most popular tool for the same. Usage of topic models (e.g., (Cai et al., 2011)) and combining evidence from topic and translation models (Zhou et al., 2015) have also met with success. The usage of deep-learning methods such as deep belief networks (Wang et al., 2011) and auto-encoders (Zhou et al., 2016) have also been explored for QA retrieval. While the problem of estimating the relevance of a QA to address a new question is related to the problem of estimating similarities between QAs to aid clustering, the latter problem is different in that both question and answer parts are available at either side. In fact, our problem, CQA clustering, has been largely unexplored among literature in CQA data processing. In the interest of benchmarking our work against techniques from the CQA processing community, we consider the correlated latent representation learnt by the recent auto-encoder based neural network (AENN) method (Zhou et al., 2016) as input to K-Means, and empirically validate our technique against the AENN+K-Means combination (referred to as AENN, for short) in our experimental study. Outside the task of retrieval, there has been work on getting QAs from experience reports (Deepak et al., 2012) and discussion forums (P and Visweswariah, 2014). Conversational transcripts from contact centres, as outlined in (Kummamuru et al., 2009), form

#	QA	Cause
QA1	**Q:** My internet connection is not working, my router shows the "Internet" led blinking in red.	Router Authentication Issue
	A: Please go to the router login page and re-login with broadband credentials; click "connect" and you should be on the internet.	
QA2	**Q:** My internet connection is not working, only the power led is lit in the router.	Router Loose Connection
	A: Check whether the router login page is loading. Else, the broadband cable may not be connected properly.	
QA3	**Q:** My Java app is picking up the old dojo 0.4.4 libraries though I have a newer version.	Multiple Libraries in Classpath
	A: Search for dojo 0.4.4 in Windows, and delete off the folder, and it should automatically start using the newer version.	
QA4	**Q:** My java application is not picking up the new dojo 1.11.1 libraries that I just installed.	Multiple Libraries in Classpath
	A: Update the java classpath variable to exclude the path to the earlier version, and add the path to the new version.	

Table 1: Example CQA Data

QA Pair		Part	Lexical Similarity
QA1	QA2	Question	Medium
QA1	QA2	Answer	Medium
QA3	QA4	Question	High
QA3	QA4	Answer	Low

Table 2: Similarity Analysis of QAs from Table 1

another rich source of QA data, but need careful segmentation due to interleaving of question and answer parts.

Multi-modal Data Clustering: The problem of clustering CQA data is an instance of the general problem of clustering multi-modal (aka multi-relational, multi-view or heterogeneous) data when the question and answer parts are seen as instantiations of the same root cause, but in question and answer 'modalities'. Clustering multi-modal data has been explored well in the context of multi-media data clustering where each data element comes in multi-modal form such as *[image, caption]* pairs or *[audio, text]* pairs. The pioneering work in this field adapted markov random fields (Bekkerman and Jeon, 2007) to generate separate clusterings for each modality. Later approaches are closer to our task of generating a unified clustering across modalities; they work by learning a unified latent space embedding of the dataset, followed by usage of K-Means clustering (MacQueen and others, 1967). Eigen-decomposition (Petkos et al., 2012), spectral methods (Blaschko and Lampert, 2008) and canonical correlation analysis (Jin et al., 2015) have been exploited for learning the latent space prior to the clustering step. A recent work (Meng et al., 2014) proposes a single-pass leader-clustering[5] style formulation called GHF-ART to progressively assign data objects to clusters. Unlike most other methods that assume that vector representations are obtained from general multimedia data, the authors of GHF-ART lay out how text data be pre-processed for usage in GHF-ART, making it an appropriate method for usage in our setting. Accordingly, we will use GHF-ART as a baseline method for our experimental study.

K-Means Extensions: The method that we propose in this paper, *MixKMeans*, draws generous inspiration from the classical K-Means clustering formulation (MacQueen and others, 1967). There have been numerous extensions to the basic K-Means formulation over the last many decades; many such extensions have been covered in focused surveys (Steinley, 2006; Jain, 2010). Of particular interest in our scenario are those relating to usage of varying (dis)similarity measures. (Patel and Mehta, 2012) discuss the usage of various popular distance measures within the K-Means framework. The point-symmetry distance, where the distance between an object and the cluster prototype is determined using other objects' information, has been explored (Su and Chou, 2001) for usage within K-Means for face recognition applications. Another work (Visalakshi and Suguna, 2009) suggests the computation of the aggregate distance as a fraction of the distance

[5] https://cran.r-project.org/web/packages/leaderCluster/index.html

along the closest attribute to that along the farthest attribute. Despite the plethora of work around extending K-Means to work with a variety of methods to aggregate distances across attributes, we have not come across previous work composing distances at the level of attribute sets (or modalities) like we will do in this work.

3 Problem Definition

Let $\mathcal{D} = \{(q_1, a_1), \ldots, (q_n, a_n)\}$ be a dataset of QAs from a CQA archive where each answer a_i was posted in response to the corresponding question q_i. The CQA clustering problem is the task of partitioning $\mathcal{D}$ into k clusters $\mathcal{C} = \{C_1, \ldots, C_k\}$ where $\cup_i C_i = \mathcal{D}$ and $\forall(i,j), i \neq j \Rightarrow C_i \cap C_j = \phi$ (disjointedness) hold such that similar QAs are grouped into the same cluster and dissimilar QAs are assigned to different clusters. The key aspect that differentiates the CQA clustering problem from general clustering of relational data is the opportunity to leverage the specifics of the CQA data, such as the two-part structure, to model the similarity measure that would drive the clustering.

Evaluation: The quality of a clustering method may be quantified by assessing how well the clustering it produces, i.e., $\mathcal{C}$, reflects the semantic similarities between QAs in $\mathcal{D}$. Given a QA $(q_i, a_i) \in \mathcal{D}$, the other QAs that share the same cluster may be thought of as the *result* set, i.e., the set of *related* QAs according to $\mathcal{C}$. In a labeled dataset such as CQADupStack (Hoogeveen et al., 2015) where related QA pairs have been manually identified for each (q_i, a_i), the quality of the results set may be assessed by contrasting against the labeled set using a standard metric such as F-score[6]. These QA-specific F-scores are then aggregated across the QAs in $\mathcal{D}$ to arrive at a single quality measure for the clustering. We will use such aggregated dataset-level F-scores as our primary evaluation measure. It may be noted that the *related* labellings may not be "clustering-friendly"; for example, there may not exist any k-clustering with no *related* labels going across clusters. Additionally, we observed that not all related QAs were labeled to be related in the CQADupStack dataset. The dataset owners confirm the problem of missing labelings in a very recent study (Hoogeveen et al., 2016). It is conceivable that only a few potential results were manually inspected to inject labellings. Thus, while the relative trends on F-score offer insights, the absolute F-scores may only be treated as a loose lower bounds.

[6] https://en.wikipedia.org/wiki/F1_score

4 *MixKMeans*: Our Method

We now describe the key details of our proposed technique, *MixKMeans*. The name is motivated by the flexibility that is built into the method to *mix* (dis)similarities across question and answer spaces in a formulation that derives inspiration from the classical K-Means algorithm (MacQueen and others, 1967). Throughout this formulation, we represent question and answer parts of QAs by their respective tf-idf vectors. We start with our objective function and move on to the iterative optimization.

4.1 Objective Function

Guided by our observation from Section 1 that the space in which a pair of QAs are more similar should hold sway in determining their overall match, we outline a penalty function for a clustering $\mathcal{C}$:

$$\mathcal{O}^* = \sum_{C \in \mathcal{C}} \sum_{(q,a) \in C} min\{w_q \, d(q, C.\mu.q), w_a \, d(a, C.\mu.a)\} \quad (1)$$

where $C.\mu = (C.\mu.q, C.\mu.a)$ is a prototypical QA vector for cluster C and the parameter pair $[w_q, w_a]$ control the relative weighting between question and answer parts. $d(.,.)$ is a dissimilarity function modeled as a simple sum of squares of element-wise differences between vector entries, i.e., $d(x,y) = \sum_i (x[i] - y[i])^2$.

Intuitively, $\mathcal{O}^*$ sums up the distance between each QA in $\mathcal{D}$ and the prototypical QA vector of the cluster to which it is assigned to, making it a penalty function. Since we use dissimilarities that are inversely related to similarities, the min function captures the idea that the aggregate (dis)similarity be estimated according to the measure in the best matching space. For optimization convenience, we replace the min construction by a differentiable approximation to get a modified objective function:

$$\mathcal{O} = \sum_{C \in \mathcal{C}} \sum_{(q,a) \in C} \Bigg(\Big(w_q d(q, C.\mu.q) \Big)^x + \Big(w_a d(a, C.\mu.a) \Big)^x \Bigg)^{\frac{1}{x}} \quad (2)$$

where x is a reasonably high negative value or $x \to -\infty$. This is used since $(a^x + b^x)^{1/x}$ approximates $min\{a, b\}$ for high negative values of x. It is worth noting that the opposite effect (i.e., max approximation) is achieved when $x \to \infty$ for usage in scenarios where a max combination is desirable. The remainder of the steps are applicable for positive values of x too.

4.2 Optimization Approach

There are two sets of variables in Equation 2, viz., cluster assignments of QAs in $\mathcal{D}$ and the cluster prototypes ($C.\mu$s). We optimize for each set of variables alternatively, much like in the EM-steps used in the classical K-Means algorithm.

4.2.1 Estimating Cluster Memberships

The cluster membership estimation directly falls out from the objective function and the current estimates of cluster prototypes since $\mathcal{O}$ (Equation 2) involves an instance-specific term for each QA. We will simply assign each QA to the cluster such that the respective instance-specific term is minimized:

$$Cluster((q,a)) = \arg\min_{C \in \mathcal{C}} \Big(d^x_{Q+A}((q,a), C.\mu) \Big)^{\frac{1}{x}} \quad (3)$$

$d^x_{Q+A}(.,.)$ is a short-hand for composite distance, composed of two terms (which we will denote as $d^x_Q(.,.)$ and $d^x_A(.,.)$ respectively):

$$d^x_{Q+A}((q,a), C.\mu^\circ) = \big(w_q \times d(q, C.\mu^\circ.q) \big)^x + \big(w_a \times d(a, C.\mu^\circ.a) \big)^x \quad (4)$$

4.2.2 Estimating Cluster Prototypes

We now estimate the cluster prototype in element-wise fashion. Consider a particular element in the $C.\mu.q$ vector, $C.\mu.q[i]$; computing the partial derivative and simplifying:

$$\frac{\partial \mathcal{O}}{\partial C.\mu.q[i]} = \sum_{(q,a) \in C} \Bigg[-2 \Big(d^x_{Q+A}((q,a), C.\mu) \Big)^{\frac{1-x}{x}} d^{x-1}_Q((q,a), C.\mu)\ w_q\ (q[i] - C.\mu.q[i]) \Bigg] \quad (5)$$

Equating the first derivative to zero and solving for $C.\mu.q[i]$ gets us to the following form:

$$C.\mu.q[i] = \frac{\sum_{(q,a) \in C} q[i] \Bigg[\Big(d^x_{Q+A}((q,a), C.\mu^\circ) \Big)^{\frac{1-x}{x}} d^{x-1}_Q((q,a), C.\mu^\circ) \Bigg]}{\sum_{(q,a) \in C} \Bigg[\Big(d^x_{Q+A}((q,a), C.\mu^\circ) \Big)^{\frac{1-x}{x}} d^{x-1}_Q((q,a), C.\mu^\circ) \Bigg]} \quad (6)$$

where $C.\mu^\circ$ is used to indicate the estimate of $C.\mu$ from the previous iteration. The corresponding estimation for $C.\mu.a[i]$ is:

$$C.\mu.a[i] = \frac{\sum_{(q,a) \in C} a[i] \Bigg[\Big(d^x_{Q+A}((q,a), C.\mu^\circ) \Big)^{\frac{1-x}{x}} d^{x-1}_A((q,a), C.\mu^\circ) \Bigg]}{\sum_{(q,a) \in C} \Bigg[\Big(d^x_{Q+A}((q,a), C.\mu^\circ) \Big)^{\frac{1-x}{x}} d^{x-1}_A((q,a), C.\mu^\circ) \Bigg]} \quad (7)$$

Equations 6 and 7 form the cluster prototype estimation steps of our method. It may be noted that for the choice of parameters ($x = 1, w_q = w_a$), either equations reduce it to the usual centroid estimation process for K-Means (since the terms within $[\ldots]$ reduce to 1.0), as intuitively expected. Thus, the modified formulation generalizes K-Means by allowing to weigh each element differently, the weight being modeled as a product two components:

- First component involves $d^x_{Q+A}(.,.)$ and is a function of the composite distance of (q,a) to the cluster prototype.
- Second component involves one of $d^{x-1}_Q(.,.)$ or $d^{x-1}_A(.,.)$ and is a function of the respective space (Q or A) to which the specific vector element belongs.

Alg. 1 ***MixKMeans***

Input. Dataset $\mathcal{D}$, number of clusters k
Hyper-parameters: x, w_q, w_a
Output. Clustering $\mathcal{C}$

1: *Initialize* $C.\mu$s *using data points from* $\mathcal{D}$
2: **while** *not yet converged* **do**
3: $\quad \forall (q,a) \in \mathcal{D}$, *assign cluster using Eq. 3*
4: $\quad \forall C \in \mathcal{C}$, *estimate* $C.\mu$ *using Eq. 6 & 7*
5: **end while**
6: *Return current clustering assignments as* $\mathcal{C}$

4.3 *MixKMeans*: The Algorithm

Having outlined the various steps, we are now ready to present the overall $MixKMeans$ algorithm in Algorithm 1. As the pseudo-code indicates, the cluster assignment and prototype estimation steps are run in a loop until the clustering converges. Additionally, we terminate after a threshold number of iterations even if the clustering does not converge by then; we set the threshold to 10.

Initialization: In the initialization step, we initialize the first cluster prototype using a random QA from $\mathcal{D}$. Each of the next cluster prototypes are initialized using the QA that has the highest sum of distances to all pre-chosen cluster prototypes, distance computed using $(d^x_{Q+A}(.,.))^{1/x}$. This is inspired by previous work on spreading out the cluster centroids (Arthur and Vassilvitskii, 2007) in K-Means initialization.

Hyperparameters: The algorithm has three hyper-parameters, viz., the exponentiation parameter x and the weight parameters w_q and w_a. As outlined in Sec. 4.1, x should be a negative value; we observed that any value beyond -3.0 does not make any significant differences to the final clustering (while higher absolute values for the exponent pose an underflow risk) and thus use $x = -3.0$ consistently. For the weights, we set $w_q = 0.2$ and $w_a = 0.8$. Due to the min-formulation in the objective function, a lower weight increases the influence of the respective space. Thus, we let our composed similarities be influenced more by the question-space similarities as in previous work (Xue et al., 2008).

4.4 Generalizing *MixKMeans*

Since the question and answer spaces are neatly segregated into different terms in the parameter update equations, ***MixKMeans*** is easily generalizable to work with more than two spaces. Consider the set of spaces to be $\mathcal{M} = \{\ldots, M, \ldots\}$ and that each object, $X \in \mathcal{D}$ be represented by an $|\mathcal{M}|$ tuple; now, the modified update equations are as follows:

$$Cluster(X) = \arg\min_{C \in \mathcal{C}} \left(d_{\sum_{M \in \mathcal{M}} M}(X, C.\mu) \right)^{\frac{1}{x}} \tag{8}$$

$$C.\mu.M[i] = \frac{\sum_{X \in C} X.M[i] \left[\left(d^x_{\sum_{M \in \mathcal{M}} M}(X, C.\mu^\circ) \right)^{\frac{1-x}{x}} d^{x-1}_M(X, C.\mu^\circ) \right]}{\sum_{X \in C} \left[\left(d^x_{\sum_{M \in \mathcal{M}} M}(X, C.\mu^\circ) \right)^{\frac{1-x}{x}} d^{x-1}_M(X, C.\mu^\circ) \right]} \tag{9}$$

where the somewhat awkward notation $d^x_{\sum_{M \in \mathcal{M}} M}(.,.)$ denotes the direct generalization of $d^x_{Q+A}(.,.)$ to cover all spaces in $\mathcal{M}$.

A simple modeling extension to use the generalized *MixKMeans* in the CQA setting is to consider the question title and question description as two separate spaces instead of using a single question space, increasing the total number of spaces to three; such a split of the question-part was used in (Qiu et al., 2013). In certain cases, one might want to use spaces that are of questionable quality due to reasons such as sparsity (e.g., set of tags associated with a question) and reliability (e.g., comments attached to a QA that could be noisy). The best way to leverage such spaces would be to include it in $\mathcal{M}$ for the modeling, but use a high weight for w_M; due to the min-style construction in the objective function, that setting will ensure that that space is called into play only when (a) signals from other spaces are not very strong, and (b) the signal from the space in question is very strong.

5 Experimental Evaluation

5.1 Datasets, Baselines and Setup

Datasets: We use the recently released data col-

lection, CQADupStack (Hoogeveen et al., 2015), for our experimental evaluation. Unlike most other datasets, this has each QA labeled with a set of *related* QAs, as alluded to in Section 3; this makes automated evaluation feasible in lieu of a laborious user study. We use the *android*, *gis*, *stats* and *physics* datasets from the CQADupStack collection, with our choice of datasets motivated by dataset size. These datasets comprise 2193, 3726, 4004 and 5044 QAs respectively.

Baselines: We use two baselines from literature in our study, (i) AENN (Zhou et al., 2016), (ii) GHF-ART (Meng et al., 2014). AENN, as alluded to in Section 2, refers to the K-Means clustering in the latent space learnt by correlated auto-encoders across the Q-A subspaces. AENN requires triplets of the form [question, answer, other answer] in the training phase; we populate the *other answer* part by the answer to a *related* question from the dataset (it may be noted that this is advantageous to AENN since it gets to *'see'* some *related* labelings in the training, whereas other methods can't). GHF-ART is the state-of-the-art multi-modal clustering approach that is targeted towards scenarios that involve a text modality. Unlike typical clustering algorithms that can generate a pre-specified (k) number of clusters, the number of clusters in the GHF-ART output is controlled by a *vigilance parameter*, ρ. Lower values of ρ result in smaller number of clusters and vice versa. A third intuitive baseline is the degenerate $x = 1$ instantiation of *MixKMeans*, which we will denote as $X1$. We are interested in evaluating the improvement achieved by *MixKMeans* over the best possible instantiation of $X1$; towards that, for every setting denoted by the combination $[dataset, k]$, we do a search over possible positive values of w_q and w_a within the locus of the line $w_q + w_a = 1$. It may be noted that this search space includes simple QA clustering using K-Means, being the case where $w_q = w_a = 0.5$. We collect the best result of $X1$ from across the grid-search for each setting. This approach, which we will denote as $X1^*$, while impractical in real scenarios due to usage of labeled data, gives an empirical upper bound of the accuracy of $X1$.

Experimental Setup: We use a latent space dimensionality of 2000 for AENN since we observed an accuracy peak around that value, and set GHF-ART parameters to their recommended values from the paper. For *MixKMeans*, we use tf-idf representation and set $(x = -3.0, w_q = 0.2, w_a = 0.8)$ as discussed earlier (Section 4.3). We use the F-score[7] measure to experimentally compare the approaches. The F-score is computed using the *related*

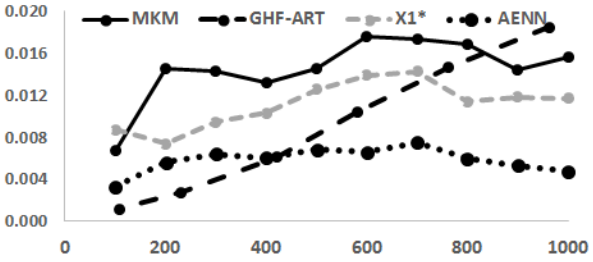

Figure 1: Android: F-Score (Y-Axis) vs. k

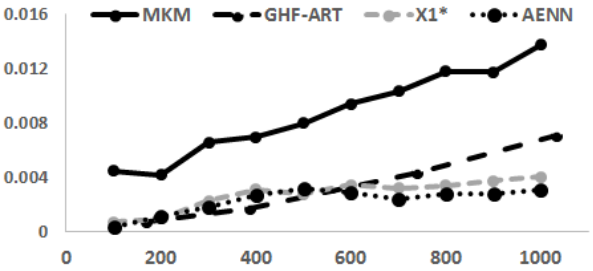

Figure 2: GIS: F-Score (Y-Axis) vs. k

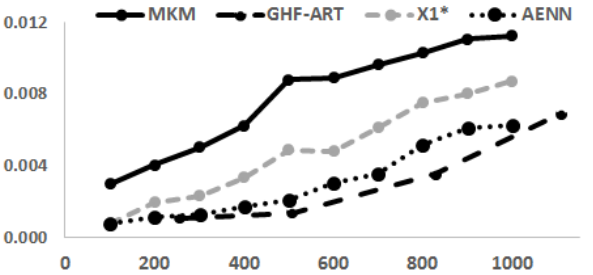

Figure 3: Stats: F-Score (Y-Axis) vs. k

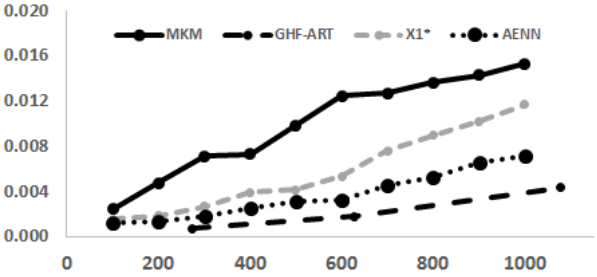

Figure 4: Physics: F-Score (Y-Axis) vs. k

[7] https://en.wikipedia.org/wiki/F1_score

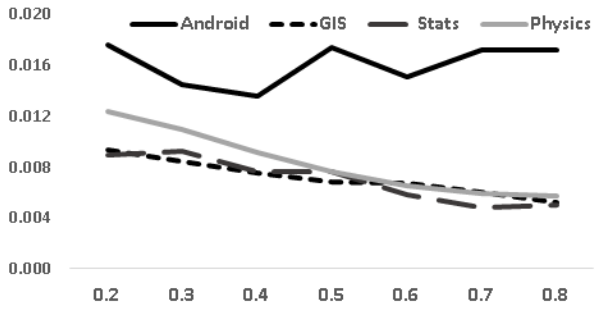

Figure 5: *MixKMeans*: F-Score (Y-Axis) vs. w_q at $k = 600$

labellings in the CQADupStack data, in a manner as described in Section 3. As pointed out therein, due to the sparse labellings, the F-score may only be regarded as a loose lower bound of their real values on a fully-labeled dataset.

5.2 Comparative Analysis

The results of the comparative analysis benchmarking our approach *MixKMeans* (MKM) against baselines $X1^*$, AENN and GHF-ART for the various datasets appear in Fig 1 (Android), Fig 2 (GIS), Fig 3 (Stats) and Fig 4 (Physics). Each of the trend-lines plot the F-Score against varying number of clusters in the output (k) in the range $\{100, 1000\}$. Since the number of clusters cannot be pre-specified for GHF-ART directly, we varied its ρ parameter to generate varying number of clusters to generate a trend-line that can be compared against *MixKMeans*, AENN and $X1^*$ directly. It may be noted that F-score is generally seen to increase when the clustering is more fine-grained (i.e., high k); this is an artifact of the sparse labeling that causes large clusters to have very low precision, causing precision and recall to diverge at low k, thus reducing the F-score. In most cases, *MixKMeans* is seen to outperform the other methods by scoring significantly higher in the F-Score, illustrating the superiority of our method. A notable exception appears in the higher values of k in the android dataset where GHF-ART quickly catches up and surpasses the others; however, it may be noted that $k \approx 1000$ is an extremely fine-grained clustering for the android dataset with 2193 QAs, and is thus not a very useful setting in practice. On the average, *MixKMeans* achieves an F-score improvement of between $30 - 100\%$ over the other methods.

5.3 *MixKMeans* Parameter Analysis

We now analyze the F-score trends of *MixKMeans* against varying values of the weight parameters. Since the relative weighting between w_q and w_a is what matters (simply scaling them both up by the same multiplier does not make any difference due to the construction of the objective), we set $w_a = (1.0 - w_q)$ and do the analysis for varying values of w_q keeping $k = 600$. As may be observed from the results in Figure 5, *MixKMeans* was seen to peak around $w_q = 0.2$-0.5 while degrading gracefully towards higher values of w_q. The android dataset, perhaps due to its relatively small size, records a different behavior as compared to the other trend-lines. Similar trends were observed for other values of k, indicating *MixKMeans* is not highly sensitive to the parameter and degrades gracefully outside the peak.

6 Conclusions and Future Work

We considered the problem of clustering question-answer archives from CQA systems. Clustering, we observed, helps in organizing CQA archival data for purposes such as manual curation and tagging. We motivated, by way of examples, as to why similarities along question and answer spaces be better composed using methods other than simple sum or average type aggregation. In particular, we noted that there are potentially different ways to answer questions pertaining to the same root-cause, mitigating the manifestation of the inherent root-cause similarity in the answer-space. Analogously, a sophisticated root-cause could be narrated differently by different people in the question part, while eliciting very similar answers. In short, we observe that legitimate reasons cause manifestation of semantic similarity between QAs to be localized on to one of the spaces. Accordingly, we propose a clustering method for QA archives, *MixKMeans*, that can heed to high similarities in either spaces to drive the clustering. *MixKMeans* works by iteratively optimizing the two sets of parameters, cluster assignments and cluster prototype learning, in an approach inspired by the classical K-Means algorithm. We empirically benchmark our method against current methods on multiple real-world datasets. Our experimental study illustrates that our method is able to significantly outperform other methods, establishing

MixKMeans as the preferred method for the task of clustering CQA datasets.

Future Work: As discussed in Section 4.4, *MixKMeans* is eminently generalizable to beyond two spaces. Considering the usage of other kinds of data (e.g., tags, comments) as additional "spaces" to extend the CQA clustering problem is an interesting direction for future work. The applicability of *MixKMeans* and it's *max* variant (i.e., with $x > 0$) for other kinds of multi-modal clustering problems from domains such as multimedia processing is worth exploring. The extension of the formulation to include a weight learning step may be appropriate for scenarios where prior information on the relative importance of the different spaces is not available. It is easy to observe that *MixKMeans* is prone to local optima issues; this makes devising better initialization strategies another potential direction. Yet another direction of interest is to make MixKMeans clusters interpretable, potentially by augmenting each cluster with word-level rules as used in earlier work on partitional document clustering (Balachandran et al., 2012).

It Takes Three to Tango: Triangulation Approach to Answer Ranking in Community Question Answering

Abstract

We address the problem of answering new questions in community forums, by selecting suitable answers to already asked questions. We approach the task as an answer ranking problem, adopting a pairwise neural network architecture that selects which of two competing answers is better. We focus on the utility of the three types of similarities occurring in the triangle formed by the original question, the related question, and an answer to the related comment, which we call *relevance, relatedness*, and *appropriateness*. Our proposed neural network models the interactions among all input components using syntactic and semantic embeddings, lexical matching, and domain-specific features. It achieves state-of-the-art results, showing that the three similarities are important and need to be modeled together. Our experiments demonstrate that all feature types are relevant, but the most important ones are the lexical similarity features, the domain-specific features, and the syntactic and semantic embeddings.

1 Introduction

In recent years, community Question Answering (cQA) forums, such as StackOverflow, Quora, Qatar Living, etc., have gained a lot of popularity as a source of knowledge and information. These forums typically organize their content in the form of multiple topic-oriented *question–comment threads*, where a question posed by a user is followed by a list of other users' comments, which intend to answer the question.

Many of such on-line forums are not moderated, which often results in (a) *noisy* and (b) *redundant* content, as users tend to deviate from the question and start asking new questions or engage in conversations, fights, etc.

Web forums try to solve problem (a) in various ways, most often by allowing users to up/down-vote answers according to their perceived usefulness, which makes it easier to retrieve useful answers in the future. Unfortunately, this negatively penalizes recent comments, which might be the most relevant and updated ones. This is due to the time it takes for a comment to accumulate votes. Moreover, voting is prone to abuse by forum trolls (Mihaylov et al., 2015; Mihaylov and Nakov, 2016a).

Problem (b) is harder to solve, as it requires that users verify that their question has not been asked before, possibly in a slightly different way. This search can be hard, especially for less experienced users as most sites only offer basic search, e.g., a site search by Google. Yet, solving problem (b) automatically is important both for site owners, as they want to prevent question duplication as much as possible, and for users, as finding an answer to their questions without posting means immediate satisfaction of their information needs.

In this paper, we address the general problem of finding good answers to a given *new question* (referred to as *original question*) in one such community-created forum. More specifically, we use a pairwise deep neural network to rank comments retrieved from different question-comment threads according to their *relevance* as answers to the original question being asked.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1586–1597,
Austin, Texas, November 1-5, 2016.

A key feature of our approach is that we investigate the contribution of the edges in the triangle formed by the pairwise interactions between the *original question*, the *related question*, and the *related comments* to rank comments in a unified fashion. Additionally, we use three different sets of features that capture such similarity: lexical, distributed (semantics/syntax), and domain-specific knowledge.

The experimental results show that addressing the answer ranking task directly, i.e., modelling only the similarity between the original question and the answer-candidate comments, yields very low results. The other two edges of the triangle are needed to obtain good results, i.e., the similarity between the original question and the related question and the similarity between the related question and the related comments. Both aspects add significant and cumulative improvements to the overall performance. Finally, we show that the full network, including the three pairs of similarities, outperforms the state-of-the-art on a benchmark dataset.

The rest of the paper is organized as follows: Section 2 discusses the similarity triangle in answer ranking for cQA, Section 3 presents our pairwise neural network model for answering new questions in community forums, which integrates multiple levels of interaction, Section 4 describes the features we used, Section 5 presents our evaluation setup, the experiments and the results, Section 6 discusses some related work, and Section 7 wraps up the paper with a brief summary of the contributions and some possible directions for future work.

2 The Similarity Triangle in cQA

Figure 1 presents an example illustrating the similarity triangle that we use when solving the answer ranking problem in cQA. In the figure, q stands for the new question, q' is an existing related question, and c is a comment within the thread of question q'.

The edge $\overline{qc}$ relates to the main cQA task addressed in this paper, i.e., deciding whether a comment for a potentially related question is a good answer to the original question. We will say that the relation captures the *relevance* of c for q.

The edge $\overline{qq'}$ represents the similarity between the original and the related questions. We will call this relation *relatedness*.

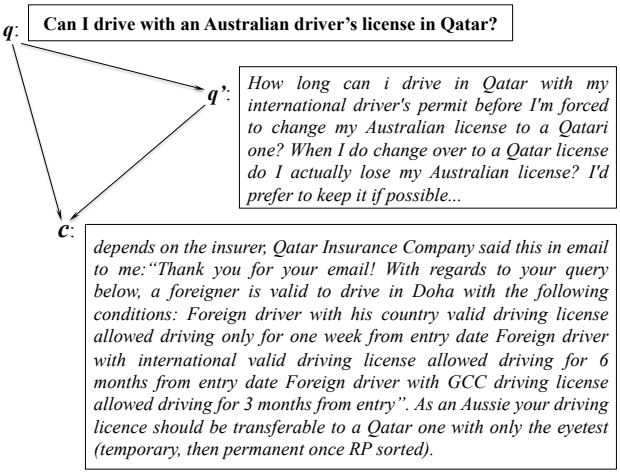

Figure 1: The similarity triangle in cQA.

Finally, the edge $\overline{q'c}$ represents the decision of whether c is a good answer for the question from its thread, q'. We will call this relation *appropriateness*.

In this particular example, q and q' are indeed related, and c is a good answer for both q' and q.[1]

In the past, the approaches to cQA were focused on using information from the new question q, an existing related question q', and a comment c within the thread of q', to solve different cQA sub-tasks. For example, *answer selection*, which selects the most appropriate comment c within the thread q', was addressed in SemEval-2015 Task 3 (Nakov et al., 2015). Similarly, *question–question similarity*, which looks for the most related questions to a given question, was addressed by many authors (Jeon et al., 2005; Duan et al., 2008; Li and Manandhar, 2011; Zhou et al., 2015; dos Santos et al., 2015).

In this paper, we solve the cQA task problem[2] in a novel way by using the three types of similarities jointly. Our main hypothesis is that *relevance*, *appropriateness*, and *relatedness* are essential to finding the best answer in a community Question Answering setting. Below we present experimental results that support this hypothesis.

[1]The essence of this triangle is also described in SemEval 2016 Task 3 to motivate a three-subtask setting for cQA (Nakov et al., 2016). In that evaluation exercise, $\overline{q'c}$ and $\overline{qq'}$ are presented as subtask A and subtask B, respectively. In this paper, we mainly use them as similarity relations to be modeled in the learning architecture to solve the answer ranking task.

[2]We use the task setup and the datasets from SemEval-2016 Task 3, focusing on subtask C (Nakov et al., 2016).

3 Neural Model for Answer Ranking

As explained above, we tackle answer ranking as a three-way similarity problem, exploring similarity features that capture lexical, distributed (semantics and syntax), and domain-specific knowledge. To achieve this, we propose a pairwise neural network (NN) approach for the cQA task, which is inspired by our NN framework for machine translation evaluation (Guzmán et al., 2015).[3] The input of the NN consists of the original question q, two competing comments, c_1 and c_2, and the questions from the threads of the two comments, q'_1 and q'_2. The output of the network is a decision about which of the two comments is a better answer to q.

The main properties of our NN approach can be summarized as follows: (*i*) it works in a pairwise fashion, which is appropriate for the ranking nature of the cQA problem; (*ii*) it allows for an easy incorporation of rich syntactic and semantic embedded representations of the input texts; (*iii*) it models non-linear relationships between all input elements (q, c_1, c_2, q'_1 and q'_2), which allows us to study the interactions and the impact of the three types of similarity (relevance, relatedness and appropriateness) when solving the answer ranking task.

3.1 Architecture

Our full NN model for pairwise answer ranking is depicted in Figure 2. We have a binary classification task with input $x = (q, q'_1, c_1, q'_2, c_2)$, which should output 1 if c_1 is a better answer to the original question q than c_2, and 0 otherwise.[4] In this setting, q'_1 and q'_2 are questions related to q, whose threads contain the comments c_1 and c_2, respectively. They provide useful information to link the two comments to the original question. On the one hand, they allow to predict whether the comments are good answers within their respective threads. On the other hand, they allow to infer whether the questions for which the comments were produced are closely related to the original question. The pair of comments can belong to the same thread (i.e., $q'_1 \equiv q'_2$) or they can come from different threads.

[3] Also, we previously used a similar framework for finding good answers in a question-comment thread (Guzmán et al., 2016a; Guzmán et al., 2016b).

[4] In this work, we do not learn to predict ties, and ties are excluded from our training data.

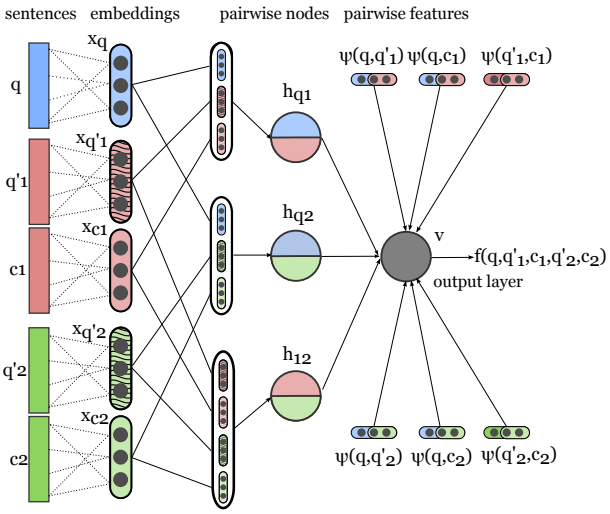

Figure 2: The overall architecture of our neural network model for pairwise answer ranking in community question answering.

The feed-forward neural network computes a sigmoid function $f(q, q'_1, c_1, q'_2, c_2) = \text{sig}(\mathbf{w_v^T}\phi(q, q'_1, c_1, q'_2, c_2) + b_v)$, where $\phi(.)$ transforms the input through the hidden layer, $\mathbf{w_v}$ are the weights from the hidden layer to the output layer, and b_v is a bias term. The function $\phi(.)$ is actually a concatenation of three subfunctions: $\phi(q, q'_1, c_1, q'_2, c_2) = [\phi_1(q, q'_1, c_1), \phi_2(q, q'_2, c_2), \phi_{1,2}(q'_1, c_1, q'_2, c_2)]$.

We first map the question and the comments to a fixed-length vector $[\mathbf{x}_q, \mathbf{x}_{q'_1}, \mathbf{x}_{c_1}, \mathbf{x}_{q'_2}, \mathbf{x}_{c_2}]$ using syntactic and semantic embeddings. Then, we feed this vector as input to the neural network, which models several types of interactions, using different groups of nodes in the hidden layer. Overall, we make use of three different groups of nodes in the hidden layer.

The first two groups include the *relevance* nodes h_{q1} and h_{q2}. These groups of hidden nodes model how relevant comment c_j is to the original question q given that it belongs to the thread of the related question q'_j. In these hidden nodes, we model complex non-linear interactions between the distributed representations of q, q'_j and c_j. Intuitively, these nodes are designed to learn to distinguish a relevant comment by extracting features from the distributed representations of a comment and of the question it is supposed to answer.

The last group of nodes in the hidden layer is the *similarity* node h_{12}. It measures the similarity between c_1 and c_2 and their respective questions q'_1 and q'_2. This node is designed to compute the non-linear interactions between the syntactic and semantic representations of comment-comment, comment-question and question-question pairs. Intuitively, this can help disambiguate when comments are very similar or were generated from the same or from very similar questions.

The model further allows to incorporate external sources of information in the form of *skip arcs* that go directly from the input to the output layer, skipping the hidden layer. These arcs represent pairwise *similarity* feature vectors inspired by the edges of the triangle in Figure 1. In Figure 2, we indicate these pairwise external feature sets as: $\psi(q, q'_1)$, $\psi(q, q'_2)$ for *relatedness*; $\psi(q'_1, c_1)$, $\psi(q'_2, c_2)$ for *appropriateness*; and $\psi(q, c_1)$, $\psi(q, c_2)$ for *relevance*. When including the *skip-arc* features, the activation at the output is $f(q, q'_1, c_1, q'_2, c_2) = \text{sig}(\mathbf{w_v^T}[\phi(q, q'_1, c_1, q'_2, c_2), \psi(q, q'_1), \psi(q, q'_2), \psi(q'_1, c_1), \psi(q'_2, c_2), \psi(q, c_1), \psi(q, c_2)] + b_v)$.

We use these feature vectors to encode machine translation evaluation measures, components thereof, cQA task-specific features, etc. The next section gives more detail about these features.

4 Features

We experiment with three kinds of features: (*i*) lexical features that measure similarity at a word, word n-gram, and paraphrase level, (*ii*) distributed representations that measure similarity at a syntactic and semantic level, (*iii*) domain-specific knowledge features, which capture similarity using thread-level information and other features that have proven valuable to solve similar tasks (Nicosia et al., 2015).

4.1 Lexical similarity features

These types of features measure similarity at a surface level between the following pairs: (q,q'_1), (q,q'_2), (q'_1, c_1), (q'_2, c_2), (q_1, c_1), and (q_2, c_2). They are inspired by our previous work on Machine Translation Evaluation (MTE) (Guzmán et al., 2015), and we previously found them useful for finding good answers in a question-comment thread (Guzmán et al., 2016a; Guzmán et al., 2016b).

MTFEATS We use (as pairwise features) the following six machine translation evaluation features: (*i*) BLEU: This is the most commonly used measure for machine translation evaluation, which is based on n-gram overlap and length ratios (Papineni et al., 2002). (*ii*) NIST: This measure is similar to BLEU, and is used at evaluation campaigns run by NIST (Doddington, 2002). (*iii*) TER: Translation error rate; it is based on the edit distance between a translation hypothesis and the reference (Snover et al., 2006). (*iv*) METEOR: A complex measure, which matches the hypothesis and the reference using synonyms and paraphrases (Lavie and Denkowski, 2009). (*v*) Unigram PRECISION and RECALL.

BLEUCOMP Following (Guzmán et al., 2015), we further use as features various components that are involved in the computation of BLEU: n-gram precisions, n-gram matches, total number of n-grams (n=1,2,3,4), lengths of the hypotheses and of the reference, length ratio between them, and BLEU's brevity penalty. Again, these are computed over the same six pairs of vectors as before.

4.2 Distributed representations

We use the following vector-based embeddings of all input components: q, c_1, c_2, q'_1, and q'_2.

GOOGLE_VEC We use the pre-trained, 300-dimensional embedding vectors from WORD2VEC (Mikolov et al., 2013). We compute a vector representation of the text by simply averaging over the embeddings of all words in the text.

QL_VEC We train in-domain word embeddings using WORD2VEC on all available QatarLiving data. Again, we use these embeddings to compute 100-dimensional vector representations for all input components by averaging over all words in the texts.

SYNTAX_VEC We parse the entire question/comment using the Stanford neural parser (Socher et al., 2013), and we use the final 25-dimensional vector that is produced internally as a by-product of parsing.

Moreover, we use the above vectors to calculate pairwise similarity features, i.e., the cosine between the following six vector pairs: (q, c_1), (q, c_2), (q'_1, c_1), (q'_2, c_2), (q, q'_1) and (q, q'_2).

4.3 Domain-specific features

We extract various domain-specific features that use thread-level and other useful information known to capture *relatedness* and *appropriateness*.

SAME_AUTHOR We have a thread-level meta-feature, which we apply to the pairs (q'_1, c_1), (q'_2, c_2). It checks whether the person answering the question is also the one who asked it, i.e., do the related question and the comment have the same author. The idea is that the person asking a question is unlikely to answer his/her own question, but s/he could ask a clarification question or thank another person who has provided a useful answer earlier in the thread.

CQ′RANK_FEAT We further have two thread-level meta-features related to the rank of the comment in the thread, which we apply to the pairs (q'_1, c_1) and (q'_2, c_2): (*i*) reciprocal rank of the comment in the thread, i.e., $1/\rho$, where ρ is the rank of the comment; (*ii*) percentile of the number of comments in the thread, calculated as follows: the first comment gets the score of 1.0, the second one gets 0.9, and so on. Note that in our dataset, there are exactly ten comments per thread.

QQ′RANK_FEAT We also have three features modeling the rank of the related question in the list of related questions for the original question, which we apply to the pairs (q, q'_1) and (q, q'_2).

In total, use the following six features: (*i*) the reciprocal rank of q'_1 or q'_2 in the list of related questions for q; (*ii*) the reciprocal ordinal rank[5] of q'_1 or q'_2 in the list of related questions for q; (*iii*) the percentile of the q'_1 or q'_2 in the list of related questions for q, calculated as for the comments.

CQRANK_FEAT. Finally, we have features for the rank of the comment in the list of 100 comments for the original question, which we apply to the pairs (q, c_1) and (q, c_2): (*i*) reciprocal rank of the comment in the list; (*ii*) percentile of the comment in the list.

TASK_FEAT. We further have features that have been proven useful in the answer selection task from SemEval 2015 Task 3 (Nakov et al., 2015). This includes some comment-specific features, which refer to c_1 and c_2 only, but which we apply twice, to generate features for the pairs (q'_1, c_1), (q'_2, c_2), (q_1, c_1), and (q_2, c_2): number of URLs/images/emails/phone numbers; number of occurrences of the string *thank*;[6] number of tokens/sentences; average number of tokens; number of nouns/verbs/adjectives/adverbs/pronouns; number of positive/negative smileys; number of single/double/triple exclamation/ interrogation symbols; number of interrogative sentences (based on parsing); number of words that are not in word2vec's Google News vocabulary.[7]

And also some question-comment pair features, which we apply to the pairs (q'_1, c_1), (q'_2, c_2), (q_1, c_1), and (q_2, c_2): (*i*) question to comment count ratio in terms of sentences/tokens/nouns/verbs/adjectives/adverbs/pronouns; (*ii*) question to comment count ratio of words that are not in word2vec's Google News vocabulary.

5 Experiments and Results

We experimented with the data from SemEval-2016 Task 3 on "Community Question Answering". More precisely, the problem addressed is subtask C (*Question–External Comment Similarity*), which is the primary cQA task. For a given new question (referred to as the *original question*), the task provides the set of the first ten related questions (retrieved by a search engine), each associated with the first ten comments appearing in the question-comment thread. The goal then is to rank the total of 100 comments according to their appropriateness with respect to the original question.

In this framework, the retrieval part of the task is done as a pre-processing step, and the challenge is to learn to rank all *good* comments above all *bad* ones. All the data comes from the QatarLiving forum, and the related questions are obtained using Google search with the original question's text limited to the `www.qatarliving.com` domain.

[5]The related questions are obtained using a query to a search engine (using words from the original question), with results limited to QatarLiving. However, some of the returned results pointed to the wrong (non-forum) sections of the website or to questions with less than ten comments, and these were skipped. Suppose that the surviving top ten related questions were at ranks 3, 7, 18, ... in the original list. Now, we can use these ranks ρ, or we can use instead the ordinal ranks r: 1, 2, 3, ...

[6]When an author thanks somebody, this post is typically a bad answer to the original question.

[7]Can detect slang, foreign language, etc., which would indicate a bad answer.

The task offers a higher quality training dataset TRAIN-PART1, which includes 200 original questions, 1,999 related questions and 19,990 comments, and a lower-quality TRAIN-PART2, which we did not use. Additionally, it provides a development set (DEV, with 50 original questions, 500 related questions and 5,000 related comments) and a TEST set (70 original questions, 700 related questions and 7,000 related comments). Apart from the class labels for subtask C, the datasets also offer class labels for subtask A (i.e., whether a comment is a good answer to the question in the thread) and subtask B (i.e., whether the related questions is relevant for the original question).

5.1 Setting

we use Theano (Bergstra et al., 2010) to train our model on TRAIN-PART1 with hidden layers of size 3 for 100 epochs with minibatches of size 30, regularization of 0.05, and a learning rate of 0.01, using stochastic gradient descent with adagrad (Duchi et al., 2011). We normalize the input feature values to the $[-1; 1]$ interval using minmax, and we initialize the NN weights by sampling from a uniform distribution as in (Bengio and Glorot, 2010).

We evaluate the model on DEV after each epoch, and ultimately we keep the model that achieves the highest accuracy;[8] in case of a tie, we prefer the parameters from a later epoch. We selected the above parameter values on the DEV dataset using the full model, and we use them for all experiments in Section 5.3, where we evaluate on the TEST dataset.

Note that, we train the NN using all pairs of (Good, Bad) comments, in both orders, ignoring ties. At test time, we compute the full ranking of comments by scoring all possible pairs, and by then accumulating the scores at the comment level.

5.2 Evaluation and baselines

The results are calculated with the official scorer from the SemEval-2016 Task 3. We report three ranking-based measures that are commonly accepted in the IR community: Mean average precision (MAP), which is the official evaluation measure of the task, average recall (AvgRec), and mean reciprocal rank (MRR).

[8] We tried Kendall's Tau (τ), but it performed slightly worse.

For comparison purposes, we report the results for two baselines. One corresponds to a random ordering of the comments, assuming zero knowledge of the task. The second one is a more realistic baseline, which keeps the question ranking from the search engine (Google search) and the chronological order of the comments within the thread of teh related question. Although this may be considered a very naïve baseline, it is actually notably informed. The question ranking from Google search takes into account the relevance of the entire thread (question and comments) to the original question. Moreover, there is a natural concentration of the best answers in the first comments of the threads.

5.3 Main results

Table 1 shows the evaluation results on the TEST dataset for several variants of our pairwise neural network architecture. Regarding our network configurations, we present the results from simpler to more complex.

Relevance The "Relevance only" network contains only the *relevance* relations and features corresponding to q, c_1 and c_2. The rest of the components are deactivated in the network. This corresponds to solving the task without any information about the related questions and the appropriateness of the comments in their threads, i.e., just by comparing the texts of the comments and of the original question. In some sense, this setup is largely less informed than the IR baseline. The results are very low, being only $\sim$7 MAP points higher than the random baseline.

Relevance + appropriateness Adding the *appropriateness* interactions between c_1 and q'_1, and between c_2 and q'_2 improves MAP by $\sim$9 points. Although more informed, as some information from the related questions is taken indirectly, the results of this system are still below the IR baseline.

Relevance + relatedness Adding the *relatedness* interactions and features between q and q'_1, and q and q'_2, turns out to be crucial. When added to the "Relevance only" basic system, the MAP score jumps to 52.43, significantly above the IR baseline. This shows that *question–question* similarity plays an important role in solving the cQA task.

System	MAP	AvgRec	MRR
Relevance relations only	21.78	20.66	22.59
+ Appropriateness	30.94	29.86	35.02
+ Relatedness	52.43	57.05	60.14
Full Network	**54.51**	**60.93**	**62.94**
Baseline 1 (random)	15.01	11.44	15.19
Baseline 2 (IR+chron.)	40.36	45.97	45.83

Table 1: Results on the answer ranking task of our full NN vs. variants using partial information.

Full Network Adding both *appropriateness* and *relatedness* interactions yields an improvement of another two MAP points absolute (to 54.51), which shows that *appropriateness* features encode information that is complementary to the information modeled by *relevance* and *relatedness*. Note that the results with the other evaluation metrics (AvgRec and MRR) follow exactly the same pattern. In summary, we can conclude that in order to solve the community question answering problem, we need to (*i*) find the best related questions, and (*ii*) judge the relevance of individual comments with respect to the new question.

5.4 Features in perspective

Table 2 shows the results of an ablation study when removing some groups of features.[9] More specifically, we drop lexical similarities, domain-specific features, and the complex semantic-syntactic interactions modeled in the hidden layer between the embeddings and the domain-specific features.

We can see that the lexical similarity features (which we modeled by MT evaluation metrics), have a large impact: excluding them from the network yields a decrease of over eight MAP points. This can be explained as the strong dependence that *relatedness* has over strict word matching. Since questions are relatively short, a better related question will be one that matches better the original question.

[9]Note that here we only show the impact of *groups* of features, e.g., we do not consider experiments with different embeddings such as GOOGLE_VEC, QL_VEC, and SYNTAX_VEC, which all belong to the lexical similarity group of features. This is because in previous work (which was limited to subtask A), our ablation study has shown that all features in a group clearly contribute to the overall performance (Guzmán et al., 2016a; Guzmán et al., 2016b).

System	MAP	AvgRec	MRR	Δ_{MAP}
Full Network	**54.51**	**60.93**	**62.94**	
– Lexical similarity	45.89	51.54	53.29	-8.62
– Domain-specific	48.48	50.46	53.78	-6.03
– Distributed rep.	51.17	56.63	56.91	-3.34
No hidden layer	52.19	58.23	59.95	-2.32

Table 2: Results of the ablation study.

As expected, eliminating the domain-specific features also hurts the performance greatly: by six MAP points absolute. Eliminating the use of distributed representation has a lesser impact: 3.3 MAP points absolute. This is in line with our previous findings (Guzmán et al., 2015; Guzmán et al., 2016a; Guzmán et al., 2016b) that semantic and syntactic embeddings are useful to make a fine-grained distinction between comments (*relevance*, *appropriateness*), which are usually longer.

We have also found that there is an interaction between features and similarity relations. For example, for *relatedness*, lexical similarity is 2.6 MAP points more informative[10] than distributed representations. In contrast, for *relevance*, distributed representations are 0.7 MAP points more informative than lexical similarities.

5.5 Impact of the hidden layer

Table 2 also presents the results of a system that has the full set of features, but eliminates the hidden layer from the neural network. This is equivalent to training a Maximum Entropy classifier with the complete set of features. This simplified system performs consistently worse than the full NN model (-2.32 MAP, -2.7 AvgRec, and -2.99 MRR points), which shows that using the hidden layer to model the non-linear interactions between information sources has a decent overall contribution.

5.6 Making appropriateness more useful

Since the SemEval-2016 Task 3 datasets also provide labeled examples for the so called "subtask A" ($\overline{q'c}$; appropriateness) and "subtask B" ($\overline{qq'}$; relatedness), one could use this supervision to help train the neural network for the primary cQA task. We observed that *relatedness* has proven quite informative. However, the improvements observed from using *appropriateness* were more modest.

[10]As measured by the relative drop in MAP performance.

System	MAP	AvgRec	MRR
Full Network	54.51	60.93	62.94
Full + *appr.* preds.	**55.82**	**61.63**	**62.39**

Table 3: Using *appropriateness* predictions.

We present here a stacked experiment in which an additional neural network trained to predict *appropriateness* is used to inform the full network model. More concretely, we train a feed-forward pairwise neural network for subtask A, which is a simplification of the architecture from Figure 2. The input is reduced to three elements (q', c_1, c_2), where q' is the thread question and c_1 and c_2 are a pair of comments in the thread. The output consists of deciding whether c_1 is a better answer to q' than c_2. All the pairwise interactions between input components are included in the hidden layer, and we use the same features to train the network as the ones described in Section 4 (obviously, this time the input and the features are reduced to those involving q', c_1 and c_2). We used this exact setting in previous work for solving subtask A (Guzmán et al., 2016a; Guzmán et al., 2016b).

We used the network to classify all subtask A examples in TRAIN-PART1, DEV and TEST, and we used the resulting scores at the comment level as skip-arc features for the full NN model: (a) alone, included in $\psi(q'_1, c_1)$ and $\psi(q'_2, c_2)$, and (b) multiplied by each of the QQ′Rank_feat features, included in $\psi(q, c_1)$ and $\psi(q, c_2)$.

In Table 3, we observe that using the pre-trained network to incorporate subtask A predictions as features yields another sizable improvement to a final MAP of 55.82 (the increase is smaller for AvgRec, and MRR is slightly hurt), which suggests that pre-training parts of the NN with labeled examples to perform a dedicated task, is a promising direction for future work.

5.7 Results in perspective

Next, in order to put our results in perspective, we compare them to the state of the art for this problem, represented by the systems that participated in SemEval-2016 Task 3, subtask C. The comparison is shown in Table 4, where we list the top-3 systems, as well as the average and the worst scores for the official runs of all participating teams.

System	MAP	AvgRec	MRR
Full Network + subtask A preds.	**55.82**	**61.63**	62.39
* 1st (Mihaylova et al., 2016)	55.41	60.66	61.48
Full Network	54.51	60.93	**62.94**
* 2nd (Filice et al., 2016)	52.95	59.27	59.23
* 3rd (Mihaylov and Nakov, 2016b)	51.68	53.43	55.96
...	...	...	...
SemEval Average	49.30	53.74	54.39
...	...	...	...
SemEval Worst	43.20	47.96	47.79
Baseline 2 (IR+chron.)	40.36	45.97	45.83

Table 4: Comparative results with the state of the art, i.e., the top-3 systems that participated in SemEval-2016 Task 3, subtask C.

We can see that all systems in the competition performed over the IR baseline with MAP scores ranging from 43.20 to 55.41. We can further see that our full network with subtask A predictions achieves the best results with 55.82 MAP. The margin over the best SemEval system is small in terms of MAP but more noticeable in terms of AvgRec and MRR. Note that, even without the Subtask A predictions, our pairwise neural network still produces results that are on par with the state of the art (with improvements slightly over one point in both cases).

6 Related Work

Recently, a variety of neural network models have been applied to community question answering tasks such as *question-question similarity* (Zhou et al., 2015; dos Santos et al., 2015; Lei et al., 2015) and *answer selection* (Severyn and Moschitti, 2015; Wang and Nyberg, 2015; Feng et al., 2015; Tan et al., 2015; Filice et al., 2016; Barrón-Cedeño et al., 2016; Mohtarami et al., 2016). Most of these papers concentrate on constructing advanced neural network architectures in order to model the problem at hand better.

For instance, dos Santos et al. (2015) propose a neural network approach combining a convolutional neural network and a bag-of-words representation for modeling question-question similarity. Similarly, Tan et al. (2015) adopt a neural attention mechanism over bidirectional long short-term memory (LSTM) neural network to generate better answer representations given the questions.

Similarly, Lei et al. (2015) use a combination of recurrent and convolutional neural models to map questions to semantic representations. The models are pre-trained within an encoder-decoder framework (from body to title) in order to de-noise the long question body from irrelevant text.

The main objective of our work here is different: we focus on studying the impact of the different input components in a novel cQA setting of ranking answers for new questions, and we use a more standard neural network.

The setting of cQA as a triangle of three interrelated subtasks, which we use here, has been recently proposed in SemEval-2016 Task 3 on *Community Question Answering* (Nakov et al., 2016). Above, we empirically compared our results to those of the best participating systems. Unfortunately, most of the systems that took part in the competition, including the winning system of the SUper team (Mihaylova et al., 2016), approached the task indirectly by solving subtask A at the thread level and then using these predictions together with the reciprocal rank of the related questions to produce a final ranking for subtask C.

One exception is the *Kelp* system (Filice et al., 2016), which was ranked second in the competition. Their approach is most similar to ours, as it also tries to combine information from different subtasks and from all input components. It does so in a modular kernel function, including stacking from independent subtask A and B classifiers, and it applies SVMs to train a Good vs. Bad classifier (Filice et al., 2016). In contrast, our approach here proceeds in a pairwise setting, it is lighter in terms of features engineering, and presents a direct way to combine the relations between the different subtasks in an integrated neural network model.

Finally, our model uses lexical features derived from machine translation evaluation. Some previous work also used MT model(s) as a feature(s) (Berger et al., 2000; Echihabi and Marcu, 2003; Jeon et al., 2005; Soricut and Brill, 2006; Riezler et al., 2007; Li and Manandhar, 2011; Surdeanu et al., 2011; Tran et al., 2015; Hoogeveen et al., 2016; Wu and Zhang, 2016), e.g., a variation of IBM model 1 (Brown et al., 1993), to compute the probability that the question is a "translation" of the candidate answer.

7 Conclusion

We presented a neural-based approach to a novel problem in cQA, where given a new question, the task is to rank comments from related question-threads according to their relevance as answers to the original question. We explored the utility of three types of similarities between the original question, the related question, and the related comment.

We adopted a pairwise feed-forward neural network architecture, which takes as input the original question and two comments together with their corresponding related questions. This allowed us to study the impact and the interaction effects of the question-question *relatedness* and comment-to-related question *appropriateness* relations when solving the primary cQA *relevance* task. The large performance gains obtained from using *relatedness* features show that question-question similarity plays a crucial role in finding relevant comments (+30 MAP points). Yet, including *appropriateness* relations is needed to achieve state-of-the-art results (+3.3 MAP) on benchmark datasets.

We also studied the impact of several types of features, especially domain-specific features, but also lexical features and syntactic embeddings. We observed that lexical similarity MTE features prove the most important, followed by domain-specific features, and syntactic and semantic embeddings. Overall, they all showed to be necessary to achieve state-of-the-art results.

In future work, we plan to use the labels for subtasks A and B, which are provided in the datasets in order to pre-train the corresponding components of the full network for answer ranking. We further want to apply a similar network to other semantic similarity problems, such as textual entailment.

Acknowledgments

This research was performed by the Arabic Language Technologies (ALT) group at the Qatar Computing Research Institute (QCRI), HBKU, part of Qatar Foundation. It is part of the Interactive sYstems for Answer Search (Iyas) project, which is developed in collaboration with MIT-CSAIL.

Last but not least, we would also like to thank the anonymous reviewers for their constructive comments, which have helped us improve the paper.

Character-Level Question Answering with Attention

David Golub

Abstract

We show that a character-level encoder-decoder framework can be successfully applied to question answering with a structured knowledge base. We use our model for single-relation question answering and demonstrate the effectiveness of our approach on the SimpleQuestions dataset (Bordes et al., 2015), where we improve state-of-the-art accuracy from 63.9% to 70.9%, without use of ensembles. Importantly, our character-level model has 16x fewer parameters than an equivalent word-level model, can be learned with significantly less data compared to previous work, which relies on data augmentation, and is robust to new entities in testing. [1]

1 Introduction

Single-relation factoid questions are the most common form of questions found in search query logs and community question answering websites (Yih et al., 2014; Fader et al., 2013). A knowledge-base (KB) such as Freebase, DBpedia, or Wikidata can help answer such questions after users reformulate them as queries. For instance, the question "Where was Barack Obama born?" can be answered by issuing the following KB query:

$$\lambda(x).place\_of\_birth(Barack\_Obama, x)$$

However, automatically mapping a natural language question such as "Where was Barack Obama born?" to its corresponding KB query remains a challenging task.

There are three key issues that make learning this mapping non-trivial. First, there are many paraphrases of the same question. Second, many of the KB entries are unseen during training time; however, we still need to correctly predict them at test time. Third, a KB such as Freebase typically contains millions of entities and thousands of predicates, making it difficult for a system to predict these entities at scale (Yih et al., 2014; Fader et al., 2014; Bordes et al., 2015). In this paper, we address all three of these issues with a character-level encoder-decoder framework that significantly improves performance over state-of-the-art word-level neural models, while also providing a much more compact model that can be learned from less data.

First, we use a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) encoder to embed the question. Second, to make our model robust to unseen KB entries, we extract embeddings for questions, predicates and entities purely from their character-level representations. Character-level modeling has been previously shown to generalize well to new words not seen during training (Ljubešić et al., 2014; Chung et al., 2016), which makes it ideal for this task. Third, to scale our model to handle the millions of entities and thousands of predicates in the KB, instead of using a large output layer in the decoder to directly predict the entity and predicate, we use a general interaction function between the question embeddings and KB embeddings that measures their semantic relevance to determine the output. The combined use of character-

Austin, Texas, November 1-5, 2016.

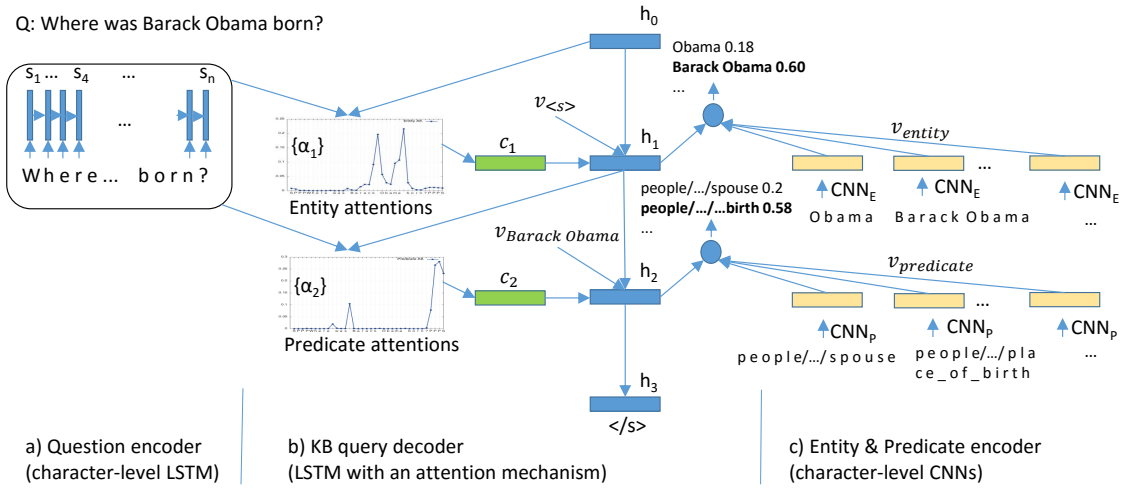

Figure 1: Our encoder-decoder architecture that generates a query against a structured knowledge base. We encode our question via a long short-term memory (LSTM) network and an attention mechanism to produce our context vector. During decoding, at each time step, we feed the current context vector and an embedding of the English alias of the previously generated knowledge base entry into an attention-based decoding LSTM to generate the new candidate entity or predicate.

level modeling and a semantic relevance function allows us to successfully produce likelihood scores for the KB entries that are not present in our vocabulary, a challenging task for standard encoder-decoder frameworks.

Our novel, character-level encoder-decoder model is compact, requires significantly less data to train than previous work, and is able to generalize well to unseen entities in test time. In particular, without use of ensembles, we achieve 70.9% accuracy in the Freebase2M setting and 70.3% accuracy in the Freebase5M setting on the SimpleQuestions dataset, outperforming the previous state-of-arts of 62.7% and 63.9% (Bordes et al., 2015) by 8.2% and 6.4% respectively. Moreover, we only use the training questions provided in SimpleQuestions to train our model, which cover about 24% of words in entity aliases on the test set. This demonstrates the robustness of the character-level model to unseen entities. In contrast, data augmentation is usually necessary to provide more coverage for unseen entities and predicates, as done in previous work (Bordes et al., 2015; Yih et al., 2014).

2 Related Work

Our work is motivated by three major threads of research in machine learning and natural language processing: semantic-parsing for open-domain question answering, character-level language modeling, and encoder-decoder methods.

Semantic parsing for open-domain question answering, which translates a question into a structured KB query, is a key component in question answering with a KB. While early approaches relied on building high-quality lexicons for domain-specific databases such as GeoQuery (Tang and Mooney, 2001), recent work has focused on building semantic parsing frameworks for general knowledge bases such as Freebase (Yih et al., 2014; Bordes et al., 2014a; Bordes et al., 2015; Berant and Liang, 2014; Fader et al., 2013; Dai et al., 2016).

Semantic parsing frameworks for large-scale knowledge bases have to be able to successfully generate queries for the millions of entities and thousands of predicates in the KB, many of which are unseen during training. To address this issue, recent work relies on producing embeddings for predicates and entities in a KB based on their textual descriptions (Bordes et al., 2014a; Bordes et al., 2015; Yih et al., 2014; Yih et al., 2015; Bishan Yang, 2015). A general interaction function can then be used to measure the semantic relevance of these embedded KB entries to the question and determine the most likely KB query.

Most of these approaches use word-level embeddings to encode entities and predicates, and therefore might suffer from the out-of-vocabulary (OOV) problem when they encounter unseen words during test time. Consequently, they often rely on significant data augmentation from sources such as Paralex (Fader et al., 2013), which contains 18 million question-paraphrase pairs scraped from WikiAnswers, to have sufficient examples for each word they encounter (Bordes et al., 2014b; Yih et al., 2014; Bordes et al., 2015).

As opposed to word-level modeling, character-level modeling can be used to handle the OOV issue. While character-level modeling has not been applied to factoid question answering before, it has been successfully applied to information retrieval, machine translation, sentiment analysis, classification, and named entity recognition (Huang et al., 2013; Shen et al., 2014; Chung et al., 2016; Zhang et al., 2015; Santos and Zadrozny, 2014; dos Santos and Gatti, 2014; Klein et al., 2003; dos Santos, 2014; dos Santos et al., 2015). Moreover, Chung et al. (2015) demonstrate that gated-feedback LSTMs on top of character-level embeddings can capture long-term dependencies in language modeling.

Lastly, encoder-decoder networks have been applied to many structured machine learning tasks. First introduced in Sutskever et al. (2014), in an encoder-decoder network, a source sequence is first encoded with a recurrent neural network (RNN) into a fixed-length vector which intuitively captures its "meaning", and then decoded into a desired target sequence. This approach and related memory-based or attention-based approaches have been successfully applied in diverse domains such as speech recognition, machine translation, image captioning, parsing, executing programs, and conversational dialogues (Amodei et al., 2015; Venugopalan et al., 2015; Bahdanau et al., 2015; Vinyals et al., 2015; Zaremba and Sutskever, 2014; Xu et al., 2015; Sukhbaatar et al., 2015).

Unlike previous work, we formulate question answering as a problem of decoding the KB query given the question and KB entries which are encoded in embedding spaces. We therefore integrate the learning of question and KB embeddings in a unified encoder-decoder framework, where the whole system is optimized end-to-end.

3 Model

Since we focus on single-relation question answering in this work, our model decodes every question into a KB query that consists of exactly two elements–the topic entity, and the predicate. More formally, our model is a function $f(q, \{e\}, \{p\})$ that takes as input a question q, a set of candidate entities $\{e\} = e_1, ..., e_n$, a set of candidate predicates $\{p\} = p_1, ..., p_m$, and produces a likelihood score $p(e_i, p_j|q)$ of generating entity e_i and predicate p_j given question q for all $i \in 1...n, j \in 1...m$.

As illustrated in Figure 1, our model consists of three components:

1. A character-level LSTM-based encoder for the question which produces a sequence of embedding vectors, one for each character (Figure 1a).

2. A character-level convolutional neural network (CNN)-based encoder for the predicates/entities in a knowledge base which produces a single embedding vector for each predicate or entity (Figure 1c).

3. An LSTM-based decoder with an attention mechanism and a relevance function for generating the topic entity and predicate to form the KB query (Figure 1b).

The details of each component are described in the following sections.

3.1 Encoding the Question

To encode the question, we take two steps:

1. We first extract one-hot encoding vectors for characters in the question, $x_1, ..., x_n$, where x_i represents the one-hot encoding vector for the i^{th} character in the question. We keep the space, punctuation and original cases without tokenization.

2. We feed $x_1, ..., x_n$ from left to right into a two-layer gated-feedback LSTM, and keep the outputs at all time steps as the embeddings for the question, i.e., these are the vectors $s_1, ..., s_n$.

3.2 Encoding Entities and Predicates in the KB

To encode an entity or predicate in the KB, we take two steps:

1. We first extract one-hot encoding vectors for characters in its English alias, $x_1, ..., x_n$, where x_i represents the one-hot encoding vector for the i^{th} character in the alias.

2. We then feed $x_1, ..., x_n$ into a temporal CNN with two alternating convolutional and fully-connected layers, followed by one fully-connected layer:

$$f(x_1, ..., x_n) = tanh(W_3 \times max(tanh(W_2 \times conv(tanh(W_1 \times conv(x_1, ..., x_n))))))$$

where $f(x_{1...n})$ is an embedding vector of size N, W_3 has size $R^{N \times h}$, $conv$ represents a temporal convolutional neural network, and max represents a max pooling layer in the temporal direction.

We use a CNN as opposed to an LSTM to embed KB entries primarily for computational efficiency. Also, we use two different CNNs to encode entities and predicates because they typically have significantly different styles (e.g., "Barack Obama" vs. "/people/person/place_of_birth").

3.3 Decoding the KB Query

To generate the single topic entity and predicate to form the KB query, we use a decoder with two key components:

1. An LSTM-based decoder with attention. Its hidden states at each time step i, h_i, have the same dimensionality N as the embeddings of entities/predicates. The initial hidden state h_0 is set to the zero vector: $\vec{0}$.

2. A pairwise semantic relevance function that measures the similarity between the hidden units of the LSTM and the embedding of an entity or predicate candidate. It then returns the mostly likely entity or predicate based on the similarity score.

In the following two sections, we will first describe the LSTM decoder with attention, followed by the semantic relevance function.

3.3.1 LSTM-based Decoder with Attention

The attention-based LSTM decoder uses a similar architecture as the one described in Bahdanau et al. (2015). At each time step i, we feed in a context vector c_i and an input vector v_i into the LSTM. At time $i = 1$ we feed a special input vector $v_{<S>} = \vec{0}$ into the LSTM. At time $i = 2$, during training, the input vector is the embedding of the true entity, while during testing, it is the embedding of the most likely entity as determined at the previous time step.

We now describe how we produce the context vector c_i. Let h_{i-1} be the hidden state of the LSTM at time $i-1$, s_j be the j^{th} question character embedding, n be the number of characters in the question, r be the size of s_j, and m be a hyperparameter. Then the context vector c_i, which represents the attention-weighted content of the question, is recomputed at each time step i as follows:

$$c_i = \sum_{j=1}^{n} \alpha_{ij} s_j,$$

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{T_x} \exp(e_{ik})}$$

$$e_{ij} = v_a^\top \tanh\left(W_a h_{i-1} + U_a s_j\right),$$

where $\{\alpha\}$ is the attention distribution that is applied over each hidden unit s_j, $W_a \in R^{m \times N}, U_a \in R^{m \times r}$, and $v_a \in R^{1 \times m}$.

3.3.2 Semantic Relevance Function

Unlike machine translation and language modeling where the vocabulary is relatively small, there are millions of entries in the KB. If we try to directly predict the KB entries, the decoder will need an output layer with millions of nodes, which is computationally prohibitive. Therefore, we resort to a relevance function that measures the semantic similarity between the decoder's hidden state and the embeddings of KB entries. Our semantic relevance function takes two vectors x_1, x_2 and returns a distance measure of how similar they are to each other. In current experiments we use a simple cosine-similarity metric: $cos(x_1, x_2)$.

Using this similarity metric, the likelihoods of generating entity e_j and predicate p_k are:

RESULTS ON SIMPLEQUESTIONS DATASET

Table 1: Experimental results on the SimpleQuestions dataset. MemNN results are from Bordes et al. (2015). WQ, SIQ and PRP stand for WebQuestions, SimpleQuestions and paraphrases from WikiAnswers.

$$P(e_j) = \frac{exp(\lambda cos(h_1, e_j))}{\sum_{i=1}^{n} exp(\lambda cos(h_1, e_i))}$$
$$P(p_k) = \frac{exp(\lambda cos(h_2, p_k))}{\sum_{i=1}^{m} exp(\lambda cos(h_2, p_i))}$$

where λ is a constant, h_1, h_2 are the hidden states of the LSTM at times $t = 1$ and $t = 2$, $e_1, ..., e_n$ are the entity embeddings, and $p_1, ..., p_m$ are the predicate embeddings. A similar likelihood function was used to train the semantic similarity modules proposed in Yih et al. (2014) and Yih et al. (2015), Palangi et al. (2016), Huang et al. (2013).

During inference, $e_1, ..., e_n$ and $p_1, ..., p_m$ are the embeddings of candidate entities and predicates. During training $e_1, ..., e_n$, $p_1, ..., p_m$ are the embeddings of the true entity and 50 randomly-sampled entities, and the true predicate and 50 randomly-sampled predicates, respectively.

3.4 Inference

For each question q, we generate a candidate set of entities and predicates, $\{e\}$ and $\{p\}$, and feed it through the model $f(q, \{e\}, \{p\})$. We then decode the most likely (entity, predicate) pair:

$$(e^*, p^*) = argmax_{e_i, p_j}(P(e_i) * P(p_j))$$

which becomes our semantic parse.

We use a similar procedure as the one described in Bordes et al. (2015) to generate candidate entities $\{e\}$ and predicates $\{p\}$. Namely, we take all entities whose English alias is a substring of the question, and remove all entities whose alias is a substring of another entity. For each English alias, we sort each entity with this alias by the number of facts that it has in the KB, and append the top 10 entities from this list to our set of candidate entities. All predicates p_j for each entity in our candidate entity set become the set of candidate predicates.

3.5 Learning

Our goal in learning is to maximize the joint likelihood $P(e_c) \cdot P(p_c)$ of predicting the correct entity e_c and predicate p_c pair from a set of randomly sampled entities and predicates. We use back-propagation to learn all of the weights in our model.

All the parameters of our model are learned jointly without pre-training. These parameters include the weights of the character-level embeddings, CNNs, and LSTMs. Weights are randomly initialized before training. For the i^{th} layer in our network, each weight is sampled from a uniform distribution between $-\frac{1}{|l^i|}$ and $\frac{1}{|l^i|}$, where $|l^i|$ is the number of weights in layer i.

4 Dataset and Experimental Settings

We evaluate the proposed model on the SimpleQuestions dataset (Bordes et al., 2015). The dataset consists of 108,442 single-relation questions and their corresponding (*topic entity*, *predicate*, *answer entity*) triples from Freebase. It is split into 75,910 train, 10,845 validation, and 21,687 test questions. Only 10,843 of the 45,335 unique words in entity aliases and 886 out of 1,034 unique predicates in the test set were present in the train set. For the proposed dataset, there are two evaluation settings, called FB2M and FB5M, respectively. The former uses a KB for candidate generation which is a sub-

set of Freebase and contains 2M entities, while the latter uses subset of Freebase with 5M entities.

In our experiments, the Memory Neural Networks (MemNNs) proposed in Bordes et al. (2015) serve as the baselines. For training, in addition to the 76K questions in the training set, the MemNNs use 3K training questions from WebQuestions (Berant et al., 2013), 15M paraphrases from WikiAnswers (Fader et al., 2013), and 11M and 12M automatically generated questions from the KB for the FB2M and FB5M settings, respectively. In contrast, our models are trained only on the 76K questions in the training set.

For our model, both layers of the LSTM-based question encoder have size 200. The hidden layers of the LSTM-based decoder have size 100, and the CNNs for entity and predicate embeddings have a hidden layer of size 200 and an output layer of size 100. The CNNs for entity and predicate embeddings use a receptive field of size 4, $\lambda = 5$, and $m = 100$. We train the models using RMSProp with a learning rate of $1e^{-4}$.

In order to make the input character sequence long enough to fill up the receptive fields of multiple CNN layers, we pad each predicate or entity using three padding symbols P, a special start symbol, and a special end symbol. For instance, $Obama$ would become $S_{start}PPPObamaPPPS_{end}$. For consistency, we apply the same padding to the questions.

5 Results

5.1 End-to-end Results on SimpleQuestions

Following Bordes et al. (2015), we report results on the SimpleQuestions dataset in terms of SQ accuracy, for both FB2M and FB5M settings in Table 1. SQ accuracy is defined as the percentage of questions for which the model generates a correct KB query (i.e., both the topic entity and predicate are correct). Our single character-level model achieves SQ accuracies of 70.9% and 70.3% on the FB2M and FB5M settings, outperforming the previous state-of-art results by 8.2% and 6.4%, respectively. Compared to the character-level model, which only has 1.2M parameters, our word-level model has 19.9M parameters, and only achieves a best SQ accuracy of 53.9%. In addition, in contrast to previous work, the OOV issue is much more severe for our word-level model, since we use no data augmentation to cover entities unseen in the train set.

5.2 Ablation and Embedding Experiments

We carry out ablation studies in Sections 5.2.1 and 5.2.2 through a set of *random-sampling* experiments. In these experiments, for each question, we randomly sample 200 entities and predicates from the test set as noise samples. We then mix the gold entity and predicate into these negative samples, and evaluate the accuracy of our model in predicting the gold predicate or entity from this mixed set.

5.2.1 Character-Level vs. Word-Level Models

We first explore using word-level models as an alternative to character-level models to construct embeddings for questions, entities and predicates.

Both word-level and character-level models perform comparably well when predicting the predicate, reaching an accuracy of around 80% (Table 3). However, the word-level model has considerable difficulty generalizing to unseen entities, and is only able to predict 45% of the entities accurately from the mixed set. These results clearly demonstrate that the OOV issue is much more severe for entities than predicates, and the difficulty word-level models have when generalizing to new entities.

In contrast, character-level models have no such issues, and achieve a 96.6% accuracy in predicting the correct entity on the mixed set. This demonstrates that character-level models encode the semantic representation of entities and can match entity aliases in a KB with their mentions in natural language questions.

5.2.2 Depth Ablation Study

We also study the impact of the depth of neural networks in our model. The results are presented in Table 2. In the ablation experiments we compare the performance of a single-layer LSTM to a two-layer LSTM to encode the question, and a single-layer vs. two-layer CNN to encode the KB entries. We find that a two-layer LSTM boosts joint accuracy by over 6%. The majority of accuracy gains are a result of improved predicate predictions, possibly because entity accuracy is already saturated in this experimental setup.

# of LSTM Layers	# of CNN Layers	Joint Accuracy	Predicate Accuracy	Entity Accuracy
2	2	**78.3**	**80.0**	96.6
2	1	77.7	79.4	**96.8**
1	2	71.5	73.9	95.0
1	1	72.2	74.7	94.9

Table 2: Results for a random sampling experiment where we varied the number of layers used for convolutions and the question-encoding LSTM. We terminated training models after 14 epochs and 3 days on a GPU.

Embedding Type	Joint Accuracy	Predicate Accuracy	Entity Accuracy
Character	**78.3**	**80.0**	**96.6**
Word	37.6	78.8	45.5

Table 3: Results for a random sampling experiment where we varied the embedding type (word vs. character-level). We used 2 layered-LSTMs and CNNs for all our experiments. Our models were trained for 14 epochs and 3 days.

5.3 Attention Mechanisms

In order to further understand how the model performs question answering, we visualize the attention distribution over question characters in the decoding process. In each sub-figure of Figure 2, the x-axis is the character sequence of the question, and the y-axis is the attention weight distribution $\{\alpha_i\}$. The blue curve is the attention distribution when generating the entity, and green curve is the attention distribution when generating the predicate.

Interestingly, as the examples show, the attention distribution typically peaks at empty spaces. This indicates that the character-level model learns that a space defines an ending point of a complete linguistic unit. That is, the hidden state of the LSTM encoder at a space likely summarizes content about the character sequence before that space, and therefore contains important semantic information that the decoder needs to attend to.

Also, we observe that entity attention distributions are usually less sharp and span longer portions of words, such as "john" or "rutters", than predicate attention distributions (e.g., Figure 2a). For entities, semantic information may accumulate gradually when seeing more and more characters, while for predicates, semantic information will become clear only after seeing the complete word. For example, it may only be clear that characters such as "song by" refer to a predicate after a space, as opposed to the name of a song such as "song bye bye love" (Figures 2a, 2b). In contrast, a sequence of characters starts to become a likely entity after seeing an incomplete name such as "joh" or "rutt".

In addition, a character-level model can identify entities whose English aliases were never seen in training, such as "phrenology" (Figure 2d). The model apparently learns that words ending with the suffix "nology" are likely entity mentions, which is interesting because it reads in the input one character at a time.

Furthermore, as observed in Figure 2d, the attention model is capable of attending disjoint regions of the question and capture the mention of a predicate that is interrupted by entity mentions. We also note that predicate attention often peaks at the padding symbols after the last character of the question, possibly because sentence endings carry extra information that further help disambiguate predicate mentions. In certain scenarios, the network may only have sufficient information to build a semantic representation of the predicate after being ensured that it reached the end of a sentence.

Finally, certain words in the question help identify both the entity and the predicate. For example, consider the word "university" in the question "What type of educational institution is eastern new mexico university" (Figure 2c). Although it is a part of the entity mention, it also helps disambiguate the predicate. However, previous semantic parsing-based QA approaches (Yih et al., 2015; Yih et al., 2014) assume that there is a clear separation between predicate and entity mentions in the question. In contrast, the proposed model does not need to make this hard categorization, and attends the word "university" when predicting both the entity and predicate.

6 Error Analysis

We randomly sampled 50 questions where the best-performing model generated the wrong KB query and categorized the errors. For 46 out of the 50 examples, the model predicted a predicate with a very similar alias to the true predicate, i.e. "/music/release/track" vs. "/music/release/track_list". For 21 out of the 50 examples, the model predicted the wrong entity, e.g., "Album" vs. "Still Here" for the question "What type of album is still here?". Finally, for 18 of the 50 examples, the model predicted the wrong entity and predicate, i.e. ("Play", "/freebase/equivalent_topic/equivalent_type") for the question "which instrument does amapola cabase play?" Training on more data, augmenting the negative sample set with words from the question that are not an entity mention, and having more examples that disambiguate between similar predicates may ameliorate many of these errors.

7 Conclusion

In this paper, we proposed a new character-level, attention-based encoder-decoder model for question answering. In our approach, embeddings of questions, entities, and predicates are all jointly learned to directly optimize the likelihood of generating the correct KB query. Our approach improved the state-of-the-art accuracy on the SimpleQuestions benchmark significantly, using much less data than previous work. Furthermore, thanks to character-level modeling, we have a compact model that is robust to unseen entities. Visualizations of the attention distribution reveal that our model, although built on character-level inputs, can learn higher-level semantic concepts required to answer a natural language question with a structured KB. In the future we want extend our system to multi-relation questions.

Abstract

To learn text understanding models with millions of parameters one needs massive amounts of data. In this work, we argue that generating data can compensate for this need. While defining generic data generators is difficult, we propose to allow generators to be "weakly" specified in the sense that a set of parameters controls how the data is generated. Consider for example generators where the example templates, grammar, and/or vocabulary is determined by this set of parameters. Instead of manually tuning these parameters, we learn them from the limited training data at our disposal. To achieve this, we derive an efficient algorithm called GENERE that jointly estimates the parameters of the model and the undetermined generation parameters. We illustrate its benefits by learning to solve math exam questions using a highly parametrized sequence-to-sequence neural network.

1 Introduction

Many tasks require a large amount of training data to be solved efficiently, but acquiring such amounts is costly, both in terms of time and money. In several situations, a human trainer can provide their domain knowledge in the form of a generator of virtual data, such as a negative data sampler for implicit feedback in recommendation systems, physical 3D rendering engines as a simulator of data in a computer vision system, simulators of physical processes to solve science exam question, and math problem generators for automatically solving math word problems.

Domain-specific data simulators can generate an arbitrary amount of data that can be treated exactly the same way as standard observations, but since they are virtual, they can also be seen as regularizers dedicated to the task we want to solve (Scholkopf and Smola, 2001). While simple, the idea of data simulation is powerful and can lead to significantly better estimations of a predictive model because it prevents overfitting. At the same time it is subject to a strong model bias, because such data generators often generate data that is different from the observed data.

Creating virtual samples is strongly linked to transfer learning when the task to transfer is correlated to the objective (Pan and Yang, 2010). The computer vision literature adopted this idea very early through the notion of *virtual samples*. Such samples have a natural interpretation: by creating artificial perturbations of an image, its semantics is likely to be unchanged, i.e. training samples can be rotated, blurred, or slightly cropped without changing the category of the objects contained in the image (Niyogi et al., 1998).

However, for natural language applications the idea of creating invariant transformations is difficult to apply directly, as simple meaning-preserving transformations – such as the replacement of words by their synonyms or active-passive verb transformations – are quite limited. More advanced meaning-preserving transformations would require an already good model that understands natural language. A more structure-driven approach is to build top-down generators, such as probabilistic grammars, with a much wider coverage of linguistic phe-

nomena. This way of being able to leverage many years of research in computational linguistics to create good data generators would be a natural and useful reuse of scientific knowledge, and better than blindly believing in the current trend of "data takes all".

While the idea of generating data is straightforward, one could argue that it may be difficult to come up with good generators. What we mean by a good generator is the ability to help predicting test data when the model is trained on the generated data. In this paper, we will show several types of generators, some contributing more than others in their ability to generalize to unseen data. When designing a good generator there are several decisions one must make: should we generate data by modifying existing training samples, or "go wild" and derive a full probabilistic context-free grammar that could possibly generate unnatural examples and add noise to the estimator? While we do not arrive at a specific framework to build programs that generate virtual data, in this work we assume that a domain expert can easily write a program in a programming language of her choice, leaving some generation parameters unspecified. In our approach these unspecified parameters are automatically learned, by selecting the ones most compatible with the model and the training data.

In the next section, we introduce GENERE, a generic algorithm that extends any gradient-based learning approach with a data generator that can be tuned while learning the model on the training data using stochastic optimization. In Section 2.2, we show how GENERE can be adapted to handle a (possibly non-differentiable) black-box sampler without requiring modifications to it. We also illustrate how this framework can be implemented in practice for a specific use case: the automatic solving of math exam problems. Further discussion is given in the concluding section.

2 Regularization Based on a Generative Model

As with any machine learning approach, we assume that given the realisation of a variable $x \in \mathcal{X}$ representing the input, we want to predict the distribution of a variable $y \in \mathcal{Y}$ representing the output. The goal is to find this predictive distribution by learning it from examples $\mathcal{D} := \{(x_i, y_i)\}_{i=1}^n$.

Building on the current success in the application of deep learning to NLP, we assume that there exists a good model family $\{f_\theta, \theta \in \Theta\}$ to predict y given x, where θ is an element of the parameter space Θ. For example, the stacked LSTM encoder-decoder is a general purpose model that has helped to improve results on relatively complex tasks, such as machine translation (Sutskever et al., 2014), syntactic parsing (Vinyals et al., 2014), semantic parsing (Dong and Lapata, 2016) and textual entailment (Rocktäschel et al., 2016).

For many applications, the amount of training data is too small or too costly to acquire. We hence look for alternative ways to regularize the model so that we can achieve good performance using few data points.

Let $p_\theta(y|x)$ be the target prediction model. Given the training dataset $\mathcal{D}$, the penalized maximum likelihood estimator is obtained by $\min_{\theta\in\Theta} \mathcal{L}(\theta)$ where:

$$\mathcal{L}(\theta) := \ell(\theta) + \lambda\Omega(\theta) \ . \tag{1}$$

where $\ell(\theta) := -\frac{1}{n}\sum_{i=1}^n \log p_\theta(y_i|x_i) = \mathbb{E}_{\hat{P}}[\log p_\theta(y|x)]$ is the negative log-likelihood. Here, $\Omega(\theta)$ is a regularizer that prevents over-fitting, $\lambda \in \mathbb{R}$ the regularization parameter that can be set by cross-validation, and $\hat{P}$ is the empirical distribution. Instead of using a standard regularizer Ω – such as the squared norm or the Lasso penalty which are domain-agnostic, – in this paper we propose to use a generative model to regularize the estimator.

Domain knowledge A natural way to inject background knowledge is to define a generative model that simulates the way the data is generated. In text understanding applications, such generative models are common and include probabilistic context-free grammars (PCFG) and natural language generation frameworks (e.g. SimpleNLG (Gatt and Reiter, 2009)). Let $P_\gamma(x, y)$ be such a generative model parametrized by a continuous parameter vector $\gamma \in \Gamma$, such as the concatenation of all the parameters of the production rules in a PCFG. One important difference between the discriminative and the generative probability distributions is that the in-

ference problem of y given x might be intractable[1] for the generative model, even if the joint model can be computed efficiently.

In this work, we use the following regularizer:

$$\Omega(\theta) \quad := \quad \min_{\gamma \in \Gamma} \mathbb{E}_{P_\gamma(x,y)} \left[\log \left(\frac{P_\gamma(y|x)}{p_\theta(y|x)} \right) \right] \quad . (2)$$

This regularizer makes intuitive sense as it corresponds to the smallest possible Kullback-Leibler divergence between the generative and discriminative models. We can see that if the generator p_γ is close to the distribution that generates the test data, the method can potentially yield good performance. However, in practice, γ is unknown and difficult to set. In this work, we focus on several techniques that can be used to estimate the generative parameter vector γ on the training data, making the regularizer data-dependent.

Minimizing the objective from Equation (1) is equivalent to minimize the following function over $\Theta \times \Gamma$:

$$\mathcal{L}(\theta, \gamma) \quad := \quad \ell(\theta) + \lambda \mathbb{E}_{P_\gamma(x,y)} \left[\log \left(\frac{p_\gamma(y|x)}{p_\theta(y|x)} \right) \right] \quad .$$

This estimator is called GENERE for *Generative Regularization* and can be viewed as a Generative-Discriminative Tradeoff estimator (GDT (Bouchard and Triggs, 2004)) that smoothly interpolates between a purely un-regularized discriminative model when $\lambda = 0$ and a generative model when λ tends to infinity.

2.1 The GENERE Algorithm

The objective $\mathcal{L}(\theta, \gamma)$ can also be written as an expectation under a mixture distribution $\tilde{P}_\gamma := \frac{1}{1+\lambda}\hat{P} + \frac{\lambda}{1+\lambda}P_\gamma$. The two components of this mixture are the empirical data distribution $\hat{P}$ and the generation distribution P_γ. The final objective is penalized by the entropy of the the generation $\mathcal{H}(\gamma) := \mathbb{E}_{P_\gamma}[\log p_\gamma(y|x)]$:

$$\mathcal{L}(\theta, \gamma) = -(1+\lambda)\mathbb{E}_{\tilde{P}_\gamma}[\log p_\theta(y|x)] - \lambda \mathcal{H}(\gamma) \quad . \quad (3)$$

This objective can be minimized using stochastic gradient descent by sampling real data or generated data according to the proportions $\frac{1}{1+\lambda}$ and $\frac{\lambda}{1+\lambda}$, respectively. The pseudocode is provided in Algorithm 1. It can be viewed as a variant of the REINFORCE algorithm which is commonly used in Reinforcement Learning (Williams, 1988) using the policy gradient. It is straightforward to verify that at each iteration, GENERE computes a noisy estimate of the exact gradient of the objective function $\mathcal{L}(\theta, \gamma)$ with respect to the model parameters θ and the generation parameters[2] γ.

An important quantity introduced in Algorithm 1 is the baseline value μ that approximates the average log-likelihood of a point sampled according to $\tilde{P}_\gamma$. Since it is unknown in general, an average estimate is obtained using a geometric averaging scheme with a coefficient α that is typically set to 0.98.

Algorithm 1 The GENERE Algorithm

Require: $\hat{P}$: real data sampler
Require: P_γ: parametric data generator
Require: λ: generative regularization strength
Require: η: learning rate
Require: α: baseline smoothing coefficient
1: Initialize parameters θ, sampling coefficients γ and baseline μ
2: **for** $t = 1, 2, \cdots$ **do**
3: $\quad x, y \sim \frac{1}{1+\lambda}\hat{P} + \frac{\lambda}{1+\lambda}P_\gamma$
4: $\quad g_\theta \leftarrow \nabla_\theta \log p_\theta(y|x)$
5: $\quad g_\gamma \leftarrow (\log p_\theta(y|x) - \mu) \nabla_\gamma \log p_\gamma(x, y)$
6: $\quad (\theta, \gamma) \leftarrow (\theta, \gamma) - \eta(g_\theta, g_\gamma)$
7: $\quad \mu \leftarrow \alpha\mu + (1-\alpha) \log p_\theta(y|x)$
8: **end for**

Generative models: interpretable sampling, intractable inference Generative modeling is natural because we can consider latent variables that add interpretable meaning to the different components of the model. For example, in NLP we can define the latent variable as being the relations that are mentioned in the sentence.

[1] Even if tractable, inference can be very costly: for example, PCFG decoding can be done using dynamic programming and has a cubic complexity in the length of the decoded sentence, which is still too high for some applications with long sentences.

[2] The derivative with respect to γ, leads to Algorithm 1 with $\mu = -1$, but the algorithm is also valid for different values of μ as the average gradient remains the same if we add a multiple of $\nabla_\gamma \log p_\gamma(x, y)$ to the gradient g_γ (line 5 in Algorithm 1) which has zero-mean on average. Choosing μ to be the average of the past gradient enables the gradient to have a lower variance.

We could consider two main types of approaches to choose a good structure for a parameterized data generator:

- Discrete data structure: we can use efficient algorithms, such as dynamic programming to perform sampling and which can propagate the gradient
- Continuous distribution: having a continuous latent variable enables easy handling of correlations across different parts of the model.

It is often laborious to design data generators which can return the probability of the samples it generates[3], as well as the gradient of this probability with respect to the input parameters γ.

In the next section, we show how to alleviate this constraint by allowing any data-generating code to be used with nearly no modification.

2.2 GENERE with a Black Box Sampler

Let us assume the data generator is a black box that takes a K-dimensional seed vector as input and outputs an input-output sample x, y. To enable GENERE to be applied without having to modify the code of data generators. The trick is to use a existing generator with parameter γ, and to create a new generator that essentially adds noise to γ. This noise will be denoted $\Delta \in \Gamma$. We used the following data generation process:

1. Sample a Gaussian seed vector $\Delta \sim \mathcal{N}(0, I)$
2. Use the data generator G_z with seed value $z := \Delta + \gamma$ to generate an input-output sample (x, y).

This two-step generation procedure enables the gradient information to be computed using the density of a Gaussian distribution. The use of a standardized centered variable for the seed is justified by the fact that the parametrization of G_z takes into account possible shifts and rescaling. Formally, this is equivalent to Algorithm 1 with the following generative model:

$$p_\gamma(x, y) = \mathbb{E}_{\Delta \sim \mathcal{N}(0,I)} \left[g_{\gamma+\Delta}(x, y) \right] \quad (4)$$

[3]This difficulty comes from the fact that generators may be using third-party code, such as rendering engines, grammars sampler, and deterministic operations such a sorting that are non-differentiable.

where g_z is the density of the black-box data generator G_z for the seed value $z \in \mathbb{R}^K$. Ideally, the second data generator that takes z as an input and generates the input/output pair (x, y) should be close to a deterministic function in order to allocate more uncertainty in the trainable part of the model which corresponds to the Gaussian distribution.[4]

Learning The pseudo-code for the Black Box GENERE variant is shown in Algorithm 2. It is similar to Algorithm 1, but here the sampling phase is decomposed into the two steps: A random Gaussian variable sampling followed by the black box sampling of generators.

Algorithm 2 Black Box GENERE

3 Application to Encoder-Decoder

In this section, we show that the GENERE algorithm is well suited to tune data generators for problems that are compatible with the encoder-decoder architecture commonly used in NLP.

3.1 Mixture-based Generators

In the experiments below, we consider mixture-based generators with known components but unknown mixture proportions. Formally, we

[4]What we mean by deterministic is that the black-box sampler has the form $\delta\{f(\Delta + \gamma) = (x, y)\}$, where δ is the indicator function.

parametrize the proportions using a softmax link $\sigma(t) := \exp(t_k)/\sum_{k'=1}^{K}\exp(t_{k'})$. In other words, the data generator distribution is:

$$p_\gamma(x,y) = \sum_{k=1}^{K} \sigma_k(\gamma+\Delta)p_k(x,y),$$

where $p_k(x,y)$ are data distributions, called *base generators*, that are provided by domain experts, and Δ is a K-dimensional centered Gaussian with an identity covariance matrix. This class of generator makes sense in practice, as we typically build multiple base generators $p_k(x,y)$, $k = 1,\cdots,K$, without knowing ahead of time which one is the most relevant. Then, the training data is used by the GENERE algorithm to automatically learn the optimal parameter γ that controls the contribution $\{\pi_k\}_{k=1}^{K}$ of each of the base generators, equal to $\pi_k := \mathbb{E}_{\Delta\sim\mathcal{N}(\mathbf{0},I)}\left[\sigma_k(\gamma+\Delta)\right]$.

3.2 Synthetic Experiment

In this section, we illustrate how GENERE can learn to identify the correct generator, when the data generating family is a mixture of multiple data generators and only one of these distributions – say p_1 – has been used to generate the data. The other distributions $(p_2,\cdots,p_K)$ are generating input-output data samples (x,y) with different distributions.

We verified that the algorithm correctly identifies the correct data distribution, and hence leads to better generalization performances than what the model achieves without the generator.

In this illustrative experiment, a simple text-to-equation translation problem is created, where inputs are sentences describing an equation such as "compute one plus three minus two", and outputs are symbolic equations, such as "X = 1 + 3 - 2". Numbers were varying between -20 and 20, and equations could have 2 or 3 numbers with 2 or 3 operations.

As our model, we used a 20-dimensional sequence-to-sequence model with LSTM recurrent units. The model was initialized using 200 iterations of standard gradient descent on the log-probability of the output. GENERE was run for 500 iterations, varying the fraction of real and generated samples from 0% to 100%. A ℓ_2 regularization of magnitude 0.1 was applied to the model. The baseline smoothing coefficient was set to 0.98 and the shrinkage parameter was set to 0.99. All the experiments were repeated 10 times and a constant learning rate of 0.1 was used.

Results are shown on Figure 1, where the average loss computed on the test data is plotted against the fraction of real data used during learning.

We can see that the best generalization performance is obtained when there is a balanced mix of real and artificial data, but the proportion depends on the amount of training data: on the left hand side, the best performance is obtained with generated data only, meaning that the number of training samples is so small that GENERE only used the training data to select the best base generator (the component p_1), and the best performance is attained using only generated data. The plot on the right hand side is interesting because it contains more training data, and the best performance is not obtained using only the generator, but with 40% of the real data, illustrating the fact that it is beneficial to jointly use real and simulated data during training.

3.3 Math word problems

To illustrate the benefit of using generative regularization, we considered a class of real world problems for which obtaining data is costly: learning to answer math exam problems. Prior work on this problem focuses on standard math problems given to students aged between 8 and 10, such as the following:[5]

> For Halloween Sarah received 66 pieces of candy from neighbors and 15 pieces from her older sister. If she only ate 9 pieces a day, how long would the candy last her?

The answer is given by the following equation: $\mathrm{X} = (66+15)/9$. Note that similarly to real world school exams, giving the final answer of (9 in this case) is not considered enough for the response to be correct.

The only publicly available word problem datasets we are aware of contain between 400 and 600 problems (see Table 2), which is not enough to properly train sufficiently rich models that capture the link between the words and the quantities involved in the problem.

[5] From the Common Core dataset (Roy and Roth, 2015)

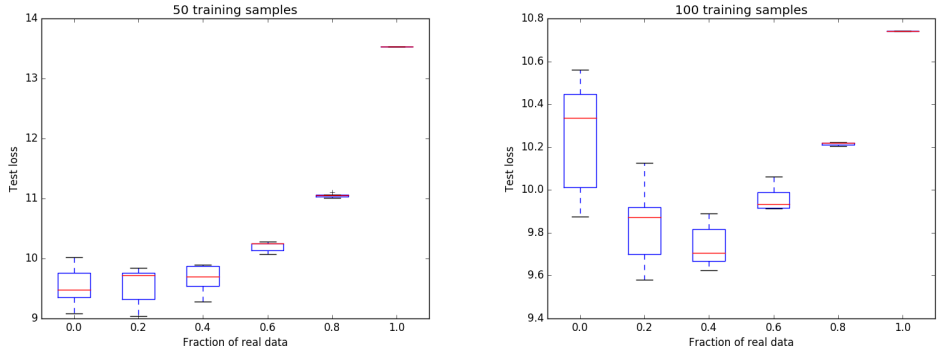

Figure 1: Test loss vs. fraction of real data used in GENERE on the text-to-equation experiment.

Sequence-to-sequence learning is the task of predicting an output sequence of symbols based on a sequence of input symbols. It is tempting to cast the problem of answering math exams as a sequence-to-sequence problem: given the sequence of words from the problem description, we can predict the sequence of symbols for the equation as output. Currently, the most successful models for sequence prediction are Recurrent Neural Nets (RNN) with non-linear transitions between states.

Treated as a translation problem, math word problem solving should be simpler than developing a machine translation model between two human languages, as the output vocabulary (the math symbols) is significantly smaller than any human vocabulary. However, machine translation can be learned on millions of pairs of already translated sentences, and such massive training datasets dwarf all previously introduced math exam datasets.

We used standard benchmark data from the literature. The first one, AI2, was introduced by Hosseini et al. (2014) and covers addition and subtraction of one or two variables or two additions scraped from two web pages. The second (IL), introduced by Roy et al. (2015), contains single operator questions but covers addition, subtraction, multiplication, and division, and was also obtained from two, although different from AI2, web pages. The last data set (CC) was introduced by Roy and Roth (2015) to cover combinations of different operators and was obtained from a fifth web page.

An overview of the equation patterns in the data is shown in Table 1. It should be noted that there are sometimes numbers mentioned in the problem description that are not used in the equation.

AI2	IL	CC
$X + Y$	$X + Y$	$X + Y - Z$
$X + Y + Z$	$X - Y$	$X * (Y + Z)$
$X - Y$	$X * Y$	$X * (Y - Z)$
	X/Y	$(X + Y)/Z$
		$(X - Y)/Z$

Table 1: Patterns of the equations seen in the datasets for one permutation of the placeholders.

	AI2	IL	CC
Train	198	214	300
Dev	66	108	100
Test	131	240	200
Total	395	562	600

Table 2: Math word problems dataset sizes.

As there are no available train/dev/test splits in the literature we introduced such splits for all three data sets. For AI2 and CC, we simply split the data randomly and for IL we opted to maintain the clusters described in Roy and Roth (2015). We then used the implementation of Roy and Roth (2015) provided by the authors, which is the current state-of-the-art for all three data sets, to obtain results to compare our model against. The resulting data sizes are shown on Table 2. We verified that there are no duplicate problems, and our splits and a fork of the baseline implementation are available online.[6]

3.4 Development of the Generator

Generators were organized as a set of 8 base generators p_k, summarized in Table 4. Each base generator

[6] https://github.com/ninjin/roy_and_roth_2015

John sprints to William's apartment. The distance is 32 yards from John's apartment to William's apartment. It takes John 2 hours to at the end get there. How fast did John go?	32 / 2
Sandra has 7 erasers. She grasps 7 more. The following day she grasps 18 whistles at the local supermarket. How many erasers does Sandra have in all?	7 + 7
A pet store had 81 puppies In one day they sold 41 of them and put the rest into cages with 8 in each cage. How many cages did they use?	(81 - 41) / 8
S1 V1 Q1 O1 C1 S1(pronoun) V2 Q2 of O1(pronoun) and V2 the rest into O3(plural) with Q3 in each O3. How many O3(plural) V3?	(Q1 - Q2) / Q3

Table 3: Examples of generated sentences (first 3 rows). The last row is the template used to generate the 3rd example where brackets indicate modifiers, symbols starting with 'S' or 'O' indicate a noun phrase for a subject or object, symbols with 'V' indicate a verb phrase, and symbols with 'Q' indicate a quantity. They are identified with a number to match multiple instances of the same token.

has several functions associated with it. The functions were written by a human over 3 days of full-time development. The first group of base generators is only based on the type of symbol the equation has, the second group is the pair (#1, #2) to represent equations with one or two symbols. Finally, the last two generators are more experimental as they correspond to simple modifications applied to the available training data. The Noise 'N' generator picks one or two random words from a training sample to create a new (but very similar) problem. Finally, the 'P' generator is based on computing the statistics of the words for the same question pattern (as one can see in Table 1), and generates data using simple biased word samples, where words are distributed according to their average positions in the training data (positions are computed relatively to the quantities appearing in the text, i.e. "before the first number", "between the 1st and the 2nd number", etc.).

3.5 Implementation Details

We use a standard stacked RNN encoder-decoder (Sutskever et al., 2014), where we varied the recurrent unit between LSTM and GRU (Cho et al., 2014), stack depth from 1 to 3, the size of the hidden states from 4 to 512, and the vocabulary threshold size. As input to the encoder, we downloaded pre-trained 300-dimensional embeddings trained on Google News data using the word2vec software (Mikolov et al., 2013). The development data was used to tune these parameters before performing the evaluation on the test set. We obtained the best performances with a single stack, GRU units, and a hidden state size of 256.

	The problem...
+	contains at least one addition
-	contains at least one subtraction
*	contains at least one multiplication
/	contains at least one division
1	has a single mathematical operation
2	has a couple of mathematical operations
N	is a training sample with words removed
P	is based on word position frequencies

Table 4: The base generators to create math exam problems.

The optimization algorithm was based on stochastic gradient descent using Adam as an adaptive step size scheme (Kingma and Ba, 2014), with mini-batches of size 32. A total of 256 epochs over the data was used in all the experiments.

To evaluate the benefit of learning the data generator, we used a hybrid method as a baseline where a fraction of the data is real and another fraction is generated using the default parameters of the generators (i.e. a uniform distribution over all the base generators). The optimal value for this fraction obtained on the development set was 15% real data, 85% generated data. For GENERE, we used a fixed

	AI2	IL	CC	Avg.
RR2015	82.4	75.4	55.5	71.1
100% Data	72.5	53.7	95.0	73.7
100% Gen	60.3	51.2	92.0	67.8
85%Gen + 15%Data	74.0	55.4	97.5	75.6
GENERE	77.9	56.7	98.5	77.7

Table 5: Test accuracies of the math-exam methods on the available datasets averaged over 10 random runs.

size learning rate of 0.1, the smoothing coefficient was selected to be 0.5, and the shrinkage coefficient to be 0.99.

We also compared our approach to the publicly available math exam solver RR2015 (Roy and Roth, 2015). This method is based on a combination of template-based features and categorizers. The accuracy performance was measured by counting the number of times the equation generated the correct results, so that 10 + 7 and 7 + 10 would both be considered to be correct. Results are shown on Table 5.

We can see that there is a large difference in performance between RR2015 and the RNN-based encoder-decoder approach. While their method seems to be very good on some datasets, it fails on CC, which is the dataset in which one needs two equations involving parentheses. On average, the trend is the following: using data only does not succeed in giving good results, and we can see that with generated data we are performing better already. This could be explained by the fact that the generators' vocabulary has a good overlap with the vocabulary of the real data. However, mixing real and generated data improves performance significantly. When GENERE is used, the sampling is tuned to the problem at hand and give better generalization performance.

To understand if GENERE learned a meaningful data generator, we inspected the coefficients $\gamma_1, \cdots, \gamma_8$ that are used to select the 8 data generators described earlier. This is shown is Figure 2.

The results are quite surprising at first sight: the AI2 dataset only involves additions and subtractions, but GENERE selects the generator generating divisions as the most important. Investigating, we noted that problems generated by the division generator were reusing some lexical items that were present in AI2, making the vocabulary very close to the problems in AI2, even if it does not cover division. We can also note that the differences in proportions are quite small among the 4 symbols $+, -, *$ and $/$ across all the datasets. We can also clearly see that the noisy generator 'N' and 'P' are not very relevant in general. We explain this by the fact that the noise induced by these generators is too artificial to generate relevant data for training. Their likelihood on the model trained on real data remains small.

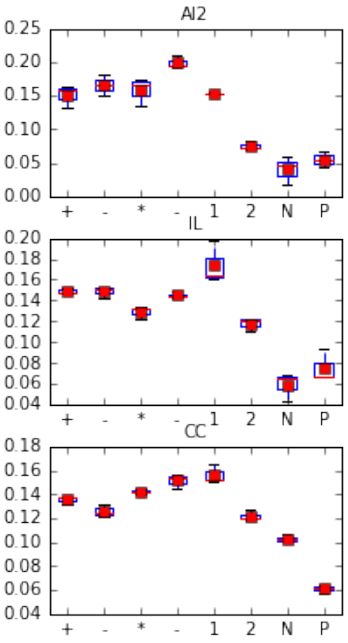

Figure 2: Base generators proportions learned by GENERE.

4 Conclusion

In this work, we argued that many problems can be solved by high-capacity discriminative probabilistic models, such as deep neural nets, at the expense of a large amount of required training data. Unlike the current trend which is to reduce the size of the model, or to define features well targeted for the task, we showed that we can completely decouple the choice of the model and the design of a data generator. We proposed to allow data generators to be "weakly" specified, leaving the undetermined coefficients to be learned from data. We derived an efficient algorithm called GENERE, that jointly estimates the parameters of the model and the undetermined sampling coefficients, removing the need for costly cross-validation. While this procedure could be viewed as a generic way of building informative priors, it does not rely on a complex integration procedure such as Bayesian optimization, but corresponds to a simple modification of the standard stochastic optimization algorithms, where the sampling alternates between the use of real and generated data. While the general framework assumes that the sampling distribution is differentiable with respect to its learnable parameters, we proposed a Gaussian integration trick that does not require the

data generator to be differentiable, enabling practitioners to use *any* data sampling code, as long as the generated data resembles the real data.

We also showed in the experiments, that a simple way to parametrize a data generator is to use a mixture of base generators, that might have been derived independently. The GENERE algorithm learns automatically the relative weights of these base generators, while optimizing the original model. While the experiments only focused on sequence-to-sequence decoding, our preliminary experiments with other high-capacity deep neural nets seem promising.

Another future work direction is to derive efficient mechanisms to guide the humans that are creating the data generation programs. Indeed, there is a lack of generic methodology to understand where to start and which training data to use as inspiration to create generators that generalize well to unseen data.

Acknowledgments

We would like to thank Subhro Roy for helping us run his model on our new data splits. We are very thankful to Thomas Demeester, Johannes Welbl and Matko Bošnjak for their valuable feedback. Lastly, we would like to thank the three anonymous reviewers for their helpful comments and feedback.

This work was supported by a Marie Curie Career Integration Award and an Allen Distinguished Investigator Award.

Abstract

Texts present coherent stories that have a particular theme or overall setting, for example science fiction or western. In this paper, we present a text generation method called *rewriting* that edits existing human-authored narratives to change their theme without changing the underlying story. We apply the approach to math word problems, where it might help students stay more engaged by quickly transforming all of their homework assignments to the theme of their favorite movie without changing the math concepts that are being taught. Our rewriting method uses a two-stage decoding process, which proposes new words from the target theme and scores the resulting stories according to a number of factors defining aspects of syntactic, semantic, and thematic coherence. Experiments demonstrate that the final stories typically represent the new theme well while still testing the original math concepts, outperforming a number of baselines. We also release a new dataset of human-authored rewrites of math word problems in several themes.

1 Introduction

Storytelling is the complex activity of expressing a plot, its events and participants in words meaningful to an audience. Automatic storytelling systems can be used for customized sport commentaries, enriching video games with personalized or dynamic plot-lines (Barros and Musse, 2007), or providing customized learning materials which meet each individual student's needs and interests (Bartlett, 2004). In this paper, we focus on generating narrative-style math word problems (Figure 1) and demonstrate that it is possible to design an algorithm that can automatically change the overall theme of a text without changing its underlying story, for example to create more engaging homework that is in the theme of a student's favorite movie.

Jim walked 0.2 of a mile from school to David's house and 0.7 of a mile from David's house to his own house. How many miles did Jim walk in all?
Star Wars Uncle Owen walked 0.2 of a mile from hangar to Luke Skywalker's room and 0.7 of a mile from Luke Skywalker's room to his own room. How many miles did Uncle Owen walk in all?
Cartoon Finn squished 0.2 of a mile from cupboard to Melissa's dock and 0.7 of a mile from Melissa's dock to his own dock. How many miles did Finn squish in all?
Western Duane strolled 0.2 of a mile from barn to Madeline's camp and 0.7 of a mile from Madeline's camp to his own camp. How many miles did Duane stroll in all?

Figure 1: An example story and rewrites in 3 themes.

A math word problem is a coherent story that provides the student with good clues to the correct mathematical operations between the numerical quantities described therein. However, the particular *theme* of a problem, whether it be about collecting apples or traveling distances through space, can vary significantly so long as the correlation between the story and underlying equation is maintained. Students' success at solving a word problem is tied to their interest in the problem's theme (Renninger

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1617–1628,
Austin, Texas, November 1-5, 2016.

et al., 2002), and personalizing word problems increases student understanding, engagement, and performance in the problem solving process (Hart, 1996; Davis-Dorsey et al., 1991).

Motivated by this need for thematically diverse, highly coherent stories, we address the problem of *story rewriting*, or transforming human-authored stories into novel, coherent stories in a new theme. Rather than synthesizing first a story plot (McIntyre and Lapata, 2009; McIntyre and Lapata, 2010) or script (Chambers and Jurafsky, 2009; Pichotta and Mooney, 2016; Granroth-Wilding and Clark, 2016) from scratch, we instead begin from an existing story and iteratively edit it towards a thematically novel but –most crucially– semantically compatible story. This approach allows us to reuse much, but not all, of the syntactic and semantic structure of the original text, resulting in the creation of more coherent and solvable math word problems.

We define a theme to be a collection of reference texts, such as a movie script or series of books. Given a theme, the *rewrite* algorithm constructs new texts by substituting thematically appropriate words and phrases, as measured with automatic metrics over the theme text collection, for parts of the original texts. This process optimizes for a number of metrics of overall text quality, including syntactic, semantics, and discourse scores. It uses no hand crafted templates and requires no theme-specific tuning data, making it easy to apply for new themes in practice. Tables 4–6 show example stories generated from the rewrite system.

To evaluate performance, we collected a corpus of 450 rewrites of math word problems in Star Wars and Children's Cartoon themes via crowdsourcing.[1] Experiments with automated metrics and human evaluations demonstrate that the approach described here outperforms a number of baselines and can produce solvable problems in multiple different themes, even with no in-domain tuning.

2 Related Work

Our approach is related to the previous work in story generation (e.g., McIntyre and Lapata (2010)) and sentence rewriting (e.g., text simplification (Xu et al., 2016)), as reviewed in this section. It has three major differences from all these approaches: First, we focus on multi-sentence stories where preserving the coherence, discourse relations, and solvability is essential. Previous work mainly focuses on rewriting single sentences. Second, we build a theme from a text corpus and show how the stories can be adapted to new themes. Third, our method leverages the human-authored story to capture the semantic skeleton and the plot of the current story, rather than synthesizing the story plot. To our knowledge, we are the first to introduce a text rewriting formulation for story generation.

Story generation has been of long interest to AI researchers (Meehan, 1976; Lebowitz, 1987; Turner, 1993; Liu and Singh, 2002; Mostafazadeh et al., 2016). Recent methods in story generation first synthesize candidate plots for a story and then compile those plots into text. Li et al. (2013) use crowdsourcing to build plot graphs. McIntyre and Lapata (2009; 2010) address story generation through the automatic deduction and reassembly of scripts (Schank and Abelson, 1977), or structured representations of events and their participants, and causal relationships involved. Leveraging the automatic script learning methods of Chambers and Jurafsky (2009), McIntyre and Lapata (2010) learn candidate entity-centered plot graphs, or possible events involving the entity and an ordering between these events, with the use of a genetic algorithm. Then plots are compiled into stories through the use of a rule-based text surface realizer (Lavoie and Rambow, 1997) and reranked using a language model.

Polozov et al. (2015) automatically generate math word problems tailored to a student's interest using Answer Set Programming to satisfy a collection of pedagogical and narrative requirements. This method naturally produces highly coherent, personalized story problems that meet pedagogical requirements, at the expense of building the thematic ontologies and discourse constraints by hand.[2]

Additionally, there is related work in text simplification (Wubben et al., 2012; Kauchak, 2013; Zhu et al., 2010; Vanderwende et al., 2007; Woodsend and Lapata, 2011b; Hwang et al., 2015), sentence

[1] Data and code available at `https://gitlab.cs.washington.edu/kedzior/Rewriter/`.

[2] According to Polozov et al. (2015) building small thematic ontologies of types, relations, and discourse tropes (100-200 entries) for each of only 3 literary settings took 1-2 person months.

compression (Filippova and Strube, 2008; Rush et al., 2015), and paraphrasing (Ganitkevitch et al., 2013; Chen and Dolan, 2011; Ganitkevitch et al., 2011). All these tasks are focused on rewriting sentences under a predefined set of constraints, such as simplicity. Different rule-based and data-driven approaches are introduced by Petersen and Ostendorf (2007), Vickrey and Koller (2008), and Siddharthan (2004). Most data-driven approaches take advantage of machine translation techniques, use source-target sentence pairs, and learn rewrite operations (Yatskar et al., 2010; Woodsend and Lapata, 2011a), or use additional external paraphrasing resources (Xu et al., 2016).

Finally, this work is related to those on automatically solving math word problems. Specific topics include number word problems (Shi et al., 2015), logic puzzle problems (Mitra and Baral, 2015), arithmetic word problems (Hosseini et al., 2014; Roy and Roth, 2015), algebra word problems (Kushman et al., 2014; Zhou et al., 2015; Koncel-Kedziorski et al., 2015a; Roy et al., 2016), and geometry word problems (Seo et al., 2015; Seo et al., 2014). Several datasets of word problems are available (Koncel-Kedziorski et al., 2016; Huang et al., 2016), though none address the need for thematic text.

3 Problem Formulation

Our system takes as input a story s and a theme t, and outputs the best rewrite s^* from generated candidates S.

A theme t is defined as a textual corpus that describes a topic or a domain. This is an intentionally broad definition that allows a variety of textual resources to serve as themes. For example, the collection of all Science Fiction stories from the Project Gutenberg can be a theme, or the script of a single movie, or a sampling of fan fiction from the Internet. This flexibility adds to the utility of our work, as varying amounts of thematic text may be available.

The generated candidate s^* is the most *thematically* fit problem that is *syntactically* and *semantically* coherent given the original problem s and the new theme t. We represent a story in terms of the words it contains, so that $s = \{w_1, w_2, \dots\ w_n\}$ and

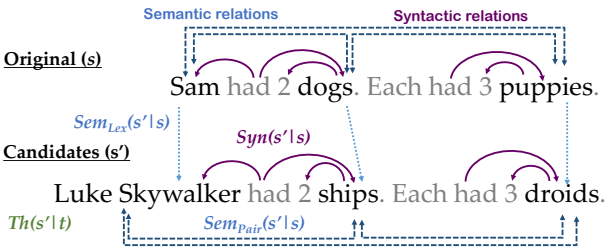

Figure 2: An overview of our method for scoring a candidate story s' given a human-authored story s and a theme t. Syn$(s'|s)$: compatibility of syntactic relations (purple arrows), Sem$_{pair}(s'|s)$: coherence of semantic relations (blue arrows), Sem$_{Lex}(s'|s)$: semantic mapping of individual words, and $Th(s'|s,t)$: thematicity.

$|s| = n$. The new story s' is defined as:

$$s' = \{f(w_1), f(w_2), \dots\ f(w_n)\}$$

where the function $f(w) : \mathcal{V}_o \rightarrow \mathcal{V}_t^K \cup \varnothing$, rewrites a word from the vocabulary of the original problem $\mathcal{V}_o$ to either a word, a trivial noun compound of length K (e.g., multi-word named entity) from the vocabulary of the the thematic vocabulary $\mathcal{V}_t$, or reduces to the empty symbol, i.e., omits the input word entirely; hence the length of s' can differ from that of the original problem.

Formally, our goal is to select the candidate $s' \in S$ by maximizing a scoring function $\mathcal{R}$ over thematic, syntactic and semantic constraints, subject to a set of parameters θ:

$$s^* = \arg\max_{s' \in S} \mathcal{R}(s'|s,t;\theta) \qquad (1)$$

In order to find the best story s^*, our problem reduces to generating candidate stories s' from the space of possible rewrites of the human-authored story s in a new theme t (Section 5). Since there are exponentially many rewrites, we follow a two-stage decoding approach: first we identify only the content words w_i in the input problem, and provide for each a list of the top-k most *salient* thematic candidate words and trivial noun compounds. We then search the space by progressively introducing more rewrites in the beam, and scoring them according to $\mathcal{R}$ (Section 4). Figure 2 shows the overview of the scoring function for a candidate sentence s'.

4 Scoring Stories

The scoring function $\mathcal{R}$ decomposes into three components, capturing aspects of syntactic compatibility, semantic coherence, and thematicity:

$$\begin{aligned}\mathcal{R}(s'|s,t;\theta) =& \alpha \times \text{Sem}(s'|s) \\ &+ \beta \times \text{Syn}(s'|s) \\ &+ \gamma \times \text{Th}(s'|s,t)\end{aligned} \quad (2)$$

The syntactic (Syn) and semantic (Sem) coherence components measure the coherence of the words in the new story s', as well as their compatibility to the syntactic and semantic relations in the original story s. On the other hand, thematicity (Th) scores the relevance and importance of words in the new story with respect to theme t.

We describe each of these components and the decoding process in the following sections.

4.1 Thematicity

Recall that a theme t is defined as a collection of documents that share a common topic, such as books in the science fiction genre, or scripts of horror movies. We define thematicity of a word w' as the measure of *salience*, or how discriminative that word is to a given theme.[3] For example, *robot* and *spaceship* are expected to be highly thematic with respect to Star Wars. In our setting we extend this definition to a candidate problem s' given s and t as:

$$\text{Th}(s'|s,t) = \sum_{i}^{|s|} Sal(w'_i, t) \quad (3)$$

where w'_i is a word from the candidate problem, and Sal is its salience score with respect to the theme. In the context of this work we argue that the thematic adaptation of the content words, i.e., nouns, verbs, named entities, and adjectives, plays the most important role in forming a new thematic problem. Therefore, we define their salience (except named entities) based on their tf-idf score over the theme t, and set it to zero for function words. Since named entities have relatively low frequencies in the theme corpus we set their salience to $1 - \frac{1}{c(w'_i)}$, where $c(w'_i)$ is the number of times w'_i occurs in the theme. In the example story in Figure 2 the thematicity score is derived as $Sal(\text{Luke Skywalker}) + Sal(\text{ships}) + Sal(\text{droids})$.

[3] We will be interchangeably referring to w' as either the word or the head of the multi-word noun compound that rewrites the equivalent word w in the original problem.

4.2 Syntactic compatibility

This work offers a new method for syntactic and discourse coherence based on preserving human-authored syntactic structure in generated text (hence our use of the term *rewriting*). The syntactic constructs in a document play a distinctive role in maintaining cohesion across sentences. We consider the human-authored syntax of the original story s as gold standard, and use it to score a candidate problem s' by considering how well the syntactic relations of s apply to s'.

Formally, given a dependency triple (w_i, w_j, l) from a parse of a sentence in s, we compute the likelihood for the corresponding triple (w'_i, w'_j, l) for w'_i, w'_j in s'. We define the syntactic score for all sentences in s' as:

$$\text{Syn}(s'|s) = \sum_{i,j,l|(w_i,w_j,l)\in \text{Dep}(s)} \mathcal{L}_{Dep}(w'_i, w'_j, l) \quad (4)$$

where $Dep(s)$ are the dependency parse trees for all sentences in s; $\mathcal{L}_{Dep}$ is a 3-gram language model over dependency triples which gives the likelihood of an arc label l being used between a pair of words (w'_i, w'_j). For example in Figure 2, the syntactic compatibility score includes dependency likelihoods of $\mathcal{L}_{Dep}(\text{ship}, 2, \textit{num})$, $\mathcal{L}_{Dep}(\text{had}, \text{ship}, \textit{dobj})$.

Therefore, the Syn function prefers stories s' that (a) have similar dependency structure to the original story s and (b) make use of a common syntactic configuration.

4.3 Semantic Coherence

The semantic coherence component expresses how well a candidate s' rewrites individual words and realizes the semantic relationships that exist in the human-authored story s. Ideally, we would like to preserve enough of the semantics of s in order to produce a coherent story s', yet we are populating s' with words taken from an unrelated theme. Therefore, we model the semantics of a story s' in terms of the lexical semantics contributed by individual words as well as semantic relationships that exist between its elements. Note that the relationships can

cross the sentence boundaries, promoting discourse coherence.

We decompose semantic relations in a story into a set of local, lexical relationships between pairs of words. Specifically, we consider semantic relations for noun-noun and verb-verb pairs as provided by WordNet (Miller, 1995). Since some relations are not directly outlined in these resources (e.g., the selectional preferences of nouns with regard to their adjectival modifiers), we also consider the word-embedding similarity between words. For example in Figure 2 the semantic relationships are denoted with blue arrows between pairs of content words in the story (e.g., {Sam, dogs}, {dogs, puppies}, etc).

More formally, we define the semantic coherence of s' with respect to s as:

$$\text{Sem}(s'|s) = \sum_{i}^{|s'|} \text{Sem}_{Lex}(w_i, w'_i) + \sum_{i,j \in CW} \text{Sem}_{Pair}(\{w_i, w_j\}, \{w'_i, w'_j\}) \quad (5)$$

where CW is the set of pairs of indices of content words (nouns, verbs, adjectives, and named entities) from s. We focus on the content words of the original problem, as they carry most of the semantic information. Sem_{Lex} and Sem_{Pair} functions are semantic adaptation scores for individual words and semantic relations respectively, described below.

Semantic Compatibility between words (Sem_{Lex}) is defined as:

$$\text{Sem}_{Lex}(w_i, w'_i) = cos(w_i, w'_i) + Resnik(w_i, w'_i) \quad (6)$$

where $cos(w_i, w'_i)$ denotes the cosine similarity between the vector space embeddings of two words w_i and w'_i[4], and $Resnik(w_i, w'_i)$ expresses the information content of the lowest subsumer of $\{w_i, w'_i\}$ in WordNet. For example in Figure 2, the semantic compatibility score incorporates lexical similarities $\text{Sem}_{Lex}(\text{dog}, \text{ship})$, etc.

Compatibility score between semantic relations (Sem_{Pair}) is defined by adding two components: $PairSim$ and $Analogy$ that compute how semantic relations between pairs of words are preserved in the new story:

$$PairSim = \cos(w_i, w_j) * \cos(w'_i, w'_j) \quad (7)$$

$$Analogy = \cos(w'_i + w_j - w_i, w'_j) \quad (8)$$

$PairSim$ preserves the similarity between pairs of words $\{w_i, w_j\}$ in s and the corresponding pair $\{w'_i, w'_j\}$ in the new story s'. Intuitively, if w_i and w_j are semantically close to each other, we would like the corresponding words to be close in the new story as well. For example in Figure 2, 'dog' and 'puppy' are similar in the original story, we expect the corresponding words 'ship' and 'droid' to be similar in the new story. The $Analogy$ function, inspired by Mikolov et al. (2013), computes the analogy of w'_j from w'_i given the relationship that holds between w_i and w_j in the vector space. For example in Figure 2, the relation between 'Sam' and 'dog' is similar to the relation between 'Luke Skywalker' and 'ship'.

5 Decoding

Our decoding process begins by first identifying the content words w_i (nouns, verbs, adjectives and named entities) in the original problem s that will be considered as *initial points* for rewriting. For each of these lexical classes we extract the top-k most thematic words and trivial noun compounds from the theme t. For example, in Figure 2, candidate nouns are: 'ships', 'robots', 'droids', etc., and for verbs: 'blast', 'soar', 'command', etc. Recall that the space of candidate rewrites is large, prohibiting an exhaustive enumeration. We therefore do approximate search with a beam by considering simultaneously all possible *paths* that start at the different initial points. At each step the decoder considers an additional rewrite from the list of candidates, adds it to the existing hypothesis path, and scores it according to function $\mathcal{R}$ (Equation 2).

All the counterpart scores are locally optimal, as they factor over each new word w'_i or pair of $\{w'_i, w'_j\}$, where w'_j is a rewrite *already* existing in the hypothesis path. At any given step we may recombine hypotheses that share the same prefix hypothesis path, and keep the top scoring one. The process terminates when there are no more rewrites left. We also experimented decoding with a variety of orderings of the text in the original problem s, including left-to-right, and head-first following the

[4]For the ease of notation, we represent the embedding of the words with w_i as well.

dependency tree of each sentence and then concatenating these linearizations; we observed that considering multiple paths achieves the best performance.

6 Data Collection

For the set of human-authored stories $\{s\}$, we use a corpus of math word problems described in Koncel-Kedziorski et al. (2016). We select a subset of 150 problems targeting 5th and 6th grade levels, all of which involve a single equation in one variable. These problems have 2.7 sentences and 29.4 words on average, 12.6 of which are considered content words by our system. In order to tune and evaluate our model, we collect a corpus of human-authored rewrites produced by workers from Amazon Mechanical Turk based on two themes: Star Wars, and Adventure Time (a children's cartoon).

We experimented with different ways of helping to define the theme for the workers, including offering automatically generated word clouds or enforcing that a response includes one of several keywords. In practice, we have found that using specific cultural elements as themes (such as famous movie or cartoon franchises) attracts workers who already have a strong knowledge of the theme, resulting in higher quality work.

To help explain the rewriting process, we show workers three examples of thematic rewrites with varying degrees of correlation to the original problems. We then show workers a random problem from the original set $\{s\}$ and a corresponding equation for that problem. We instruct the workers to "rewrite" the problem according to the theme, ensuring that their rewritten problem can be solved by the provided equation. The final dataset collection comprises of 450 human-authored rewrites. We collect 3 rewrites for 100 of the original problems for the Star Wars theme (based on the popular Star Wars sequel movies), and 3 rewrites for the rest of the 50 original problems, for the Children Cartoons Theme (CARTOON), based on the Adventure Time TV show. We keep 150 examples from the Star Wars theme for development (STAR$_{dev}$), and the rest 150 for testing (STAR$_{test}$).

We collected the STAR$_{dev}$ and CARTOON data based on workers with the "master" designation and at least 95% approval rating. Then we proceeded collecting STAR$_{test}$ by a subset of the authors of STAR$_{dev}$ who self-identify as theme experts and whose quality of work is manually confirmed.

7 Experiments

7.1 Setup

Implementation Details We pre-process the themes using the Stanford CoreNLP tools (Manning et al., 2014) for tokenization, Named Entity Recognition (Finkel et al., 2005), and dependency parsing (Chen and Manning, 2014). For calculating salience scores, we use the ScriptBase dataset of movie scripts (Gorinski and Lapata, 2015). The Star Wars theme is constructed from the available script, roughly 7300 words. The Cartoon theme is constructed from fan-authored scripts of the first 10 episodes of the show (Springfield, 2016) totaling 1370 words. Since our thematic options are taken from arbitrary text, we use the lists of offensive terms published by The Racial Slur database (Database, 2016) and FrontGate Media (Media, 2016) to filter out offensive content. To prohibit overgeneration, we forbid the transformation of stop words or math-specific words (Survivors, 2013; Koncel-Kedziorski et al., 2015b).

For syntactic compatibility score Syn (Equation 4) we use the English Fiction subset of the Google Syntactic N-grams corpus (Goldberg and Orwant, 2013) and train a 3-gram language model using KenLM (Heafield, 2011). For Sem_{Lex}, $PairSim$ and $Analogy$ (Equations 6-8) we use the pretrained word embeddings of Levy and Goldberg (2014). These embeddings are trained using dependency contexts rather than windows of adjacent words, allowing them to capture functional word similarity. Finally, we tune the parameters of our model (Equation 2) on the development set STAR$_{dev}$ and pick those values[5] that maximize METEOR score (Denkowski and Lavie, 2014) against 3 human references.

Evaluation We compare two ablated configurations of our method against our full model (FULL): -SYN that only uses semantic and thematicity components and does not incorporate the syntactic compatibility score, -SEM replaces the semantic coher-

[5] We set $\alpha = 0.1$, $\beta = 0.1$ and $\gamma = 1$

Model	STAR$_{dev}$	STAR$_{test}$	CARTOON
FULL	31.82	29.16	32.08
-SEM	28.72	25.55	27.55
-SYN	31.92	29.14	32.04

Table 1: METEOR results for different configuration of our model on STAR$_{dev}$, STAR$_{test}$ and CARTOON datasets.

ence score with the simpler $\cos(w_i, w_i')$, effectively rewriting only single words, and not pairs. We refrained from ablating the thematicity score as it is the core part of our model that drives the rewriting process into a new theme.

We evaluate our method using an automatic metric, and via eliciting human judgments on Amazon Mechanical Turk. For automatic evaluation, we compute the METEOR score, comparing the output of each model for a given problem and theme to the 3 human rewrites we collected, on STAR$_{dev}$, STAR$_{test}$ and CARTOON. METEOR is a recall-oriented metric, widely used in the MT community; the additional stemming, synonym and paraphrase matching modules make it more applicable for our use, given the nature of our rewriting task.[6]

For human evaluation, we conduct pairwise comparison tests, pairing FULL against a human rewrite (HUMAN), FULL against -SYN, and FULL against -SEM. Participants were given a short description of the theme, and the output of each system. For each test we asked 40 subjects to select which problem they preferred over 5 pairs of outputs; we obtained a total of 200 (5x40) responses for STAR$_{test}$ and CARTOON.

In order to better understand the strengths and weaknesses of the generated stories, we conducted a more detailed human evaluation. 8 participants were presented with the output of the three automatic systems, human rewrites (HUMAN), and a theme. The participants were asked to rate the stories across three dimensions: coherence (how coherent is the text of the problem?), solvability (can elementary school students solve it?), and thematicity (how well does the problem express them?) on a scale from 1 to 5. We collected ratings over 16 outputs from STAR$_{test}$, resulting in 128 responses.

[6]The average METEOR score comparing 1 annotator against the other 2 is 0.26, indicating that there are diverse correct strategies for solving the rewriting problem.

Model	STAR$_{test}$	CARTOON
FULL	65.0	57.9
-SYN	35.0	42.1
FULL	68.8	69.4
-SEM	31.2	30.6
FULL	17.9	10.0
HUMAN	82.1	90.0

Table 2: Human evaluation results on pairwise comparisons between FULL and -SYN, and FULL and HUMAN, on STAR$_{test}$ and CARTOON datasets.

Model	Thematicity	Coherence	Solvability
HUMAN	3.7	3.175	4.025
FULL	3.7	3.025	3.9
-SYN	3.375	3.075	3.825
-SEM	3.325	2.65	3.7

Table 3: Human evaluation results for FULL, -SYN, -SEMand HUMAN on thematicity, coherence and solvability on STAR$_{test}$.

7.2 Results

Table 1 reports METEOR; we notice that removing the semantic coherence scores in -SEM hurts the performance compared to FULL; this confirms our claim that semantic compatibility is crucial for building coherent stories. On the other hand, -SYN performs similarly to FULL. Closer inspection of the -SYN system's output reveals a greater diversity in thematic elements as a result of the relaxed syntactic compatibility constraints. Hence it is more likely to have greater overlap with any of the reference rewrites, resulting in higher METEOR scores.

However, a pairwise comparison between FULL and -SYN (Table 2) reveals that human subjects consistently prefer the output of FULL instead of -SYN both for STAR$_{test}$ and CARTOON. Table 2 also reports that HUMAN outperforms the output of the FULL model, and a pairwise comparison of FULL and -SEM which yields a result in line with the METEOR scores.

Table 3 shows the results of the detailed comparison of Thematicity, Coherence, and Solvability. This table clearly shows the strong contribution of the semantic component of our system. The specific contribution of the syntactic component is to pro-

Star Wars
s_1. Wendy bought 4 new chairs and 4 new tables for her house. If she spent 6 minutes on each piece furniture putting it together, how may minutes did it take her to finish?
s'_1. Leia bought 4 new ships and 4 new guns for her room. If she spent 6 minutes on each wasteland weapon putting it together, how many minutes did it take her to terminate?
s_2. My car gets 20 miles per gallon of gas. How many miles can I drive on 5 gallons of gas?
s'_2. My cruiser gets 20 miles per gallon of light. How many miles can I drive on 5 gallons of light?

Cartoon
s_7. Dave was helping the cafeteria workers pick up lunch trays, but he could only carry 9 trays at a time. If he had to pick up 17 trays from one table and 55 trays from another, how many trips will he make?
s'_7. Finn was helping the cupboard men pick up candy bottles, but he could only carry 9 bottles at a time. If he had to pick up 17 bottles from one ring and 55 bottles from another, how many swords will he make?
s_8. If books came from all the 4 continents that Bryan had been into and he collected 122 books per continent, how many books does he have from all 4 continents combined?
s'_8. If dances came from all the 4 mountains that Finn had been into and he collected 122 dances per mountain, how many dances does he have from all 4 mountains combined?
s_9. A bucket contains 3 gallons of water. If Derek adds 6.8 gallons more, how many gallons will there be in all?
s'_9. A bottle makes 3 gallons of serum. If Finn adds 6.8 gallons more, how many gallons will there be in all?

Table 5: Examples of the original stories s_i and rewritten math word problems s'_i in Cartoon theme.

duce overall more solvable and thematically satisfying problems, although it can slightly affect coherence especially when automatic parses fail. Finally, the overall high ratings for human-authored stories across all three dimensions, confirm the high quality of the crowd-sourced stories.

7.3 Qualitative Examples

Table 4–6 shows some problems generated by our method. Recall that since our system needs no annotated thematic training data, we can easily generate from any theme where thematic text is available. To demonstrate this fact, we include generated examples in a Western theme from novels from the Project Gutenberg corpus. Many of the results of our system are very legible, with only minor agreement errors. Coherent, thematic semantic relations are evident in problems such as s'_1, where ships, guns, and weapons combine to effect the Star Wars theme; this is also evident in s'_5, where people with western sounding names like Kurt and Madeline trade in cigarettes, an old-fashioned pre-cursor to e-cigarettes.

In some cases, semantic inconsistencies result in weird sounding problems, such as in s'_6 where the main character receives "wheat of grub". But because of the syntactic compatibility component, our model scores this candidate higher because of the connection between "wheat" and "graze".

Semantic incoherence is less of a problem in the cartoon theme, where absurd interactions between characters are expected. However, a difficulty for our system is demonstrated in s'_7, where the physical entity "swords" is substituted for the nominalization of an event "trips". Improvements to the semantic coherence component could resolve such issues.

Table 7 shows some instances where the rewrite algorithm produces unusable results. An example of under-generation is s'_{10}. Here, too many words are left untouched, resulting in both ungrammaticality and semantic incoherence. In s'_{11}, we witness some limitations of using word vectors. The rare word "Ferris" is not close to anything in the Star Wars theme, and is thus mapped almost arbitrarily to "int" (movie script shorthand for an interior shot). Better treatment of noun compounds and the use of phrase vectors would reduce such errors.

8 Conclusion

We formalized the problem of story rewriting as automatically changing the theme of a text without

Western

s_{10}. It rained 0.9 inches on Monday. On Tuesday, it rained 0.7 inches less than on Monday. How much did it rain on Tuesday?
s'_{10}. It blasted 0.9 inches on Monday. On Tuesday, it blasted 0.7 inches less than on Monday. How much did it light on Tuesday?
s_{11}. The Ferris wheel in Paradise Park has 14 seats. Each seat can hold 6 people. How many people can ride the Ferris wheel at the same time?
s'_{11}. The int grab in chewbacca mesa has 14 areas. Each area can hold 6 troops. How many troops can ride the int grab at the same time?

Table 7: Examples of the original stories s_i and poorer rewrites s'_i in the Star Wars theme.

altering the underlying story and developed an approach for rewriting algebra word problems where the rewriting model optimized for a number of measures of overall text coherence. Experiments on a newly gathered dataset demonstrated our model can produce themed texts that are usually solvable.

Future work could improve the thematicity and solvability components by incorporating domain-specific and commonsense knowledge, leveraging information extraction. Additionally, neural network architectures (e.g., LSTMs, seq2seq) can be trained to rewrite coherently with less reliance on brittle syntactic parses. Additionally, we plan to study rewriting in other domains such as children's short stories and extend the model to generate math word problems directly from equations. Finally, we intend to incorporate the generated problems in educational technology and tutoring systems.

Context-Sensitive Lexicon Features for Neural Sentiment Analysis

Zhiyang Teng, Duy-Tin Vo and **Yue Zhang**
Singapore University of Technology and Design
{zhiyang_teng, duytin_vo}@mymail.sutd.edu.sg
yue_zhang@sutd.edu.sg

Abstract

Sentiment lexicons have been leveraged as a useful source of features for sentiment analysis models, leading to the state-of-the-art accuracies. On the other hand, most existing methods use sentiment lexicons without considering context, typically taking the count, sum of strength, or maximum sentiment scores over the whole input. We propose a context-sensitive lexicon-based method based on a simple weighted-sum model, using a recurrent neural network to learn the sentiments strength, intensification and negation of lexicon sentiments in composing the sentiment value of sentences. Results show that our model can not only learn such operation details, but also give significant improvements over state-of-the-art recurrent neural network baselines without lexical features, achieving the best results on a Twitter benchmark.

1 Introduction

Sentiment lexicons (Hu and Liu, 2004; Wilson et al., 2005; Esuli and Sebastiani, 2006) have been a useful resource for opinion mining (Kim and Hovy, 2004; Agarwal et al., 2011; Moilanen and Pulman, 2007; Choi and Cardie, 2008; Mohammad et al., 2013; Guerini et al., 2013; Vo and Zhang, 2015). Containing sentiment attributes of words such as polarities and strengths, they can serve to provide a word-level foundation for analyzing the sentiment of sentences and documents. We investigate an effective way to use sentiment lexicon features.

A traditional way of deciding the sentiment of a document is to use the sum of sentiment values of all words in the document that exist in a sentiment lexicon (Turney, 2002; Hu and Liu, 2004). This simple method has been shown to give surprisingly competitive accuracies in several sentiment analysis benchmarks (Kiritchenko et al., 2014), and is still the standard practice for specific research communities with mature domain-specific lexicons, such as finance (Kearney and Liu, 2014) and product reviews (Ding et al., 2008).

It's an **insignificant** [criticism]$_{-1\rightarrow-0.5}$.
Nobody gives a [good]$_{+3\rightarrow-1}$ performance in this movie
She's **not** [terrific]$_{+5\rightarrow+1}$ but **not** [terrible]$_{-5\rightarrow-1}$ either.
It's **not** a **very** [good]$_{+3\rightarrow-0.25}$ movie song!
It **removes** my [doubts]$_{-3\rightarrow+1}$.

Figure 1: Example sentiment compositions.

More sophisticated sentence-level features such as the counts of positive and negative words, their total strength, and the maximum strength, etc, have also been exploited (Kim and Hovy, 2004; Wilson et al., 2005; Agarwal et al., 2011). Such lexicon features have been shown highly effective, leading to the best accuracies in the SemEval shared task (Mohammad et al., 2013). On the other hand, they are typically based on bag-of-word models, hence suffering two limitations. First, they do not explicitly handle *semantic compositionality* (Polanyi and Zaenen, 2006; Moilanen and Pulman, 2007; Taboada et al., 2011), some examples of which are shown in Figure 1. The composition effects can exhibit intricacies such as negation over intensification (e.g. not very good), shifting (e.g. not terrific) vs flip-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1629–1638,
Austin, Texas, November 1-5, 2016.

ping negation (e.g. not acceptable), content word negation (e.g. removes my doubts) and unbounded dependencies (e.g. No body gives a good performance).

Second, they cannot effectively deal with *word sense variations* (Devitt and Ahmad, 2007; Denecke, 2009). Guerini et al. (2013) show challenges in modeling the correlation between context-dependent posterior word sentiments and their context independent priors. For example, the sentiment value of "cold" varies between "cold beer", "cold pizza" and "cold person" due to sense and context differences. Such variations raise difficulties for a sentiment classifier with bag-of-word nature, since they can depend on semantic information over long phrases or the full sentence.

We investigate a method that can potentially address the above issues, by using a recurrent neural network to capture context-dependent semantic composition effects over sentences. Shown in Figure 2, the model is conceptually simple, using a weighted sum of lexicon sentiments and a sentence-level bias to estimate the sentiment value of a sentence. The key idea is to use a bi-directional long-short-term-memory (LSTM) (Hochreiter and Schmidhuber, 1997; Graves et al., 2013) model to capture global syntactic dependencies and semantic information, based on which the weight of each sentiment word together with a sentence-level sentiment bias score are predicted. Such weights are context-sensitive, and can express flipping negation by having negative values.

The advantages of the recurrent network model over existing semantic-composition-aware discrete models such as (Choi and Cardie, 2008) include its capability of representing non-local and subtle semantic features without suffering from the challenge of designing sparse manual features. On the other hand, compared with neural network models, which recently give the state-of-the-art accuracies (Li et al., 2015; Tai et al., 2015), our model has the advantage of leveraging sentiment lexicons as a useful resource. To our knowledge, we are the first to integrate the operation into sentiment lexicons and a deep neural model for sentiment analysis.

The conceptually simple model gives strong empirical performances. Results on standard sentiment benchmarks show that our method gives competitive

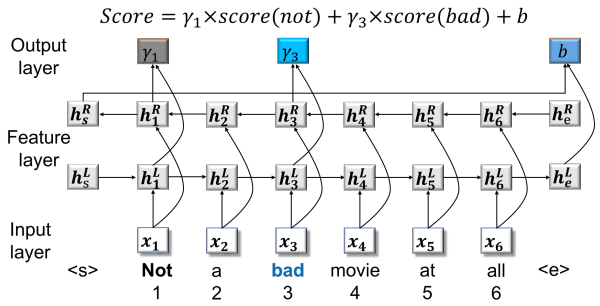

Figure 2: Overall model structure. The sentiment score of the sentence "not a bad movie at all" is a weighted sum of the scores of sentiment words "not", "bad" and a sentence-level bias score b. $score(not)$ and $score(bad)$ are prior scores obtained from sentiment lexicons. γ_1 and γ_3 are context-sensitive weights for sentiment words "not" and "bad", respectively.

accuracies to the state-of-the-art models in the literature. As a by-product, the model can also correctly identify the compositional changes on the sentiment values of each word given a sentential context.

Our code is released at https://github.com/zeeeyang/lexicon_rnn.

2 Related Work

There exist many statistical methods that exploit sentiment lexicons (Kim and Hovy, 2004; Agarwal et al., 2011; Mohammad et al., 2013; Guerini et al., 2013; Tang et al., 2014b; Vo and Zhang, 2015; Cambria, 2016). Mohammad et al. (2013) leverage a large sentiment lexicon in a SVM model, achieving the best results in the SemEval 2013 benchmark on sentence-level sentiment analysis (Nakov et al., 2013). Compared to these methods, our model has two main advantages. First, we use a recurrent neural network to model context, thereby exploiting *non-local* semantic information. Second, our model offers *context-sensitive* operational details on each word.

Several previous methods move beyond bag-of-word models in leveraging lexicons. Most notably, Moilanen and Pulman (2007) introduce the ideas from compositional semantics (Montague, 1974) into sentiment operations, developing a set of composition rules for handling negations. Along the line, Taboada et al. (2011) developed a lexicon and a collection of sophisticated rules for addressing intensification, negation and other phenomena. Differ-

ent from these *rule-based* methods, Choi and Cardie (2008) use a structured linear model to *learn* semantic compositionality relying on a set of *manual* features. In contrast, we leverage a recurrent neural model for inducing semantic composition features *automatically*. Our weighted-sum representation of semantic compositionality is formally simpler compared with fine-grained rules such as (Taboada et al., 2011). However, it is sufficient for describing the *resulting effect* of complex and context-dependent operations, with the semantic composition process being modeled by LSTM. Our sentiment analyzer also enjoys a more competitive LSTM baseline compared to a traditional discrete models.

Our work is also related to recent work on using deep neural networks for sentence-level sentiment analysis, which exploits convolutional (Kalchbrenner et al., 2014; Kim, 2014; Ren et al., 2016), recursive (Socher et al., 2013; Dong et al., 2014; Nguyen and Shirai, 2015) and recurrent neural networks (Liu et al., 2015; Wang et al., 2015; Zhang et al., 2016), giving highly competitive accuracies. As our baseline, LSTM (Tai et al., 2015; Li et al., 2015) stands among the best neural methods. Our model is different from these prior methods in mainly two aspects. First, we introduce sentiment lexicon features, which effectively improve classification accuracies. Second, we learn extra operation details, namely the weights on each word, automatically as hidden variables. While the baseline uses LSTM features to perform end-to-end mapping between sentences and *sentiments*, our model uses them to induce the *lexicon weights*, via which word level sentiment are composed to derive sentence level sentiment.

3 Model

Formally, given a sentence $s = w_1 w_2 ... w_n$ and a sentiment lexicon *D*, denote the subjective words in s as $w^D_{j_1} w^D_{j_2} ... w^D_{j_m}$. Our model calculates the sentiment score of s according to *D* in the form of

$$Score(s) = \sum_{t=1}^{m} \gamma_{j_t} score(w^D_{j_t}) + b, \qquad (1)$$

where $Score(w^D_{j_t})$ is the sentiment value of w_{j_t}, γ_{j_t} are sentiment weights and b is a sentence-level bias. The sentiment values of words and sentences are real numbers, with the sign indicating the polarity and the absolute value indicating the strength.

As shown in Figure 2, our neural model consists of three main layers, namely the *input layer*, the *feature layer* and the *output layer*. The input layer maps each word in the input sentence into a dense real-value vector. The feature layer exploits a bidirectional LSTM (Graves and Schmidhuber, 2005; Graves et al., 2013) to extract non-local semantic information over the sequence. The output layer calculates a weight score for each sentiment word, as well as an overall sentiment bias of the sentence.

In this figure, the score of the sentence "not a bad movie at all" is decided by a weighted sum of the sentiments of "bad" and "not"[1], and a sentiment shift bias based on the sentence structure. Ideally, the weight on "not" should be a small negative value, which results in a slightly positive sentiment shift. The weight on "bad" should be negative, which represents a flip in the polarity. These weights jointly model a negation effect that involves both shifting and flipping.

3.1 Bidirectional LSTM

We use LSTM (Hochreiter and Schmidhuber, 1997) for feature extraction, which recurrently processes sentence s token by token. For each word w_t, the model calculate a hidden state vector $\mathbf{h_t}$. A LSTM cell block makes use of an input gate $\mathbf{i_t}$, a memory cell $\mathbf{c_t}$, a forget gate $\mathbf{f_t}$ and an output gate $\mathbf{o_t}$ to control information flow from the history $\mathbf{x_1}...\mathbf{x_t}$ and $\mathbf{h_1}...\mathbf{h_{t-1}}$ to the current state $\mathbf{h_t}$. Formally, $\mathbf{h_t}$ is computed as follows:

$$\begin{aligned}
\mathbf{i_t} &= \sigma(\mathbf{W_i x_t} + \mathbf{U_i h_{t-1}} + \mathbf{V_i c_{t-1}} + \mathbf{b_i}) \\
\mathbf{f_t} &= \mathbf{1.0} - \mathbf{i_t} \\
\mathbf{g_t} &= \tanh(\mathbf{W_g x_t} + \mathbf{U_g h_{t-1}} + \mathbf{b_g}) \\
\mathbf{c_t} &= \mathbf{f_t} \odot \mathbf{c_{t-1}} + \mathbf{i_t} \odot \mathbf{g_t} \\
\mathbf{o_t} &= \sigma(\mathbf{W_o x_t} + \mathbf{U_o h_{t-1}} + \mathbf{V_o c_t} + \mathbf{b_o}) \\
\mathbf{h_t} &= \mathbf{o_t} \odot \tanh(\mathbf{c_t})
\end{aligned}$$

Here $\mathbf{x_t}$ is the word embedding of word w_t, σ denotes the sigmoid function, $\odot$ is element-wise multiplication. $\mathbf{W_i}$, $\mathbf{U_i}$, $\mathbf{V_i}$, $\mathbf{b_i}$, $\mathbf{W_g}$, $\mathbf{U_g}$, $\mathbf{b_g}$, $\mathbf{W_o}$, $\mathbf{U_o}$, $\mathbf{V_o}$ and $\mathbf{b_o}$ are LSTM parameters.

[1] Most sentiment lexicons assign a negative score to the word "not".

We apply a bidirectional extension of LSTM (BiLSTM) (Graves and Schmidhuber, 2005; Graves et al., 2013), shown in Figure 2, to encode the input sentence s both left-to-right and right-to-left. The BiLSTM model maps each word w_t to a pair of hidden vectors $\mathbf{h_t^L}$ and $\mathbf{h_t^R}$, which denote the hidden vector of the left-to-right LSTM and right-to-left LSTM, respectively. We use different parameters for the left-to-right LSTM and the right-to-left LSTM. These state vectors are used as features for calculating the sentiment weights γ.

In addition, we append a sentence end marker $w_{<e>}$ to the left-to-right LSTM and a sentence start marker $w_{<s>}$ to the right-to-left LSTM. The hidden state vector of $w_{<s>}$ and $w_{<e>}$ are denoted as $\mathbf{h_s^R}$ and $\mathbf{h_e^L}$, respectively.

3.2 Output Layer

The base score. Given a lexicon word w_{j_t} in the sentence s ($w_{j_t} \in D$), we use the hidden state vectors $\mathbf{h_{j_t}^L}$ and $\mathbf{h_{j_t}^R}$ in the feature layer to calculate a weight value τ_{j_t}. As shown in Figure 3, a two-layer neural network is used to induce τ_{j_t}. In particular, a hidden layer combines $\mathbf{h_t^L}$ and $\mathbf{h_t^R}$ using a nonlinear $tanh$ activation

$$\mathbf{p_{j_t}^s} = \tanh(\mathbf{W_{ps}^L h_{j_t}^L} + \mathbf{W_{ps}^R h_{j_t}^R} + \mathbf{b_{ps}}) \quad (2)$$

The resulting hidden vector $\mathbf{p_{j_t}^s}$ is then mapped into τ_{j_t} using another $tanh$ layer.

$$\tau_{j_t}^s = 2\tanh(\mathbf{W_{pw} p_{j_t}^s} + \mathbf{b_{pw}}) \quad (3)$$

We choose the $2tanh$ function to make the learned weights conceptually useful. The factor 2 is introduced for modelling the effect of intensification. Since the range of $tanh$ function is $[-1, 1]$, the range of $2tanh$ is $[-2, 2]$. Intuitively, a weight value of 1 maps the word sentiment directly to the sentence sentiment, such as the weight for "good" in "This is good". A weight value in $(1, 2]$ represents intensification, such as the weight for "bad" in "very bad". Similarly, a weight value in $(0, 1)$ represents weakening, and a weight in $(-2, 0)$ represents various scales of negations.

Given all lexicon words $w_{j_t}^D$ in the sentence, we calculate a base score for the sentence

$$S_{base} = \frac{\sum_{t=1}^{m} \tau_{j_t} score(w_{j_t}^D)}{m} \quad (4)$$

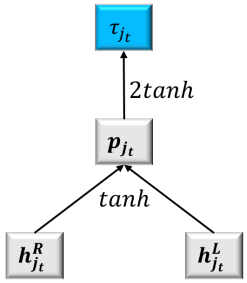

Figure 3: Weight score calculation.

By averaging the score of each word, the resulting S_{base} is confined to $[-2\alpha, 2\alpha]$, where α is the maximum absolute value of word sentiment. In the above equations, $\mathbf{W_{ps}^L}$, $\mathbf{W_{ps}^R}$, $\mathbf{b_{ps}}$, $\mathbf{W_{pw}}$ and $\mathbf{b_{pw}}$ are model parameters.

The bias score. We use the same neural network structure in Figure 3 to calculate the overall bias of the input sentence. The input to the neural network includes $\mathbf{h_s^R}$ and $\mathbf{h_e^L}$, and the output is a bias score S_{bias}. Intuitively, the calculation of S_{bias} relies on information of the full sentence. $\mathbf{h_s^R}$ and $\mathbf{h_e^L}$ are chosen because they have commonly been used in the research literature to represent overall sentential information (Graves et al., 2013; Cho et al., 2014).

We use a dedicated set of parameters for calculating the bias, where

$$\mathbf{p^B} = \tanh(\mathbf{W_{pb}^L h_e^L} + \mathbf{W_{pb}^R h_s^R} + \mathbf{b_{pb}}) \quad (5)$$

and

$$S_{bias} = 2\tanh(\mathbf{W_b p^B} + \mathbf{b_p}) \quad (6)$$

$\mathbf{W_{pb}^L}$, $\mathbf{W_{pb}^R}$, $\mathbf{b_{pb}}$, $\mathbf{W_b}$ and $\mathbf{b_p^L}$ are parameters.

3.3 Final Score Calculation

The base S_{base} and bias S_{bias} are linearly interpolated to derive the final sentiment value for the sentence s.

$$Score(s) = \lambda S_{base} + (1 - \lambda) S_{bias} \quad (7)$$

$\lambda \in [0, 1]$ reflects the relative importance of the base score in the sentence. It offers a new degree of model flexibility, and should be calculated for each sentence specifically. We use the attention model (Bahdanau et al., 2014) to this end. In particular, the base score features $\mathbf{h_t^L}$/$\mathbf{h_t^R}$ and the bias score features $\mathbf{h_e^L}$/$\mathbf{h_s^R}$ are combined in the calculation

$$\lambda = \sigma(\mathbf{W_{s\lambda} h_{base}} + \mathbf{W_{b\lambda} h_{bias}} + \mathbf{b}_\lambda) \quad (8)$$

where

$$\mathbf{h_{bias}} = \mathbf{h_e^L} \oplus \mathbf{h_s^R} \quad (9)$$

and

$$\mathbf{h_{base}} = \frac{\sum_{t=1}^{m} \mathbf{h_{jt}^L} \oplus \mathbf{h_{jt}^R}}{m} \quad (10)$$

Here σ denotes the sigmoid activation function and $\oplus$ denotes vector concatenation. $\mathbf{W_{s\lambda}}$, $\mathbf{W_{b\lambda}}$ and $\mathbf{b}_\lambda$ are model parameters.

The final score of the sentence is

$$\begin{aligned} Score(s) &= \lambda S_{base} + (1-\lambda) S_{bias} \\ &= \frac{\lambda}{m} \sum_{t=1}^{m} \tau_{jt} score(w_{jt}^D) + (1-\lambda) S_{bias} \end{aligned}$$

This corresponds to the original Equation 1 by $\gamma_{j_t} = \frac{\lambda}{m}\tau_{j_t}$ and $b = (1-\lambda)S_{bias}$.

3.4 Training and Testing

Our training data contains two different settings. The first is binary sentiment classification. In this task, every sentence s_i is annotated with a sentiment label l_i, where $l_i = 0$ and $l_i = 1$ to indicate negative and positive sentiment, respectively. We apply logistic regression on the output layer. Denote the probability of a sentence s_i being positive and negative as $p_{s_i}^1$ and $p_{s_i}^0$ respectively. $p_{s_i}^0$ and $p_{s_i}^1$ are estimated as

$$\begin{aligned} p_{s_i}^1 &= \sigma(Score(s_i)) \\ p_{s_i}^0 &= 1 - p_{s_i}^1 \end{aligned} \quad (11)$$

Suppose that there are N training sentences, the loss function over the training set is defined as

$$L(\mathbf{\Theta}) = -\sum_{i=1}^{N} \log p_{s_i}^{l_i} + \frac{\lambda_r}{2} ||\mathbf{\Theta}||^2, \quad (12)$$

where Θ is the set of model parameters. λ_r is a parameter for L2 regularization.

The second setting is multi-class classification. In this task, every sentence s_i is assigned a sentiment label l_i from 0 to 4, which represent *very negative*, *negative*, *neutral*, *positive* and *very positive*, respectively. We apply least square regression on the output layer. Since the output range of $2tanh$ is [-2, 2], the value of the base score and the bias score both belongs to [-2, 2]. The final score is a weighted sum of the base score and the bias score, also belonging to [-2, 2]. However, the gold sentiment label ranges from 0 to 4. We add an offset -2 to every gold sentiment label to both adapt our model to the training data and to increase the interpretability of the learned weights. The loss function for this problem is then defined as

$$L(\mathbf{\Theta}) = \sum_{i=1}^{N} (Score(s_i) - l_i)^2 + \frac{\lambda_r}{2} ||\mathbf{\Theta}||^2 \quad (13)$$

During testing, we predict the sentiment label l_i^* of a sentence s_i by

$$l_i^* = \begin{cases} -2 \text{ if } Score(s_i) \leq -1.5 \\ -1 \text{ if } -1.5 < Score(s_i) \leq -0.5 \\ 0 \text{ if } -0.5 < Score(s_i) \leq 0.5 \\ 1 \text{ if } 0.5 < Score(s_i) \leq 1.5 \\ 2 \text{ if } Score(s_i) > 1.5 \end{cases} \quad (14)$$

tree is given. Each internal constituent node is annotated with a sentiment label ranging from 0 to 4. We follow Socher et al. (2011) and Li et al. (2015) to perform five-class and binary classification, with the data statistics being shown in Table 2.

In order to examine cross-domain robustness, we apply our model on a product review corpus (Täckström and McDonald, 2011), which contains 196 documents covering 5 domains: books, dvds, electronics, music and videogames. The document distribution is listed in Table 3.

Lexicons. We use four sentiment lexicons, namely *TS-Lex*, *S140-Lex*, *SD-Lex* and *SWN-Lex*. **TS-Lex**[3] is a large-scale sentiment lexicon built from Twitter by Tang et al. (2014a) for learning sentiment-specific phrase embeddings. **S140-Lex**[4] is the *Sentiment140* lexicon, which is built from point-wise mutual information using distant supervision (Go et al., 2009; Mohammad et al., 2013).

SD-Lex is built from SST. We construct a sentiment lexicon from the training set by excluding all neutral words and adding the aforementioned offset -2 to each entry. **SWN-Lex** is a sentiment lexicon extracted from SentimentWordNet3.0 (Baccianella et al., 2010). For words with different part-of-speech tags, we keep the minimum negative score or the maximum positive score. The original score in the SentimentWordNet3.0 is a probability value between 0 and 1, and we scale it to [-2, 2][5].

When building these lexicons, we only use the sentiment scores for unigrams. Ambiguous words are discarded. Both TS-Lex and S140-Lex are Twitter-specific sentiment lexicons. They are used in the Twitter sentiment classification task. SD-Lex and SWN-Lex are exploited for the Stanford dataset. The statistics of lexicons are listed in Table 4.

[3]http://ir.hit.edu.cn/ dytang/paper/14coling/data.zip

[4]http://saifmohammad.com/Lexicons/Sentiment140-Lexicon-v0.1.zip

[5]Taboada et al. (2011) also mentioned two methods to derive sentiment score for a sentiment word from SentimentWordNet. We leave them for future work.

Lexicon	Positive	Negative	Total
SD-Lex	2,547	2,448	4,995
SWN-Lex	15,568	17,412	32,980
TS-Lex	33,997	32,026	66,023
S140-Lex	24,156	38,312	62,468

Table 4: Statistics of sentiment lexicons.

4.2 Implementation Details

We implement our model based on the CNN toolkit.[6] Parameters are optimized using stochastic gradient descent with momentum (Sutskever et al., 2013). The decay rate is 0.1. For initial learning rate, L2 and other hyper-parameters, we adopt the default values provided by the CNN toolkits. We select the best model parameter according to the classification accuracy on the development set.

For the Twitter data, we use the *glove.twitter.27B*[7] as pretrained word embeddings. For the Stanford dataset, following Li et al. (2015), we use *glove.840B.300d*[8] as pretrained word embeddings. Words that do not exist in both the training set and the pretrained lookup table are treated as out-of-vocabulary (OOV) words. Following Dyer et al. (2015), singletons in the training data are randomly mapped to UNK with a probability p_{unk} during training. We set $p_{unk} = 0.1$. All word embeddings are fine-tuned. We use dropout (Srivastava et al., 2014) in the input layer to prevent overfitting during training.

One-layered BiLSTM is used for all tasks. The dimension of the hidden vector in LSTM is 150. The size of the second layer in Figure 3 is 64.

4.3 Development Results

Table 5 shows results on the Twitter development set. **Bi-LSTM** is our model using the bias score S_{bias} only, which is equivalent to bidirectional LSTM model of Li et al. (2015) and Tai et al. (2015), since they use same features and only differ in the output layer. **Bi-LSTM+avg.lexicon** is a baseline model integrating the average sentiment scores of lexicon words as a feature, and **Bi-LSTM+flex.lexicon** is our final model, which considers both the Bi-LSTM score (S_{bias}) and the context-sensitive score (S_{base}).

[7]http://nlp.stanford.edu/data/glove.twitter.27B.zip

[8]http://nlp.stanford.edu/data/glove.840B.300d.zip

Method	Dict	Dev(%)
Bi-LSTM	None	84.2
Bi-LSTM+avg.lexicon	S140-Lex	84.9
Bi-LSTM+flex.lexicon	S140-Lex	**86.4**

Table 5: Results on the Twitter development set.

Method	Test(%)
SVM6 (Zhu et al., 2014)	78.5
Tang et al. (2014a)	82.4
Bi-LSTM	86.7
Bi-LSTM + TS-Lex	87.6
Bi-LSTM + S140-Lex	**88.0**

Table 6: Results on the Twitter test set.

Bi-LSTM+avg.lexicon improves the classification accuracy over **Bi-LSTM** by 0.7 point, which shows the usefulness of sentiment lexicons to *recurrent neural models* using a vanilla method. It is consistent with previous research on *discrete* models. By considering *context-sensitive* weighting for sentiment words **Bi-LSTM+flex.lexicon** further outperforms **Bi-LSTM+avg.lexicon**, improving the accuracy by 1.5 points ($84.9 \rightarrow 86.4$), which demonstrates the strength of context-sensitive scoring. Base on the development results, we use **Bi-LSTM+flex.lexicon** for the remaining experiments.

4.4 Main Results

Twitter. Table 6 shows results on the Twitter test set. **SVM6** is our implementation of Zhu et al. (2014), which extracts six types of manual features from TS-Lex for SVM classification. The features include: (1) the number of sentiment words in the sentence; (2) the total sentiment scores of the sentence; (3) the maximum sentiment score; (4) the total positive and negative sentiment scores; (5) the sentiment score of the last word in the sentence. The system of Tang et al. (2014a) is a state-of-the-art system that extracts various manually designed features from TS-Lex, such as bag-of-words, term frequency, parts-of-speech, the sum of sentiment scores of all words in a tweet, etc, for SVM. The **Bi-LSTM** rows are our final models with different lexicons.

Both **SVM6** and Tang et al. (2014a) exploit discrete features. Compared to them, **Bi-LSTM** gives better accuracies without using lexicons, which demonstrates the relative strength of deep neural network for sentiment analysis. Compared with Tang et al. (2014a), our **Bi-LSTM+TS-Lex** model improves the sentiment classification accuracy from 82.4 to 87.6, which again shows the strength of context-sensitive features. S140-Lex gives slight improvements over TS-Lex.

Method	5-class	2-class
RAE (Socher et al., 2011)	43.2	82.4
MV-RNN (Socher et al., 2012)	44.4	82.9
RNTN (Socher et al., 2013)	45.7	85.4
DRNN (Irsoy and Cardie, 2014)	49.8	88.6
Dependency TreeLSTM (Tai et al., 2015)	48.4	85.7
Constituency TreeLSTM (Tai et al., 2015)	51.0	88.0
Constituency TreeLSTM (Li et al., 2015)	50.4	86.7
S-LSTM (Zhu et al., 2015)	50.1	-
LSTM-RNN (Le and Zuidema, 2015)	49.9	88.0
CNN-non-static (Kim, 2014)	48.0	87.2
CNN-multichannel (Kim, 2014)	47.4	88.1
DCNN (Kalchbrenner et al., 2014)	48.5	86.8
Paragraph-Vec (Le and Mikolov, 2014)	48.7	87.8
NBoW (Kalchbrenner et al., 2014)	42.4	80.5
SVM (Socher et al., 2013)	40.7	79.4
BiLSTM (Tai et al., 2015)	49.1	87.5
BiLSTM (Li et al., 2015)	49.8	86.7
Hier-Sequence (Li et al., 2015)	50.7	86.9
Bi-LSTM+SD-Lex	50.0	88.1
Bi-LSTM+SWN-Lex	**51.1**	**89.2**

Table 7: Results on SST. **5-class** shows fine-grained classification. The last block lists our results.

SST. Table 7 shows the results on SST. We include various results of recursive (the first block), convolutional (the second block), and sequential LSTM models (the fourth block). These neural models give the recent state-of-the-art on this dataset. Our method achieves highly competitive accuracies. In particular, compared to sequential LSTMs, our best model gives the top result both on the binary and fine-grained classification task. This shows the usefulness of lexicons to neural models. In addition, SWN-Lex gives better results compared with SD-Lex. This is intuitive because SD-Lex is a smaller lexicon compared to SWN-Lex (4,999 entries v.s. 32,980 entries). SD-Lex does not bring external knowledge to this dataset, while SWN-Lex does.

Cross-domain Results. Lexicon-based methods can be robust for cross-domain sentiment analysis (Taboada et al., 2011). We test the robustness of our model in the mixed domain dataset of product reviews (Täckström and McDonald, 2011). This dataset contains document level sentiments. We take the majority voting strategy to transform sentiment

Model	Train	Test	Books	Dvds	Electronics	Music	Videogames	Average
Bi-LSTM	None	None	71.79	89.74	65.79	95	**85**	81.63
Bi-LSTM+flex.lexicon	SD-Lex	SD-Lex	76.92	84.62	**78.95**	92.5	80	82.65
Bi-LSTM+flex.lexicon	SD-Lex	SWN-Lex	82.05	**92.31**	73.68	92.5	80	84.18
Bi-LSTM+flex.lexicon	SWN-Lex	SWN-Lex	**84.62**	**92.31**	68.42	**100**	**85**	**86.22**

Table 8: Cross-domain sentiment analysis. Training domain is movie review.

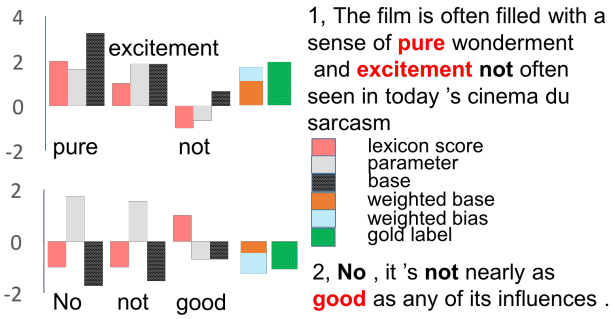

Figure 4: Sentiment composition examples.

ID	Sentence	Bi-LSTM	SWN-Lex
1	The issue of faith is not explored very deeply	0	-1
2	Steers turns in a snappy screenplay that curls at the edges; it 's so clever you want to hate it.	2	1
3	A film so tedious that it is impossible to care whether that boast is true or not.	-2	-1

Table 9: Example predictions made by the Bi-LSTM model and our Bi-LSTM+SWN-Lex model for fine-grained classification task. Red words and blue words are positive and negative entries in the SentimentWordNet3.0 lexicon, respectively.

of sentences to the document level. We compare the effects of different lexicons over a baseline Bi-LSTM trained on SST (movie domain).

Table 8 shows the results. Introducing the sentiment lexicons SD-Lex and SWN-Lex consistently improves the classification accuracy across five domains compared with the baseline **Bi-LSTM** model. When trained and tested using the same lexicon, SWN-Lex gives better performances on three out of five domains. SD-Lex gives better results only on Electronics. This shows that the results are sensitive to the domain of the sentiment lexicon, which is intuitive.

We also investigate a model trained using SD-Lex but tested by replacing SD-Lex with SWN-Lex. This is to examine the generalizability of a source-domain model on different target domains by plugging in relevant domain-specific lexicons, without being retrained. Results show that the mode still outperforms the SD-Lex lexicon on two out of five domains, but is less accurate than full retraining using SWN-Lex.

4.5 Discussion

Figure 4 shows the details of sentiment composition for two sentences in the SST, learned automatically by our model. For the first sentence, the three subjective words in the lexicon "pure", "excitement" and "not" receives weights of 1.6, 1.9 and -0.6, respectively, and the overall bias of the sentence is positive. A λ value (0.58) that slightly biases towards the base score leads to a final sentiment score is 1.8, which is close to the gold label 2.

In the second example, both negation words received positive weight values, and the bias over the sentence is negative. A λ (0.3) value that biases towards the bias score results in a final score of -1.2, which is close to the gold label -1. These results demonstrate the capacity of the model to decide how word-level sentiments composite according to sentence-level context.

Table 9 shows three sentences in the Stanford test set which are incorrectly classified by Bi-LSTM model, but correctly labeled by our Bi-LSTM+SWN-Lex model. These examples show that our model is more sensitive to context-dependent sentiment changes, thanks to the use of lexicons as a basis.

5 Conclusion

We proposed a conceptually-simple, yet empirically effective method of introducing sentiment lexicon features to state-of-the-art LSTM models for sentiment analysis. Compared to the simple averag-

ing method in traditional bag-of-word models, our system leverages the strength of semantic feature learning by LSTM models to calculate a context-dependent weight for each word given an input sentence. The method gives competitive results on various sentiment analysis benchmarks. In addition, thanks to the use of lexicons, our model can improve the cross-domain robustness of recurrent neural models for sentiment analysis.

Abstract

In this paper, we present our work in emotion cause extraction. Since there is no open dataset available, the lack of annotated resources has limited the research in this area. Thus, we first present a dataset we built using SINA city news. The annotation is based on the scheme of the W3C Emotion Markup Language. Second, we propose a 7-tuple definition to describe emotion cause events. Based on this general definition, we propose a new event-driven emotion cause extraction method using multi-kernel SVMs where a syntactical tree based approach is used to represent events in text. A convolution kernel based multi-kernel SVM are used to extract emotion causes. Because traditional convolution kernels do not use lexical information at the terminal nodes of syntactic trees, we modify the kernel function with a synonym based improvement. Even with very limited training data, we can still extract sufficient features for the task. Evaluations show that our approach achieves 11.6% higher F-measure compared to referenced methods. The contributions of our work include resource construction, concept definition and algorithm development.

1 Introduction

With the rapid growth of Internet, people can easily share experiences and emotions through this powerful medium anywhere and anytime. How to analyze the emotions of individuals through their writings becomes a new challenge for NLP. In recent years, studies in emotion analysis focus on emotion classification including detection of emotions expressed by writers of text (Gao et al., 2013) as well as prediction of reader emotions (Chang et al., 2015). There are also some information extraction tasks in emotion analysis, such as extracting the feeler of emotion (Das and Bandyopadhyay, 2010). However, these methods need to observe emotion linked expressions. Sometimes, however, we care more about the stimuli, or the cause of an emotion. For instance, manufacturers want to know why people love, or hate a certain product. The White House may also prefer to know the cause of the emotional text "Let us hit the streets" rather than the distribution of different emotions.

There are three main challenges in the study of emotion cause extraction. The first is that, up to now, there is no open dataset available for emotion cause extraction. This may explain why there are only few studies on emotion causes. The second is that, there is no formal definition about event in emotion cause extraction even though some researches claim that they extract events of emotion causes (Lee et al., 2010; Chen et al., 2010). The third is that, due to the complexity in annotation, the size of corpus for emotion cause extraction is usually very small. Due to this limitation, many machine learning methods are not suited for emotion cause detection. How to mine deep knowledge of a language for emotion causes is another thorny issue.

In this paper, we first present an annotated dataset for emotion cause extraction to be released to the public. We then propose to use a 7-tuple to define emotion cause events. Based on this general defi-

*corresponding author

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1639–1649,
Austin, Texas, November 1-5, 2016.

nition, we then present a new event-driven emotion cause extraction method. The basic idea is to extract events in the context of emotional text through dependency parsing. Then, a syntactic structure is used to represent nearby events. Based on this structured representation of events, a modified convolution kernel which also takes lexical features(as terminal nodes) is used to determine whether an event is emotion cause relevant. This method can detect all possible combinations of syntactic structures to obtain sufficient features for emotion analysis using a limited training set. Compared to existing methods, which either use manual rules or commonsense knowledge to extend information, our approach is completely machine learning based and it still achieves state-of-the-art performance. The contributions of this work include both resource development and algorithm development.

The rest of the paper is organized as follows. Section 2 provides a review of related works on emotion analysis. Section 3 presents emotion cause related definitions and the construction of emotion cause extraction corpus. Section 4 gives the event-driven emotion cause extraction method and section 5 is the evaluations and discussions. Section 6 concludes this work and gives the future directions.

2 Related Works

Identifying emotion categories in text is an essential subject in NLP and its applications (Liu, 2015). Moreover, emotion causes can provide important information on why there is any emotion changes. In this section, we introduce related works on the emotion analysis and emotion cause extraction.

The first issue in emotion analysis is to determine the taxonomy of emotions. Researchers have proposed a list of primary emotions(Plutchik, 1980; Ekman, 1984; Turner, 2000). In this study, we adopt Ekman's emotion classification (Ekman, 1984), which identifies six primary emotions, namely *happiness, sadness, fear, anger, disgust* and *surprise*, known as the "Big6"[1] scheme in the W3C Emotion Markup Language. This list is agreed upon by most previous works in Chinese emotion analysis.

The second issue is how to do emotion classification and emotion information extraction. Beck (Beck et al., 2014) proposed a Multi-task Gaussian-process based method for emotion classification. Xu (Xu et al., 2012) used a coarse to fine method to classify emotions in Chinese blog. Gao (Gao et al., 2013) proposed a joint model to co-train a polarity classifier and an emotion classifier. Chang (Chang et al., 2015) used linguistic template to predict reader's emotions. Das (Das and Bandyopadhyay, 2010) used an unsupervised method to extract emotion feelers from Bengali blog. There are other studies focused on joint learning with sentiment (Luo et al., 2015; Mohtarami et al., 2013), emotion in tweets or blog (Hasegawa et al., 2013; Qadir and Riloff, 2014; Ou et al., 2014; Liu et al., 2013; Quan and Ren, 2009), and emotional lexicon construction (Yang et al., 2014; Staiano and Guerini, 2014; Mohammad and Turney, 2013). However, these related works all focused on analysis of emotion expressions rather than emotion causes..

Sophia M. Y. Lee first proposed a task on emotion cause extraction (Lee et al., 2010). They manually constructed a corpus from Academia Sinica Balanced Chinese Corpus. Based on this corpus, Chen and Lee (Chen et al., 2010) proposed a rule based method to detect emotion causes. The basic idea is to make linguistic rules for cause extraction. Some studies (Gui et al., 2014; Li and Xu, 2014; Gao et al., 2015) extended the rule based method to in-formal text in Weibo text (Chinese tweets).

Other than rule based methods, Ghazi (Ghazi et al., 2015) used CRFs to extract emotion causes. However, it requires emotion cause and emotion keywords to be in the same sentence. I. Russo (Russo et al., 2011) proposed a crowd-sourcing method to obtain emotion cause related commonsense knowledge. But it is challenging to extend the commonsense knowledgebase automatically.

Resources used in the above works are not publicly accessible. Most of the methods used are rule based. Learning based methods are quite limited because annotated data is quite small in size due to high cost for annotation. Thus, rule based methods seem to be the easiest way to achieve acceptable performance. Since machine learning methods require more knowledge, which is difficult to generalize. So automatic methods only focused on simple text genre.

3 Construction of Emotion Cause Corpus

In this section, we first describe the linguistic phenomenon in emotion expressions. It serves as the inspiration to develop the annotated dataset. We then introduce details of the annotation scheme, followed by the construction of the dataset.

3.1 Linguistic Phenomenon of Emotion Causes

Emotion causes play an important role in emotion expressions. An emotion cause reveals the stimulus of an emotion. Considering linguistic phenomenon of emotion causes, we follow three basic principles in corpus construction: (1) Keep the whole context of emotion expression; (2) The basic processing unit is at the clause level; and (3) Use of formal text.

In written text, there is an emotion keyword, which is used to express an emotion, in the context of the emotion cause. Thus, finding the appropriate context of emotion keywords in the annotation is the pre-requisite to identify its cause. It is the reason why we keep the whole context of emotion keywords.

Another important kind of cues is the presence of conjunctions and prepositions. These words indicate the discourse information between clauses. In order to make use of discourse information, the basic analysis unit should be at clause level rather than at sentence level.

In the third principle, we choose the formal text in corpus construction. According to the related works, emotion expressions can have overlapping emotion cause and emotion target (Gui et al., 2014) in informal text. This is why some studies even incorporate cause extraction with target identification to improve performance. However, our focus is on emotion cause identification. We use formal news text to avoid the potential mix up.

3.2 Collection and Annotation

We first take 3 years (2013-15) Chinese city news from NEWS SINA[2] containing 20,000 articles as the raw corpus. Based on a list of 10,259 Chinese primary emotion keywords (**keywords** for short) (Xu et al., 2008), we extract 15,687 instances by keyword matching from the raw data. Here, we call the presence of an emotion keyword as an **instance** in the corpus. For each matched keyword, we extract three preceding clauses and three following clauses as the context of an instance. If a sentence has more than 3 clauses in each direction, the context will include the rest of the sentence to make the context complete. For simplicity, we omit cross paragraph context.

Note that the presence of keywords does not necessarily convey emotional information due to different possible reasons such as negative polarity and sense ambiguity. For example, "祝愿/wishes" is an emotion word of "happiness". It can also be the name of a song. Also, the presence of emotion keywords does not necessarily guarantee the existence of emotional cause neither. After removing those irrelevant instances, there are 2,105 instances remain. For each emotional instance, two annotators manually annotate the emotion categories and the cause(es) in the W3C Emotion Markup Language (EML) format. Ex1 shows an example of an annotated emotional sentence in the corpus, presented by the original simplified Chinese, followed by its English translation. To save space, we remove the xml tags in the annotation. The original annotated data is in a subsidiary file[3]. The basic analysis unit is a clause. Emotion cause is marked by <cause>, and the emotion keyword is marked by <keywords>. Emotion type, POS, position and the length of annotation are also annotated in Emotionml format.

Ex.1: 朱某今年*55*岁，*1979*年参加工作时才*19*岁，已有*36*年的手艺。"我当时被分到丹阳南京理发店工作，这是当时丹阳最大的理发店。我在那儿获得了好多证书和荣誉。" *<cause POS="v" Dis="-1">*说起自己的荣誉*</cause>*，朱某很是*<keywords type=happiness>*自豪*</keywords>*。

Mr. Zhu is 55 years old. He started working in 1979 as a barber when he was 19 , and has 36 years of experience. "I was assigned to work at the Barbershop in Danyang, Nanjing. It is the largest barbershop in Danyang. I won many awards and honors there." <cause POS="v" Dis="-1">Talking about his honors</cause>, Mr. Zhu is so <keywords type="happiness"> proud </keywords>.

Ex.1 only contains one cause. However, one keyword may have more than one corresponding emotion causes. In Ex.2, there are two relevant causes

for one keyword. In our dataset, only 59 instances have two or more causes.

Ex.2: 劝说过程中，消防官兵了解到，该女子是由于*<cause POS="v" Dis="-2">*对方拖欠工程款*</cause>*，*<cause POS="v" Dis="-1">*家中又急需用钱*</cause>*，*<keywords type=sadness>*无奈*</keywords>*才选择跳楼轻生。

During persuasion, firemen realized that the woman attempted suicide because of <cause POS="v" Dis="-2">the hold back of wages by the employer</cause>, and <cause POS="v" Dis="-1">her family asked for money urgently</cause>, she feels <keywords type=sadness>helpless</keywords> and thus

3.3 Details of Dataset and Its Annotations

Each instance in our dataset contains only one emotion keyword and at least one emotion cause. It is ensured that the keyword instance and the causes are relevant. The number of extracted instances, clauses, and emotion causes are listed in Table 1. Note that 97.2% of the instances has only one emotion cause, and instances that have two and three emotion causes hold 2.6% and 0.2% respectively. Table 2 shows the distribution of emotion types and Table 3 shows the distribution of cause positions. In the latter we can see that 78% emotion causes adjoin the emotion keywords at the clause level. Apparently, position plays a very important role in emotion cause extraction. Thus, using distance based features for emotion cause extraction is rational and necessary. Table 4 lists the phrase types of emotion causes. Verbs and verb phrases cover 93% of all cause events. Thus, our learning algorithm mainly focus on them.

Two annotators work independently during the annotation process. The key point is to distinguish clause level and phrase level in cause annotation. The clause level labels the clause which contains the emotion cause. The phrase level determines the boundary of an emotion cause. When two annotators have different opinion on one instance at clause level, we involve a third annotator as the arbitrator. In the phrase level, we use the larger boundary of the two annotations when they have the same annotation at the clause level. We reach 0.9287 for the kappa value on clause level annotation which confirmed the reliability of our annotation.

4 Event-Driven Emotion Cause Extraction

Due to the complexity of annotation in emotion cause identification, the size of annotated corpus is usually small. Since we aim to use machine learning methods to automatically learn and identify causes, we use a convolution kernel to detect all possible combinations in the syntactic structure. This allows learning from syntactic representations for emotion cause extraction. The basic idea of our proposed method is to use a tree-structure representation to capture features for emotion cause identification. For training data, we extract all valid tree structures for each event, referred to as the ETs (Event Trees). If an event is a cause, the corresponding ET is positive. Otherwise, the corresponding ET is negative. Then, we train a convolution kerneland a

POS/phrase type	Number	Percentage
Noun/Noun phrase	147	6.78%
Verb/Verb phrase	2020	93.21%

Table 4: Distribution of the POS Tag

multi-kernel SVMs using the training set to classify candidate ETs in the testing set. Since more than 97% emotion keywords only have one cause, and more than 95% causes are near the emotion keywords, candidate ETs are extracted from the context of emotion keywords. We only choose the ET with the highest probability in the classification result as the emotion cause.

4.1 Event Tree Construction

Even though there are related works on event identification in emotion cause detection, there is no formal definition of events In area of artificial intelligence (AI), researchers, such as Radinsky (Radinsky et al., 2012), gave a formal definition of an event as "action, actor, object, instrument, location and time". In our work, we need to give clear definition of event first.

In emotion cause extraction, the components of an event should be simpler. We are only interested in the action, the actor and the object, which are denoted as P, O_1, O_2, respectively, following the conventions in AI. Since Chinese is a SVO language, the actor is the subject and the action is the verb. The subject and the object of a sentence may have attributes and a predicate may have adverbial and complement. Since these components may also be helpful in emotion cause extraction, we formally define an emotion cause event as a 7-tuple:

$e = (Att_{O_1}, O_1, Adv, P, Cpl, Att_{O_2}, O_2)$.

Here, Att_{O_1} is the attribute of O_1; Att_{O_2} is the attribute of O_2; Adv is the adverbial of the predicate P; and Cpl is P's complement. In case syntactic components are not present, NIL values are used. Note that the main cue in an event is P, the action. So, in our algorithm, we extract all verbs from the text, and use dependency parsing[4] to extract all relevant syntactic components specified in e. Then, we can construct an ET.

An ET has has a fixed height of four levels. The top level is the root node. Since Chinese is a SVO language, the descendant of the root is S(subject), V(verb), and O(object). Then, the seven event components can be categorized and filled up in the relevant slots. (Att_{O_1},O_1) belongs to $S(O_1)$, (Adv,P,Cpl) belong to V, and (Att_{O_2},O_2) belongs to O. Then we can get the ET based on the definition of an event.

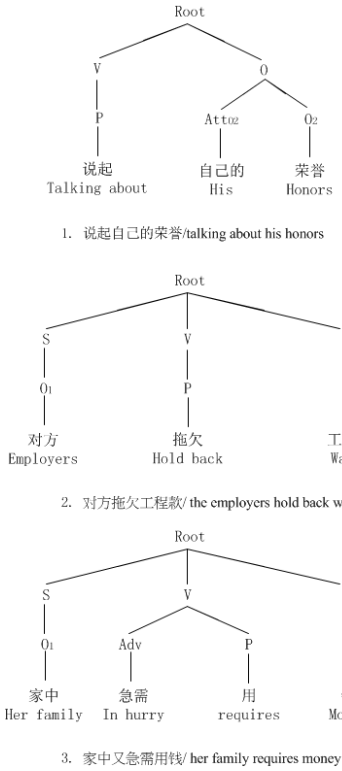

Figure 1: Example ETs of Emotion Causes.

Let us review Ex.1 and Ex.2 again. There are three emotion cause events below with their corresponding ETs shown in Figure 1.

1."说起自己的荣誉/Talking about his honors"

2."对方拖欠工程款/ the hold back wages by employers"

3."家中又急需用钱/ her family asked for money urgently"

After the construction of the ETs, emotion cause extraction becomes a classification problem. If an ET is an emotion cause, the label should be positive. Otherwise, the label should be negative. A binary classifier should be used.

4.2 Emotion Cause Extraction

After the construction of ETs, we obtain positive and negative ET samples. Due to small amount of training samples, it is necessary to capture all features in the ETs. We choose convolution kernel based SVMs because it can search all possible syntactic features under a tree structure.

Convolution kernel function

[4]https://github.com/HIT-SCIR/ltp

The convolution kernel, also known as the tree kernel (Collins and Duffy, 2002), is widely used in many NLP tasks (Srivastava et al., 2013; Moschitti, 2006). For any two inputs T_1 and T_2 based on a tree structure , the kernel is defined as:

$$K(T_1, T_2) = \sum_{n_1 \in T_1} \sum_{n_2 \in T_2} \delta(n_1, n_2). \quad (1)$$

Here, n_1 and n_2 are tree nodes. δ is a function defined recursively:
1.$\delta(n_1, n_2) = 0$ if the productions of n_1 and n_2 are different; 2.Else, $\delta(n_1, n_2) = 1$ if n_1 and n_2 are matching in pre-terminals; 3.Otherwise,

$$\delta(n_1, n_2) = \prod_i (1 + \delta(c(n_1, i), c(n_2, i))).$$

Here, $c(n, i)$ is the *i*-th node of n.

However, the above tree kernel definition does not consider terminals, which means that the actual words in a sentence are ignored. As emotions causes are semantically meaningful, we need to incorporate lexical information into the convolution kernel.

Modified kernel function

In order to distinguish different ETs, we need to modify the definition of the tree kernel to include lexical words in a clause. So we add one more definition to include the terminals:
4.If n_1 and n_2 are terminal nodes, $\delta(n_1, n_2) = 1$ if and only if n_1 and n_2 are synonyms. Otherwise $\delta(n_1, n_2) = 0$.

Here a synonym is defined in Tongyici Cilin (Extended).[5] which has 17,817 synonyms and 77,343 words. We use the synonym rather than word matching because the size of the corpus is limited. simple word matching is quite sparse.

Let K_{ET-O} denote the original kernel and K_{ET-M} denote the modified kernel, respectively. It can be easily proven that K_{ET-M} is a valid kernel function. Following the notation in (Collins and Duffy, 2002), $K_{ET-O} = \sum_i h_i(T_1) \cdot h_i(T_2)$, where $h_i(T_1) = \sum_{n_1 \in N_1} I_i(n_1)$, $h_i(T_2) = \sum_{n_2 \in N_2} I_i(n_2)$ and the function $I_i(n)$ is 1 if the sub-tree i is rooted at node n and 0 otherwise. So the original tree kernel is an inner product and the kernel matrix is semi-definite. In our modified kernel, the function $I_i(n)$ is more complicated. Beside the definition above, it has the following additional definition : $I_i(n)$ is 1 if i is a terminal node and it is a synonym of n. The new indicator is marked as $I'_i(n)$. Then we have: $K_{ET-M}(T_1, T_2) = \sum_{n_1 \in T_1} \sum_{n_2 \in T_2} \sum_i I'_i(n_1) I'_i(n_2)$. This means that the modified kernel is symmetrical and the kernel matrix is semi-definite. In our work, K_{ET-M} uses SVM optimization and the code is from SVM-light-TK[6].

Multi-kernel function

Since there are only syntactic information and synonyms in the convolution kernel based method, we need to add some lexical features. Given a 7-tuple event e, we obtain the bag-of-words based or word embedding based representation for each component in e, and the distance between a component and emotion keywords are used as the features, respectively. Let the features of each component in e be R_i, for every $i \in e$. Then, we can capture the feature set, F, of an ET by a joint operation, called the ET features:

$$F = \{R_{Att_{O_1}} \oplus R_{O_1} \oplus ... \oplus R_{Att_{O_2}}\}. \quad (2)$$

We can join the ET features with syntactic information by a multi-kernel function. For any two ETs T_1 and T_2, with the respective features F_1 and F_2, the two new multi-kernels can be defined as:

$$K_{new+O}(T_1, T_2) = K_{ET-O}(T_1, T_2) + K_{vec}(F_1, F_2), \quad (3)$$

$$K_{new*O}(T_1, T_2) = K_{ET-O}(T_1, T_2) \times K_{vec}(F_1, F_2), \quad (4)$$

$$K_{new+M}(T_1, T_2) = K_{ET-M}(T_1, T_2) + K_{vec}(F_1, F_2), \quad (5)$$

$$K_{new*M}(T_1, T_2) = K_{ET-M}(T_1, T_2) \times K_{vec}(F_1, F_2). \quad (6)$$

Here, K_{vec} denotes a kernel function which can be a linear kernel, a polynomial kernel or a Gaussian kernel. The next step is to train the classifier based on the multi-kernel function.

The training data is already in labeled ET format. To prepare testing data, we extract all ETs from a given instance as candidate ETs. A classifier is used to obtain the probability of emotion cause for each ET to produce a ranked list of candidate ETs. The ET with the highest rank serves as the cause event for the current instance.

[6]http://disi.unitn.it/moschitti/Tree-Kernel.htm

5 Performance Evaluations

5.1 Experimental Setup

In the experiments, we stochastically select 90% of the dataset as training data and 10% as testing data. In order to obtain statistically credible results, we evaluate our methods and the reference methods 25 times. We conduct two sets of experiments. The first one evaluates the performance at the clause level to identify the clauses that contain emotion causes. The second one evaluates emotion causes using verb classification. This is because 93.21% of emotion causes are verb/verb phrase and verbs serve as the action component in event definition.

5.2 Emotion Cause Extraction

We use the commonly accepted measure proposed by Lee (Lee et al., 2010) for emotion cause extraction (Gao et al., 2015; Li and Xu, 2014). In this measure, if a roposed emotion cause covers the annotated answer, the sequence is considered correct. Te precision, recall, and F-measure are defined by

$$Precision = \frac{\sum correct\_cause1}{\sum proposed\_cause1},$$
$$Recall = \frac{\sum correct\_cause1}{\sum annotated\_cause1},$$
$$F - measure = \frac{2 \times Precision \times Recall}{Precision + Recall}.$$

In the experiment, evaluation is conducted for the following works:

1.**RB**(Rule based method): Among several rule based methods (Lee et al., 2010; Gui et al., 2014; Li and Xu, 2014). We use lee2010's rules (listed in **Appendix** of this paper).

2.**CB**(Commonsense based method): In order to reproduce this method (Russo et al., 2011), we use the Chinese Emotion Cognition Lexicon (Xu et al., 2013) as the commonsense. The lexicon contains more than 5,000 emotion stimulations and their corresponding reflection words.

3.**ML**(Rule base features for machine learning): Rules are used as features with other manual features for emotion cause classification (Chen et al., 2010).

4. K_{vec} : Features are defined in Formula (2) in the training of classifier.

Method	Precision	Recall	F-measure
RB	**0.6747**	0.4287	0.5243
CB	0.2672	**0.7130**	0.3887
RB+CB	0.5435	0.5307	0.5370
RB+CB+ML	0.5921	0.5307	**0.5597**
K_{vec}	0.4200	0.4375	0.4285
$K_{word2vec}$	0.4301	0.4233	0.4136
K_{ET-O}	0.3982	0.4134	0.4057
K_{ET-M}	0.4583	0.4745	0.4662
K_{new+O}	0.6446	0.6779	0.6608
K_{new*O}	0.6492	0.6701	0.6595
K_{new+M}	0.6588	**0.6927**	0.6752
K_{new*M}	**0.6673**	0.6841	**0.6756**

Table 5: Performance on the Dataset

5.$K_{word2vec}$: Word2vec (Mikolov et al., 2013) is used to learn word representation. Use the representation according to Formula (2) in the training of classifier.

6.K_{ET-O} : This is the original tree kernel.

7.K_{ET-M} : This is the modified tree kernel in Formula (1).

8.K_{new+O}, K_{new*O}, K_{new+M} and K_{new*M}: Use the multi-kernel gives by formulas from (3) to (6).

The performance result is given in Table 5. Among all methods, K_{new*M} achieves the top performance in F-measure. Compared to other methods, the improvement is significant with p-value less than 0.01 in t-test.

Even though RB achieves the top precision, its F-measure is limited by the low recall. Since CB is opposite to RB, the performance by RB+CB is improved. However, the improvement is quite limited, at 0.0127 in F-measure. The F-measure of our reproduced RB is similar to mentioned result of other references (Gui et al., 2014; Li and Xu, 2014). They repeat Lee's (Lee et al., 2010) method and achieve the F-measure with 0.55 more or less.

(Chen et al., 2010) reported that by using handcrafted rules as features to train a classifier with some additional features such as conjunction, action and epistemic verbs, performance can be improved significantly. In our experiment, the result is opposite to this claim. The main reason is the samples in (Chen et al., 2010) are less complex. About 85% of the emotion causes are in the same clause where the emotion keywords are. Our corpus is quite different. The percentage of causes in the same clause where the emotion keyword itself is has only about

23.6%. (Chen et al., 2010)'s method does not handle long distance relations well. This explains why it does not work well for our dataset. Although (RB+CB+ML) does not perform well, there is still 0.0334 improvement in F-measure compare to RB. Among our proposed methods, K_{vec} on the ET feature achieves 0.4285 in F-measure. Compare to CB and ML, the performance is not satisfactory. However, as a simple feature to represent lexical information, the performance is acceptable. word2vec also yield similar result. Maybe the joint operation is too simple to handle composition.

For the modified tree kernel K_{ET-M}, the performance is 0.0605 higher than the original tree kernel K_{ET-O} in F-measure. It means that the consideration of terminal node improves the performance of the tree kernel significantly. The modified tree kernel K_{ET-M} is also 0.0377 higher than K_{vec}, and 0.0526 higher than $K_{word2vec}$ in F-measure. This means kernel based syntactic representation does have better generalization ability. The original kernel function K_{ET-O} has syntactic information but no lexicon, and it not only underperforms compared to K_{ET-M} but also K_{vec} and $K_{word2vec}$. This demonstrates our modified kernel function can effectively turn an inferior method into a superior one. Compared to rule based method, the performance still needs to be enhanced and a multi-kernel is necessary. After the combination with ET feature using a multi-kernel, the performance of K_{new*M} achieves a higher level with 0.6756 in F-measure. Compare to RB, the improvement in F-measure is 0.1513. Compare to the combination of existing methods, the improvement is 0.1159. The reason is that our method represents events at the syntactic level. Synonym information gives the model more generalization ability.

5.3 Verb Classification for Emotion Cause

In this section, we examine the performance of ETs classification with respect to verbs identified in the emotion clauses.

ETs Classification

Our method is based on ETs classification to choose the candidate ET with the highest probability. The performance is measured by the verbs in the identified ET. Results are shown in Table 6.

Note that $K_{word2vec}$ performs much better than K_{vec} in verb identification, contrary to their similar performance in clause identification. The reason is that extraction result is based on ranking and only top ranked event affects the performance. In other words, precision is more important than recall here. For the same reason, K_{new+M} is better than K_{new*M} in classification of ETs, although only marginally. Nonetheless, using revised convolution kernel with multi-kernel training is still significantly better than the original kernel K_{new*M} which achieves the best performance in Table 5. When the precision of the two methods are similar, such as K_{ET-O} and K_{ET-M}, the effect of recall becomes important.

Method	Precision	Recall	F-measure
K_{vec}	0.3500	0.2951	0.3192
$K_{word2vec}$	0.3200	0.4833	0.3848
K_{ET-O}	0.3906	0.2773	0.3228
K_{ET-M}	0.3978	0.3303	0.3473
K_{new+O}	0.4211	0.7219	0.5319
K_{new*O}	0.4197	0.7305	0.5331
K_{new+M}	0.4407	**0.7694**	**0.5651**
K_{new*M}	**0.4532**	0.7504	0.5646

Table 6: Performance on ETs Classification

The multi-kernel not only achieves the best performance on both precision and recall, the increase in performance is also significant with at least 0.2173 (between K_{ET-M} and K_{new*M}). Obviously, multi-kernel is not just a simple voting or joint for the components, it benefits from two kernels to achieve better performance.

5.4 Error Analysis

There are mainly three types of errors in our model. We use case examples to show them.

a) Cascading Events

In some cases, events may happen like a chain reaction. An event that leads to an emotion may be the consequent of another event. Identifying the right event in a chain is more challenging. In the following example:

Ex.3: 约兰·沃森坠入冰冷的水中。<*cause*>刺骨的冰水</*cause*>让他感到极其寒冷与<*keywords*>害怕</*keywords*>，约兰·沃森慌忙用不太流利的中文大呼“救命”。

John Watson fell into icy water. <*cause*>*The chilly water*</*cause*> *made him feel so cold and* <*keywords*>*scared*</*keywords*> *John Watson had to*

use his broken Chinese to call for help.

the emotion cause should be "刺骨的冰水*/the chilly water*". Our method output "坠入冰冷的水中*/fell into icy water*" as the emotion cause with probability 60.83%. The probability of the correct cause is 58.89%. As a probability based method, our method does not have the ability to analyze the sequence of events nor the relation between them.

b) Sensory verbs

Sensory verbs usually indicate the emotion cause. There are exceptional cases as shown below:

Ex.4: 了解霸凌事件后。教务主任说，这三名学生知道错了也感到很<*keywords*>害怕</*keywords*>，他们<*cause*>可能面临劳动服务</*cause*>

After investigation on bullying, the head says that the students realized their mistake and were also <keywords>scared</keywords>. They <cause> may need to do community service</cause>

In this case, the cause of "scared" is the punishment of community service. But the template of *"*知道…感到*/realized ... and felt"* usually indicate that there is an emotion cause between the two sensory verbs. Our algorithm gives *"*知道错了*/ realized their mistake"* a probability of 61.65% as a cause, although this is incorrect. But, this actually indicates that our method can learn latent patterns in text.

c) Coverage of cause candidates

In the construction of ETs, we use actions as the cue to construct candidate events. However, 6.78% of our clauses do not have action words. So, these clauses are not selected as candidates.

6 Conclusion

In this paper, we present our work on emotion cause extraction. Due to the lack of open resources for this area of study, we first construct an annotated dataset from news text which will be released for public use. We also propose an event-driven emotion cause extraction method to capture the triggering events emotion changes. In this method, we propose a 7-tuple representation of events using syntactic structures to identify events. Based on this structured representation of events and the inclusion of lexical features, a convolution kernel based learning method is designed to train a multi-kernel classifier to identify emotion cause events. Compared to manually constructed rules and commonsense knowledge based methods, our proposed model can automatically obtain structure features and lexical features to achieve state-of-the-art performance on this dataset.

Abstract

Document-level sentiment classification aims to predict user's overall sentiment in a document about a product. However, most of existing methods only focus on local text information and ignore the global user preference and product characteristics. Even though some works take such information into account, they usually suffer from high model complexity and only consider word-level preference rather than semantic levels. To address this issue, we propose a hierarchical neural network to incorporate global user and product information into sentiment classification. Our model first builds a hierarchical LSTM model to generate sentence and document representations. Afterwards, user and product information is considered via attentions over different semantic levels due to its ability of capturing crucial semantic components. The experimental results show that our model achieves significant and consistent improvements compared to all state-of-the-art methods. The source code of this paper can be obtained from `https://github.com/thunlp/NSC`.

1 Introduction

Sentiment analysis aims to analyze people's sentiments or opinions according to their generated texts and plays a critical role in the area of data mining and natural language processing. Recently, sentiment analysis draws increasing attention of researchers with the rapid growth of online review sites such as Amazon, Yelp and IMDB, due to its importance to personalized recommendation.

In this work, we focus on the task of document-level sentiment classification, which is a fundamental problem of sentiment analysis. Document-level sentiment classification assumes that each document expresses a sentiment on a single product and targets to determine the overall sentiment about the product.

Most existing methods take sentiment classification as a special case of text classification problem. Such methods treat annotated sentiment polarities or ratings as categories and apply machine learning algorithms to train classifiers with text features, e.g., bag-of-words vectors (Pang et al., 2002). Since the performance of text classifiers heavily depends on the extracted features, such studies usually attend to design effective features from text or additional sentiment lexicons (Ding et al., 2008; Taboada et al., 2011).

Motivated by the successful utilization of deep neural networks in computer vision (Ciresan et al., 2012), speech recognition (Dahl et al., 2012) and natural language processing (Bengio et al., 2006), some neural network based sentiment analysis models are proposed to learn low-dimensional text features without any feature engineering (Glorot et al., 2011; Socher et al., 2011; Socher et al., 2012; Socher et al., 2013; Kim, 2014). Most proposed neural network models take the text information in a sentence or a document as input and generate the semantic representations using well-designed neural networks. However, these methods only focus

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1650–1659,
Austin, Texas, November 1-5, 2016.

on the text content and ignore the crucial characteristics of users and products. It is a common sense that the user's preference and product's characteristics make significant influence on the ratings.

To incorporate user and product information into sentiment classification, (Tang et al., 2015b) bring in a text preference matrix and a representation vector for each user and product into CNN sentiment classifier. It modifies the word meaning in the input layer with the preference matrix and concatenates the user/product representation vectors with generated document representation before softmax layer. The proposed model achieves some improvements but suffers the following two problems: (1) The introduction of preference matrix for each user/product is insufficient and difficult to be well trained with limited reviews. For example, most users in IMDB and Yelp only have several tens of reviews, which is not enough to obtain a well-tuned preference matrix. (2) The characteristics of user and product should be reflected on the semantic level besides the word level. For example, a two star review in Yelp said "great place to grab a steak and I am a huge fan of the hawaiian pizza $\cdots$ but I don't like to have to spend 100 bucks for a diner and drinks for two". It's obvious that the poor rating result mainly relies on the last sentence compared with others.

To address these issues, we propose a novel hierarchical LSTM model to introduce user and product information into sentiment classification. As illustrated in Fig. 1, our model mainly consists of two parts. Firstly, we build a hierarchical LSTM model to generate sentence-level representation and document-level representation jointly. Afterwards, we introduce user and product information as attentions over different semantic levels of a document. With the consideration of user and product information, our model can significantly improve the performance of sentiment classification in several real-world datasets.

To summarize, our effort provide the following three contributions:

(1) We propose an effective Neural Sentiment Classification model by taking global user and product information into consideration. Comparing with (Tang et al., 2015b), our model contains much less parameters and is more efficient for training.

(2) We introduce user and product information based attentions over different semantic levels of a document. Traditional attention-based neural network models only take the local text information into consideration. In contrast, our model puts forward the idea of user-product attention by utilizing the global user preference and product characteristics.

(3) We conduct experiments on several real-world datasets to verify the effectiveness of our model. The experimental results demonstrate that our model significantly and consistently outperforms other state-of-the-art models.

2 Related Work

With the trends of deep learning in computer vision, speech recognition and natural language processing, neural models are introduced into sentiment classification field due to its ability of text representation learning. (Glorot et al., 2011) use Stacked Denoising Autoencoder in sentiment classification for the first time. Socher conducts a series of recursive neural network models to learn representations based on the recursive tree structure of sentences, including Recursive Autoencoder (RAE) (Socher et al., 2011), Matrix-Vector Recursive Neural Network (MV-RNN) (Socher et al., 2012) and Recursive Neural Tensor Network (RNTN) (Socher et al., 2013). Besides, (Kim, 2014) and (Johnson and Zhang, 2014) adopt convolution neural network (CNN) to learn sentence representations and achieve outstanding performance in sentiment classification.

Recurrent neural network also benefits sentiment classification because it is capable of capturing the sequential information. (Li et al., 2015), (Tai et al., 2015) investigate tree-structured long-short term memory (LSTM) networks on text or sentiment classification. There are also some hierarchical models proposed to deal with document-level sentiment classification (Tang et al., 2015a; Bhatia et al., 2015), which generate different levels (e.g., phrase, sentence or document) of semantic representations within a document. Moreover, attention mechanism is also introduced into sentiment classification, which aims to select important words from a sen-

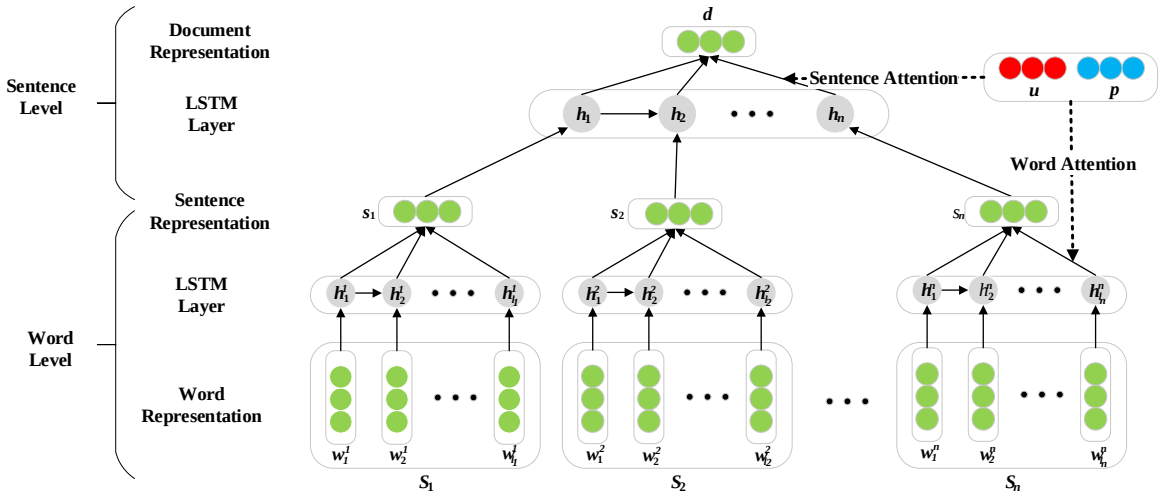

Figure 1: The architecture of User Product Attention based Neural Sentiment Classification model.

tence or sentences from a document (Yang et al., 2016).

Most existing sentiment classification models ignore the global user preference and product characteristics, which have crucial effects on the sentiment polarities. To address this issue, (Tang et al., 2015b) propose to add user/product preference matrices and representation vectors into CNN models. Nevertheless, it suffers from high model complexity and only considers word-level preference rather than semantic levels. In contrast, we propose an efficient neural sentiment classification model with users and products to serve as attentions in both word and semantic levels.

3 Methods

In this section, we will introduce our User Product Attention (UPA) based Neural Sentiment Classification (NSC) model in detail. First, we give the formalizations of document-level sentiment classification. Afterwards, we discuss how to obtain document semantic representation via the Hierarchical Long Short-term Memory (HLSTM) network . At last, we present our attention mechanisms which incorporates the global information of users and products to enhance document representations. The enhanced document representation is used as features for sentiment classification. An overall illustration of UPA based NSC model is shown in Fig. 1.

3.1 Formalizations

Suppose a user $u \in U$ has a review about a product $p \in P$. We represent the review as a document d with n sentences $\{\mathbf{S}_1, \mathbf{S}_2, \cdots, \mathbf{S}_n\}$. Here, l_i is the length of i-th sentence. The i-th sentence $\mathbf{S}_i$ consists of l_i words as $\{w_1^i, w_2^i, \cdots, w_{l_i}^i\}$. Document-level sentiment classification aims to predict the sentiment distributions or ratings of these reviews according to their text information.

3.2 Neural Sentiment Classification Model

According to the principle of compositionality (Frege, 1892), we model the semantic of a document through a hierarchical structure composed of word-level, sentence-level and document-level. To model the semantic representations of sentences, we adopt Long Short-Term Memory (LSTM) network because of its excellent performance on sentiment classification, especially for long documents. Similarly, we also use LSTM to learn document representations.

In word level, we embed each word in a sentence into a low dimensional semantic space. That means, each word w_j^i is mapped to its embedding $\mathbf{w}_j^i \in \mathbb{R}^d$. At each step, given an input word $\mathbf{w}_j^i$, the current cell state $\mathbf{c}_j^i$ and hidden state $\mathbf{h}_j^i$ can be updated with the previous cell state $\mathbf{c}_{j-1}^i$ and hidden state $\mathbf{h}_{j-1}^i$ as

follows:

$$\begin{bmatrix} \mathbf{i}_j^i \\ \mathbf{f}_j^i \\ \mathbf{o}_j^i \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \end{bmatrix} (\mathbf{W} \cdot \left[\ \mathbf{h}_{j-1}^i, \mathbf{w}_j^i \ \right] + \mathbf{b}), \quad (1)$$

$$\hat{\mathbf{c}}_j^i = \tanh(\mathbf{W} \cdot \left[\ \mathbf{h}_{j-1}^i, \mathbf{w}_j^i \ \right] + \mathbf{b}), \quad (2)$$

$$\mathbf{c}_j^i = \mathbf{f}_j^i \odot \mathbf{c}_{j-1}^i + \mathbf{i}_j^i \odot \hat{\mathbf{c}}_j^i, \quad (3)$$

$$\mathbf{h}_j^i = \mathbf{o}_j^i \odot \tanh(\mathbf{c}_j^i), \quad (4)$$

where $\mathbf{i}, \mathbf{f}, \mathbf{o}$ are gate activations, $\odot$ stands for element-wise multiplication, σ is sigmoid function, $\mathbf{W}, \mathbf{b}$ are the parameters we need to train. We then feed hidden states $[\mathbf{h}_1^i, \mathbf{h}_2^i, \cdots, \mathbf{h}_{l_i}^i]$ to an average pooling layer to obtain the sentence representation $\mathbf{s}_i$.

In sentence level, we also feed the sentence embeddings $[\mathbf{s}_1, \mathbf{s}_2, \cdots, \mathbf{s}_n]$ into LSTM and then obtain the document representation $\mathbf{d}$ through an average pooling layer in a similar way.

3.3 User Product Attention

We bring in User Product Attention to capture the crucial components over different semantic levels for sentiment classification. Specifically, we employ word-level UPA to generate sentence representations and sentence-level UPA to obtain document representation. We give the detailed implementations in the following parts.

It is obvious that not all words contribute equally to the sentence meaning for different users and products. Hence, in word level, instead of feeding hidden states to an average pooling layer, we adopt a user product attention mechanism to extract user/product specific words that are important to the meaning of sentence. Finally, we aggregate the representations of those informative words to form the sentence representation. Formally, the enhanced sentence representation is a weighted sum of hidden states as:

$$\mathbf{s}_i = \sum_{j=1}^{l_i} \alpha_j^i \mathbf{h}_j^i, \quad (5)$$

where α_j^i measures the importance of the j-th word for current user and product. Here, we embed each user u and each product p as continuous and real-valued vectors $\mathbf{u} \in \mathbb{R}^{d_u}$ and $\mathbf{p} \in \mathbb{R}^{d_p}$, where d_u and d_p are the dimensions of user embeddings and product embeddings respectively. Thus, the attention weight α_j^i for each hidden state can be defined as:

$$\alpha_j^i = \frac{\exp(e(\mathbf{h}_j^i, \mathbf{u}, \mathbf{p}))}{\sum_{k=1}^{l_i} \exp(e(\mathbf{h}_k^i, \mathbf{u}, \mathbf{p}))}, \quad (6)$$

where e is a score function which scores the importance of words for composing sentence representation. The score function e is defined as:

$$\begin{aligned} &e(\mathbf{h}_j^i, \mathbf{u}, \mathbf{p}) = \\ &\mathbf{v}^{\mathrm{T}} \tanh(\mathbf{W}_H \mathbf{h}_{ij} + \mathbf{W}_U \mathbf{u} + \mathbf{W}_P \mathbf{p} + \mathbf{b}), \end{aligned} \quad (7)$$

where $\mathbf{W}_H$, $\mathbf{W}_U$ and $\mathbf{W}_P$ are weight matrices, $\mathbf{v}$ is weight vector and $\mathbf{v}^{\mathrm{T}}$ denotes its transpose.

The sentences that are clues to the meaning of the document vary in different users and products. Therefore, in sentence level, we also use a attention mechanism with user vector $\mathbf{u}$ and product vector $\mathbf{p}$ in word level to select informative sentences to compose the document representation. The document representation $\boldsymbol{d}$ is obtained via:

$$\mathbf{d} = \sum_{i=1}^{n} \beta_i \mathbf{h}_i, \quad (8)$$

where β_i is the weight of hidden state $\boldsymbol{h_i}$ in sentence level which can be calculated similar to the word attention.

3.4 Sentiment Classification

Since document representation $\boldsymbol{d}$ is hierarchically extracted from the words and sentences in the documents, it is a high level representation of the document. Hence, we regard it as features for document sentiment classification. We use a non-linear layer to project document representation $\boldsymbol{d}$ into the target space of C classes:

$$\hat{\mathbf{d}} = \tanh(\mathbf{W}_c \mathbf{d} + \mathbf{b}_c). \quad (9)$$

Afterwards, we use a softmax layer to obtain the document sentiment distribution:

$$p_c = \frac{\exp(\hat{d}_c)}{\sum_{k=1}^{C} \exp(\hat{d}_k)}, \quad (10)$$

where C is the number of sentiment classes, p_c is the predicted probability of sentiment class c. In

Datasets	#classes	#docs	#users	#products	#docs/user	#docs/product	#sens/doc	#words/sen

Yelp 2013	5	78,966	1,631	1,633	48.42	48.36	10.89	17.38

Table 1: Statistics of IMDB, Yelp2013 and Yelp2014 datasets

our model, cross-entropy error between gold sentiment distribution and our model's sentiment distribution is defined as loss function for optimization when training:

$$L = -\sum_{d \in D} \sum_{c=1}^{C} p_c^g(d) \cdot \log(p_c(d)), \qquad (11)$$

where p_c^g is the gold probability of sentiment class c with ground truth being 1 and others being 0, D represents the training documents.

4 Experiments

In this section, we introduce the experimental settings and empirical results on the task of document-level sentiment classification.

4.1 Experimental Settings

We evaluate the effectiveness of our NSC model on three sentiment classification datasets with user and product information: IMDB, Yelp 2013 and Yelp 2014, which are built by (Tang et al., 2015b). The statistics of the datasets are summarized in Table 1. We split the datasets into training, development and testing sets in the proportion of 8:1:1, with tokenization and sentence splitting by Stanford CoreNLP (Manning et al., 2014). We use two metrics including $Accuracy$ which measures the overall sentiment classification performance and $RMSE$ which measures the divergences between predicted sentiment classes and ground truth classes. The $Accuracy$ and $RMSE$ metrics are defined as:

$$Accuracy = \frac{T}{N} \qquad (12)$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}(gd_i - pr_i)^2}{N}}, \qquad (13)$$

where T is the numbers of predicted sentiment ratings that are identical with gold sentiment ratings, N is the numbers of documents and gd_i, pr_i represent the gold sentiment rating and predicted sentiment rating respectively.

Word embeddings could be randomly initialized or pre-trained. We pre-train the 200-dimensional word embeddings on each dataset in (Tang et al., 2015a) with SkipGram (Mikolov et al., 2013). We set the user embedding dimension and product embedding dimension to be 200, initialized to zero. The dimensions of hidden states and cell states in our LSTM cells are set to 200. We tune the hyper parameters on the development sets and use adadelta (Zeiler, 2012) to update parameters when training. We select the best configuration based on performance on the development set, and evaluate the configuration on the test set.

4.2 Baselines

We compare our NSC model with several baseline methods for document sentiment classification:

Majority regards the majority sentiment category in training set as the sentiment category of each document in test set.

Trigram trains a SVM classifier with unigrams, bigrams and trigrams as features.

TextFeature extracts text features including word and character n-grams, sentiment lexicon features, etc, and then train a SVM classifier.

UPF extracts use-leniency features (Gao et al., 2013) and corresponding product features from training data, which is further concatenated with the features in **Trigram** an **TextFeature**.

AvgWordvec averages word embeddings in a document to obtain document representation which is fed into a SVM classifier as features.

SSWE generates features with sentiment-specific word embeddings (SSWE) (Tang et al., 2014) and then trains a SVM classifier.

RNTN + RNN represents each sentence with the Recursive Neural Tensor Network (RNTN) (Socher et al., 2013) and feeds sentence representations into

the Recurrent Neural Network (RNN). Afterwards, the hidden vectors of RNN are averaged to obtain document representation for sentiment classification.

Paragraph Vector implements the PVDM (Le and Mikolov, 2014) for document sentiment classification.

JMARS considers the information of users and aspects with collaborative filtering and topic modeling for document sentiment classification.

UPNN brings in a text preference matrix and a representation vector for each user and product into CNN sentiment classifier (Kim, 2014). It modifies the word meaning in the input layer with the preference matrix and concatenates the user/product representation vectors with generated document representation before softmax layer.

For all baseline methods above, we report the results in (Tang et al., 2015b) since we use the same datasets.

4.3 Model Comparisons

We list the experimental results in Table 2. As shown in this table, we manually divide the results into two parts, the first one of which only considers the local text information and the other one incorporates both local text information and the global user product information.

From the first part in Table 2, we observe that NSC, the basic implementation of our model, significantly outperforms all the other baseline methods which only considers the local text information. To be specific, NSC achieves more than 4% improvements over all datasets compared to typical well-designed neural network models. It demonstrates that NSC is effective to capture the sequential information, which can be a crucial factor to sentiment classification. Moreover, we employ the idea of local semantic attention (LA) in (Yang et al., 2016) and implement it in NSC model (denoted as NSC+LA). The results shows that the attention based NSC obtains a considerable improvements than the original one. It proves the importance of selecting more meaningful words and sentences in sentiment classification, which is also a main reason of introducing global user and product information in an attention form.

In the second part of Table 2, we show the performance of models with user product information. From this part, we have the following observations:

(1) The global user and product information is

Basic Model	Level		IMDB		Yelp2013		Yelp2014	
	Word	Sentence	Acc	RMSE	Acc	RMSE	Acc	RMSE
NSC	AVG	AVG	0.443	1.465	0.627	0.701	0.637	0.686
	AVG	ATT	0.498	1.336	0.632	0.701	0.653	0.672
	ATT	AVG	0.513	1.330	0.640	**0.686**	0.662	0.657
	ATT	ATT	**0.533**	**1.281**	**0.650**	0.692	**0.667**	**0.654**

Table 3: Effect of attention mechanisms in word and sentence level. AVG means an average pooling layer, and ATT represents the attention mechanism in word or sentence level.

Basic Model	Attention Type	IMDB		Yelp2013		Yelp2014	
		Acc	RMSE	Acc	RMSE	Acc	RMSE
NSC	ATT	0.487	1.381	0.631	0.706	0.630	0.715
	PA	0.485	1.456	0.630	0.704	0.644	0.676
	UA	0.525	**1.276**	0.645	0.699	0.644	0.680
	UPA	**0.533**	1.281	**0.650**	**0.692**	**0.667**	**0.654**

Table 4: Effect of user and product attention mechanisms. UA represents the user attention mechanism, and PA indicates the product attention mechanism.

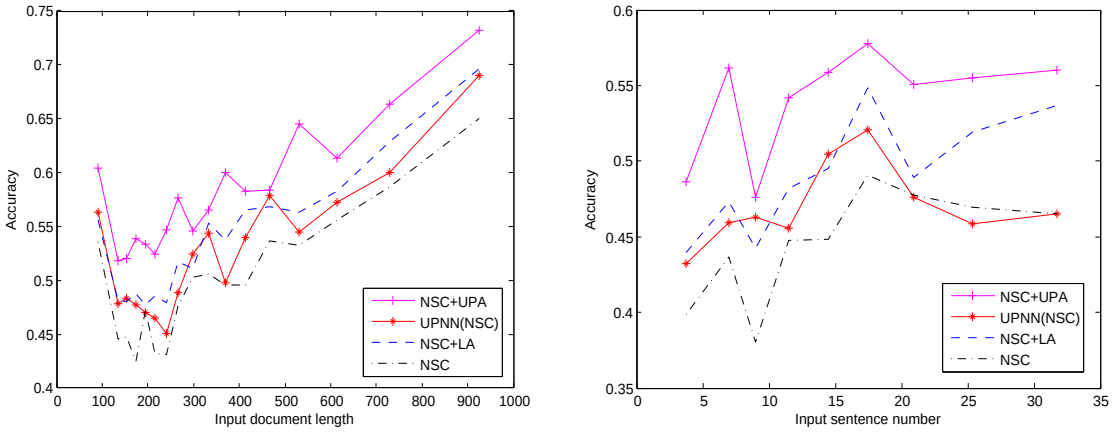
helpful to neural network based models for sentiment classification. With the consideration of such information in IMDB, UPNN achieves 3% improvement and our proposed NSC+UPA obtains 9% improvement in accuracy. The significant improvements state the necessity of considering these global information in sentiment classification.

(2) Our proposed NSC model with user production attention (NSC+UPA) significantly and consistently outperforms all the other baseline methods. It indicates the flexibility of our model on various real-world datasets. Note that, we also implement (Tang et al., 2015b)'s method to deal with user and product information on NSC (denoted as UPNN (NSC)). Though the employment of NSC improves the performance of UPNN, it is still not comparable to our model. More specifically, UPNN exceed the memory of our GPU (12G) when dealing with Yelp2014 dataset due to the high complexity of its parameters. Compared to UPNN which utilizes the user product information with matrices and vectors simultaneously, our model only embeds each user and product as a vector, which makes it suitable to large-scale datasets. It demonstrates that our NSC model is more effective and efficient to handle additional user and product information.

Observations above demonstrate that NSC with user product attention (NSC+UPA) is capable of capturing meanings of multiple semantic layers within a document. Comparing with other user product based models, our model incorporates global user product information in an effective and efficient way. Furthermore, the model is also robust and achieves consistent improvements than state-of-the-art methods on various real-world datasets.

4.4 Model Analysis: Effect of Attention Mechanisms in Word and Sentence Level

Table 3 shows the effect of attention mechanisms in word or sentence level respectively. From the table, we can observe that: (1) Both the attention mechanisms applied in word level and sentence level improve the performance for document sentiment classification compared with utilizing average pooling in word and sentence level; (2) The attention mechanism in word level improves more for our model as compared to sentence level. The reason is that the word attention mechanism can capture the informative words in all documents, while the sentence attention mechanism may only work in long documents with various topics. (3) The model considering both word level attention and sentence level attention outperforms the ones considering only one semantic level attention. It proves that the characteristics of users and products are reflected on multiple semantic levels, which is also a critical motivation of introducing User Product Attention into sentiment classification.



(a) Accuracy over document length

(b) Accuracy over sentence number

Figure 2: Accuracy over various input document lengths on IMDB test set

4.5 Model Analysis: Effect of User Product Attention Mechanisms

Table 4 shows the performance of attention mechanisms with the information of users or products. From the table, we can observe that:

(1) The information of both users and products contributes to our model as compared to a semantic attention. It demonstrates that our attention mechanism can catch the specific characteristic of a user or a product.

(2) The information of users is more effective than the products to enhance document representations. Hence, the discrimination of user preference is more obvious than product characteristics.

4.6 Model Analysis: Performance over Sentence Numbers and Lengths

To investigate the performance of our model over documents with various lengths, we compare the performance of different implementations of NSC under different document lengths and sentence number settings. Fig. 2 shows the accuracy of sentiment classification generated by NSC, NSC+ATT, UPNN(NSC) and NSC+UPA on the IMDB test set with respect to input document lengths and input sentence numbers in a document. From Fig. 2, we observe that our model NSC with attention mechanism of user and product information consistently outperforms other baseline methods for all input document lengths and sentence numbers. It indicates the robustness and flexibility of NSC on different datasets.

4.7 Case Study

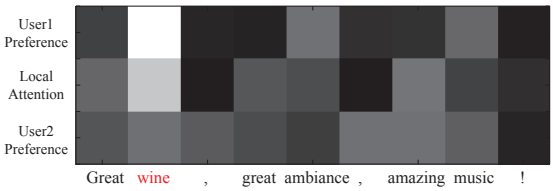


Figure 3: Visualization of attentions over words

To demonstrate the effectiveness of our global attention, we provide a review instance in Yelp2013 dataset for example. The content of this review is "Great wine, great ambiance, amazing music!". We visualize the attention weights in word-level for two distinct users and the local semantic attention (LA) in Fig 3. Here, the local semantic attention represents the implementation in (Yang et al., 2016), which calculates the attention without considering the global information of users and products. Note that, darker color means lower weight.

According to our statistics, the first user often mentions "wine" in his/her review sentences. On the contrary, the second user never talks about "wine" in his/her review sentences. Hence, we infer that the first user may has special preference to wine while the second one has no concern about wine. From the figure, we observe an interesting phenomenon which confirms to our inference. For the word "wine", the first user has the highest atten-

tion weight and the second user has the lowest attention weight. It indicates that our model can capture the global user preference via our user attention.

5 Conclusion and Future Work

In this paper, we propose a hierarchical neural network which incorporates user and product information via word and sentence level attentions. With the user and product attention, our model can take account of the global user preference and product characteristics in both word level and semantic level. In experiments, we evaluate our model on sentiment analysis task. The experimental results show that our model achieves significant and consistent improvements compared to other state-of-the-art models.

We will explore more in future as follows:

(1) In this paper, we only consider the global user preference and product characteristics according to their personal behaviors. In fact, most users and products usually have some text information such as user and product profiles. We will take advantages of those information in sentiment analysis in future.

(2) Aspect level sentiment classification is also a fundamental task in the field of sentiment analysis. The user preference and product characteristics may also implicitly influence the sentiment polarity of the aspect. We will explore the effectiveness of our model on aspect level sentiment classification.

Abstract

Recently, neural networks have achieved great success on sentiment classification due to their ability to alleviate feature engineering. However, one of the remaining challenges is to model long texts in document-level sentiment classification under a recurrent architecture because of the deficiency of the memory unit. To address this problem, we present a Cached Long Short-Term Memory neural networks (CLSTM) to capture the overall semantic information in long texts. CLSTM introduces a cache mechanism, which divides memory into several groups with different forgetting rates and thus enables the network to keep sentiment information better within a recurrent unit. The proposed CLSTM outperforms the state-of-the-art models on three publicly available document-level sentiment analysis datasets.

1 Introduction

Sentiment classification is one of the most widely used natural language processing techniques in many areas, such as E-commerce websites, online social networks, political orientation analyses (Wilson et al., 2009; O'Connor et al., 2010), etc.

Recently, deep learning approaches (Socher et al., 2013; Kim, 2014; Chen et al., 2015; Liu et al., 2016) have gained encouraging results on sentiment classification, which frees researchers from handcrafted feature engineering. Among these methods, Recurrent Neural Networks (RNNs) are one of the most prevalent architectures because of the ability to handle variable-length texts.

Sentence- or paragraph-level sentiment analysis expects the model to extract features from limited source of information, while document-level sentiment analysis demands more on selecting and storing global sentiment message from long texts with noises and redundant local pattern. Simple RNNs are not powerful enough to handle the overflow and to pick up key sentiment messages from relatively far time-steps .

Efforts have been made to solve such a scalability problem on long texts by extracting semantic information hierarchically (Tang et al., 2015a; Tai et al., 2015), which first obtain sentence representations and then combine them to generate high-level document embeddings. However, some of these solutions either rely on explicit *a priori* structural assumptions or discard the order information within a sentence, which are vulnerable to sudden change or twists in texts especially a long-range one (McDonald et al., 2007; Mikolov et al., 2013). Recurrent models match people's intuition of reading word by word and are capable to model the intrinsic relations between sentences. By keeping the word order, RNNs could extract the sentence representation implicitly and meanwhile analyze the semantic meaning of a whole document without any explicit boundary.

Partially inspired by neural structure of human brain and computer system architecture, we present the Cached Long Short-Term Memory neural networks (CLSTM) to capture the long-range sentiment information. In the dual store memory model

Austin, Texas, November 1-5, 2016.

proposed by Atkinson and Shiffrin (1968), memories can reside in the short-term "buffer" for a limited time while they are simultaneously strengthening their associations in long-term memory. Accordingly, CLSTM equips a standard LSTM with a similar cache mechanism, whose internal memory is divided into several groups with different forgetting rates. A group with high forgetting rate plays a role as a cache in our model, bridging and transiting the information to groups with relatively lower forgetting rates. With different forgetting rates, CLSTM learns to capture, remember and forget semantics information through a very long distance.

Our main contributions are as follows:

- We introduce a cache mechanism to diversify the internal memory into several distinct groups with different memory cycles by squashing their forgetting rates. As a result, our model can capture the local and global emotional information, thereby better summarizing and analyzing sentiment on long texts in an RNN fashion.
- Benefiting from long-term memory unit with a low forgetting rate, we could keep the gradient stable in the long back-propagation process. Hence, our model could converge faster than a standard LSTM.
- Our model outperforms state-of-the-art methods by a large margin on three document-level datasets (Yelp 2013, Yelp 2014 and IMDB). It worth noticing that some of the previous methods have utilized extra user and product information.

2 Related Work

In this section, we briefly introduce related work in two areas: First, we discuss the existing document-level sentiment classification approaches; Second, we discuss some variants of LSTM which address the problem on storing the long-term information.

2.1 Document-level Sentiment Classification

Document-level sentiment classification is a sticky task in sentiment analysis (Pang and Lee, 2008), which is to infer the sentiment polarity or intensity of a whole document. The most challenging part is that not every part of the document is equally informative for inferring the sentiment of the whole document (Pang and Lee, 2004; Yessenalina et al., 2010). Various methods have been investigated and explored over years (Wilson et al., 2005; Pang and Lee, 2008; Pak and Paroubek, 2010; Yessenalina et al., 2010; Moraes et al., 2013). Most of these methods depend on traditional machine learning algorithms, and are in need of effective handcrafted features.

Recently, neural network based methods are prevalent due to their ability of learning discriminative features from data (Socher et al., 2013; Le and Mikolov, 2014; Tang et al., 2015a). Zhu et al. (2015) and Tai et al. (2015) integrate a tree-structured model into LSTM for better semantic composition; Bhatia et al. (2015) enhances document-level sentiment analysis by using extra discourse paring results. Most of these models work well on sentence-level or paragraph-level sentiment classification. When it comes to the document-level sentiment classification, a bottom-up hierarchical strategy is often adopted to alleviate the model complexity (Denil et al., 2014; Tang et al., 2015b; Li et al., 2015).

2.2 Memory Augmented Recurrent Models

Although it is widely accepted that LSTM has more long-lasting memory units than RNNs, it still suffers from "forgetting" information which is too far away from the current point (Le et al., 2015; Karpathy et al., 2015). Such a scalability problem of LSTMs is crucial to extend some previous sentence-level work to document-level sentiment analysis.

Various models have been proposed to increase the ability of LSTMs to store long-range information (Le et al., 2015; Salehinejad, 2016) and two kinds of approaches gain attraction. One is to augment LSTM with an external memory (Sukhbaatar et al., 2015; Monz, 2016), but they are of poor performance on time because of the huge external memory matrix. Unlike these methods, we fully exploit the potential of internal memory of LSTM by adjusting its forgetting rates.

The other one tries to use multiple time-scales to distinguish different states (El Hihi and Bengio, 1995; Koutnik et al., 2014; Liu et al., 2015). They partition the hidden states into several groups and each group is activated and updated at different frequencies (e.g. one group updates every 2 time-step,

the other updates every 4 time-step). In these methods, different memory groups are not fully interconnected, and the information is transmitted from faster groups to slower ones, or vice versa.

However, the memory of slower groups are not updated at every step, which may lead to sentiment information loss and semantic inconsistency. In our proposed CLSTM, we assign different forgetting rates to memory groups. This novel strategy enable each memory group to be updated at every time-step, and every bit of the long-term and short-term memories in previous time-step to be taken into account when updating.

3 Long Short-Term Memory Networks

Long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997) is a typical recurrent neural network, which alleviates the problem of gradient diffusion and explosion. LSTM can capture the long dependencies in a sequence by introducing a memory unit and a gate mechanism which aims to decide how to utilize and update the information kept in memory cell.

Formally, the update of each LSTM component can be formalized as:

$$\mathbf{i}^{(t)} = \sigma(\mathbf{W}_i\mathbf{x}^{(t)} + \mathbf{U}_i\mathbf{h}^{(t-1)}), \quad (1)$$

$$\mathbf{f}^{(t)} = \sigma(\mathbf{W}_f\mathbf{x}^{(t)} + \mathbf{U}_f\mathbf{h}^{(t-1)}), \quad (2)$$

$$\mathbf{o}^{(t)} = \sigma(\mathbf{W}_o\mathbf{x}^{(t)} + \mathbf{U}_o\mathbf{h}^{(t-1)}), \quad (3)$$

$$\tilde{\mathbf{c}}^{(t)} = \tanh(\mathbf{W}_c\mathbf{x}^{(t)} + \mathbf{U}_c\mathbf{h}^{(t-1)}), \quad (4)$$

$$\mathbf{c}^{(t)} = \mathbf{f}^{(t)} \odot \mathbf{c}^{(t-1)} + \mathbf{i}^{(t)} \odot \tilde{\mathbf{c}}^{(t)}, \quad (5)$$

$$\mathbf{h}^{(t)} = \mathbf{o}^{(t)} \odot \tanh(\mathbf{c}^{(t)}), \quad (6)$$

where σ is the logistic sigmoid function. Operator $\odot$ is the element-wise multiplication operation. $\mathbf{i}^{(t)}$, $\mathbf{f}^{(t)}$, $\mathbf{o}^{(t)}$ and $\mathbf{c}^{(t)}$ are the input gate, forget gate, output gate, and memory cell activation vector at time-step t respectively, all of which have the same size as the hidden vector $\mathbf{h}^{(t)} \in \mathbb{R}^H$. $\mathbf{W}_i$, $\mathbf{W}_f$, $\mathbf{W}_o \in \mathbb{R}^{H\times d}$ and $\mathbf{U}_i$, $\mathbf{U}_f$, $\mathbf{U}_o \in \mathbb{R}^{H\times H}$ are trainable parameters. Here, H and d are the dimensionality of hidden layer and input respectively.

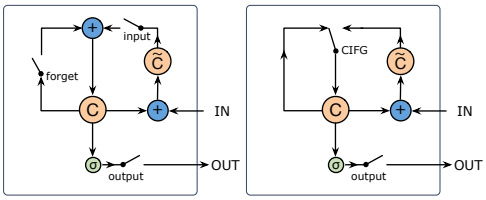

Figure 1: (a) A standard LSTM unit and (b) a CIFG-LSTM unit. There are three gates in (a), the input gate, forget gate and output gates, while in (b), there are only two gates, the CIFG gate and output gate.

4 Cached Long Short-Term Memory Neural Network

LSTM is supposed to capture the long-term and short-term dependencies simultaneously, but when dealing with considerably long texts, LSTM also fails on capturing and understanding significant sentiment message (Le et al., 2015). Specifically, the error signal would nevertheless suffer from gradient vanishing in modeling long texts with hundreds of words and thus the network is difficult to train.

Since the standard LSTM inevitably loses valuable features, we propose a cached long short-term memory neural networks (CLSTM) to capture information in a longer steps by introducing a cache mechanism. Moreover, in order to better control and balance the historical message and the incoming information, we adopt one particular variant of LSTM proposed by Greff et al. (2015), the Coupled Input and Forget Gate LSTM (CIFG-LSTM).

Coupled Input and Forget Gate LSTM Previous studies show that the merged version gives performance comparable to a standard LSTM on language modeling and classification tasks because using the input gate and forget gate simultaneously incurs redundant information (Chung et al., 2014; Greff et al., 2015).

In the CIFG-LSTM, the input gate and forget gate are coupled as one uniform gate, that is, let $\mathbf{i}^{(t)} = \mathbf{1} - \mathbf{f}^{(t)}$. We use $\mathbf{f}^{(t)}$ to denote the coupled gate. Formally, we will replace Eq. 5 as below:

$$\mathbf{c}^{(t)} = \mathbf{f}^{(t)} \odot \mathbf{c}^{(t-1)} + (\mathbf{1} - \mathbf{f}^{(t)}) \odot \tilde{\mathbf{c}}^{(t)} \quad (7)$$

Figure 1 gives an illustrative comparison of a standard LSTM and the CIFG-LSTM.

Cached LSTM Cached long short-term memory neural networks (CLSTM) aims at capturing the long-range information by a cache mechanism, which divides memory into several groups, and different forgetting rates, regarded as filters, are assigned to different groups.

Different groups capture different-scale dependencies by squashing the scales of forgetting rates. The groups with high forgetting rates are short-term memories, while the groups with low forgetting rates are long-term memories.

Specially, we divide the memory cells into K groups $\{G_1, \cdots, G_K\}$. Each group includes a internal memory $\mathbf{c}_k$, output gate $\mathbf{o}_k$ and forgetting rate $\mathbf{r}_k$. The forgetting rate of different groups are squashed in distinct ranges.

We modify the update of a LSTM as follows.

$$\mathbf{r}_k^{(t)} = \psi_k \left(\sigma(\mathbf{W}_r^k \mathbf{x}^{(t)} + \sum_{j=1}^{K} \mathbf{U}_f^{j \to k} \mathbf{h}_j^{(t-1)}) \right), \tag{8}$$

$$\mathbf{o}_k^{(t)} = \sigma(\mathbf{W}_o^k \mathbf{x}^{(t)} + \sum_{j=1}^{K} \mathbf{U}_o^{j \to k} \mathbf{h}_j^{(t-1)}), \tag{9}$$

$$\tilde{\mathbf{c}}_k^{(t)} = \tanh(\mathbf{W}_c^k \mathbf{x}^{(t)} + \sum_{j=1}^{K} \mathbf{U}_c^{j \to k} \mathbf{h}_j^{(t-1)}), \tag{10}$$

$$\mathbf{c}_k^{(t)} = (1 - \mathbf{r}_k^{(t)}) \odot \mathbf{c}_k^{(t-1)} + (\mathbf{r}_k^{(t)}) \odot \tilde{\mathbf{c}}_k^{(t)}, \tag{11}$$

$$\mathbf{h}_k^{(t)} = \mathbf{o}_k^{(t)} \odot \tanh(\mathbf{c}_k^{(t)}), \tag{12}$$

where $\mathbf{r}_k^{(t)}$ represents forgetting rate of the k-th memory group at step t; ψ_k is a squash function, which constrains the value of forgetting rate $\mathbf{r}_k$ within a range. To better distinguish the different role of each group, its forgetting rate is squashed into a distinct area. The squash function $\psi_k(\mathbf{z})$ could be formalized as:

$$\mathbf{r}_k = \psi_k(\mathbf{z}) = \frac{1}{K} \cdot \mathbf{z} + \frac{k-1}{K}, \tag{13}$$

where $\mathbf{z} \in (0, 1)$ is computed by logistic sigmoid function. Therefore, $\mathbf{r}_k$ can constrain the forgetting rate in the range of $(\frac{k-1}{K}, \frac{k}{K})$.

Intuitively, if a forgetting rate $\mathbf{r}_k$ approaches to $\mathbf{0}$, the group k tends to be the long-term memory; if a $\mathbf{r}_k$ approaches to $\mathbf{1}$, the group k tends to be the short-term memory. Therefore, group G_1 is the slowest, while group G_K is the fastest one. The faster groups are supposed to play a role as a cache, transiting information from faster groups to slower groups.

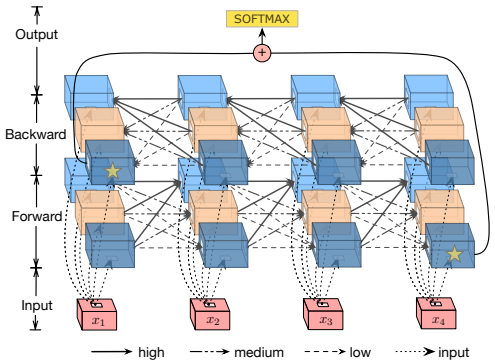

Figure 2: An overview of the proposed architecture. Different styles of arrows indicate different forgetting rates. Groups with stars are fed to a fully connected layers for softmax classification. Here is an instance of B-CLSTM with text length equal to 4 and the number of memory groups is 3.

Bidirectional CLSTM Graves and Schmidhuber (2005) proposed a Bidirectional LSTM (B-LSTM) model, which utilizes additional backward information and thus enhances the memory capability.

We also employ the bi-directional mechanism on CLSTM and words in a text will receive information from both sides of the context. Formally, the outputs of forward LSTM for the k-th group is $[\overrightarrow{\mathbf{h}}_k^{(1)}, \overrightarrow{\mathbf{h}}_k^{(2)}, \ldots, \overrightarrow{\mathbf{h}}_k^{(T)}]$. The outputs of backward LSTM for the k-th group is $[\overleftarrow{\mathbf{h}}_k^{(1)}, \overleftarrow{\mathbf{h}}_k^{(2)}, \ldots, \overleftarrow{\mathbf{h}}_k^{(T)}]$.

Hence, we encode each word w_t in a given text $w_{1:T}$ as $\mathbf{h}_k^{(t)}$:

$$\mathbf{h}_k^{(t)} = \overrightarrow{\mathbf{h}}_k^{(t)} \oplus \overleftarrow{\mathbf{h}}_k^{(t)}, \tag{14}$$

where the $\oplus$ indicates concatenation operation.

Task-specific Output Layer for Document-level Sentiment Classification With the capability of modeling long text, we can use our proposed model to analyze sentiment in a document. Figure 2 gives an overview of the architecture.

Since the first group, the slowest group, is supposed to keep the long-term information and can better represent a whole document, we only utilize the

Dataset	Type	Train Size	Dev. Size	Test Size	Class	Words/Doc	Sents/Doc
IMDB	Document	67426	8381	9112	10	394.6	16.08
Yelp 2013	Document	62522	7773	8671	5	189.3	10.89
Yelp 2014	Document	183019	22745	25399	5	196.9	11.41

Table 1: Statistics of the three datasets used in this paper. The rating scale (Class) of Yelp2013 and Yelp2014 range from 1 to 5 and that of IMDB ranges from 1 to 10. Words/Doc is the average length of a sample and Sents/Doc is the average number of sentences in a document.

final state of this group to represent a document. As for the B-CLSTM, we concatenate the state of the first group in the forward LSTM at T-th time-step and the first group in the backward LSTM at first time-step.

Then, a fully connected layer followed by a softmax function is used to predict the probability distribution over classes for a given input. Formally, the probability distribution $\mathbf{p}$ is:

$$\mathbf{p} = \text{softmax}(\mathbf{W}_p \times \mathbf{z} + \mathbf{b}_p), \tag{15}$$

where $\mathbf{W}_p$ and $\mathbf{b}_p$ are model's parameters. Here $\mathbf{z}$ is $\overrightarrow{\mathbf{h}}_1^{(T)}$ in CLSTM, and $\mathbf{z}$ is $[\overrightarrow{\mathbf{h}}_1^{(T)} \oplus \overleftarrow{\mathbf{h}}_1^{(1)}]$ in B-CLSTM.

5 Training

The objective of our model is to minimize the cross-entropy error of the predicted and true distributions. Besides, the objective includes an L_2 regularization term over all parameters. Formally, suppose we have m train sentence and label pairs $(w_{1:T_i}^{(i)}, y^{(i)})_{i=1}^m$, the object is to minimize the objective function $J(\theta)$:

$$J(\theta) = -\frac{1}{m}\sum_{i=1}^{m} \log \mathbf{p}_{y^{(i)}}^{(i)} + \frac{\lambda}{2}||\theta||^2, \tag{16}$$

where θ denote all the trainable parameters of our model.

6 Experiment

In this section, we study the empirical result of our model on three datasets for document-level sentiment classification. Results show that the proposed model outperforms competitor models from several aspects when modelling long texts.

6.1 Datasets

Most existing datasets for sentiment classification such as Stanford Sentiment Treebank (Socher et al., 2013) are composed of short paragraphs with several sentences, which cannot evaluate the effectiveness of the model under the circumstance of encoding long texts. We evaluate our model on three popular real-world datasets, Yelp 2013, Yelp 2014 and IMDB. Table 1 shows the statistical information of the three datasets. All these datasets can be publicly accessed[1]. We pre-process and split the datasets in the same way as Tang et al. (2015b) did.

- **Yelp 2013** and **Yelp 2014** are review datasets derived from Yelp Dataset Challenge[2] of year 2013 and 2014 respectively. The sentiment polarity of each review is 1 star to 5 stars, which reveals the consumers' attitude and opinion towards the restaurants.
- **IMDB** is a popular movie review dataset consists of 84919 movie reviews ranging from 1 to 10 (Diao et al., 2014). Average length of each review is 394.6 words, which is much larger than the length of two Yelp review datasets.

6.2 Evaluation Metrics

We use Accuracy (Acc.) and MSE as evaluation metrics for sentiment classification. Accuracy is a standard metric to measure the overall classification result and Mean Squared Error (MSE) is used to figure out the divergences between predicted sentiment labels and the ground truth ones.

6.3 Baseline Models

We compare our model, CLSTM and B-CLSTM with the following baseline methods.

- **CBOW** sums the word vectors and applies a non-linearity followed by a softmax classification layer.

Table 2: Sentiment classification results of our model against competitor models on IMDB, Yelp 2014 and Yelp 2013. Evaluation metrics are classification accuracy (Acc.) and MSE. Models with * use user and product information as additional features. Best results in each group are in bold.

Dataset	IMDB	Yelp13	Yelp14
Hidden layer units	120	120	120
Number of groups	3	4	4
Weight Decay	$1e{-4}$	$1e{-4}$	$5e{-4}$
Batch size	128	64	64

Table 3: Optimal hyper-parameter configuration for three datasets.

- **JMARS** is one of the state-of-the-art recommendation algorithm (Diao et al., 2014), which leverages user and aspects of a review with collaborative filtering and topic modeling.
- **CNN** UPNN (CNN) (Tang et al., 2015b) can be regarded as a CNN (Kim, 2014). Multiple filters are sensitive to capture different semantic features during generating a representation in a bottom-up fashion.
- **RNN** is a basic sequential model to model texts (Elman, 1991).
- **LSTM** is a recurrent neural network with memory cells and gating mechanism (Hochreiter and Schmidhuber, 1997).
- **BLSTM** is the bidirectional version of LSTM, and can capture more structural information and longer distance during looking forward and back (Graves et al., 2013).
- **CIFG-LSTM & CIFG-BLSTM** are Coupled Input Forget Gate LSTM and BLSTM, denoted as CIFG-LSTM and CIFG-BLSTM respectively (Greff et al., 2015). They combine the input and forget gate of LSTM and require smaller number of parameters in comparison with the standard LSTM.

6.4 Hyper-parameters and Initialization

For parameter configuration, we choose parameters on validation set mainly according to classification accuracy for convenience because MSE always has strong correlation with accuracy. The dimension of pre-trained word vectors is 50. We use 120 as the dimension of hidden units, and choose weight decay among $\{ 5e{-4}, 1e{-4}, 1e{-5} \}$. We use Adagrad (Duchi et al., 2011) as optimizer and its initial learning rate is 0.01. Batch size is chosen among $\{$ 32, 64, 128 $\}$ for efficiency. For CLSTM, the number of memory groups is chosen upon each dataset, which will be discussed later. We remain the total number of the hidden units unchanged. Given 120 neurons in all for instance, there are four memory groups and each of them has 30 neurons. This makes model comparable to (B)LSTM. Table 3 shows the optimal hyper-parameter configurations for each dataset.

For model initialization, we initialize all recurrent matrices with randomly sampling from uniform distribution in [-0.1, 0.1]. Besides, we use GloVe(Pennington et al., 2014) as pre-trained word vectors. The word embeddings are fine-tuned during training. Hyper-parameters achieving best results on

the validation set are chosen for final evaluation on test set.

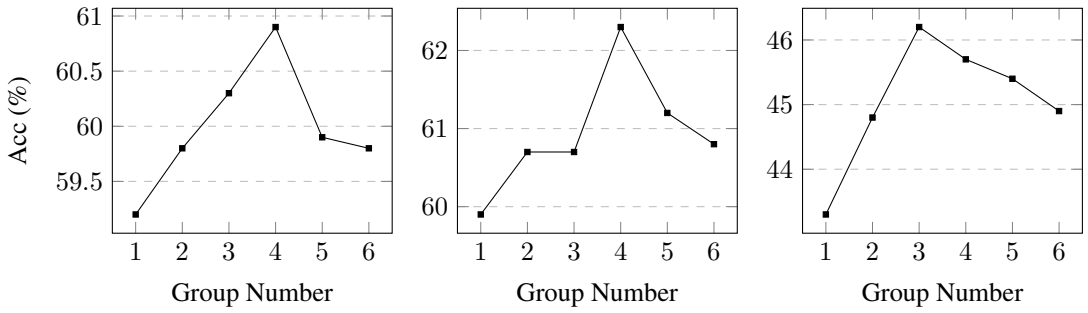
6.5 Results

The classification accuracy and mean square error (MSE) of our models compared with other competitive models are shown in Table 2. When comparing our models to other neural network models, we have several meaningful findings.

1. Among all unidirectional sequential models, RNN fails to capture and store semantic features while vanilla LSTM preserves sentimental messages much longer than RNN. It shows that internal memory plays a key role in text modeling. CIFG-LSTM gives performance comparable to vanilla LSTM.
2. With the help of bidirectional architecture, models could look backward and forward to capture features in long-range from global perspective. In sentiment analysis, if users show their opinion at the beginning of their review, single directional models will possibly forget these hints.
3. The proposed CLSTM beats the CIFG-LSTM and vanilla LSTM and even surpasses the bidirectional models. In Yelp 2013, CLSTM achieves 59.4% in accuracy, which is only 0.4 percent worse than B-CLSTM, which reveals that the cache mechanism has successfully and effectively stored valuable information without the support from bidirectional structure.
4. Compared with existing best methods, our model has achieved new state-of-the-art results by a large margin on all document-level datasets in terms of classification accuracy. Moreover, B-CLSTM even has surpassed JMARS and CNN (UPNN) methods which utilized extra user and product information.
5. In terms of time complexity and numbers of parameters, our model keeps almost the same as its counterpart models while models of hierarchically composition may require more computational resources and time.

6.6 Rate of Convergence

We compare the convergence rates of our models, including CIFG-LSTM, CIFG-BLSTM and B-CLSTM, and the baseline models (LSTM and BLSTM). We configure the hyper-parameter to make sure every competing model has approximately the same numbers of parameters, and various models have shown different convergence rates in Figure 3. In terms of convergence rate, B-CLSTM beats other competing models. The reason why B-CLSTM converges faster is that the splitting memory groups can be seen as a better initialization and constraints during the training process.



(a) Acc on Yelp 2013 (b) Acc on Yelp 2014 (c) Acc on IMDB

Figure 4: Classification accuracy on different number of memory group on three datasets. X-axis is the number of memory group(s).

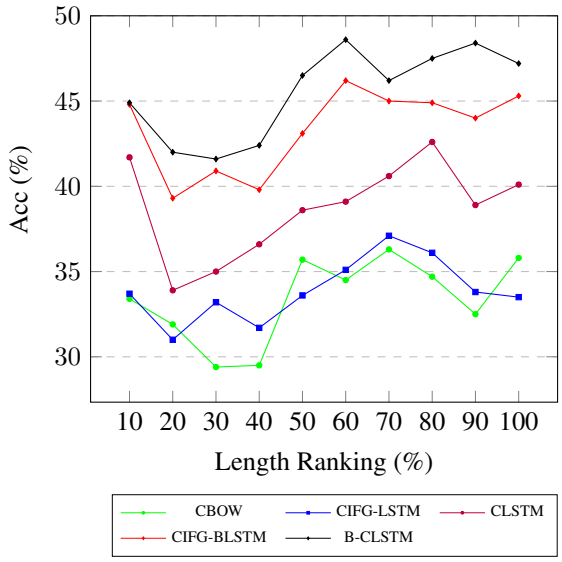


Figure 5: Study of model sensitivity on document length on IMDB. All test samples are sorted by their length and divided into 10 parts. Left most dot means classification accuracy on the shortest 10% samples. X-axis is length ranking from 0% to 100%.

6.7 Effectiveness on Grouping Memory

For the proposed model, the number of memory groups is a highlight. In Figure 4, we plot the best prediction accuracy (Y-axis) achieved in validation set with different number of memory groups on all datasets. From the diagram, we can find that our model outperforms the baseline method. In Yelp 2013, when we split the memory into 4 groups, it achieves the best result among all tested memory group numbers. We can observe the dropping trends when we choose more than 5 groups.

For fair comparisons, we set the total amount of neurons in our model to be same with vanilla LSTM. Therefore, the more groups we split, the less the neurons belongs to each group, which leads to a worse capacity than those who have sufficient neurons for each group.

6.8 Sensitivity on Document Length

We also investigate the performance of our model on IMDB when it encodes documents of different lengths. Test samples are divided into 10 groups with regard to the length. From Figure 5, we can draw several thoughtful conclusions.

1. Bidirectional models have much better performance than the counterpart models.
2. The overall performance of B-CLSTM is better than CIFG-BLSTM. This means that our model is adaptive to both short texts and long documents. Besides, our model shows power in dealing with very long texts in comparison with CIFG-BLSTM.
3. CBOW is slightly better than CIFG-LSTM due to LSTM forgets a large amount of information during the unidirectional propagation.

7 Conclusion

In this paper, we address the problem of effectively analyzing the sentiment of document-level texts in an RNN architecture. Similar to the memory structure of human, memory with low forgetting rate captures the global semantic features while memory with high forgetting rate captures the local semantic features. Empirical results on three real-world

document-level review datasets show that our model outperforms state-of-the-art models by a large margin.

For future work, we are going to design a strategy to dynamically adjust the forgetting rates for fine-grained document-level sentiment analysis.

Deep Neural Networks with Massive Learned Knowledge

Zhiting Hu, Zichao Yang, Ruslan Salakhutdinov, Eric P. Xing
School of Computer Science
Carnegie Mellon University
{zhitingh,zichaoy,rsalakhu,epxing}@cs.cmu.edu

Abstract

Regulating deep neural networks (DNNs) with human structured knowledge has shown to be of great benefit for improved accuracy and interpretability. We develop a general framework that enables learning knowledge and its confidence jointly with the DNNs, so that the vast amount of fuzzy knowledge can be incorporated and automatically optimized with little manual efforts. We apply the framework to sentence sentiment analysis, augmenting a DNN with massive linguistic constraints on discourse and polarity structures. Our model substantially enhances the performance using less training data, and shows improved interpretability. The principled framework can also be applied to posterior regularization for regulating other statistical models.

1 Introduction

Deep neural networks (DNNs) have achieved remarkable success in a large variety of application domains (Krizhevsky et al., 2012; Hinton et al., 2012; Bahdanau et al., 2014). However, the powerful end-to-end learning comes with limitations, including the requirement on massive amount of labeled data, uninterpretability of prediction results, and difficulty of incorporating human intentions and domain knowledge.

To alleviate these drawbacks, recent work has focused on training DNNs with extra domain-specific features (Collobert et al., 2011), combining oracle similarity constraints (Karaletsos et al., 2016), modeling output correlations (Deng et al., 2014), and others. Recently, Hu et al. (2016) proposed a general distillation framework that transfers knowledge expressed as first-order logic (FOL) rules into neural networks, where FOL constraints are integrated via posterior regularization (Ganchev et al., 2010). Despite the intuitiveness of FOL rules and the impressive performance in various tasks, the approach, as with the previous posterior constraint methods (Ganchev et al., 2010; Liang et al., 2009; Zhu et al., 2014), has been limited to simple *a priori* fixed constraints with manually selected weights, lacking the ability of inducing and adapting abstract knowledge from data. This issue is further exacerbated in the context of regulating DNNs that map raw data directly into the label space, leaving a huge semantic gap in between, and making it unfeasible to express rich human knowledge built on the intermediate abstract concepts.

In this paper, we introduce a generalized framework which enables a learning procedure for knowledge representations and their weights jointly with the regulated DNN models. This greatly extends the applicability to massive structures in diverse forms, such as structured models and soft logic rules, facilitating practitioners to incorporate rich domain expertise and fuzzy constraints. Specifically, we propose a *mutual* distillation method that iteratively transfers information between DNN and structured knowledge, resulting in effective integration of the representation learning capacity of DNN and the generalization power of structured knowledge. Our method does not require additional supervision beyond raw data-labels for knowledge learning.

We present an instantiation of our method in the task of sentence sentiment analysis. We aug-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1670–1679,
Austin, Texas, November 1-5, 2016.

ment a base convolutional network with linguistic knowledge that encourages coherent sentiment transitions across the clauses in terms of discourse relations. All uncertain modules, such as clause relation and polarity identification, are automatically learned from data, freeing practitioners from exhaustive specification. We further improve the model by integrating thousands of soft word polarity and negation rules, with their confidence directly induced from the data.

Trained with only sentence level supervisions, our model substantially outperforms plain neural networks learned from both sentence and clause labels. Our method also shows enhanced generalization on limited data size, and improved interpretability of predictions.

Our work enjoys general versatility on diverse types of structured knowledge and neural architectures. The principled knowledge and weight learning approach can also be applied to the posterior constraint frameworks (Ganchev et al., 2010; Liang et al., 2009) for regulating other statistical models.

2 Related Work

Deep Networks with Structured Knowledge Combining the powerful deep neural models with structured knowledge has been of increasing interest to enhance generalization and improve interpretability (Li et al., 2015; Deng et al., 2014; Johnson et al., 2016). Recently, Hu et al. (2016) proposed to transfer logical knowledge information into neural networks with diverse architectures (e.g., convolutional networks and recurrent networks). They developed an iterative distillation framework that trains the neural network to emulate the predictions of a "teacher" model which is iteratively constructed by imposing posterior constraints on the network. The framework has shown to be effective in regulating different neural models. However, the method has required fixed constraints and manually specified weights, making it unsuitable to incorporate large amount of fuzzy human intuitions where adaptation to data is necessary to obtain meaningful knowledge representations.

The limitation is in fact shared with the general-purpose posterior regularization methods (Ganchev et al., 2010; Liang et al., 2009; Zhu et al., 2014). Though attempts have been made to learn the constraint weights from additional supervisions (Mei et al., 2014) or for tractability purposes (Steinhardt and Liang, 2015), learning and optimizing knowledge expressions jointly with the regulated models from data is still unsolved, and critically restricting the application scope.

Sentiment Analysis Sentence level sentiment classification is to identify the sentiment polarity (e.g., positive or negative) of a sentence (Pang and Lee, 2008). Recently, a number of neural models have been developed and achieved new levels of performance (Kim, 2014; Socher et al., 2013; Lei et al., 2015). Despite the impressive success, most of the existing neural network approaches require large amount of labeled data while encoding very limited linguistic knowledge, making them inefficient to handle sophisticated linguistic phenomena, such as contrastive transitions and negations (Choi and Cardie, 2008; Bhatia et al., 2015).

Hu et al. (2016) combines a neural network with a logic rule that captures contrastive sense by observing the word "but" in a sentence. However, such simple deterministic rules suffer from limited generality and robustness. This paper develops a new sentiment neural model that combines a large diverse set of linguistic knowledge through our enhanced framework. Our method efficiently captures complex linguistic patterns from limited data, and yields highly interpretable predictions.

3 Mutual Distillation

This section introduces the proposed framework that enables joint learning of knowledge components and their weights with the neural network models. In particular, we generalize the one-sided distillation method of (Hu et al., 2016) (section 3.1), and propose to mutually transfer information between the neural network and the structured constraints for effective knowledge learning (section 3.2), and optimize the weights by considering jointly all components (section 3.3).

We consider input variable $\boldsymbol{x} \in \mathcal{X}$ and target variable $\boldsymbol{y} \in \mathcal{Y}$. For clarity we focus on classification where $\boldsymbol{y}$ is a one-hot encoding of the class labels, though our method also applies to other contexts. Let $(\boldsymbol{X}, \boldsymbol{Y})$ denote a set of instances of $(\boldsymbol{x}, \boldsymbol{y})$.

A neural network defines a conditional probability $p_\theta(\boldsymbol{y}|\boldsymbol{x})$ parameterized by $\boldsymbol{\theta}$. We will omit the subscript θ when there is no ambiguity.

3.1 Network Learning with Knowledge Distillation

We first review the iterative distillation method (Hu et al., 2016) that transfers structured knowledge into neural networks. Consider constraint functions $f_l \in \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$, indexed by l, that encode the knowledge and we want to satisfy (i.e., maximize by optimizing the predictions $\boldsymbol{y}$) with confidence weights $\lambda_l \in \mathbb{R}$. Given the current state of the neural network parameters $\boldsymbol{\theta}$ at each iteration, a structure-enriched teacher network q is obtained by solving

$$\min_{q \in \mathcal{P}} \mathrm{KL}(q(\boldsymbol{Y}) \| p_\theta(\boldsymbol{Y}|\boldsymbol{X})) - C \sum\nolimits_l \lambda_l \mathbb{E}_q[f_l(\boldsymbol{X}, \boldsymbol{Y})], \quad (1)$$

where $\mathcal{P}$ denotes the appropriate distribution space; and C is the regularization parameter. Problem (1) is convex and has a closed-form solution

$$q^*(\boldsymbol{Y}) \propto p_\theta(\boldsymbol{Y}|\boldsymbol{X}) \exp\left\{C \sum\nolimits_l \lambda_l f_l(\boldsymbol{X}, \boldsymbol{Y})\right\}, \quad (2)$$

whose normalization term can be calculated efficiently according to how the constraints factorize (Hu et al., 2016). The neural network p_θ at iteration t is then updated with a distillation objective (Hinton et al., 2015) that balances between imitating soft predictions of teacher q and predicting true hard labels:

$$\begin{aligned}\boldsymbol{\theta}^{(t+1)} = \arg\min_{\theta \in \Theta} \frac{1}{N} \sum_{n=1}^{N} (1-\pi)\ell(\boldsymbol{y}_n, \boldsymbol{\sigma}_\theta(\boldsymbol{x}_n)) \\ + \pi \ell(\boldsymbol{s}_n^{(t)}, \boldsymbol{\sigma}_\theta(\boldsymbol{x}_n)),\end{aligned} \quad (3)$$

where ℓ denotes the loss function (e.g., cross entropy loss for classification); $\boldsymbol{\sigma}_\theta(\boldsymbol{x})$ is the softmax output of p_θ on $\boldsymbol{x}$; $\boldsymbol{s}_n^{(t)}$ is the soft prediction vector of q on training point $\boldsymbol{x}_n$ at iteration t; N is the training size; and π is the imitation parameter calibrating the relative importance of the two objectives. The training procedure iterates between Eq.(2) and Eq.(3), resulting in the richly structured teacher model q and the knowledge distilled student network p. While q generally provides better accuracy, p is more lightweight and applicable to many different contexts (Hu et al., 2016; Liang et al., 2008).

In (Hu et al., 2016), the constraint $f_l(\boldsymbol{X}, \boldsymbol{Y})$ has been limited to be of the form $r_l(\boldsymbol{X}, \boldsymbol{Y}) - 1$, where r_l is an FOL function yielding truth values in $[0, 1]$, and is required to be fully-specified *a priori* and fixed throughout the training. Besides, the constraint weight λ_l has to be manually selected. This severely deviates from the characters of human knowledge which is usually abstract, fuzzy, built on high-level concepts (e.g., discourse relations, visual attributes) as opposed to low-level observations (e.g., word sequences, image pixels), and thus incomplete in the sense of end-to-end learning that maps raw input directly into target space of interest. This necessitates expressing structured knowledge allowing some modules unknown and induced automatically from observations.

3.2 Knowledge Learning

To substantially extend the scope of knowledge used in the framework, we introduce learnable modules $\boldsymbol{\phi}$ in the knowledge expression denoted as f_ϕ. The module $\boldsymbol{\phi}$ is general, and can be, e.g., free parameters of structured metrics, or dependency structures over semantic units. We assume f_ϕ can be optimized in terms of $\boldsymbol{\phi}$ against a given objective (e.g., through gradient descent for parameter updating). We aim to learn the knowledge by determining $\boldsymbol{\phi}$ from data.

For clarity we consider one knowledge constraint and omit the index l. We further assume the constraint factorizes over data instances. Note that our method can straightforwardly be applied to the case of multiple constraints and constraints spanning multiple instances. As any meaningful knowledge is expected to be consistent with the observations, a straightforward way is then to directly optimize against the training data: $\boldsymbol{\phi}^* = \arg\max_{\boldsymbol{\phi}} \frac{1}{N} \sum_n f_\phi(\boldsymbol{x}_n, \boldsymbol{y}_n)$, and insert the resulting f_{ϕ^*} in Eq.(1) for subsequent steps. However, such a pipelined method fails to establish interactions between the knowledge and network learning, and can lead to a sub-optimal system, as shown in our experiments.

To address this, we inspect the posterior regularization objective in Eq.(1), and write it in an analogous form to the variational free energy of some model evidence. Specifically, let $\log h_\phi(\boldsymbol{X}, \boldsymbol{Y}) \triangleq C\lambda f_\phi(\boldsymbol{X}, \boldsymbol{Y})$, then the objective can be written as

$$-\sum_{\boldsymbol{Y}} q(\boldsymbol{Y}) \log \frac{p(\boldsymbol{Y}|\boldsymbol{X}) h_\phi(\boldsymbol{X}, \boldsymbol{Y})}{q(\boldsymbol{Y})}. \quad (4)$$

Intuitively, we can view the output distribution of the neural network $p(\boldsymbol{Y}|\boldsymbol{X})$ as a prior distribution over the labels, while considering $h_\phi(\boldsymbol{X}, \boldsymbol{Y})$ as defining a "likelihood" metric w.r.t the observations, making the objective analogous to a (negative) variational lower bound of the respective "model". This naturally inspires an EM-type algorithm (Neal and Hinton, 1998) to optimize relevant parameters and improve the "evidence": the E-step optimizes over q, yielding Eq.(2); and the M-step optimizes over $\boldsymbol{\phi}$. Further incorporating the true training labels with balancing parameter π', we obtain the update for $\boldsymbol{\phi}$:

$$\boldsymbol{\phi}^{(t+1)} = \arg\max_{\phi\in\Phi} \frac{1}{N}\sum_{n=1}^{N}(1-\pi')h_\phi(\boldsymbol{x}_n, \boldsymbol{y}_n) + \pi'\mathbb{E}_{q^{(t)}(\boldsymbol{y})}[h_\phi(\boldsymbol{x}_n, \boldsymbol{y})] \tag{5}$$

The update rule resembles the distillation objective for learning parameters $\boldsymbol{\theta}$ in Eq.(3). Indeed, the expectation term in Eq.(5) in effect optimizes h_ϕ on examples labeled by $q(\boldsymbol{y})$, i.e., forcing the knowledge function to mimic the predictions of the teacher model and distill encoded information. Thus, besides transferring from structured knowledge to a neural model by Eq.(3), we now further bridge from the neural network to the knowledge constraints for joint learning and better integrating the best of both worlds. We call our framework with the symmetric objectives as *mutual distillation*. In fact, we can view Eq.(4) as a single joint objective and we are alternating optimization of $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$, resulting in the update rules in Eq.(3) and Eq.(5) with the supervised loss terms included, respectively (and with the loss function in Eq.(3) being cross-entropy loss).

Additionally, the resemblance of the two objectives indicates that we can readily translate the successful neural learning method to knowledge learning. For instance, the expectation term in Eq.(5), as the second loss term in Eq.(3), can be evaluated on rich unlabeled data in addition to labeled examples, enabling semi-supervised learning which has shown to be useful (Hu et al., 2016). Empirical studies show superiority of the proposed method over several potential alternatives (section 5).

3.3 Weight Learning

Besides optimizing the knowledge representations, we also aim to automate the selection of constraint weights by learning from data. This would enable us to incorporate massive amount of noisy knowledge, without the need to worry about the confidence which is usually unfeasible to set manually.

As the constraint weights serve to balance between the different components of the whole framework, we learn the weights by optimizing the regularized joint model q (see Eq.(2)):

$$\boldsymbol{\lambda}^{(t+1)} = \arg\max_{\boldsymbol{\lambda}\geq 0} \frac{1}{N}\sum_{n=1}^{N} q_\lambda(\boldsymbol{y}_n) \tag{6}$$

This is also validated in the view of regularized Bayes (Zhu et al., 2014) where q is a generalized posterior function by regularizing the standard posterior p (see Eq.(1)). Although here, we omit the Bayesian treatment of the weights $\boldsymbol{\lambda}$ and instead optimize them directly to find the posterior. It is straightforward to impose priors over $\boldsymbol{\lambda}$ to encode preferences. In practice, Eq. (6) can be carried out through gradient descent.

The training procedure of the proposed mutual distillation is summarized in Algorithm 1.

Algorithm 1 Mutual Distillation

Input: Training data $\mathcal{D} = \{(\boldsymbol{x}_n, \boldsymbol{y}_n)\}_{n=1}^N$,
Initial knowledge constraints $\mathcal{F} = \{f_{\phi,l}\}_{l=1}^L$,
Initial neural network p_θ,
Parameters: π, π' – imitation parameters
C – regularization parameters

1: Initialize neural network parameters $\boldsymbol{\theta}$
2: Initialize knowledge parameters $\boldsymbol{\phi}$ and weights $\boldsymbol{\lambda}$
3: **while** not converged **do**
4: Sample a minibatch $(\boldsymbol{X}, \boldsymbol{Y}) \subset \mathcal{D}$
5: Build the teacher model q with Eq.(2) and Eq.(6)
6: Update p_θ with distillation objective Eq.(3)
7: Update f_l $(l = 1, \ldots, L)$ with distillation objective Eq.(5)
8: **end while**

Output: Learned network p, knowledge modules $\mathcal{F}$, and the joint teacher network q

4 Sentiment Classification

This section provides a concrete instance of our general framework in the task of sentence sentiment analysis. We augment a base convolutional network with a large diverse set of linguistic knowledge, including 1) sentiment transition structure for coherent multi-level prediction, 2) conjunction word rules

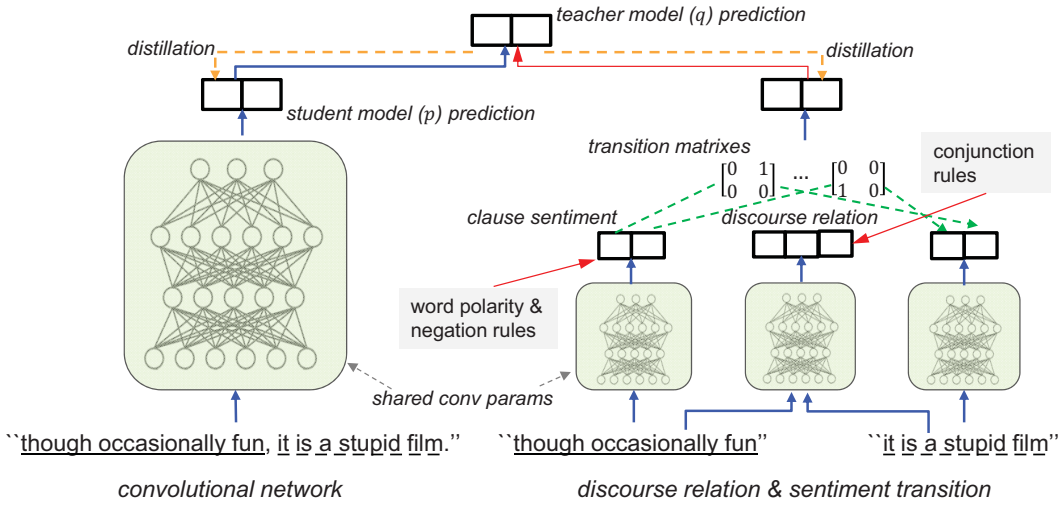

Figure 1: Our sentiment classification model. The left part is the base convolutional network over sentences, and the right part is the knowledge component over clauses. Blue arrows denote neural feed-forwards; red arrows denote knowledge incorporation steps; and the orange dashed arrows denote the distillation processes. The convolutional parameters are shared across all the networks.

for improving discourse relation identification, and 3) word polarity rules for tackling negations. These knowledge structures are fulfilled with neural network modules that are learned jointly within our framework. The resulting model efficiently captures sophisticated linguistic patterns from limited data, and produces interpretable predictions.

Figure 1 shows an overview of our model. We assume binary sentiment labels (i.e., positive-1 and negative-0). The left part of the figure is the base neural network for sentence classification. Since our framework is agnostic to the neural architecture, we can use any off-the-shelf neural models such as convolutional network and recurrent network. Here we choose the simple yet effective convolutional network proposed in (Kim, 2014). The network takes as input the word embedding vectors of a given sentence, and extracts feature maps with a convolutional layer followed by max-over-time pooling. A final fully-connected layer with softmax activation transforms the extracted features into a prediction vector.

We next introduce the three types of domain knowledge, which leverage rich fine-grained level structures, from clauses to words, to guide sentence level prediction. The clause segmentation of sentences is obtained using the public Stanford parser [1].

Sentiment transition by discourse relation Discourse structures characterize how the clauses (i.e., discourse units) of a sentence are connected with each other and thereby provide clues for coherent sentence and clause labeling. Instead of using standard general-purpose discourse relation system, we define three types of relations between adjacent clauses (denoted as c_i and c_{i+1}) specific to sentiment change, namely, *consistent* (c_i and c_{i+1} have the same polarity), *contrastive* (c_{i+1} opposes c_i and is the main part), and *concessive* (c_{i+1} opposes c_i and is secondary). The relations also indicate the connections between clauses and the whole sentence. For instance, a contrastive relation typically indicates c_{i+1} has the same polarity with the full sentence (we reasonably assume a sentence has contrastive sense in at most one position). To encode these dependencies we define sentiment *transition matrices* conditioned on discourse relation r and sentence polarity y, denoted as $M_{r,y}$. For instance, given $r = \textit{contrastive}$ and $y = 0$, we expect the sentiment change between two adjacent clauses to follow

$$M_{r=\textit{contrastive},y=0} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}, \tag{7}$$

i.e., transiting from positive polarity of c_i to negative of c_{i+1}. We list all transition matrices in supplement.

We now design a constraint on sentence predictions leveraging the above knowledge. Using the identification modules presented shortly, we first get the discourse relation probabilities $\boldsymbol{p}^r_{i,i+1}$ as well as

[1] http://nlp.stanford.edu/software/openie.html

the sentiment polarity probabilities $\boldsymbol{p}_i^c$ and $\boldsymbol{p}_{i+1}^c$ of adjacent clauses (c_i, c_{i+1}). For a given sentence label y_s, we then compute the expected transition matrix at each position by $\bar{M}_{i,y_s} = \mathbb{E}_{\boldsymbol{p}_{i,i+1}^r}[M_{r,y_s}]$. The value of the constraint function on $y = y_s$ is then defined as the probability of the most likely clause polarity configuration according to the clause predictions $\boldsymbol{p}_\cdot^c$ and the averaged transitions $\bar{M}_{\cdot,y_s}$:

$$f^{st}(\boldsymbol{x}, y_s) = \max_{\boldsymbol{a}\in\{0,1\}^m} \prod_i \boldsymbol{p}_{i,a_i}^r \cdot \bar{M}_{i,y_s,a_i a_{i+1}}, \quad (8)$$

where $\boldsymbol{a}$ is the polarity configuration and m is the number of clauses. We use the Viterbi algorithm for efficient computation.

We need the clause relation and polarity probabilities $\boldsymbol{p}^r$ and $\boldsymbol{p}^c$, which are unfeasible to identify from raw text with only simple deterministic rules. We apply a convolutional network for each module, with similar network architectures to the base network (we describe details in the supplement). For efficiency, we tie the convolutional parameters across all the networks, while leaving the parameters of the fully-connected layers to be learned individually.

Conjunction word rules We enhance the discourse relation neural network with robust clues from explicit discourse connectives (e.g., "but", "and", etc.) that occur in the sentence. In particular, we collect a set of conjunction words (listed in the supplement) and specify a rule constraint for each of them. For instance, the conjunction "and" results in the following constraint function:

$$f^{rel}(c_i, c_{i+1}, r) = \left(\mathbf{1}_{\text{and}}(c_i, c_{i+1}) \Rightarrow r = \textit{consistent}\right),$$

where $\mathbf{1}_{\text{and}}(c_i, c_{i+1})$ is an indicator function that takes 1 if the two clauses are connected by "and", and 0 otherwise. Note that these rules are soft, with the confidence weights learned from data. We use the regularized joint model over the base discourse network for predicting the relations.

Negation and word polarity rules Negations reverse the polarity of relevant statements. Identifying negation sense has been a challenging problem for accurate sentiment prediction. We address this by incorporating rich lexicon rules at the clause level. That is, if a polarity-carrying word (e.g., "good") occurs in the scope of a negator (e.g., "not"), then the sentiment prediction of the clause is encouraged to be the opposite polarity. We specify one separate rule for each polarity-carrying word from public lexicons (see the supplement), e.g.,

$$f^{lex}(c_i, y_c) = \left(\mathbf{1}_{\text{good}}(c_i) \Rightarrow y_c = \textit{negative}\right), \quad (9)$$

where $\mathbf{1}_{\text{good}}(c_i)$ is an indicator function that takes 1 if word "good" occurs in a negation scope in the clause text, and 0 otherwise. This results in over 3,000 rules, and our automated weight optimization frees us from manually selecting the weights exhaustively. We define the negation scope to be the 4 words following a negator (Choi and Cardie, 2008).

Though polarities of single words can be brittle features for determining the sentiment of a long statement due to complex semantic compositions, they are more robust and effective at the level of clauses which are generally short and simple. Moreover, inaccurate rules will be downplayed through the weight learning procedure.

We have presented our neural sentiment model. We tackle several long-standing challenges by directly incorporating linguistic knowledge. Comparing to previous work that designs various neural architectures and relies on substantial annotations for specific issues (Socher et al., 2013; Bhatia et al., 2015), our knowledge framework is more straightforward, interpretable, and general, while still preserving the power of neural methods.

Notably, even with several additional components to be learned for knowledge representation, our method does not require extra supervision signals beyond the raw sentence-labels, making our framework generally applicable to many different tasks (Neelakantan et al., 2016).

The sentiment transition knowledge is expressed in the form of structured model with features extracted using neural networks. Though apparently similar to recent deep structured models such as neural-CRFs (Durrett and Klein, 2015; Ammar et al., 2014; Do et al., 2010), ours is different since we parsimoniously extract features that are necessary for precise and efficient knowledge expression, as opposed to neural-CRFs that learn as rich representations as possible for final prediction.

5 Experiments

We evaluate our method on the widely-used sentiment classification benchmarks. Our knowledge

		Model	Accuracy (%)
sentences	1	CNN (Kim, 2014)	86.6
	2	CNN+REL	q: 87.8; p: 87.1
	3	CNN+REL+LEX	q: **88.0**; p: **87.2**
sentences	4	MC-CNN (Kim, 2014)	86.8
	5	Tensor-CNN (Lei et al., 2015)	87.0
	6	CNN+But-q (Hu et al., 2016)	87.1
+phrases	7	CNN (Kim, 2014)	87.2
	8	Tree-LSTM (Tai et al., 2015)	88.0
	9	MC-CNN (Kim, 2014)	88.1
	10	CNN+But-q (Hu et al., 2016)	89.2
	11	MVCNN (Yin and Schutze, 2015)	89.4

Table 1: Classification performance on SST2. The top and second blocks use only sentence-level annotations for training, while the bottom block uses both sentence- and phrases-level annotations. We report the accuracy of both the regularized teacher model q and the student model p after distillation.

enriched model significantly outperforms plain neural networks. We obtain even higher improvements with limited data sizes. Comparison with extensive other potential knowledge learning methods shows the effectiveness of our framework. Our model also shows improved interpretability.

5.1 Setup

Datasets Two classification benchmarks are used: 1) Stanford Sentiment Treebank-2 (**SST2**) (Socher et al., 2013) is a binary classification dataset that consists of 6920/872/1821 moview review sentences in the train/dev/test sets, respectively. Besides sentence-level annotations, the dataset also provides exhaustive gold-standard labels at fine-grained levels, from clauses to phrases. The resulting full training set includes 76,961 labeled instances. We train our model using only the *sentence-level* annotations, and compare to baselines learned from either training set. 2) Customer Reviews (**CR**) (Hu and Liu, 2004) consists of 3,775 product reviews with positive and negative polarities. Following previous work we use 10-fold cross-validation.

Model configurations We evaluate two variants of our model: CNN+REL leverages the knowledge of sentiment transition and discourse conjunctions, and CNN+REL+LEX additionally incorporates the negation lexicon rules.

Throughout the experiments we set the regularization parameter to $C = 10$. The imitation parameters π and π' decay as $\pi^{(t)} = \pi'^{(t)} = 0.9^t$ where t is the iteration number (Bengio et al., 2015; Hu et al., 2016). For the base neural network, we choose the "non-static" version from (Kim, 2014) and use the same configurations.

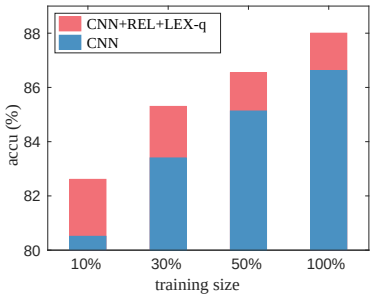

Figure 2: Performance with varying sizes of training examples.

5.2 Classification Results

Table 1 shows the classification performance on the SST2 dataset. From rows 1-3 we see that our proposed sentiment model that integrates the diverse set of knowledge (section 4) significantly outperforms the base CNN (Kim, 2014). The improvement of the student network p validates the effectiveness of the iterative mutual distillation process. Consistent with the observations in (Hu et al., 2016), the regularized teacher model q provides further performance boost, though it imposes additional computational overhead for explicit knowledge representations. Note that our models are trained with only sentence-level annotations. Compared with the baselines trained in the same setting (rows 4-6), our model with the full knowledge, CNN+REL+LEX, performs the best. CNN+But-q (row 6) is the base CNN augmented with a logic rule that identifies contrastive sense through explicit occurrence of word "but" (section 3.1) (Hu et al., 2016). Our enhanced framework enables richer knowledge and achieves much better performance.

Our method further outperforms the base CNN that is additionally trained with dense phrase-level annotations (row 7), showing improved generalization of the knowledge-enhanced model from limited data. Figure 2 further studies the performance with varying training sizes. We can clearly observe that the incorporated knowledge tends to offer higher improvement with less training data. This property can be particularly desirable in applications of structured predictions where manual annotations are expensive while rich human knowledge is available.

	Model	Accuracy (%)
1	CNN (Kim, 2014)	84.1±0.2
2	CNN+REL	q: 85.0±0.2; p: 84.7±0.2
3	CNN+REL+LEX	q: **85.3**±**0.3**; p: **85.0**±**0.2**
4	MC-CNN (Kim, 2014)	85.0
5	Bi-RNN (Lai et al., 2015)	82.6
6	CRF-PR (Yang and Cardie, 2014)	82.7
7	AdaSent (Zhao et al., 2015)	**86.3**

Table 2: Classification performance on the CR dataset. We report the average accuracy±one standard deviation with 10-fold CV. The top block compares the base CNN (row 1) with the knowledge-enhanced CNNs by our framework.

Table 2 shows model performance on the CR dataset. Our model again surpasses the base network and several other competitive neural methods by a large margin. Though falling behind AdaSent (row 7) which has a more specialized and complex architecture than standard convolutional networks, the proposed framework indeed is general enough to apply on top of it for further enhancement.

To further evaluate the proposed mutual distillation framework for learning knowledge, we compare to an extensive set of other possible knowledge optimization approaches. Table 3 shows the results. In row 2, the "opt-joint" method optimizes the regularized joint model of Eq.(2) directly in terms of both the neural network and knowledge parameters. Row 3, "opt-knwl-pipeline", is an approach that first optimizes the standalone knowledge component and then inserts it into the previous framework of (Hu et al., 2016) as a fixed constraint. Without interaction between the knowledge and neural network learning, the pipelined method yields inferior results. Finally, rows 4-5 display a method that adapts the knowledge component at each iteration by optimizing the joint model q in terms of the knowledge parameters. We report the accuracy of both the student network p (row 4) and the joint teacher network q (row 5), and compare with our method in row 6 and 7, respectively. We can see that both models performs poorly, achieving the accuracy of only 68.6% for the knowledge component, similar to the accuracy achieved by the "opt-joint" method.

In contrast, our mutual distillation framework offers the best performance. Table 3 shows that the knowledge component as a standalone classifier does not achieve high accuracy (the numbers in parentheses). As discussed in section 4, this is because of the parsimonious formulation for the precise knowledge expression, while leaving the expressive base NN to extract rich representations. The enhanced performance of the combination indicates complementary effects of the two parts.

	Model	Accuracy (%)
1	CNN (Kim, 2014)	86.6
2	opt-joint	86.9 (68.8)
3	opt-knwl-pipeline	86.7 (70.4)
4	opt-joint-iterative-p	86.9
5	opt-joint-iterative-q	87.6 (68.6)
6	mutual-p	87.2
7	mutual-q	**88.0** (72.5)

Table 3: Comparisons between our mutual distillation (rows 4-5) and other knowledge optimization methods, on SST2. See the text for details. The numbers in parentheses are the accuracy of the learned knowledge component (Figure 1, right part) if we take it as a standalone classifier. All knowledge is used.

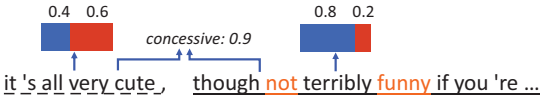

Figure 3: An example sentence and the results of the learned knowledge modules applied on it. Red denotes *positive*, and blue denotes *negative*. The snippet "not ... funny" triggers the negation rule.

enough, good, strong, engaging, great	awful, loses, fake doubt, bad

Table 4: The top 5 positive (left) and negative (right) words with the largest weights of the negation rules.

5.3 Qualitative Analysis

Our model not only provides better classification performance, but also shows improved interpretability due to the learned structured knowledge representation. Figure 3 illustrates an example sentence from test set. We see that the clause sentiments as well as the discourse relation are correctly captured. The negation rule of "not ... funny" (Eq.(9)) also helps to identify the right polarity.

Table 4 lists the top-5 positive and negative words that are most confident for the negation rules, providing insights into the linguistic norms in the movie review context.

6 Conclusion

In this paper we have developed a framework that learns structured knowledge and its weights for regulating deep neural networks through mutual distillation. We instantiated our framework for the sentiment classification task. Using massive learned linguistic knowledge, our neural model provides substantial improvements over many of the existing approaches, especially in the limited data setting. In the future work, we plan to apply our framework to other text and vision applications.

Abstract

One major deficiency of most semantic representation techniques is that they usually model a word type as a single point in the semantic space, hence conflating all the meanings that the word can have. Addressing this issue by learning distinct representations for individual meanings of words has been the subject of several research studies in the past few years. However, the generated sense representations are either not linked to any sense inventory or are unreliable for infrequent word senses. We propose a technique that tackles these problems by de-conflating the representations of words based on the deep knowledge that can be derived from a semantic network. Our approach provides multiple advantages in comparison to the previous approaches, including its high coverage and the ability to generate accurate representations even for infrequent word senses. We carry out evaluations on six datasets across two semantic similarity tasks and report state-of-the-art results on most of them.

1 Introduction

Modeling the meanings of linguistic items in a machine-interpretable form, i.e., semantic representation, is one of the oldest, yet most active, areas of research in Natural Language Processing (NLP). The field has recently experienced a resurgence of interest with neural network-based models that view the representation task as a language modeling problem and learn dense representations (usually referred to as *embeddings*) by efficiently processing massive amounts of texts. However, either in its conventional count-based form (Turney and Pantel, 2010) or the recent predictive approach, the prevailing objective of representing each word type as a single point in the semantic space has a major limitation: it ignores the fact that words can have multiple meanings and conflates all these meanings into a single representation. This objective can have negative impacts on accurate semantic modeling, e.g., semantically unrelated words that are synonymous to different senses of a word are pulled towards each other in the semantic space (Neelakantan et al., 2014). For example, the two semantically-unrelated words *squirrel* and *keyboard* are pulled towards each other in the semantic space for their similarities to two different senses of *mouse*, i.e., rodent and computer input device.

Recently, there has been a growing interest in addressing the meaning conflation deficiency of word representations. A series of techniques have been developed to associate a word to multiple points in the semantic space by clustering its contexts in a given text corpus and learning distinct representations for individual clusters (Reisinger and Mooney, 2010; Huang et al., 2012). However, these techniques usually assume a fixed number of word senses per word type, disregarding the fact that the number of senses per word can range from one (monosemy) to dozens. Neelakantan et al. (2014) tackled this issue by allowing the number to be dynamically adjusted for each word during training. However, the approach and all the other clustering-based techniques still suffer from the fact that the computed sense representations are not linked to

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1680–1690,
Austin, Texas, November 1-5, 2016.

any sense inventory, a linking which would require large amounts of sense-annotated data (Agirre et al., 2006). In addition, because of their dependence on knowledge derived from a text corpus, these techniques are generally unable to learn accurate representations for word senses that are infrequent in the underlying corpus.

Knowledge-based techniques tackle these issues by deriving sense-specific knowledge from external sense inventories, such as WordNet (Fellbaum, 1998), and learning representations that are linked to the sense inventory. These approaches either use sense definitions and employ Word Sense Disambiguation (WSD) to gather sense-specific contexts (Chen et al., 2014; Iacobacci et al., 2015) or take advantage of the properties of WordNet, such as synonymy and direct semantic relations (Rothe and Schütze, 2015). However, the non-optimal WSD techniques and the shallow utilization of knowledge from WordNet do not allow these techniques to learn accurate and high-coverage semantic representations for all senses in the inventory.

We propose a technique that de-conflates a given word representation into its constituent sense representations by exploiting deep knowledge from the semantic network of WordNet. Our approach provides the following three main advantages in comparison to the past work: (1) our representations are linked to the WordNet sense inventory and, accordingly, the number of senses for a word is a dynamic parameter which matches that defined by WordNet; (2) the deep exploitation of WordNet's semantic network allows us to obtain accurate semantic representations, even for word senses that are infrequent in generic text corpora; and (3) our methodology involves only minimal parameter tuning and can be effectively applied to any sense inventory that is viewable as a semantic network and to any word representation technique. We evaluate our sense representations in two tasks: word similarity (both in-context and in-isolation) and cross-level semantic similarity. Experimental results show that the proposed technique can provide consistently high performance across six datasets, outperforming the recent state of the art on most of them.

2 De-Conflated Representations

Preliminaries. Our proposed approach takes a set of pre-trained word representations and uses the graph structure of a semantic lexical resource in order to de-conflate the representations into those of word senses. Therefore, our approach firstly requires a set of pre-trained word representations (e.g., word embeddings). Any model that maps a given word to a fixed-size vector representation (i.e., vector space model) can be used by our approach. In our experiments, we opted for a set of publicly available word embeddings (cf. §3.1).

Secondly, we require a lexical resource whose semantic relations allow us to view it as a graph $G = (V, E)$ where each vertex in the set of vertices V corresponds to a concept and edges in E denote lexico-semantic relationships among these vertices. Each concept $c \in V$ is mapped to a set of word senses by a mapping function $\mu(c) : c \rightarrow \{s_1, \ldots, s_l\}$. WordNet, the *de facto* community standard sense inventory, is a suitable resource that satisfies these properties. WordNet can be readily represented as a semantic graph in which vertices are synsets and edges are the semantic relations that connect these synsets (e.g., hypernymy and meronymy). The mapping function in WordNet maps each synset to the set of synonymous words it contains (i.e., word senses).

2.1 Overview of the approach

Our goal is to compute a semantic representation that places a given word sense in an existing semantic space of words. We achieve this by leveraging word representations as well as the knowledge derived from WordNet. The gist of our approach lies in its computation of a list of *sense biasing words* for a given word sense. To this end, we first analyze the semantic network of WordNet and extract a list of most representative words that can effectively pinpoint the semantics of individual synsets (§2.2). We then leverage an effective technique which learns semantic representations for individual word senses by placing the senses in the proximity of their corresponding sense biasing words (§2.3).

2.2 Determining sense biasing words

Algorithm 1 shows the procedure we use to extract from WordNet a list of sense biasing words for a

Algorithm 1 Get sense biasing words for synset y_t

Require: Graph $G = (V, E)$ of vertices $V = \{y_i\}_{i=1}^{m}$ (of m synsets) and edges E (semantic relationships between synsets)
Require: Function $\mu(y_i)$ that returns for a given synset y_i the words it contains
Require: Target synset $y_t \in V$ for which a sense biasing word sequence is required
Ensure: The sequence $\mathcal{B}_t$ of sense biasing words for synset y_t

1: $\mathcal{B}_t \leftarrow ()$
2: **for all** word w in $\mu(y_t)$ **do**
3: $\quad \mathcal{B}_t \leftarrow \mathcal{B}_t \cup (w)$
4: **for** $y_i \in V : y_i \neq y_t$ **do**
5: $\quad p_i \leftarrow \text{PERSONALIZEDPAGERANK}(y_i, y_t, G)$
6: $(y_h^*)_{h=1}^{m-1} \leftarrow \text{SORT}(V \setminus \{y_t\})$ according to scores p_i
7: **for** $h : 1$ to $m - 1$ **do**
8: $\quad$ **for all** word w in $\mu(y_h^*)$ **do**
9: $\quad\quad$ **if** $w \notin \mathcal{B}_t$ **then**
10: $\quad\quad\quad \mathcal{B}_t \leftarrow \mathcal{B}_t \cup (w)$
11: **return** sequence $\mathcal{B}_t$

given target synset y_t. The algorithm receives as its inputs the semantic graph of WordNet and the mapping function $\mu(\cdot)$, and outputs an ordered list of biasing words $\mathcal{B}_t$ for y_t. The list comprises the most semantically-related words to synset y_t which can best represent and pinpoint its meaning. We leverage a graph-based algorithm for the computation of the sense biasing words.

Specifically, we use the Personalized PageRank (Haveliwala, 2002, PPR) algorithm which has been extensively used by several NLP applications (Yeh et al., 2009; Niemann and Gurevych, 2011; Agirre et al., 2014). To this end, we first represent the semantic network of WordNet as a row-stochastic transition matrix $\mathbf{M} \in \mathbb{R}^{m \times m}$ where m is the number of synsets in WordNet ($|V|$). The cell M_{ij} of $\mathbf{M}$ is set to the inverse of the degree of i if there is a semantic relationship between synsets i and j and to zero otherwise. We compute the PPR distribution for a target synset y_t by using the power iteration method $\mathcal{P}^{t+1} = (1 - \sigma)\mathcal{P}^0 + \sigma\mathbf{M}\mathcal{P}^t$, where σ is the damping factor (usually set to 0.85) and $\mathcal{P}^0$ is a one-hot initialization vector with the corresponding dimension of y_t being set to 1.0. The weight p_i in line 5 is the value of the i^{th} dimension of the PPR vector $\mathcal{P}$ computed for the synset y_t. This weight can be seen as the importance of the corresponding synset of the i^{th} dimension (i.e., y_i) to y_t. When applied to a semantic network, such as the WordNet graph, this importance can be interpreted as semantic relevance. Hence, the value of p_i denotes the extent of semantic relatedness between y_i and y_t. We use this notion and retrieve a list of most semantically-related words to y_t.

To achieve this, we sort the synsets $\{y^* \in V : y^* \neq y_t\}$ according to their PPR values $\{p_i\}_{i=1}^{m-1}$ (line 6). We then iterate (lines 7-10) the sorted list (y^*) and for each synset y_h^* append the list $\mathcal{B}_t$ with all the words in y_h^* (i.e., $\mu(y_h^*)$). However, in order to ensure that the words in the target synset y_t appear as the most representative words in $\mathcal{B}_t$, we first assign these words to the list (line 3). Finally, the algorithm returns the ordered list $\mathcal{B}_t$ of sense biasing words for the target synset y_t.

#	Sense biasing words

Table 1: The top sense biasing words for the synsets containing the anatomical (#1) and numerical (#2) senses of the noun *digit*.

Table 1 shows a sample of top biasing words extracted for the two senses of the noun *digit*: the numerical and the anatomical senses.[1] We explain in §2.3 how we use the sense biasing lists to learn sense-specific representations. Note that the size of the list is equal to the total number of strings in WordNet. However, we observed that taking a very small portion of the top-ranking elements in the lists is enough to generate representations that perform very similarly to those generated when using the full-sized lists (please see §3.1).

2.3 Learning sense representations

Let $\mathcal{V}$ be the set of pre-trained d-dimensional word representations. Our objective here is to compute a set $\mathcal{V}^* = \{v_{s_1}^*, \ldots, v_{s_n}^*\}$ of representations for n word senses $\{s_1, \ldots, s_n\}$ in the same d-dimensional semantic space of words. We achieve this for each sense s_i by de-conflating the representation v_{s_i} of its corresponding lemma and biasing it towards the

[1] The first and third senses of the noun *digit* in WordNet 3.0.

representations of the words in $\mathcal{B}_i$. Specifically, we obtain a representation $v^*_{s_i}$ for a word sense s_i by solving:

$$\arg\min_{v^*_{s_i}} \alpha\ d(v^*_{s_i}, v_{s_i}) + \sum_{b_{ij} \in \mathcal{B}_i} \delta_{ij}\ d(v^*_{s_i}, v_{b_{ij}}) \quad (1)$$

where v_{s_i} and $v_{b_{ij}}$ are the respective word representations ($\in\ \mathcal{V}$) of the lemma of s_i and the j^{th} biasing word in the list of biasing words for s_i, i.e, $\mathcal{B}_i$. The distance $d(v, v')$ between vectors v and v' is measured by squared Euclidean distance $\|v - v'\|^2 = \sum_k (v_k - v'_k)^2$. The first term in Formula 1 requires the representation of the word sense s_i (i.e., $v^*_{s_i}$) to be similar to that of its corresponding lemma, i.e., v_{s_i}, whereas the second term encourages $v^*_{s_i}$ to be in the proximity of its biasing words in the semantic space. The above criterion is similar to the frameworks of Das and Smith (2011) and Faruqui et al. (2015) which, though being convex, is usually solved for efficiency reasons by an iterative method proposed by Bengio et al. (2007). Following these works, we obtain the below equation for computing the representation of a word sense s_i:

$$v^*_{s_i} = \frac{\alpha v_{s_i} + \sum_{b_{ij} \in \mathcal{B}_i} \delta_{ij} v_{b_{ij}}}{\alpha + \sum_j \delta_{ij}}. \quad (2)$$

We define δ_{ij} as $\frac{e^{-\lambda r(i,j)}}{|\mathcal{B}_i|}$ where $r(i, j)$ denotes the rank of the word b_{ij} in the list $\mathcal{B}_i$. This is essentially an exponential decay function that gives more importance to the top-ranking biasing words for s_i. The hyperparameter α denotes the extent to which $v^*_{s_i}$ is kept close to its corresponding lemma representation v_{s_i}. Following Faruqui et al. (2015), we set α to 1. The only parameter to be tuned in our experiments is λ. We discuss the tuning of this parameter in §3.1. The representation of a synset y_i can be accordingly calculated as the centroid of the vectors of its associated word senses, i.e.,

$$\{\frac{v_{y_i}}{\|v_{y_i}\|} : v_{y_i} = \sum_{s \in \mu(y_i)} \hat{v}^*_s, \hat{v}^*_s = \frac{v^*_s}{\|v^*_s\|}\}. \quad (3)$$

As a result of this procedure, we obtain the set $\mathcal{V}^*$ of n sense representations in the same semantic space as word representations in $\mathcal{V}$. In fact, we now have a unified semantic space which enables a direct comparison of the two types of linguistic items. In §3.3 we evaluate our approach in the word to sense similarity measurement framework.

#	Closest words
1	crappie, trout, guitar, shad, walleye, bassist, angler, catfish, trombone, percussion, piano, drummer, saxophone, jigs, fish
2	baritone, piano, guitar, trombone, saxophone, cello, percussion, tenor, saxophonist, clarinet, pianist, vocals, solos, harmonica
3	fish, trout, shrimp, anglers, fishing, bait, guitar, salmon, shark, fisherman, lakes, seafood, drummer, whale, fisheries

Table 2: Ten most similar words to the word *bass* (#1) and two of its senses: music (#2) and fish (#3).

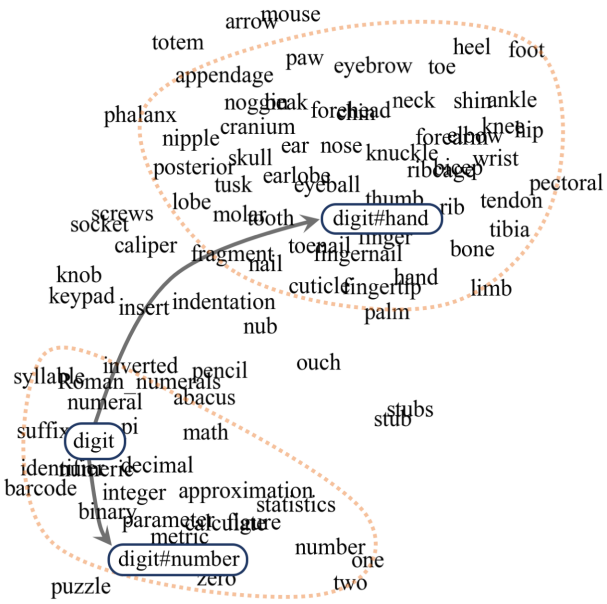

Figure 1: The illustration of the word *digit* and two of its computed senses in our unified 2-d semantic space.

We show in Table 2 the closest words to the word *bass* and two of its senses, music and fish,[2] in our unified semantic space. We can see in row #1 a mixture of both meanings when the word representation is used whereas the closest words to the senses (rows #2 and #3) are mostly in-domain and specific to the corresponding sense.

To exhibit another interesting property of our sense representation approach, we depict in Figure 1 the word *digit* and its numerical and anatomical senses (from the example in Table 1) in a 2-d semantic space, along with a sample set of words in their

[2]The first and fourth senses in WordNet 3.0, respectively defined as "the lowest part of the musical range" and "the lean flesh of a saltwater fish of the family Serranidae."

proximity.[3] We can see that the word *digit* is placed in the semantic space in the neighbourhood of words from the numerical domain (lower left of the figure), mainly due the dominance (Sanderson and Van Rijsbergen, 1999) of this sense in the general-domain corpus on which the word embeddings in our experiments were trained (cf. §3.1). However, upon de-conflation, the emerging anatomical sense of the word is shifted towards the region in the semantic space which is occupied by anatomical words (upper right of the figure). A clustering-based sense representation technique would have failed in accurately representing the infrequent anatomical meaning of *digit* by analyzing a general domain corpus (such as the one used here). But our sense representation technique, thanks to its proper usage of knowledge from a sense inventory, is effective in unveiling and accurately modeling less frequent or domain-specific senses of a given word.

Please note that any vector space model representation technique can be used for the pre-training of word representations in $\mathcal{V}$. Also, the list of sense biasing words can be obtained for larger sense inventories, such as FreeBase (Bollacker et al., 2008) or BabelNet (Navigli and Ponzetto, 2012). We leave the exploration of further ways of computing sense biasing words to future work.

3 Experiments

We benchmarked our sense representation approach against several recent techniques on two standard tasks: word similarity (§3.2), for which we evaluate on both in-isolation and in-context similarity datasets, and cross-level semantic similarity (§3.3).

3.1 Experimental setup

Pre-trained word representations. As our word representations, we used the 300-d Word2vec (Mikolov et al., 2013) word embeddings trained on the Google News dataset[4] mainly for their popularity across different NLP applications. However, our approach is equally applicable to any count-based representation technique (Baroni and Lenci, 2010; Turney and Pantel, 2010) or any other embedding approach (Pennington et al., 2014; LeCun et al., 2015). We leave the evaluation and comparison of various word representation techniques with different training approaches, objectives, and dimensionalities to future work.

Parameter tuning. Recall from §2.3 that our procedure for learning sense representations needs only one parameter to be tuned, i.e., λ. We did not perform an extensive tuning on the value of this parameter and set its value to 1/5 after trying four different values (1, 1/2, 1/5, and 1/10) on a small validation dataset. We leave the more systematic tuning of the parameter and the choice of alternative decay functions (cf. §2.3) to future work.

The size of the sense biasing words lists. Also recall from §2.2 that the extracted lists of sense biasing words were originally as large as the total number of unique strings in WordNet (around 150K in ver. 3.0). But, given that we use an exponential decay function in our learning algorithm (cf. §2.3), the impact of the low-ranking words in the list is negligible. In fact, we observed that taking a very small portion of the top-ranking words, i.e., the top 25, produces similarity scores that are on par with those generated when the full lists were considered. Therefore, we experimented with the down-sized lists which enabled us to generate very quickly sense representations for all word senses in WordNet.

3.2 Word similarity

Comparison systems. We compared our results against nine other sense representation techniques: the WordNet-based approaches of Pilehvar and Navigli (2015), Chen et al. (2014), Rothe and Schütze (2015), Jauhar et al. (2015), and Iacobacci et al. (2015) and the clustering-based approaches of Huang et al. (2012), Tian et al. (2014), Neelakantan et al. (2014), and Liu et al. (2015) (please see §4 for more details). We also compared against the approach of Faruqui et al. (2015) which uses knowledge derived from WordNet for improving word representations. From the different configurations presented in (Faruqui et al., 2015) we chose the system that uses GloVe (Pennington et al., 2014) with *all* WordNet relations which is their best performing monolingual system. As for the approach of Jauhar et al. (2015), we show the results of the

[3] We used the t-SNE algorithm (van der Maaten and Hinton, 2008) for dimensionality reduction.

[4] https://code.google.com/archive/p/word2vec/

EM+RETERO system which performs most consistently across different datasets.

Benchmarks. As our word similarity benchmark, we considered five datasets: RG-65 (Rubenstein and Goodenough, 1965), YP-130 (Yang and Powers, 2005), MEN-3K (Bruni et al., 2014), SimLex-999 (Hill et al., 2015, SL-999), and Stanford Contextual Word Similarity (Huang et al., 2012, SCWS). The latter benchmark provides for each word a context that triggers a specific meaning of it, making the dataset very suitable for the evaluation of sense representation. For each datasets, we list the results that are reported by any of our comparison systems.

Similarity measurement. For the SCWS dataset, we follow the past works (Reisinger and Mooney, 2010; Huang et al., 2012) and report the results according to two system configurations: (1) AvgSim: where the similarity between two words is computed as the average of all the pairwise similarities between their senses, and (2) AvgSimC: where each pairwise sense similarity is weighted by the relevance of each sense to its corresponding context. For all the other datasets, since words are not provided with any context (they are in isolation), we measure the similarity between two words as that between their most similar senses. In all the experiments, we use the cosine distance as our similarity measure.

3.2.1 Experimental results

Tables 4 and 3 show the results of our system, DECONF, and the comparison systems on the SCWS and the other four similarity datasets, respectively. In both tables we also report the word vectors baseline, whenever they are available, which is computed by directly comparing the corresponding word representations of the two words ($\in \mathcal{V}$). Note that the word-based baseline does not apply to the approach of Pilehvar and Navigli (2015) as it is purely based on the semantic network of WordNet and does not use any pre-trained word embeddings.

We can see from the tables that our sense representations obtain considerable improvements over those of words across the five datasets. This highlights the fact that the de-conflation of word representations into those of their individual meanings has been highly beneficial. On the SCWS dataset, DECONF outperforms all the recent state-of-the-art sense representation techniques (in their best settings) which proves the effectiveness of our approach in capturing the semantics of specific meanings of the words. The improvement is consistent across both system configurations (i.e., AvgSim and AvgSimC). Moreover, the state-of-the-art WordNet-based approach of Rothe and Schütze (2015) uses the same initial word vectors as DECONF does (cf. §3.1). Hence, the improvement we obtain indicates that our approach has made better use of the sense-specific knowledge encoded in WordNet.

As seen in Table 3 our approach shows competitive performance on the other four datasets. The YP-130 dataset focuses on verb similarity, whereas SimLex-999 contains verbs and adjectives and MEN-3K has word pairs with different parts of speech (e.g., a noun compared to a verb). The results we obtain on these datasets exhibit the reliability of our approach in modeling non-nominal word senses.

3.2.2 Discussion

The similarity scale of the SimLex-999 dataset is different from our other word similarity benchmarks in that it assigns relatively low scores to antonymous pairs. For instance, *sunset-sunrise* and *man-woman* in this dataset are assigned the respective similarities of 2.47 and 3.33 (in a $[0, 10]$ similarity scale) which is in the same range as the similarity between word pairs with slight domain relatedness, such as *head-nail* (2.47), *air-molecule* (3.05), or *succeed-try* (3.98). In fact, we observed that tweaking the similarity scale of our system in a way that it diminishes the similarity scores between antonyms can result in a significant performance improvement on this dataset. To this end, we performed an experiment in which the similarity of a word pair was simply divided by 3 whenever the two words belonged to synsets that were linked by an antonymy relation in WordNet.[5] We observed that the performance on the SimLex-999 dataset increased to 61.6 (from 54.2) and 59.1 (from 51.7) according to Pearson ($r \times 100$) and Spearman ($\rho \times 100$) correlation scores, respectively.

[5] We chose 3 so as to transform a pair with high similarity score (around 9.0) to one with slight semantic similarity (around 3.0) in the $[0, 10]$ similarity scale of SimLex-999. We also tested for other values in $[2, 6]$ an observed similar performance gains.

Dataset	Approach	Sense-based score		Word-based score	
		r	ρ	r	ρ
MEN-3K	Iacobacci et al. (2015)	–	**80.5**	–	66.5

Initial word vectors	65.1	

Table 4: Spearman correlation scores ($\rho \times 100$) on the Stanford Contextual Word Similarity (SCWS) dataset. We report the AvgSim and AvgSimC scores (cf. §3.2) for each system, where available.

3.3 Cross-Level semantic similarity

In addition to the word similarity benchmark, we evaluated the performance of our representations in the cross-level semantic similarity measurement framework. For this, we opted for the SemEval-2014 task on Cross-Level Semantic Similarity (Jurgens et al., 2014, CLSS). The word to sense similarity subtask of this task, with 500 instances in its test set, provides a suitable benchmark for the evaluation of sense representation techniques.

For a word sense s and a word w, we compute the similarity score according to four different strategies: the similarity of s to the most similar sense of w (**MaxSim**), the average similarity of s to individual senses of w (**AvgSim**), the direct similarity of s to w when the latter is modeled as its word representation (Sense-to-Word or **S2W**) or as the centroid of its senses' representations (Sense to aggregated word senses or **S2A**). For this task, we can only compare against the publicly-available sense representations of Iacobacci et al. (2015), Rothe and Schütze (2015), Pilehvar and Navigli (2015) and Chen et al. (2014) which are linked to the WordNet sense inventory.

3.3.1 Experimental results

Table 5 shows the results on the word to sense dataset of the SemEval-2014 CLSS task, according to Pearson ($r \times 100$) and Spearman ($\rho \times 100$) correlation scores and for the four strategies. As can be seen from the low overall performance, the task is a very challenging benchmark with many WordNet out-of-vocabulary or slang terms and rare usages. Despite this, DECONF provides consistent improvement over the comparison sense representation techniques according to both measures and for all the strategies.

Across the four strategies, S2A proves to be the most effective for DECONF and the representations of Rothe and Schütze (2015). The representations of Chen et al. (2014) perform best with the S2W strat-

Table 5: Evaluation results on the word to sense similarity test dataset of the SemEval-14 task on Cross-Level Semantic Similarity, according to Pearson ($r \times 100$) and Spearman ($\rho \times 100$) correlations. We show results for four similarity computation strategies (see §3.3). The best results per strategy are shown in bold whereas they are underlined for the best strategies per system. Systems marked with $*$ are evaluated on a slightly smaller dataset (474 of the original 500 pairs) so as to have a fair comparison with Rothe and Schütze (2015) and Chen et al. (2014) that use older versions of WordNet (1.7.1 and 1.7, respectively).

egy whereas those of Iacobacci et al. (2015) do not show a consistent trend with relatively low performance across the four strategies. Also, a comparison of our results across the S2W and S2A strategies reveals that a word's aggregated representation, i.e., the centroid of the representations of its senses, is more accurate than its original word representation.

Our analysis showed that the performance of the approaches of Rothe and Schütze (2015) and Iacobacci et al. (2015) were hampered partly due to their limited coverage. In fact, the former was unable to model around 35% of the synsets in WordNet 1.7.1, mainly for its shallow exploitation of knowledge from WordNet, whereas the latter approach did not cover around 15% of synsets in WordNet 3.0. Chen et al. (2014) provide near-full coverage for word senses in WordNet. However, the relatively low performance of their system shows that the usage of glosses in WordNet and the automated disambiguation have not resulted in accurate sense representations. Thanks to its deep exploitation of the underlying resource, our approach provides more reliable representations and full coverage for all word senses and synsets in WordNet.

The three best-performing systems in the task are Meerkat_Mafia (Kashyap et al., 2014) ($r = 37.5$, $\rho = 39.3$), SimCompass (Banea et al., 2014) ($r = 35.4$, $\rho = 34.9$), and SemantiKLUE (Proisl et al., 2014) ($r = 17.9$, $\rho = 18.8$). Note that these systems are specifically designed for the cross-level similarity measurement task. For instance, the best-ranking system in the task leverages a compilation of several dictionaries, including The American Heritage Dictionary, Wiktionary and WordNet, in order to handle slang terms and rare usages, which leads to its competitive performance (Kashyap et al., 2014).

4 Related Work

Learning semantic representations for individual senses of words has been an active area of research for the past few years. Based on the way they view the problem, the recent techniques can be classified into two main branches: (1) those that, similarly to our work, extract knowledge from external sense inventories for learning sense representations; and (2) those techniques that cluster the contexts in which a word appears in a given text corpus and learn distinct representations for individual clusters.

Examples for the first branch include the approaches of Chen et al. (2014), Jauhar et al. (2015) and Rothe and Schütze (2015), all of which use WordNet as an external resource and obtain sense representations for this sense inventory. Chen et al. (2014) uses the content words in the definition of a word sense and WSD. However, the sole usage of glosses as sense-distinguishing contexts and the non-optimal WSD make the approach inaccurate, particularly for highly polysemous words with similar senses and for word senses with short definitions. Similarly, Rothe and Schütze (2015) use only polysemy and synonymy properties of words in WordNet along with a small set of semantic re-

lations. This significantly hampers the reliability of the technique in providing high coverage (discussed further in §3.3.1). Our approach improves over these works by exploiting deep knowledge from the semantic network of WordNet, coupled with an effective training approach. ADW (Pilehvar and Navigli, 2015) is another WordNet-based approach which exploits only the semantic network of this resource and obtains interpretable sense representations. Other work in this branch include SensEmbed (Iacobacci et al., 2015) and Nasari (Camacho-Collados et al., 2015; Camacho-Collados et al., 2016) which are based on the BabelNet sense inventory (Navigli and Ponzetto, 2012). The former technique first disambiguates words in a given corpus with the help of a knowledge-based WSD system and then uses the generated sense-annotated corpus as training data for Word2vec. Nasari combines structural knowledge from the semantic network of BabelNet with corpus statistics derived from Wikipedia for representing BabelNet synsets. However, the approach falls short of modeling non-nominal senses as Wikipedia, due to its very encyclopedic nature, does not cover verbs, adjectives, or adverbs.

The second branch, which is usually referred to as *multi-prototype* representation, is often associated with clustering. Reisinger and Mooney (2010) proposed one of the recent pioneering techniques in this branch. Other prominent work in the category include topical word embeddings (Liu et al., 2015) which use latent topic models for assigning topics to each word in a corpus and learn topic-specific word representations, and the technique proposed by Huang et al. (2012) which incorporates "global document context." Tian et al. (2014) modified the Skip-gram model in order to learn multiple embeddings for each word type. Despite the fact that these techniques do not usually take advantage of the knowledge encoded in structured knowledge resource, they generally suffer from two disadvantages. The first limitation is that they usually make an assumption that a given word has a fixed number of senses, ignoring the fact that polysemy is highly dynamic across words that can range from monosemous to highly ambiguous with dozens of associated meanings (McCarthy et al., 2016). Neelakantan et al. (2014) tackled this issue by estimating the number of senses for a word type during the learning process. However, all techniques in the second branch suffer from another disadvantage that their computed sense representations are not linked to any sense inventory, a linking which itself would require the existence of high coverage sense-annotated data (Agirre et al., 2006).

Another notable line of research incorporates knowledge from external resources, such as PPDB (Ganitkevitch et al., 2013) and WordNet, to improve word embeddings (Yu and Dredze, 2014; Faruqui et al., 2015). Neither of the two techniques however, provide representations for word senses.

5 Conclusions

We put forward a sense representation technique, namely DECONF, that provides multiple advantages in comparison to the recent state of the art: (1) the number of word senses in our technique is flexible and the computed representations are linked to word senses in WordNet; (2) DECONF is effective in providing accurate representation of word senses, even for those senses that do not usually appear frequently in generic text corpora; and (3) our approach is general in that it can be readily applied to any set of word representations and any semantic network without the need for extensive parameter tuning. Our experimental results showed that DECONF can outperform recent state of the art on several datasets across two tasks. The computed representations for word senses in WordNet 3.0 are released at `https://pilehvar.github.io/deconf/`. We intend to apply our technique to the task of harmonizing biomedical terms in the PheneBank project. As future work, we plan to investigate the possibility of using larger semantic networks, such as FreeBase and BabelNet, which would also allow us to apply the technique to languages other than English. We also plan to evaluate the performance of our approach with other decay functions as well as with other initial word representations.

Abstract

Distributional models are derived from co-occurrences in a corpus, where only a small proportion of all possible plausible co-occurrences will be observed. This results in a very sparse vector space, requiring a mechanism for inferring missing knowledge. Most methods face this challenge in ways that render the resulting word representations uninterpretable, with the consequence that semantic composition becomes hard to model. In this paper we explore an alternative which involves explicitly inferring unobserved co-occurrences using the distributional neighbourhood. We show that distributional inference improves sparse word representations on several word similarity benchmarks and demonstrate that our model is competitive with the state-of-the-art for adjective-noun, noun-noun and verb-object compositions while being fully interpretable.

1 Introduction

The aim of distributional semantics is to derive meaning representations based on observing co-occurrences of words in large text corpora. However not all plausible co-occurrences will be observed in any given corpus, resulting in word representations that only capture a fragment of the meaning of a word. For example the verbs "walking" and "strolling" may occur in many different and possibly disjoint contexts, although both verbs would be equally plausible in numerous cases. This subsequently results in incomplete representations for both lexemes. In addition, models based on counting co-occurrences face the general problem of sparsity in a very high-dimensional vector space. The most common approaches to these challenges have involved the use of various techniques for dimensionality reduction (Bullinaria and Levy, 2012; Lapesa and Evert, 2014) or the use of low-dimensional and dense neural word embeddings (Mikolov et al., 2013; Pennington et al., 2014). The common problem in both of these approaches is that composition becomes a black-box process due to the lack of interpretability of the representations. Count-based models are therefore a very attractive line of work with regards to a number of important long-term research challenges, most notably the development of an adequate model of distributional compositional semantics. In this paper we propose the use of distributional inference (DI) to inject unobserved but plausible distributional semantic knowledge into the vector space by leveraging the intrinsic structure of the distributional neighbourhood. This results in richer word representations and furthermore mitigates the sparsity effect common in high-dimensional vector spaces, while remaining fully interpretable.

Our contributions are as follows: we show that typed and untyped sparse word representations, enriched by distributional inference, lead to performance improvements on several word similarity benchmarks, and that a higher-order dependency-typed vector space model, based on "Anchored Packed Dependency Trees (APTs)" (Weir et al., 2016), is competitive with the state-of-the-art for adjective-noun, noun-noun and verb-object compositions. Using our method, we are able to bridge the gap in performance between high dimensional interpretable mod-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1691–1702,
Austin, Texas, November 1-5, 2016.

els and low dimensional non-interpretable models and offer evidence to support a possible explanation of why high-dimensional models usually perform worse, together with a simple, practical method for over-coming this problem. We furthermore demonstrate that *intersective* approaches to composition benefit more from distributional inference than composition by *union* and highlight the ability of composition by *intersection* to disambiguate the meaning of a phrase in a local context.

The remainder of this paper is structured as follows: we discuss related work in section 2, followed by an introduction of the APT framework for semantic composition in section 3. We describe distributional inference in section 4 and present our experimental work, together with our results in section 5. We conclude this paper and outline future work in section 6.

2 Related Work

Our method follows the distributional smoothing approach of Dagan et al. (1994) and Dagan et al. (1997). In these works the authors are concerned with smoothing the probability estimate for unseen words in bigrams. This is achieved by measuring which unobserved bigrams are more likely than others on the basis of the Kullback-Leibler divergence between bigram distributions. This has led to significantly improved performance on a language modelling for speech recognition task, as well as for word-sense disambiguation in machine translation (Dagan et al., 1994; Dagan et al., 1997). More recently Padó et al. (2013) used a distributional approach for smoothing derivationally related words, such as *oldish – old*, as a back-off strategy in case of data sparsity. However, none of these approaches have used distributional inference as a general technique for directly enriching sparse distributional vector representations, or have explored its behaviour for semantic composition.

Compositional models of distributional semantics have become an increasingly popular topic in the research community. Starting from simple pointwise additive and multiplicative approaches to composition, such as Mitchell and Lapata (2008; 2010), and Blacoe and Lapata (2012), to tensor based models, such as Baroni and Zamparelli (2010), Coecke et al. (2010), Grefenstette et al. (2013) and Paperno et al. (2014), and neural network based approaches, such as Socher et al. (2012), Le and Zuidema (2015), Mou et al. (2015) and Tai et al. (2015). Zanzotto et al. (2015) provide a decompositional analysis of how similarity is affected by distributional composition, and link compositional models to convolution kernels. Most closely related to our approach of composition are the works of Thater et al. (2010), Thater et al. (2011) and Weeds et al. (2014), which aim to provide a general model of compositionality in a typed distributional vector space. In this paper we adopt the approach to distributional composition introduced by Weir et al. (2016), whose APT framework is based on a higher-order dependency-typed vector space, however they do not address the issue of sparsity in their work.

3 Background

Distributional vector space models can broadly be categorised into untyped proximity based models and typed models (Baroni and Lenci, 2010). Examples of the former include Deerwester et al. (1990); Lund and Burgess (1996); Curran (2004); Sahlgren (2006); Bullinaria and Levy (2007) and Turney and Pantel (2010). These models count the number of times every word in a large corpus co-occurs with other words within a specified spatial context window, without leveraging the structural information of the text. Typed models on the other hand, take the grammatical relation between two words for a co-occurrence event into account. Early proponents of that approach are Grefenstette (1994) and Lin (1998). More recent work by Padó and Lapata (2007), Erk and Padó (2008) and Weir et al. (2016) uses dependency paths to build a structured vector space model. In both kinds of models, the raw counts are usually transformed by Positive Pointwise Mutual Information (PPMI) or a variant of it (Church and Hanks, 1990; Niwa and Nitta, 1994; Scheible et al., 2013; Levy and Goldberg, 2014).

In the following we will give an explanation of the theory of composition with APTs as introduced by Weir et al. (2016), which we adopt in this paper. In addition to direct relations between two words, the APT model also considers *inverse* and *higher*

order relations. Inverse relations are denoted with a horizontal bar above the dependency relation, such as $\overline{\texttt{amod}}$ for an inverse adjectival modifier. Higher order dependencies are separated by a colon as in the second order distributional feature $\overline{\texttt{dobj}}\texttt{:nsubj}$. The example below illustrates how raw text is processed to retrieve elementary representations in our APT model. As an example we consider a lowercased corpus consisting of the sentences:

we folded the clean clothes
i like your clothes
we bought white shoes yesterday
he folded the white sheets

We dependency parse the raw sentences and, following Weir et al. (2016), align and aggregate the resulting parse trees according to their dependency type as shown in Figure 1. For example the lexeme *clothes* has the distributional features $\texttt{amod:}dry$ and $\overline{\texttt{dobj}}\texttt{:nsubj:}we$ among others. Over a large corpus, this results in a very high-dimensional and sparse vector space, which due to its typed nature is much sparser than for untyped models.

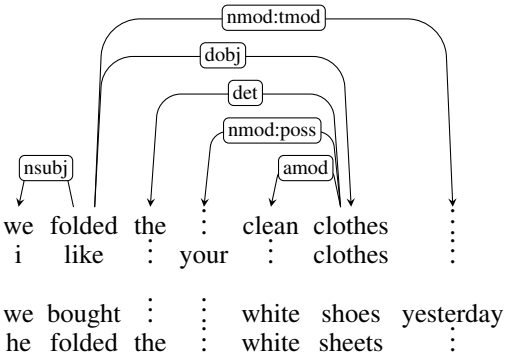

Figure 1: Aligned Packed Dependency Tree representation of the example sentences.

Composition with APTs

Composition is linguistically motivated by the principle of compositionality, which states that the meaning of a complex expression is fully determined by its structure and the meanings of its constituents (Frege, 1884). Many simple approaches to semantic composition neglect the structure and lose information in the composition process. For example, the phrases *house boat* and *boat house* have the exact same representation when composition is done via a pointwise arithmetic operation. Despite performing well in a number of studies, this commutativity is not desirable for a fine grained understanding of the semantics of natural language. When performing composition with APTs, we adopt the method introduced by Weir et al. (2016) which views distributional composition as a process of contextualisation. For composing the adjective *white* with the noun *clothes* via the dependency relation $\texttt{amod}$ we need to consider how the adjective interacts with the noun in the vector space. The distributional features of white describe things that are white via their first order relations such as $\overline{\texttt{amod}}$, and things that can be done to white things, such as *bought* via $\overline{\texttt{amod}}\texttt{:}\overline{\texttt{dobj}}$ in the example above.

Table 1 shows a number of features extracted from the aligned dependency trees in Figure 1 and highlights that adjectives and nouns do not share many features if only first order dependencies would be considered. However through the inclusion of inverse and higher order dependency paths we can observe that the second order features of the adjective align with the first order features of the noun. For composition, the adjective *white* needs to be offset by its *inverse* relation to *clothes*[1] making it distributionally similar to a noun that has been modified by *white*. Offsetting can be seen as shifting the current viewpoint in the APT data structure and is necessary for aligning the feature spaces for composition (Weir et al., 2016). We are then in a position to compose the offset representation of *white* with the vector for *clothes* by the *union* or the *intersection* of their features.

Table 2 shows the resulting feature spaces of the composed vectors. It is worth noting that any arithmetic operation can be used to combine the counts of the aligned features, however for this paper we use pointwise addition for both composition functions. One of the advantages of this approach to composition is that the inherent interpretability of count-based models naturally expands beyond the word level, allowing us to study the distributional semantics of phrases in the same space as words. Due to offsetting one of the constituents, the composition operation is not commutative and hence avoids identical representations for *house boat* and *boat house*. However, the typed nature of our vector space re-

[1] The inverse of $\overline{\texttt{amod}}$ is just $\texttt{amod}$.

sults in extreme sparsity, for example while the untyped VSM has 130k dimensions, our APT model can have more than 3m dimensions. We therefore need to enrich the elementary vector representations with the distributional information of their nearest neighbours to ease the sparsity effect and infer missing information. Due to the syntactic nature of our composition operation it is not straightforward to apply common dimensionality reduction techniques such as SVD, as the type information needs to be preserved.

4 Distributional Inference

Following Dagan et al. (1994) and Dagan et al. (1997), we propose a simple unsupervised algorithm for enriching sparse vector representations with their nearest neighbours. We show that our distributional inference algorithm improves performance for untyped and typed models on several word similarity benchmarks, as well as being competitive with the state-of-the-art on semantic composition. As shown in algorithm 1 below, we iterate over all word vectors w in a given distributional model M, and add the vector representations of the nearest neighbours n, determined by cosine similarity, to the representation of the enriched word vector w'. The parameter α in line 4 scales the contribution of the original word vector to the resulting enriched representation. In this work we always chose α to be identical to the number of neighbours used for distributional inference. For example, if we used 10 neighbours for DI, we would set $\alpha = 10$, which we found sufficient to prevent the neighbours from dominating the vector representation. In our experiments we kept the input distributional model fixed, however it is equally possible to update the given model in an online fashion, adding some amount of stochasticity to the enriched word vector representations. There is a number of possibilities for the neighbour retrieval function $neighbours()$ and we explore several options in this paper. The algorithm furthermore is agnostic to the input distributional model, for example it is possible to use completely different vector space models for querying neighbours and enrichment.

Algorithm 1 Distributional Inference

```
1:  procedure DIST_INFERENCE(M)
2:      init M'
3:      for all w in M do
4:          w' ← w × α
5:          for all n in neighbours(M, w) do
6:              w' ← w' + n
7:              add w' to M'
8:          end for
9:      end for
10:     return M'
11: end procedure
```

Static Top n Neighbour Retrieval

The perhaps simplest way is to choose the top n most similar neighbours for each word in the vector space and enrich the respective vector representations with them.

Density based Neighbour Retrieval

This approach has its roots in kernel density estimation (Parzen, 1962), however instead of defining a static global parzen window, we set the window size for every word individually, depending on the distance to its nearest neighbour, plus a threshold. For example if the cosine distance between the target vector and its top neighbour is 0.5, we use a window size of $0.5 + \epsilon$ for that word. In our experiments we typically define ϵ to be proportional to the distance of the nearest neighbour (e.g. $\epsilon = 0.5 \times 0.1$).

WordNet based Neighbour Retrieval

Instead of leveraging the intrinsic structure of our distributional vector space, we retrieve neighbours by querying WordNet (Fellbaum, 1998), and treat synsets with agreeing PoS tags as the nearest neighbours of any target vector. This restricts the retrieved neighbours to synonyms only.

5 Experiments

Our model is based on a cleaned October 2013 Wikipedia dump, which excludes all pages with fewer than 20 page views, resulting in a corpus of approximately 0.6 billion tokens (Wilson, 2015). The corpus is lowercased, tokenised, lemmatised, PoS tagged and dependency parsed with the Stanford NLP tools, using universal dependencies (Manning et al., 2014; de Marneffe et al., 2014). We then build our APT model with first, second and third order relations. We remove distributional features with a count of less than 10, and vectors containing fewer than 50 non-zero entries. The raw counts are subsequently transformed to PPMI weights. The untyped vector space model is built from the same lowercased, tokenised and lemmatised Wikipedia corpus. We discard terms with a frequency of less than 50 and apply PPMI to the raw co-occurrence counts.

Shifted PPMI

We explore a range of different values for shifting the PPMI scores as these have a significant impact on the performance of the APT model. The effect of shifting PPMI scores for untyped vector space models has already been explored in Levy and Goldberg (2014), and Levy et al. (2015), thus we only present results for the APT model. As shown in equation 1, PMI is defined as the log of the ratio of the joint probability of observing a word w and a context c together, and the product of the respective marginals of observing them separately. In our APT model, a context c is defined as a dependency relation together with a word.

$$\begin{aligned} PMI(w,c) &= \log \frac{P(w,c)}{P(w)P(c)} \\ SPPMI(w,c) &= \max(PMI(w,c) - \log k, 0) \end{aligned} \tag{1}$$

As PMI is negatively unbounded, PPMI is used to ensure that all values are greater than or equal to 0. Shifted PPMI (SPPMI) subtracts a constant from any PMI score before applying the PPMI threshold. We experiment with values of 1, 5, 10, 40 and 100 for the shift parameter k.

5.1 Word Similarity Experiments

We first evaluate our models on 3 word similarity benchmarks, MEN (Bruni et al., 2014), which is testing for *relatedness* (e.g. meronymy or holonymy) between terms, SimLex-999 (Hill et al., 2015), which is testing for *substitutability* (e.g. synonymy, antonymy, hyponymy and hypernymy), and WordSim-353 (Finkelstein et al., 2001), where we use the version of Agirre et al. (2009), who split the dataset into a *relatedness* and a *substitutability* subset. Baroni and Lenci (2011) have shown that untyped models are typically better at capturing *relatedness*, whereas typed models are better at encoding *substitutability*. Performance is measured by computing Spearman's ρ between the cosine similarities of the vector representations and the corresponding aggregated human similarity judgements. For these experiments we keep the number of neighbours that a word vector can consume fixed at 30. This value is based on preliminary experiments on WordSim-353 (see Figure 2) using the static top n neighbour retrieval function and a PPMI shift of $k = 40$. Figure 2 shows that distributional inference improves performance for any number of neighbours over a model without DI (marked as horizontal dashed lines for each WordSim-353 subset) and peaks at a value of

30. Performance slightly degrades with more neighbours. For the untyped VSM we use a symmetric window of 5 on either side of the target word.

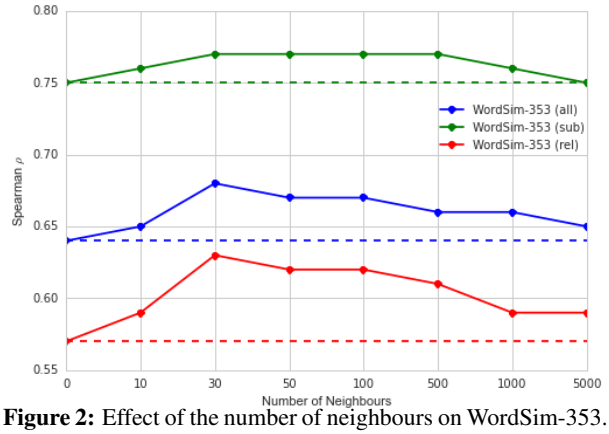

Figure 2: Effect of the number of neighbours on WordSim-353.

Table 3 highlights the effect of the SPPMI shift parameter k, while keeping the number of neighbours fixed at 30 and using the static top n neighbour retrieval function. For the APT model, a value of $k = 40$ performs best (except for SimLex-999, where smaller shifts give better results), with a performance drop-off for larger shifts. In our experiments we find that a shift of $k = 1$ results in top performance for the untyped vector space model. It appears that shifting the PPMI scores in the APT model has the effect of cleaning the vectors from noisy PPMI artefacts, which reinforces the predominant sense, while other senses get suppressed. Subsequently, this results in a cleaner neighbourhood around the word vector, dominated by a single sense. This explains why distributional inference slightly degrades performance for smaller values of k.

Table 4 shows that distributional inference successfully infers missing information for both model types, resulting in improved performance over models without the use of DI on all datasets. The improvements are typically larger for the APT model, suggesting that it is missing more distributional knowledge in its elementary representations than untyped models. The density window and static top n neighbour retrieval functions perform very similar, however the static approach is more consistent and never underperforms the baseline for either model type on any dataset. The WordNet based neighbour retrieval function performs particularly well on SimLex-999. This can be explained by the fact that antonyms, which frequently happen to be among the nearest neighbours in distributional vector spaces, are regarded as dissimilar in SimLex-999, whereas the WordNet neighbour retrieval function only returns synonyms. The results furthermore confirm the effect that untyped models perform better on datasets modelling *relatedness*, whereas typed models work better for *substitutability* tasks (Baroni and Lenci, 2011).

5.2 Composition Experiments

Our approach to semantic composition as described in section 3 requires the dimensions of our vector space models to be meaningful and interpretable. However, the problem of missing information is amplified in compositional settings as many compatible dimensions between words are not observed in the source corpus. It is therefore crucial that distributional inference is able to inject some of the missing information in order to improve the composition process. For the experiments involving semantic composition, we enrich the elementary representations of the phrase constituents before composition.

We first conduct a qualitative analysis for our APT model and observe the effect of distributional inference on the nearest neighbours of composed adjective-noun, noun-noun and verb-object compounds. In these experiments, we show how distributional inference changes the neighbourhood in which composed phrases are embedded, and highlight the difference between composition by *union* and composition by *intersection*. For this experiment we use the static top n neighbour retrieval function with 30 neighbours and $k = 40$.

Table 5 shows a small number of example phrases together with their top 3 nearest neighbours, computed from the union of all words in the Wikipedia corpus and all phrase pairs in the Mitchell and Lapata (2010) dataset. As can be seen, nearest neighbours of phrases can be either single words or other composed phrases. Words or phrases marked with "*" in Table 5 mean that DI introduced, or failed to downrank, a spurious neighbour, while boldface means that performing distributional inference resulted in a neighbourhood more coherent with the query phrase than without DI.

Table 5 shows that composition by *union* is unable to

Table 4: Neighbour retrieval function comparison. Boldface means best performance on a dataset *per* VSM type. *) With 3 significant figures, the density window approach (0.713) is slightly better than the baseline without DI (0.708), static top n (0.710) and WordNet (0.710).

downrank unrelated neighbours introduced by distributional inference. For example *large quantity* is incorrectly introduced as a top ranked neighbour for the phrase *small house*, due to the proximity of *small* and *large* in the vector space. The phrases *market leader* and *television programme* are two examples of incoherent neighbours, which the composition function was unable to downrank and where DI could not improve the neighbourhood. Composition by *intersection* on the other hand vastly benefits from distributional inference. Due to the increased sparsity induced by the composition process, a neighbourhood without DI produces numerous spurious neighbours as in the case of the verb *have* as a neighbour for *win battle*. Distributional inference introduces qualitatively better neighbours for almost all phrases. For example, *government leader* and *opposition member* are introduced as top ranked neighbours for the phrase *party leader*, and *stress importance* and *underline* are introduced as new top neighbours for the phrase *emphasise need*. These results show that composition by *union* does not have the ability to disambiguate the meaning of a word in a given phrasal context, whereas composition by *intersection* has that ability but requires distributional inference to unleash its full potential.

For a quantitative analysis of distributional inference for semantic composition, we evaluate our model on the composition dataset of Mitchell and Lapata (2010), consisting of 108 adjective-noun, 108 noun-noun, and 108 verb-object pairs. The task is to compare the model's similarity estimates with the human judgements by computing Spearman's ρ. For comparing the performance of the different neighbour retrieval functions, we choose the same parameter settings as in the word similarity experiments ($k = 40$ and using 30 neighbours for DI).

Table 6 shows that the static top n and density window neighbour retrieval functions perform very similar again. The density window retrieval function outperforms static top n for composition by *intersection* and *vice versa* for composition by *union*. The WordNet approach is competitive for composition by *union*, but underperfoms the other approaches for composition by *intersection* significantly. For further experiments we use the static top n approach as it is computationally cheap and easy to interpret due to the fixed number of neighbours. Table 6 also shows that while composition by *intersection* is significantly improved by distributional

Phrase	Comp.	Union	Union (with DI)	Intersection	Intersection (with DI)

inference, composition by *union* does not appear to benefit from it.

Composition by *Union* or *Intersection*

Both model types in this study support composition by *union* as well as composition by *intersection*. In untyped models, composition by *union* and composition by *intersection* can be achieved by pointwise addition and pointwise multiplication respectively. The major difference between composition in the APT model and the untyped model is that in the former, composition is not commutative due to offsetting the modifier in a dependency relation (see section 3). Blacoe and Lapata (2012) showed that an intersective composition function such as pointwise multiplication represents a competitive and robust approach in comparison to more sophisticated composition methods. For the final set of experiments on the Mitchell and Lapata (2010) dataset, we present results the APT model and the untyped model, using composition by *union* and composition by *intersection*, with and without distributional inference. We compare our models with the best performing untyped VSMs of Mitchell and Lapata (2010), and Blacoe and Lapata (2012), the best performing APT model of Weir et al. (2016), as well as with the recently published state-of-the-art methods by Hashimoto et al. (2014), and Wieting et al. (2015), who are using neural network based approaches. For our models, we use the static top n approach as neighbour retrieval function and tune the remaining parameters, the SPPMI shift k (1, 5, 10, 40, 100) and the number of neighbours (10, 30, 50, 100, 500, 1000, 5000), for both model types, and the sliding window size for the untyped VSM (1, 2, 5), on the development portion of the Mitchell and Lapata (2010) dataset. We keep the vector configuration (k and window size) fixed for all phrase types and only tune the number of neighbours used for DI individually. The best vector configuration for the APT model is achieved with $k = 10$ and for the untyped VSM with $k = 1$. For composition by *intersection* best performance on the dev set was achieved with 1000 neighbours for ANs, 10 for NNs and 50 for VOs with DI. For composition by *union*, top performance was obtained with 100 neighbours for ANs, 30 neighbours for NNs and 50 for VOs. The best results for the untyped model on the dev set are achieved with a symmetric window size of 1 and using 5000 neighbours for ANs, 10 for NNs and 1000 for VOs with composition by pointwise multiplication, and 30 neighbours for ANs, 5000 for NNs and 5000 for VOs for composition by pointwise addition. The validated numbers of neighbours on the development set show that the problem of missing information appears to be more severe for semantic composition than for word similarity tasks. Even though a neighbour at rank 1000 or lower does not appear to have a close relationship to the target word, it still can contribute useful co-occurrence information not observed in the original vector.

Table 7 shows that composition by *intersection* with distributional inference considerably improves upon the best results for APT models without distributional inference and for untyped count-based models, and is competitive with the state-of-the-art neural network based models of Hashimoto et al. (2014) and Wieting et al. (2015). Distributional inference also improves upon the performance of an untyped VSM where composition by pointwise multiplication is outperforming the models of Mitchell and Lapata (2010), and Blacoe and Lapata (2012). Table 7 furthermore shows that DI has a smaller effect on

the APT model based on composition by *union* and the untyped model based on composition by pointwise addition. The reason, as pointed out in the discussion for Table 5, is that the composition function has no disambiguating effect and thus cannot eliminate unrelated neighbours introduced by distributional inference. An intersective composition function on the other hand is able to perform the disambiguation locally in any given phrasal context. This furthermore suggests that for the APT model it is not necessary to explicitly model different word senses in separate vectors, as composition by *intersection* is able to disambiguate any word in context individually. Unlike the models of Hashimoto et al. (2014) and Wieting et al. (2015), the elementary word representations, as well as the representations for composed phrases and the composition process in our models are fully interpretable[2].

6 Conclusion and Future Work

One of the major challenges in count-based models is dealing with sparsity and missing information. To address this challenge, we contribute an unsupervised algorithm for enriching sparse word representations by exploiting the distributional neighbourhood. We have demonstrated its benefit to typed and untyped vector space models on a range of tasks and have shown that with distributional inference our APT model is competitive with the state-of-the-art for adjective-noun, noun-noun and verb-object compositions while being fully interpretable. With our method, we are able to bridge the gap in performance between low-dimensional non-interpretable and high-dimensional interpretable representations. Lastly, we have investigated the different behaviour of composition by *union* and composition by *intersection* and have shown that an *intersective* composition function, together with distributional inference, has the ability to locally disambiguate the meaning of a phrase.

In future work we aim to scale our approach to semantic composition with distributional inference to longer phrases and full sentences. We furthermore plan to investigate whether the number of neighbours required for improving elementary vector representations remains as high for other compositional tasks and longer phrases as in this study.

Abstract

Recently, there is rising interest in modelling the interactions of two sentences with deep neural networks. However, most of the existing methods encode two sequences with separate encoders, in which a sentence is encoded with little or no information from the other sentence. In this paper, we propose a deep architecture to model the strong interaction of sentence pair with two coupled-LSTMs. Specifically, we introduce two coupled ways to model the interdependences of two LSTMs, coupling the local contextualized interactions of two sentences. We then aggregate these interactions and use a dynamic pooling to select the most informative features. Experiments on two very large datasets demonstrate the efficacy of our proposed architectures.

1 Introduction

Distributed representations of words or sentences have been widely used in many natural language processing (NLP) tasks, such as text classification (Kalchbrenner et al., 2014; Liu et al., 2015), question answering and machine translation (Sutskever et al., 2014) and so on. Among these tasks, a common problem is modelling the relevance/similarity of the sentence pair, which is also called text semantic matching.

Recently, deep learning based models is rising a substantial interest in text semantic matching and have achieved some great progresses (Hu et al., 2014; Qiu and Huang, 2015; Wan et al., 2016).

*Corresponding author.

According to the phases of interaction between two sentences, previous models can be classified into three categories.

Weak interaction Models Some early works focus on sentence level interactions, such as ARC-I(Hu et al., 2014), CNTN(Qiu and Huang, 2015) and so on. These models first encode two sequences with some basic (Neural Bag-of-words, BOW) or advanced (RNN, CNN) components of neural networks separately, and then compute the matching score based on the distributed vectors of two sentences. In this paradigm, two sentences have no interaction until arriving final phase.

Semi-interaction Models Some improved methods focus on utilizing multi-granularity representation (word, phrase and sentence level), such as MultiGranCNN (Yin and Schütze, 2015) and Multi-Perspective CNN (He et al., 2015). Another kind of models use soft attention mechanism to obtain the representation of one sentence by depending on representation of another sentence, such as ABCNN (Yin et al., 2015), Attention LSTM(Rocktäschel et al., 2015; Hermann et al., 2015). These models can alleviate the weak interaction problem, but are still insufficient to model the contextualized interaction on the word as well as phrase level.

Strong Interaction Models These models directly build an interaction space between two sentences and model the interaction at different positions, such as ARC-II (Hu et al., 2014), MV-LSTM (Wan et al., 2016) and DF-LSTMs(Liu et al., 2016). These models can easily capture the difference between semantic capacity of two sentences.

In this paper, we propose a new deep neural network architecture to model the strong interactions

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1703–1712,
Austin, Texas, November 1-5, 2016.

of two sentences. Different with modelling two sentences with separated LSTMs, we utilize two interdependent LSTMs, called coupled-LSTMs, to fully affect each other at different time steps. The output of coupled-LSTMs at each step depends on both sentences. Specifically, we propose two interdependent ways for the coupled-LSTMs: loosely coupled model (LC-LSTMs) and tightly coupled model (TC-LSTMs). Similar to bidirectional LSTM for single sentence (Schuster and Paliwal, 1997; Graves and Schmidhuber, 2005), there are four directions can be used in coupled-LSTMs. To utilize all the information of four directions of coupled-LSTMs, we aggregate them and adopt a dynamic pooling strategy to automatically select the most informative interaction signals. Finally, we feed them into a fully connected layer, followed by an output layer to compute the matching score.

The contributions of this paper can be summarized as follows.

1. Different with the architectures of using similarity matrix, our proposed architecture directly model the strong interactions of two sentences with coupled-LSTMs, which can capture the useful local semantic relevances of two sentences. Our architecture can also capture the multiple granular interactions by several stacked coupled-LSTMs layers.

2. Compared to previous works on text matching, we perform extensive empirical studies on two very large datasets. The massive scale of the datasets allows us to train a very deep neural network and present an elaborate qualitative analysis of our models, which gives an intuitive understanding how our model worked.

2 Sentence Modelling with LSTM

Long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997) is a type of recurrent neural network (RNN) (Elman, 1990), and specifically addresses the issue of learning long-term dependencies.

We define the LSTM *units* at each time step t to be a collection of vectors in $\mathbb{R}^d$: an *input gate* $\mathbf{i}_t$, a *forget gate* $\mathbf{f}_t$, an *output gate* $\mathbf{o}_t$, a *memory cell* $\mathbf{c}_t$ and a hidden state $\mathbf{h}_t$. d is the number of the LSTM units. The elements of the gating vectors $\mathbf{i}_t$, $\mathbf{f}_t$ and $\mathbf{o}_t$ are in $[0, 1]$.

The LSTM is precisely specified as follows.

$$\begin{bmatrix} \tilde{\mathbf{c}}_t \\ \mathbf{o}_t \\ \mathbf{i}_t \\ \mathbf{f}_t \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} T_{\mathbf{A},\mathbf{b}} \begin{bmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{bmatrix}, \quad (1)$$

$$\mathbf{c}_t = \tilde{\mathbf{c}}_t \odot \mathbf{i}_t + \mathbf{c}_{t-1} \odot \mathbf{f}_t, \quad (2)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t), \quad (3)$$

where $\mathbf{x}_t$ is the input at the current time step; $T_{\mathbf{A},\mathbf{b}}$ is an affine transformation which depends on parameters of the network $\mathbf{A}$ and $\mathbf{b}$. σ denotes the logistic sigmoid function and $\odot$ denotes elementwise multiplication.

The update of each LSTM unit can be written precisely as follows

$$(\mathbf{h}_t, \mathbf{c}_t) = \mathbf{LSTM}(\mathbf{h}_{t-1}, \mathbf{c}_{t-1}, \mathbf{x}_t). \quad (4)$$

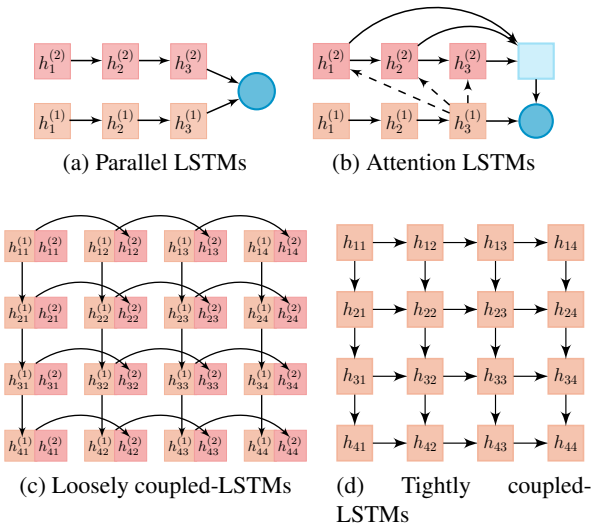
Here, the function $\mathbf{LSTM}(\cdot, \cdot, \cdot)$ is a shorthand for Eq. (1-3).

3 Coupled-LSTMs for Strong Sentence Interaction

To deal with two sentences, one straightforward method is to model them with two separate LSTMs. However, this method is difficult to model local interactions of two sentences. An improved way is to introduce attention mechanism, which has been used in many tasks, such as machine translation (Bahdanau et al., 2014) and question answering (Hermann et al., 2015).

Inspired by the multi-dimensional recurrent neural network (Graves et al., 2007; Graves and Schmidhuber, 2009; Byeon et al., 2015) and grid LSTM (Kalchbrenner et al., 2015) in computer vision community, we propose two models to capture the interdependences between two parallel LSTMs, called **coupled-LSTMs** (C-LSTMs).

To facilitate our models, we firstly give some definitions. Given two sequences $X = x_1, x_2, \cdots, x_n$ and $Y = y_1, y_2, \cdots, y_m$, we let $\mathbf{x}_i \in \mathbb{R}^d$ denote the embedded representation of the word x_i. The standard LSTM have one temporal dimension. When dealing with a sentence, LSTM regards the position as time step. At position i of sentence $x_{1:n}$,



(a) Parallel LSTMs (b) Attention LSTMs

(c) Loosely coupled-LSTMs (d) Tightly coupled-LSTMs

Figure 1: Four different coupled-LSTMs.

the output $\mathbf{h}_i$ reflects the meaning of subsequence $x_{0:i} = x_0, \cdots, x_i$.

To model the interaction of two sentences as early as possible, we define $\mathbf{h}_{i,j}$ to represent the interaction of the subsequences $x_{0:i}$ and $y_{0:j}$.

Figure 1(c) and 1(d) illustrate our two propose models. For intuitive comparison of weak interaction parallel LSTMs, we also give parallel LSTMs and attention LSTMs in Figure 1(a) and 1(b)[1].

We describe our two proposed models as follows.

3.1 Loosely Coupled-LSTMs (LC-LSTMs)

To model the local contextual interactions of two sentences, we enable two LSTMs to be interdependent at different positions. Inspired by Grid LSTM (Kalchbrenner et al., 2015) and word-by-word attention LSTMs (Rocktäschel et al., 2015), we propose a loosely coupling model for two interdependent LSTMs.

More concretely, we refer to $\mathbf{h}^{(1)}_{i,j}$ as the encoding of subsequence $x_{0:i}$ in the first LSTM influenced by the output of the second LSTM on subsequence $y_{0:j}$. Meanwhile, $\mathbf{h}^{(2)}_{i,j}$ is the encoding of subsequence $y_{0:j}$ in the second LSTM influenced by the output of the first LSTM on subsequence $x_{0:i}$

[1]In Rocktäschel et al. (2015) model, conditioned LSTM was used, meaning that $\mathbf{h}^{(1)}_1$ is produced conditioned on $\mathbf{h}^{(2)}_3$

$\mathbf{h}^{(1)}_{i,j}$ and $\mathbf{h}^{(2)}_{i,j}$ are computed as

$$\mathbf{h}^{(1)}_{i,j} = \mathbf{LSTM}^1(\mathbf{H}^{(1)}_{i-1}, \mathbf{c}^{(1)}_{i-1,j}, \mathbf{x}_i), \quad (5)$$

$$\mathbf{h}^{(2)}_{i,j} = \mathbf{LSTM}^2(\mathbf{H}^{(2)}_{j-1}, \mathbf{c}^{(2)}_{i,j-1}, \mathbf{y}_j), \quad (6)$$

where

$$\mathbf{H}^{(1)}_{i-1} = [\mathbf{h}^{(1)}_{i-1,j}, \mathbf{h}^{(2)}_{i-1,j}], \quad (7)$$

$$\mathbf{H}^{(2)}_{j-1} = [\mathbf{h}^{(1)}_{i,j-1}, \mathbf{h}^{(2)}_{i,j-1}]. \quad (8)$$

3.2 Tightly Coupled-LSTMs (TC-LSTMs)

The hidden states of LC-LSTMs are the combination of the hidden states of two interdependent LSTMs, whose memory cells are separated. Inspired by the configuration of the multi-dimensional LSTM (Byeon et al., 2015), we further conflate both the hidden states and the memory cells of two LSTMs. We assume that $\mathbf{h}_{i,j}$ directly model the interaction of the subsequences $x_{0:i}$ and $y_{0:j}$, which depends on two previous interaction $\mathbf{h}_{i-1,j}$ and $\mathbf{h}_{i,j-1}$, where i, j are the positions in sentence X and Y.

We define a tightly coupled-LSTMs *units* as follows.

$$\begin{bmatrix} \tilde{\mathbf{c}}_{i,j} \\ \mathbf{o}_{i,j} \\ \mathbf{i}_{i,j} \\ \mathbf{f}^1_{i,j} \\ \mathbf{f}^2_{i,j} \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} T_{\mathbf{A},\mathbf{b}} \begin{bmatrix} \mathbf{x}_i \\ \mathbf{y}_j \\ \mathbf{h}_{i,j-1} \\ \mathbf{h}_{i-1,j} \end{bmatrix}, \quad (9)$$

$$\mathbf{c}_{i,j} = \tilde{\mathbf{c}}_{i,j} \odot \mathbf{i}_{i,j} + [\mathbf{c}_{i,j-1}, \mathbf{c}_{i-1,j}]^{\mathrm{T}} \begin{bmatrix} \mathbf{f}^1_{i,j} \\ \mathbf{f}^2_{i,j} \end{bmatrix} \quad (10)$$

$$\mathbf{h}_{i,j} = \mathbf{o}_t \odot \tanh(\mathbf{c}_{i,j}) \quad (11)$$

where the gating units $\mathbf{i}_{i,j}$ and $\mathbf{o}_{i,j}$ determine which memory units are affected by the inputs through $\tilde{\mathbf{c}}_{i,j}$, and which memory cells are written to the hidden units $\mathbf{h}_{i,j}$. $T_{\mathbf{A},\mathbf{b}}$ is an affine transformation which depends on parameters of the network $\mathbf{A}$ and $\mathbf{b}$. In contrast to the standard LSTM defined over time, each memory unit $\mathbf{c}_{i,j}$ of a tightly coupled-LSTMs has two preceding states $\mathbf{c}_{i,j-1}$ and $\mathbf{c}_{i-1,j}$ and two corresponding forget gates $\mathbf{f}^1_{i,j}$ and $\mathbf{f}^2_{i,j}$.

3.3 Analysis of Two Proposed Models

Our two proposed coupled-LSTMs can be formulated as

$$(\mathbf{h}_{i,j}, \mathbf{c}_{i,j}) = \mathbf{C\text{-}LSTMs}(\mathbf{h}_{i-1,j}, \mathbf{h}_{i,j-1}, \mathbf{c}_{i-1,j}, \mathbf{c}_{i,j-1}, \mathbf{x}_i, \mathbf{y}_j), \quad (12)$$

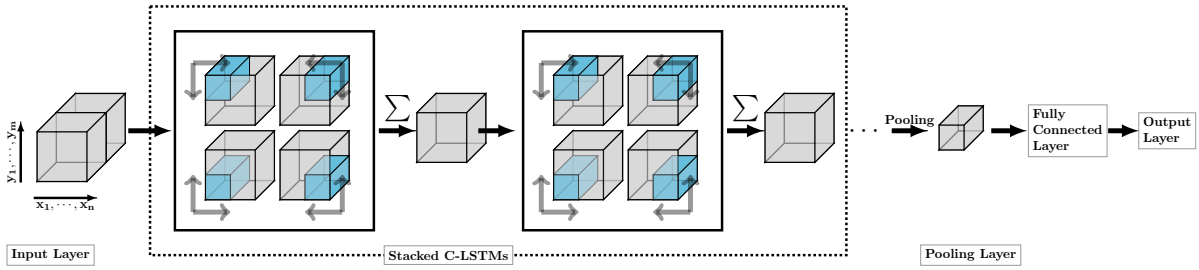


Figure 2: Architecture of coupled-LSTMs for sentence-pair encoding. Inputs are fed to four C-LSTMs followed by an aggregation layer. Blue cuboids represent different contextual information from four directions.

where **C-LSTMs** can be either **TC-LSTMs** or **LC-LSTMs**.

The input consists of two type of information at step (i, j) in coupled-LSTMs: temporal dimension $\mathbf{h}_{i-1,j}, \mathbf{h}_{i,j-1}, \mathbf{c}_{i-1,j}, \mathbf{c}_{i,j-1}$ and depth dimension $\mathbf{x}_i, \mathbf{y}_j$. The difference between TC-LSTMs and LC-LSTMs is the dependence of information from temporal and depth dimension.

Interaction Between Temporal Dimensions The TC-LSTMs model the interactions at position (i, j) by merging the internal memory $\mathbf{c}_{i-1,j}$ $\mathbf{c}_{i,j-1}$ and hidden state $\mathbf{h}_{i-1,j}$ $\mathbf{h}_{i,j-1}$ along row and column dimensions. In contrast with TC-LSTMs, LC-LSTMs firstly use two standard LSTMs in parallel, producing hidden states $\mathbf{h}^1_{i,j}$ and $\mathbf{h}^2_{i,j}$ along row and column dimensions respectively, which are then merged together flowing next step.

Interaction Between Depth Dimension In TC-LSTMs, each hidden state $\mathbf{h}_{i,j}$ at higher layer receives a fusion of information $\mathbf{x}_i$ and $\mathbf{y}_j$, flowed from lower layer. However, in LC-LSTMs, the information $\mathbf{x}_i$ and $\mathbf{y}_j$ are accepted by two corresponding LSTMs at the higher layer separately.

The two architectures have their own characteristics, TC-LSTMs give more strong interactions among different dimensions while LC-LSTMs ensures the two sequences interact closely without being conflated using two separated LSTMs.

Comparison of LC-LSTMs and word-by-word Attention LSTMs The characteristic of attention LSTMs is that they obtain the attention weighted representation of one sentence considering he alignment between the two sentences, which is asymmetric unidirectional encoding. Nevertheless, in LC-LSTM, each hidden state of each step is obtained with the consideration of interaction between two sequences with symmetrical encoding fashion.

4 End-to-End Architecture for Sentence Matching

In this section, we present an end-to-end deep architecture for matching two sentences, as shown in Figure 2.

4.1 Embedding Layer

To model the sentences with neural model, we firstly need transform the one-hot representation of word into the distributed representation. All words of two sequences $X = x_1, x_2, \cdots, x_n$ and $Y = y_1, y_2, \cdots, y_m$ will be mapped into low dimensional vector representations, which are taken as input of the network.

4.2 Stacked Coupled-LSTMs Layers

A basic block consists of five layers. We firstly use four directional coupled-LSTMs to model the local interactions with different information flows. And then we sum the outputs of these LSTMs by aggregation layer. To increase the learning capabilities of the coupled-LSTMs, we stack the basic block on top of each other.

4.2.1 Four Directional Coupled-LSTMs Layers

The C-LSTMs is defined along a certain predefined direction, we can extend them to access to the surrounding context in all directions. Similar to bi-directional LSTM, there are four directions in coupled-LSTMs.

$$(\mathbf{h}^1_{i,j}, \mathbf{c}^1_{i,j}) = \textbf{C-LSTMs}(\mathbf{h}_{i-1,j}, \mathbf{h}_{i,j-1}, \mathbf{c}_{i-1,j}, \mathbf{c}_{i,j-1}, \mathbf{x}_i, \mathbf{y}_j),$$
$$(\mathbf{h}^2_{i,j}, \mathbf{c}^2_{i,j}) = \textbf{C-LSTMs}(\mathbf{h}_{i-1,j}, \mathbf{h}_{i,j+1}, \mathbf{c}_{i-1,j}, \mathbf{c}_{i,j+1}, \mathbf{x}_i, \mathbf{y}_j),$$
$$(\mathbf{h}^3_{i,j}, \mathbf{c}^3_{i,j}) = \textbf{C-LSTMs}(\mathbf{h}_{i+1,j}, \mathbf{h}_{i,j+1}, \mathbf{c}_{i+1,j}, \mathbf{c}_{i,j+1}, \mathbf{x}_i, \mathbf{y}_j),$$

$$(\mathbf{h}^4_{i,j}, \mathbf{c}^4_{i,j}) = \textbf{C-LSTMs}(\mathbf{h}_{i+1,j}, \mathbf{h}_{i,j-1}, \mathbf{c}_{i+1,j}, \mathbf{c}_{i,j-1}, \mathbf{x}_i, \mathbf{y}_j).$$

4.2.2 Aggregation Layer

The aggregation layer sums the outputs of four directional coupled-LSTMs into a vector.

$$\hat{\mathbf{h}}_{i,j} = \sum_{d=1}^{4} \mathbf{h}^d_{i,j}, \tag{13}$$

where the superscript t of $\mathbf{h}_{i,j}$ denotes the different directions.

4.2.3 Stacking C-LSTMs Blocks

To increase the capabilities of network of learning multiple granularities of interactions, we stack several blocks (four C-LSTMs layers and one aggregation layer) to form deep architectures.

4.3 Pooling Layer

The output of stacked coupled-LSTMs layers is a tensor $\mathbf{H} \in \mathbb{R}^{n \times m \times d}$, where n and m are the lengths of sentences, and d is the number of hidden neurons. We apply dynamic pooling to automatically extract $\mathbb{R}^{p \times q}$ subsampling matrix in each slice $\mathbf{H}_i \in \mathbb{R}^{n \times m}$, similar to (Socher et al., 2011).

More formally, for each slice matrix $\mathbf{H}_i$, we partition the rows and columns of $\mathbf{H}_i$ into $p \times q$ roughly equal grids. These grid are non-overlapping. Then we select the maximum value within each grid thereby obtaining a $p \times q \times d$ tensor.

4.4 Fully-Connected Layer

The vector obtained by pooling layer is fed into a full connection layer to obtain a final more abstractive representation.

4.5 Output Layer

The output layer depends on the types of the tasks, we choose the corresponding form of output layer. There are two popular types of text matching tasks in NLP. One is ranking task, such as community question answering. Another is classification task, such as textual entailment.

1. For ranking task, the output is a scalar matching score, which is obtained by a linear transformation after the last fully-connected layer.

	MQA	RTE
Embedding size	100	100
Hidden layer size	50	50
Initial learning rate	0.05	0.005
Regularization	$5E{-}5$	$1E{-}5$
Pooling (p, q)	(2,1)	(1,1)

Table 1: Hyper-parameters for our model on two tasks.

2. For classification task, the outputs are the probabilities of the different classes, which is computed by a softmax function after the last fully-connected layer.

5 Training

Our proposed architecture can deal with different sentence matching tasks. The loss functions varies with different tasks. More concretely, we use max-margin loss (Bordes et al., 2013; Socher et al., 2013) for ranking task and cross-entropy loss for classification task.

To minimize the objective, we use stochastic gradient descent with the diagonal variant of AdaGrad (Duchi et al., 2011). To prevent exploding gradients, we perform gradient clipping by scaling the gradient when the norm exceeds a threshold (Graves, 2013).

6 Experiment

In this section, we investigate the empirical performances of our proposed model on two different text matching tasks: classification task (recognizing textual entailment) and ranking task (matching of question and answer).

6.1 Hyperparameters and Training

The word embeddings for all of the models are initialized with the 100d GloVe vectors (840B token version, (Pennington et al., 2014)) and fine-tuned during training to improve the performance. The other parameters are initialized by randomly sampling from uniform distribution in $[-0.1, 0.1]$.

For each task, we take the hyperparameters which achieve the best performance on the development set via an small grid search over combinations of the initial learning rate $[0.05, 0.0005, 0.0001]$, l_2 regularization $[0.0, 5E{-}5, 1E{-}5, 1E{-}6]$ and the threshold

value of gradient norm [5, 10, 100]. The final hyper-parameters are set as Table 1.

6.2 Competitor Methods

- Neural bag-of-words (NBOW): Each sequence as the sum of the embeddings of the words it contains, then they are concatenated and fed to a MLP.
- Single LSTM: A single LSTM to encode the two sequences, which is used in (Rocktäschel et al., 2015).
- Parallel LSTMs: Two sequences are encoded by two LSTMs separately, then they are concatenated and fed to a MLP.
- Attention LSTMs: An attentive LSTM to encode two sentences into a semantic space, which used in (Hermann et al., 2015; Rocktäschel et al., 2015).
- Word-by-word Attention LSTMs: An improvement of attention LSTM by introducing word-by-word attention mechanism, which used in (Hermann et al., 2015; Rocktäschel et al., 2015).

6.3 Experiment-I: Recognizing Textual Entailment

Recognizing textual entailment (RTE) is a task to determine the semantic relationship between two sentences. We use the Stanford Natural Language Inference Corpus (SNLI) (Bowman et al., 2015). This corpus contains 570K sentence pairs, and all of the sentences and labels stem from human annotators. SNLI is two orders of magnitude larger than all other existing RTE corpora. Therefore, the massive scale of SNLI allows us to train powerful neural networks such as our proposed architecture in this paper.

6.3.1 Results

Table 2 shows the evaluation results on SNLI. The 3rd column of the table gives the number of parameters of different models without the word embeddings.

Our proposed two C-LSTMs models with four stacked blocks outperform all the competitor models, which indicates that our thinner and deeper network does work effectively.

Model	k	$\|\theta\|_M$	Test
NBOW	100	80K	75.1
single LSTM (Rocktäschel et al., 2015)	100	111K	80.9
parallel LSTMs (Bowman et al., 2015)	100	221K	77.6
Attention LSTMs (Rocktäschel et al., 2015)	100	252K	82.3
Attention(w-by-w) LSTMs (Rocktäschel et al., 2015)	100	252K	83.5
LC-LSTMs (Single Direction)	50	45K	80.5
LC-LSTMs	50	45K	80.9
four stacked LC-LSTMs	50	135K	84.3
TC-LSTMs (Single Direction)	50	77.5K	80.1
TC-LSTMs	50	77.5K	81.6
four stacked TC-LSTMs	50	190K	**85.1**

Table 2: Results on SNLI corpus.

Besides, we can see both LC-LSTMs and TC-LSTMs benefit from multi-directional layer, while the latter obtains more gains than the former. We attribute this discrepancy between two models to their different mechanisms of controlling the information flow from depth dimension.

Compared with attention LSTMs, our two models achieve comparable results to them using much fewer parameters (nearly $1/5$). By stacking C-LSTMs[2] , the performance of them are improved significantly, and the four stacked TC-LSTMs achieve 85.1% accuracy on this dataset.

Moreover, we can see TC-LSTMs achieve better performance than LC-LSTMs on this task, which need fine-grained reasoning over pairs of words as well as phrases.

6.3.2 Understanding Behaviors of Neurons in C-LSTMs

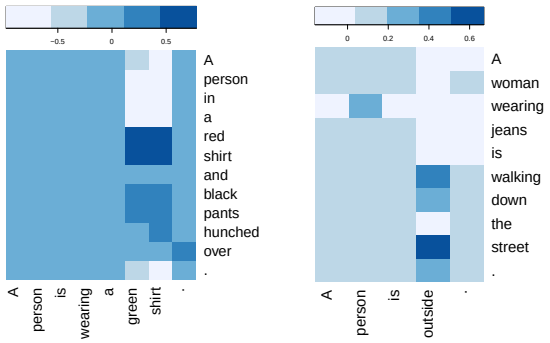
To get an intuitive understanding of how the C-LSTMs work on this problem, we examined the neuron activations in the last aggregation layer while evaluating the test set using TC-LSTMs. We find that some cells are bound to certain roles.

Let $h_{i,j,k}$ denotes the activation of the k-th neuron at the position of (i, j), where $i \in \{1, \ldots, n\}$ and $j \in \{1, \ldots, m\}$. By visualizing the hidden state $\mathbf{h}_{i,j,k}$ and analyzing the maximum activation, we

[2]To make a fair comparison, we also train a stacked attention-based LSTM with the same setting as our models, while it does not make significant improvement with 83.7% accuracy.

Index of Cell	Word or Phrase Pairs
3-th	(in a pool, swimming), (near a fountain, next to the ocean), (street, outside)
9-th	(doing a skateboard, skateboarding), (sidewalk with, inside), (standing, seated)
17-th	(blue jacket, blue jacket), (wearing black, wearing white), (green uniform, red uniform)
25-th	(a man, two other men), (a man, two girls), (an old woman, two people)

Table 3: Multiple interpretable neurons and the word-pairs/phrase-pairs captured by these neurons.



(a) 3rd neuron (b) 17th neuron

Figure 3: Illustration of two interpretable neurons and some word-pairs capture by these neurons. The darker patches denote the corresponding activations are higher.

can find that there exist multiple interpretable neurons. For example, when some contextualized local perspectives are semantically related at point (i, j) of the sentence pair, the activation value of hidden neuron $h_{i,j,k}$ tend to be maximum, meaning that the model could capture some reasoning patterns.

Figure 3 illustrates this phenomenon. In Figure 3(a), a neuron shows its ability to monitor the local contextual interactions about color. The activation in the patch, including the word pair "`(red, green)`", is much higher than others. This is informative pattern for the relation prediction of these two sentences, whose ground truth is contradiction. An interesting thing is there are two words describing color in the sentence "`A person in a red shirt and black pants hunched over.`". Our model ignores the useless word "`black`", which indicates that this neuron selectively captures pattern by contextual understanding, not just word level interaction.

In Figure 3(b), another neuron shows that it can capture the local contextual interactions, such as "`(walking down the street, outside)`". These patterns can be easily captured by pooling layer and provide a strong support for the final prediction.

Table 3 illustrates multiple interpretable neurons and some representative word or phrase pairs which can activate these neurons. These cases show that our models can capture contextual interactions beyond word level.

6.3.3 Error Analysis

Although our models C-LSTMs are more sensitive to the discrepancy of the semantic capacity between two sentences, some semantic mistakes at the phrasal level still exist. For example, our models failed to capture the key informative pattern when predicting the entailment sentence pair "`A girl` **`takes off her shoes`** `and eats blue cotton candy/The girl is eating while` **`barefoot.`**"

Besides, despite the large size of the training corpus, it's still very different to solve some cases, which depend on the combination of the world knowledge and context-sensitive inferences. For example, given an entailment pair "`a man grabs his crotch during a political demonstration/The man is making a crude gesture`", all models predict "`neutral`". This analysis suggests that some architectural improvements or external world knowledge are necessary to eliminate all errors instead of simply scaling up the basic model.

6.4 Experiment-II: Matching Question and Answer

Matching question answering (MQA) is a typical task for semantic matching. Given a question, we need select a correct answer from some candidate answers.

In this paper, we use the dataset collected from Yahoo! Answers with the getByCategory function

Model	k	P@1(5)	P@1(10)
Random Guess	-	20.0	10.0
NBOW	50	63.9	47.6
single LSTM	50	68.2	53.9
parallel LSTMs	50	66.9	52.1
Attention LSTMs	50	73.5	62.0
Attention LSTMs (w-by-w)	50	75.1	64.0
LC-LSTMs (Single Direction)	50	75.4	63.0
LC-LSTMs	50	76.1	64.1
three stacked LC-LSTMs	50	**78.5**	**66.2**
TC-LSTMs (Single Direction)	50	74.3	62.4
TC-LSTMs	50	74.9	62.9
three stacked TC-LSTMs	50	77.0	65.3

Table 4: Results on Yahoo question-answer pairs dataset.

provided in Yahoo! Answers API, which produces $963,072$ questions and corresponding best answers. We then select the pairs in which the length of questions and answers are both in the interval $[4, 30]$, thus obtaining $220,000$ question answer pairs to form the positive pairs.

For negative pairs, we first use each question's best answer as a query to retrieval top $1,000$ results from the whole answer set with Lucene, where 4 or 9 answers will be selected randomly to construct the negative pairs.

The whole dataset is divided into training, validation and testing data with proportion $20 : 1 : 1$. Moreover, we give two test settings: selecting the best answer from 5 and 10 candidates respectively.

6.4.1 Results

Results of MQA are shown in the Table 4. For our models, due to stacking block more than three layers can not make significant improvements on this task, we just use three stacked C-LSTMs.

By analyzing the evaluation results of question-answer matching in table 4, we can see strong interaction models (attention LSTMs, our C-LSTMs) consistently outperform the weak interaction models (NBOW, parallel LSTMs) with a large margin, which suggests the importance of modelling strong interaction of two sentences.

Our proposed two C-LSTMs surpass the competitor methods and C-LSTMs augmented with multi-directions layers and multiple stacked blocks fully utilize multiple levels of abstraction to directly boost the performance.

Additionally, LC-LSTMs is superior to TC-LSTMs. The reason may be that MQA is a relative simple task, which requires less reasoning abilities, compared with RTE task. Moreover, the parameters of LC-LSTMs are less than TC-LSTMs, which ensures the former can avoid suffering from overfitting on a relatively smaller corpus.

7 Related Work

Our architecture for sentence pair encoding can be regarded as strong interaction models, which have been explored in previous models.

An intuitive paradigm is to compute similarities between all the words or phrases of the two sentences. Socher et al. (2011) firstly used this paradigm for paraphrase detection. The representations of words or phrases are learned based on recursive autoencoders.

A major limitation of this paradigm is the interaction of two sentence is captured by a pre-defined similarity measure. Thus, it is not easy to increase the depth of the network. Compared with this paradigm, we can stack our C-LSTMs to model multiple-granularity interactions of two sentences.

Rocktäschel et al. (2015) used two LSTMs equipped with attention mechanism to capture the iteration between two sentences. This architecture is asymmetrical for two sentences, where the obtained final representation is sensitive to the two sentences' order.

Compared with the attentive LSTM, our proposed C-LSTMs are symmetrical and model the local contextual interaction of two sequences directly.

8 Conclusion and Future Work

In this paper, we propose an end-to-end deep architecture to capture the strong interaction information of sentence pair. Experiments on two large scale text matching tasks demonstrate the efficacy of our proposed model and its superiority to competitor models. Besides, we present an elaborate qualitative analysis of our models, which gives an intuitive understanding how our model worked.

In future work, we would like to incorporate some gating strategies into the depth dimension of our proposed models, like highway or residual network, to enhance the interactions between depth and other di-

mensions thus training more deep and powerful neural networks.

Universal Decompositional Semantics on Universal Dependencies

Aaron Steven White Drew Reisinger Keisuke Sakaguchi Tim Vieira

Abstract

We present a framework for augmenting data sets from the Universal Dependencies project with *Universal Decompositional Semantics*. Where the Universal Dependencies project aims to provide a syntactic annotation standard that can be used consistently across many languages as well as a collection of corpora that use that standard, our extension has similar aims for semantic annotation. We describe results from annotating the English Universal Dependencies treebank, dealing with word senses, semantic roles, and event properties.

1 Introduction

This paper describes the *Universal Decompositional Semantics* (Decomp) project, which aims to augments Universal Dependencies (UD) data sets with robust, scalable semantic annotations based in linguistic theory. The UD project[1] aims to provide (i) a syntactic dependency annotation standard that can be used consistently across many languages and (ii) a collection of corpora that use that standard (De Marneffe et al., 2014; Nivre et al., 2015). Decomp provides complementary semantic annotations that scale across different types of semantic information and different languages and can integrate seamlessly with any UD-annotated corpus.

Decomp has two mutually supportive tenets—*semantic decomposition* and *simplicity*. As we discuss further in the next section, these tenets allow us to collect annotations from everyday speakers of a language that are rooted in basic, commonsensical aspects of meaning and that can be straightforwardly explained and generally agreed upon in context.

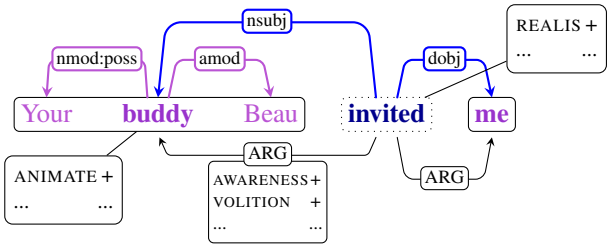

Figure 1: Decompositional semantics atop syntax.

In this paper, we describe Decomp protocols for three domains—semantic role decomposition, event decomposition, and word sense decomposition—and we present annotation results on top of the English UD v1.2 (EUD1.2) treebank.[2] We begin in §2 by connecting Decomp with previous work on decomposition in linguistic theory. In §3, we present *PredPatt*, which is a software package for preprocessing UD annotated corpora for input into Decomp protocols. In §4, we present a major revision to Reisinger et al.'s (2015) semantic role decomposition protocol (SPR1). Our revision, SPR2, brings SPR1 into full alignment with Decomp while adding various new features. In §5, we present Decomp-aligned annotation of event properties, focusing specifically on event realis. Finally, in §6, we describe a Decomp-aligned word sense decomposition protocol and associated set of annotations.

2 Universal Decompositional Semantics

A range of perspectives suggest that the proper representation for word meanings is *decompositional*.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1713–1723,
Austin, Texas, November 1-5, 2016.

For example, Dowty (1979) followed by a substantial amount of research (e.g. Jackendoff 1990; Rappaport-Hovav and Levin 1998; Levin and Rappaport Hovav 2005) suggests that word meanings can be factored into (i) idiosyncratic, item-specific components and (ii) general components, such as CAUSATION, that are used across the lexicon. In the domain of thematic roles, Dowty (1991) argues that notions such as AGENT should be decomposed into simpler, more primitive properties such as volitional participation in an event. Pustejovsky (1991) decomposes word meanings into *qualia structures* that again incorporate more primitive properties of events and individuals. In spite of this wealth of theory, existing annotation protocols rarely take the idea into account, operating at the level that the above approaches decompose with very few exceptions (Greene and Resnik, 2009; Hartshorne et al., 2013; Reisinger et al., 2015). Decomp's premise is that a decompositional approach to large-scale annotation has benefits for both the annotation process and downstream uses of annotated data (cf. He et al. 2015; Bos et al. 2017 for recent non-decompositional approaches).

To capture these benefits, Decomp incorporates *semantic decomposition* directly into its protocols by mapping from decompositional theories, such as Dowty's, into straightforward questions on binary properties that are easily answered. This method of constructing annotation protocols gives rise to *simplicity* in the protocol, since the resulting questions are much more commonsensical and easily explained than the concepts they are decomposing. For instance, Dowty (1991) decomposes the relatively unintuitive notion (for ordinary speakers) of AGENT into much simpler properties, such as VOLITION and MOVEMENT. Instead of asking about whether a verbal argument is an AGENT (with the concomitant complex training process for annotators), a Decomp protocol might then ask about whether the referent of the argument had volition in or moved as a result of the event. Simplicity in the protocol in turn allows a Decomp protocol to gather annotations from untrained native (and naïve) speakers of a language. In large part, the current paper is focused on developing questions that everyday speakers can agree on and that are key for lexical representations.

An added benefit of questions on binary properties is they allow the use of ordinal prompts (Likert scales), allowing annotators to record subjective uncertainty of a property in a given context, which can then be aggregated across multiple responses with less severe impact to inter-annotator agreement.

3 Predicative patterns

In this section, we introduce PredPatt, which is a lightweight tool for identifying the structure of predicates and arguments from Universal Dependencies. We use the PredPatt's output as input to the Decomp aligned annotation protocols we describe in §4 – §6. To ensure that this output is accurate, we evaluate on multiple UD-annotated corpora: automatically generated English parses and gold treebanks in Chinese, English, Hebrew, Hindi, and Spanish.[3]

PredPatt employs deterministic, unlexicalized rules over UD parses. We provide a high-level overview of the process here.[4]

Input UD Parse with Universal POS tags
1. Predicate and argument root identification
2. Argument resolution
3. Predicate and argument phrase extraction
4. Optional Post-processing

Output collection of predicate-argument structures

UD Parse A universal dependency (UD) parse, is a set of labeled pairs. Each pair has the form RELATION(DEPENDENT, GOVERNOR). The UD parse also includes a sequence of Universal POS tags. An example of a UD parse is in Figure 1.

Predicate and argument root identification Predicate and argument roots (i.e., dependency tree nodes) are identified by local configurations—specifically, edges in the UD parse. The simplest example is NSUBJ(s, v) and DOBJ(o, v), which indicate that v is a predicate root, and that s and o are argument roots. Similarly, roots of clausal subjects and clausal complements are also predicate roots. Nominal modifiers inside adverbial modifiers

[3] While we are not aware of a similar tool for Universal Dependencies, PredPatt is similar to ClausIE (Del Corro and Gemulla, 2013) and ArgOE (Gamallo et al., 2012), which supports Spanish, Portuguese, Galician and English.

[4] A detailed description of PredPatt is available at `https://github.com/hltcoe/PredPatt`. PredPatt derives from the system described by Rudinger and Van Durme (2014).

are arguments to the verb being modified, e.g., *Investors turned away from [the stock market]*. PredPatt also extracts relations from appositives, possessives, copula, and adverbial modifiers.

Argument resolution PredPatt includes argument resolution rules to handle missing arguments of many syntactic constructions, including predicate coordination, relative clauses, and embedded clauses. Argument resolution is crucial in languages that mark arguments using morphology, such as Spanish and Portuguese, because there are more cases of covert subjects. Other common cases for argument resolution are when predicates appear in a conjunction, e.g., *Chris likes to sing and dance*, has no arc from *dance* to its subject *Chris*. In relative clauses, the arguments of an embedded clause appear outside the subtree, e.g., *borrowed* in *The books John borrowed from the library are overdue.* has *books* as an argument and so does *are-overdue*.

Predicate extraction PredPatt extracts a descriptive name for *complex predicates*. For example, ***[PredPatt] finds [structure] in [text]*** has a 3-place predicate named (`?a` **finds** `?b` **in** `?c`). The primary logic here is (a) to lift mark and case tokens (e.g., *in*) out of the argument subtree, (b) to add adverbial modifiers, auxiliaries, and negation (e.g., ***[Chris] did not sleep quietly***). PredPatt uses the text order of tokens and arguments to derive a name for the predicate; no effort is made to further canonicalize this name, nor align it to a verb ontology.

Argument phrase extraction Argument extraction filters tokens from the dependency subtree below the argument root. These filters primarily simplify the subtree, e.g., removing relative clauses and appositives inside an argument. The default set of filters were chosen to preserve meaning, since it is not generally the case that all modifiers can safely be dropped (more aggressive argument simplification settings are available as options).

Post-processing PredPatt implements a number of optional post-processing routines, such as conjunction expansion, argument simplification (which filters out non-core arguments, leaving only subjects and objects), and language-specific hooks.[5]

Lang	#Sent	#Output	Precision
Chinese	98	375	69.1% ±4.7%
English	79	210	86.2% ±4.7%
Hebrew	12	30	66.7% ±17.9%
Hindi	22	50	52.0% ±14.3%
Spanish	27	55	70.9% ±12.4%

Table 1: Results of manual evaluation of PredPatt on UD

Gold treebanks in multiple languages We evaluated PredPatt manually on several randomly sampled sentences taken from the UD banks of Chinese, English, Hebrew, Hindi and Spanish. This evaluation runs PredPatt with the gold standard UD parse. We report the number of sentences evaluated along with the number of extractions from those sentences (a proxy for recall) and precision (95% confidence interval) for each language in Table 1.

4 Semantic role decomposition

A decompositional strategy has been successfully used by Reisinger et al. (2015) to annotate thematic role information under their Semantic Proto-Role labeling protocol (SPR1), which is based on Dowty's (1991) seminal thematic proto-role theory.[6]

In this section, we present a major revision to SPR1 aimed at strengthening and generalizing the protocol beyond Reisinger et al.'s dataset. We present three pilots aimed at validating our new protocol as well as a bulk annotation of a large subset of core arguments in EUD1.2. Finally, we describe, deploy, and validate methods for extending SPR2's reach beyond this subset, resulting in SPR2.1.

4.1 SPR1 protocol

In the SPR1 protocol, each core argument of a verb is annotated for the likelihood that particular properties hold of that argument's referent as a participant in the event denoted by the verb.

Property questions The properties selected for this purpose, given in Table 2, are based on those invoked by Dowty (1991) in his prototype-theoretic

[5]UD itself allows for language-specific exceptions to the "universal" standard, and we therefore allow that practice here.

[6]See Kako 2006; Greene and Resnik 2009; Madnani et al. 2010; Hartshorne et al. 2013 for work using similar protocols.

Role property	How likely or unlikely is it that...
instigation	ARG caused the PRED to happen?
volition	ARG chose to be involved in the PRED?
awareness	ARG was/were aware of being involved in the PRED?
sentient	ARG was/were sentient?
change of location	ARG changed location during the PRED?
-exists as physical	ARG existed as a physical object?
existed before	ARG existed before the PRED began?
existed during	ARG existed during the PRED?
existed after	ARG existed after the PRED stopped?
change of possession	ARG changed possession during the PRED?
change of state	ARG was/were altered or somehow changed during or by the end of the PRED?
-stationary	ARG was/were stationary during the PRED?
-location of event	ARG described the location of the PRED?
-physical contact	ARG made physical contact with someone or something else involved in the PRED?
was used	ARG was/were used in carrying out the PRED?
-pred changed arg	The PRED caused a change in ARG?
+was for benefit	PRED happened for the benefit of ARG?
+partitive	*Only* a part or portion of ARG was involved in the PRED?
+change of state continuous	The change in ARG happened throughout the PRED?

Table 2: Questions posed to annotators. + indicates questions new to SPR2; - indicates SPR1 questions dropped in SPR2.

reconstruction of linking theory. Reisinger et al.'s (2015) SPR1 dataset, produced under this protocol, provides annotations of the Wall Street Journal portions of the Penn Treebank (PTB; Marcus et al. 1993) that are also annotated for core argument PropBank (Palmer et al., 2005) roles.

Filtering and data collection In Reisinger et al. 2015, verbs were excluded that occur in certain syntactic environments that interfere with property judgments. In particular, participles and imperatives were excluded, as well as verbs in embedded clauses, in questions, and under negation or auxiliaries. We carry these filters forward to our own bulk annotation by implementing them over PredPatt output and then show how these filters can be lifted.

Annotators To ensure internal consistency of the judgments, Reisinger et al.'s data was based on a single Amazon Mechanical Turk annotator.

4.2 SPR2 protocol

First we update both the set of questions and the method for presenting these questions in order to streamline the annotation process and simplify Reisinger et al.'s protocol. Second, to deal with potentially ungrammatical sentences, as well as to add an extra layer of quality control to the generation of property questions, we add an acceptability judgment question to the protocol. Finally, we collect annotations from multiple trusted annotators with two-way redundancy, allowing us to normalize the data in a way that is impossible with SPR1.

Property questions While Reisinger et al.'s properties were mainly motivated by linguistic theory, in the process of developing SPR2 we identified several redundancies as well as potential sources of error; these changes are summarized in Table 2. Redundancies include `stationary` being essentially the negation of `change of location`, and `predicate changed argument` being almost identical to `change of state`. The property `exists as physical` was dropped because it is a purely referential (non-relational) property of the argument; thus, it is redundant with our more elaborated decompositional word sense protocol. The `location of event` and `physical contact` properties were removed because of lower interannotator agreement and high within-annotator response variance in SPR1.

In addition to this streamlining, we added three new properties that target new types of arguments: benefactives, partitives, and incremental themes. Benefactive arguments and partitive arguments often have special morphosyntactic properties in many languages. In English, for example, benefactives can appear in double-object constructions with verbs like *buy*, and in many languages they correlate with special morphology. Partitives involve partial affectedness and similarly are often marked with morphological case (Kiparsky, 1998). The third new property, `change of state continuous`, is a plain-language version of Dowty's (1991) *incremental theme* proto-role property, which Reisinger et al. (2015) did not include. An argument is an INCREMENTAL THEME with respect to an event if the temporal progress of the event can be measured in terms of, or put into correspondence with, the part-whole structure of that argument which undergoes some gradual change (Tenny, 1987; Krifka, 1989, a.o.). For example, in an event of *mowing the lawn*, *the lawn* is an incremental theme because the progress of mowing is directly related to the portion of the lawn that has been mowed. Though incremental theme is quite abstract in comparison to other proto-role properties, it is widely agreed that something like this property is involved in linking thematic roles to syntactic position.

Dynamic reveal The question corresponding to the `change of state continuous` property

presupposes that the argument under consideration did, in fact, undergo some change of state. This means that if an annotator has previously determined that the property `change of state` does not apply, then asking about `change of state continuous` is at best inefficient, since we can deterministically predict that the answer should be *NA*, and at worst confusing to the annotator, since the question triggers a presupposition failure.

To avoid such presupposition failures in SPR2, which we suspect led to additional noise and annotation time as part of SPR1, we modified the annotation interface so that certain questions are revealed dynamically based on the answers to other questions. The set of questions is now organized hierarchically instead of as a flat list. In this hierarchical structure, `change of state` is a parent of `change of state continuous`, which means that the latter question only appears if the annotator gives a high ordinal value to the former. Questions that remain hidden are assumed to have *NA* as their answer. For SPR2, this pair of properties is the only one affected by the dynamic reveal feature, though this aspect of the protocol will be extended in later versions.

Acceptability judgments Two kinds of grammatical acceptability judgments were collected. The first kind, collected on a five-point scale, asked about the acceptability of the sentence containing the argument in question. The second kind, collected as a binary judgment, asked whether the question was hard to answer because of grammatical errors. This second was triggered only when annotators gave a response on the bottom three values of the ordinal scale for the relevant property question. We do not analyze these judgments here for reasons of space, but they are available as part of the released dataset.

Multiple annotators with redundancy Reisinger et al.'s (2015) reason for not using redundant annotations was that a single annotator would provide internally consistent judgments, but this consistency comes at the cost of potential bias in the judgments.[7] In order to evaluate bias, we move to

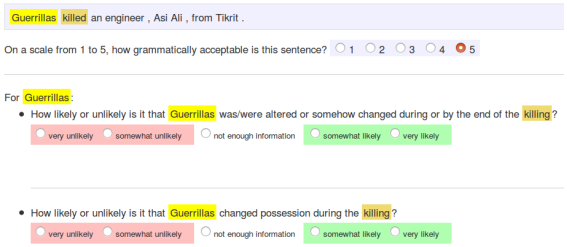

Figure 2: Example of semantic role decomposition task.

two-way redundancy (and later versions of the protocol are compatible with greater redundancy).

Heterogeneous data SPR2 extends the coverage of Semantic Proto-Role Labeling to heterogeneous genres. The SPR1 dataset contains only annotations of newswire text. This is not ideal for either practical or scientific purposes, since newswire tends to be biased toward otherwise rare word senses—often pertaining to financial markets—but low coverage of otherwise common word sense.

To remedy these coverage issues, we extend SPR1 to the English Universal Dependencies (version 1.2) treebank (EUD1.2). EUD1.2 is based on the Linguistic Data Consortium's English Web Treebank (Bies et al., 2012) and contains a much wider set of genres than the Penn Treebank—including weblogs, newsgroup discussions, emails from the EnronSent Corpus, reviews from English Google reviews, and answers from Yahoo! Answers. EUD1.2 has the added benefit of being natively annotated with gold-standard Universal Dependencies (UD) parses (Nivre et al., 2015).

4.3 Pilot experiments

In this section, we present three pilot experiments conducted on a subset of EUD1.2 and aimed at validating the updated protocol in preparation for deployment of the full task. In the first, we use the SPR1 protocol to obtain judgments on a small sample of EUD1.2 sentences from the same trusted annotator that produced SPR1. In the second, we open the same task to multiple annotators. And in the third, we deploy our updated SPR2 protocol on the

[7] For example, in analyzing the SPR1 dataset that Reisinger et al. make available, we noted that their annotator has a somewhat idiosyncratic way of answering the `was used` question, which aims at identifying instruments: the annotator marks *him* in (i) as likely to have been used in carrying out the advising.

(i) Sen. Bill Bradley of New Jersey *advised* **him** that the Dow Jones Industrial Average had declined by 190 points.

This is a general pattern for this question for this annotator.

same subset of EUD1.2—again, open to multiple annotators. We use these three pilots to evaluate interannotator agreement within and across protocols (where possible) and to construct a pool of trusted annotators to work on the full annotation task.

Item selection For each pilot, the same set of sentences were used. These sentences were selected based on properties of both the predicate and its corresponding arguments in each sentence. The pilot experiments were limited to the same 10 verbs (*want*, *put*, *think*, *see*, *know*, *look*, *say*, *take*, *tell*, *give*) that were considered in Reisinger et al.'s pilot.

As in Reisinger et al. 2015, tokens were excluded with verbs that occur in certain syntactic environments that interfere with property judgments. We used the same filters described by those authors, modified for UD. Additionally, verbs occurring as the second item in a conjunction were removed, as EUD1.2 does not have sufficient annotation to identify all arguments of such verbs from the syntax.

Verbal arguments were defined as the subtrees governed by a verb via a core grammatical relation (`nsubj`, `nsubpass`, `dobj`, and `iobj`). In addition, occurrences of the pronoun *it* in subject position were excluded because of inconsistencies in the annotation of expletive subjects in EUD1.2.

Pilots 1 & 2: SPR1 protocol Pilot 1, designed to compare SPR1 directly to SPR2, used the same protocol described in Reisinger et al. 2015 and was deployed on 99 argument tokens selected based on the method above.[8] To ensure that the only difference between SPR1 and this pilot was which sentences were annotated, we obtained the AMT identifier for the SPR1 annotator from Reisinger et al. Thus, the only annotator in this pilot was the same one that produced all the annotations for the SPR1 dataset.

The data from this pilot cannot be compared to the SPR1 dataset on a token level, since the items do not come from the same dataset. But these data can be compared to the SPR1 dataset on a type level by averaging responses to particular questions asked about particular argument positions (e.g., `nsubj`, `dobj`, etc.) for a particular predicate (e.g., *want*, *put*, etc.) and then comparing the correlation between these averages. The average type-level correlation between the average by-predicate, by-argument relation ratings in the SPR1 dataset and those in the current pilot was high for all verb-argument pairs (Spearman ρ=0.82).

Pilot 2 uses the same materials and protocol as Pilot 1. The only difference between the two is that this pilot was open to multiple annotators. A total of 33 annotators participated, one of whom was the same annotator that produced all the annotations for the SPR1 dataset and participated in Pilot 1.

For each argument token, we collected five judgments per property question. Interannotator agreement was calculated by argument token for the likelihood responses using pairwise Spearman rank correlations. The mean ρ across all annotator pairs and argument tokens was 0.562 (95% CI=[0.549, 0.574]) and, due to heavy left skew, the median was 0.618 (95% CI=[0.603, 0.631]). This agreement is relatively high, suggesting that different annotators tend to agree on the relative likelihood of a property applying to an argument.

Since the SPR1 and Pilot 1 annotator was among this group, we can also assess the extent to which the Pilot 1 annotator is consistent with other annotators. Comparing this annotator to every other annotator that annotated the same argument token, the mean ρ was 0.499 (95% CI=[0.451, 0.546]), and the median was 0.565 (95% CI=[0.504, 0.637]). This suggests that, on average, the other annotators are even more consistent with each other than they are with the original SPR1 annotator, vindicating the use of multiple annotators.

Pilot 3: SPR2 protocol Pilot 3 uses the same materials as Pilots 1 and 2 but introduces the SPR2 protocol laid out above. A total of 57 annotators participated in this pilot. For each argument token, we again collected five judgments per property.

Interannotator agreement was calculated by argument token for the likelihood responses using pairwise Spearman rank correlations. The mean ρ across all annotator pairs and argument tokens was 0.622 (95% CI=[0.610, 0.634]) and, again due to heavy left skew, the median was 0.677 (95% CI=[0.662, 0.690]). This higher agreement compared to Pilot 2 likely arises due to the fact that we have fewer questions in the SPR2 protocol and suggests that we suc-

[8] For each verb, 10 arguments were selected, with the exception of *see*, which only had 9 due to an off-by-one error.

ceeded in removing noisy questions without adding questions that were similarly noisy.

Since we use the same materials as Pilots 1 and 2, we can also compare the SPR1 and SPR2 protocols on the subset of questions they share. We find similar mean agreement, at 0.593 (95% CI=[0.580, 0.607]), and median agreement, at 0.665 (95% CI=[0.652, 0.672]), to that we found within the Pilots 2 and 3 results. This suggests that the addition and subtraction of questions does not substantially alter annotators' judgments on the questions that both protocols share.

4.4 Trusted annotator pool

To ensure annotation consistency in our bulk annotation, we constructed a pool of trusted annotators from those annotators that participated in Pilots 2 and 3. We used two metrics to construct this pool: rating agreement and applicability agreement. Both of these metrics control for various factors that might raise or lower agreement independent of the annotator—e.g., the particular question, the particular sentence, the particular argument type, etc.—using generalized linear mixed effects models. This pool contains a total of 86 trusted annotators.

4.5 Bulk task

For our bulk task, we used the SPR2 protocol to annotate a total of 3,806 argument tokens spanning 2,759 unique predicate lemmas. These argument tokens were part of a filtered set constructed using Reisinger et al.'s filtering scheme described above.

We collected two judgments per property, per argument token. Interannotator agreement was calculated in the same way as for the pilots. The mean ρ was 0.617 (95% CI=[0.611, 0.623]), and the median was 0.679, (95% CI=[0.673, 0.686]). This agreement is very close to that found in the pilots, suggesting that rating consistency extends beyond the constrained set of predicates used in the pilots.

One issue with SPR1 that remains unaddressed in SPR2 is the use of filters. This significantly reduces the potential coverage of the protocol and relies on extremely rich syntactic annotation. This second is not problematic when we have gold standard treebanks like EUD1.2, but it becomes an issue when moving beyond such treebanks.

To alleviate this filter issue, we propose a further revision of SPR2. In this version (SPR2.1), we alter the SPR2 instructions to take into account cases where the property questions may be difficult to answer. These fall into at least three categories: eventualities that haven't happened (*irrealis eventualities*), generics, and habituals. In SPR2.1, annotators are instructed about each case and to answer as if a specific event of that kind did actually happen.

We annotated predicates that occurred in a sentence from the previous bulk task but were filtered from that task based on Reisinger et al.'s (2015) filters. We have so far annotated all such predicates with less than 100 instances in all of EUD1.2 and plan to continue annotation to get full coverage of these sentences.

A total of 26 annotators from our trusted pool participated in this annotation. As in the previous bulk task, we collected two judgments per property, per argument token. The interannotator agreement was calculated in the same way as for the previous bulk task and pilots and was reasonably high with a mean ρ of 0.528 (95% CI=[0.522, 0.535]) and median ρ of 0.571 (95% CI=[0.563, 0.580]). This somewhat lower agreement is to be expected, since these predicates were selected to be harder than those in the previous task.

4.6 Discussion

We presented a major revision to Reisinger et al.'s (2015) decompositional Semantic Proto-Role Labeling protocol (SPR1) and deployed this revised protocol (SPR2) in three validation pilots and a bulk task. We then described two extensions to this protocol aimed at expanding the annotable arguments.

One issue that arises with SPR2.1 is that it substantially complicates the instructions, clashing with Decomp *simplicity* tenet. In the next section, we describe a task aimed at allowing us to better target predicates that need these more elaborated instructions, allowing us to use the simpler SPR2 protocol where possible.

5 Event decomposition

As discussed in §4, SPR1 and SPR2 employ filters that run on top of dependency parses to ensure that proto-role property questions about particular argu-

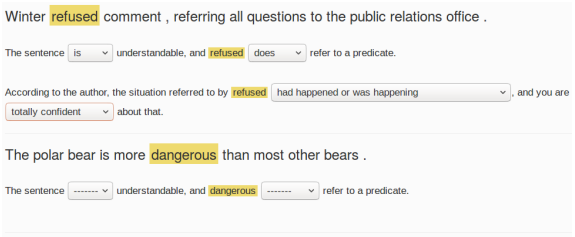

Figure 3: Example of the event decomposition task

ments are answerable. We showed that these filters can be bypassed by altering the instructions given to annotators. This approach substantially increases the length of the tasks instructions, however, and so ideally, these lengthened instructions should be used only when absolutely necessary. One place it seems likely to be necessary is when the event in a sentence did not in fact occur.

In this section, we present a protocol, inspired by the one developed by de Marneffe et al. (2012), for targeting these sorts of sentence with special instructions in future versions of SPR (see also Saurí and Pustejovsky 2012). A major benefit of this protocol is that it produces a foundation for future decompositional event annotations.

Protocol The protocol has four major components: questions about (i) whether or not a particular word refers to an eventuality (event or state); (ii) whether the sentence is understandable; (iii) whether or not, according to the author, the event has already happened is currently happening; and (iv) how confident the annotator is about their answer to (iii).

The first two components were included to filter out items that are either incorrectly labeled as predicates or that the annotator could not annotate for components (iii) and (iv), and if an annotator answered *no* to either for a particular predicate candidate, (iii) and (iv) did not appear. Thus, like SPR2.x, this protocol incorporates a hierarchy of questions that can be elaborated in future versions.

Data collection We applied this protocol to every predicate candidate found in an EUD1.2 sentence annotated under SPR2 and SPR2.1. This yields annotations for a superset of the predicates annotated under SPR2.x, and thus components (i) and (ii) of these annotations can be used as a *post hoc* filter on the SPR2.x annotations or to decide on whether to include a predicate for future SPR2.x tasks.

A total of 6,930 predicate candidates were annotated in batches of 10 by 24 unique annotators recruited from the trusted annotator pool built for SPR2.x. Each predicate candidate was judged by two distinct annotators.

Data validation For each of the four components interannotator agreement was computed by each group of 10 predicates. For the categorical responses, we would ideally use Cohen's κ, but there were so many cases of perfect agreement for the categorical responses that Cohen's κ is ill-defined in many cases. As such, we report raw agreement here.

The mean raw agreement for whether each predicate candidate was a predicate was 0.955 (95% CI=[0.950, 0.960]). The mean raw agreement for whether the sentence was understandable was [0.976, (95% CI=[0.971, 0.980]); and the mean raw agreement for whether the eventuality happened or was happening was 0.820 (95% CI=[0.811, 0.829]).

Discussion We presented the first version of a new event decomposition protocol. This protocol integrates with and is in the same spirit as the SPR2.x protocols produced in the previous section.

In the next section, we describe a complementary protocol for decomposing word sense, focusing specifically on noun senses. This last protocol completes a picture wherein we decompose predicate argument semantics into three parts: the properties of a predicate independent of its arguments, the properties of a predicate's arguments in relation to the event the predicate denotes, and the properties of an argument independent of the predicate.

6 Word sense decomposition

In §4 and §5, we focused on semantic questions that deal with eventualities. In this section, we describe a Decomp protocol for decomposing word sense. Our goal is similar to that in previous sections: elicit responses from everyday speakers of the language regarding basic properties, in relation to the context of a natural language sentence.

Protocol If directly following the strategy explored thus far, we would create an interface that enumerated many dozens (or hundreds) of semantic properties one might ask about a word in context, and in further developments of Decomp there may

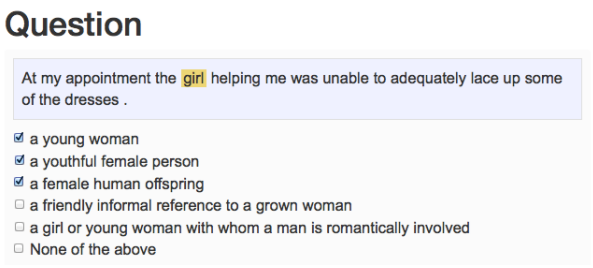

Figure 4: Example of the word sense task.

be specific properties that are deemed essential for direct querying of annotators. However, here we rely on the rich pre-existing taxonomy of lexical knowledge captured in the WordNet hierarchy (Miller, 1995) in order to more efficiently gather implicit property responses. Everyday speakers can perform basic word sense disambiguation (Snow et al., 2008): this falls under the simplicity tenant of Decomp. Once a word is disambiguated in context we then can infer automatically whether an instance is, e.g., a `physical object`.

While WordNet is a valuable resource, the selection of a specific categorical sense under an enumerated set of prespecified options is troubling in a similar way as Dowty was concerned with thematic roles (see Kilgarriff 1997). Therefore we follow a path similar to Sussna (1993) in asking annotators for zero or more senses that are appropriate.[9]

Candidate senses are extracted from WordNet *synsets*. We have grounded argument tokens in WordNet in order to make efficient use of existing lexical semantic resourses, but this protocol could in principle be used with any other lexical semantic resource. We believe these annotations will be useful already in the context of the other annotations, but in addition, future work will use these sense groundings to derive commonsense properties beyond those directly encoded in the WordNet hierarchy.

Data collection A total of 18,054 word tokens (arguments) in 10,833 total sentences extracted from EUD1.2 were annotated for sense by at least three annotators recruited from Amazon Mechanical Turk. Each token had an average of 5.63 candidates senses for annotators to choose from (Figure 4). In total, 1,065 unique annotators participated.

[9]Not only does this weaken the commitment to a single categorical meaning, but it also reduces concerns of annotators being confused by overly fine-grain definitions (Navigli, 2006).

Data validation Inter-annotator agreement was computed by lemma by taking the Jaccard index for each pair of annotators that judged the senses for that lemma: $\frac{\text{\# of senses checked by both annotators}}{\text{\# of senses checked by either annotator}}$. The overall inter-annotator agreement using this measure was 0.592: this is reasonably high considering the extremely low chance-level.

In total, 9,317 token-sense pairs were agreed upon by all annotators. We refer to these token-sense pairs as *gold word sense(s)* for the token. If we relax the agreement threshold for a token-sense pair to be gold to 0.5—i.e. half or more annotators agreed on that pair—the number of *gold word sense(s)* goes up to 27,326. Out of 18,054 individual arguments, 8,553 of them have a single *gold word sense* and 370 have two or more *gold word senses* as in the example in Figure 4. Similarly, if we relax the agreement threshold down to 0.5, 9,656 arguments have a single *gold word sense* and 17,281 arguments have two or more *gold word senses*.

7 Conclusion

We have described the *Universal Decompositional Semantics* (Decomp) project, which aims to construct and deploy a set of cross-linguistically robust semantic annotation protocols that are based in linguistic theory and that integrate seamlessly with the Universal Dependencies project. We then proposed Decomp-aligned protocols for three domains—semantic role decomposition, event decomposition, and word sense decomposition—and presented annotations, all freely available, that use these protocols and are constructed on top of the English UD v1.2 treebank. In future work, we intend to further revise and extend these protocols as well as produce novel protocols aligned with Decomp.

Abstract

We present a probabilistic model of the influence of language on the behavior of the U.S. Supreme Court, specifically influence of amicus briefs on Court decisions and opinions. The approach assumes that amici are rational, utility-maximizing agents who try to win votes or affect the language of court opinions. Our model leads to improved predictions of justices' votes and perplexity of opinion language. It is amenable to inspection, allowing us to explore inferences about the persuasiveness of different amici and influenceability of different justices; these are consistent with earlier findings.

"Language is the central tool of our trade."
John G. Roberts, 2007 (Garner, 2010)

1 Introduction

The Supreme Court of the United States (SCOTUS), the highest court in the American judiciary, makes decisions with far-reaching effects. In a typical case, there are four participating parties: **petitioners** and **respondents** who file briefs arguing the merits of their sides of a case ("merits briefs"); third-party entities with an interest (but not a direct stake) in the case, who file **amicus curiae**[1] briefs to provide further arguments and recommendations on either side; and **justices** who, after oral arguments and discussions, vote on the case and write "opinions" to explain the Court's decisions.[2]

In recent years, amicus briefs are increasingly being employed as a lobbying tool to influence the Court's decision-making process (Franze and Anderson, 2015; Kearney and Merrill, 2000). The content of these briefs reveals explicit attempts to persuade justices and provides a fascinating setting for empirical study of influence through language. As such, we take the perspective of an amicus, proposing a probabilistic model of the various parties to a case that accounts for the amicus' goals.

Our model of SCOTUS is considerably more comprehensive than past work in political science, which has focused primarily on **ideal point** models that use votes as evidence. Text has been incorporated more recently as a way of making such models more interpretable, but without changing the fundamental assumptions (Lauderdale and Clark, 2014). Here, we draw on decision theory to posit amici as rational agents. We assume these amici-agents maximize their expected utility by framing their arguments to sway justices towards favorable outcomes.

We build directly on Sim et al. (2015), who used utility functions to explicitly model the goals of amici in a probabilistic setting. Their approach only considered amici in aggregate, inferring nothing about any specific amicus, such as experience or motivation for filing briefs. Here, we enrich their model to allow such analysis and also introduce Court opinions as evidence. By modeling the justices' author-

[1] *Amicus curiae* is Latin for "friends of the court." Hereafter, we use *amicus* in singular and *amici* in plural to refer to these interested third parties. It is common for several amici to co-author a single brief, which we account for in our model.

[2] We use the term *opinions* to refer to these decision-explaining documents, not to abstract positions as the term is used in much NLP research.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1724–1733,
Austin, Texas, November 1-5, 2016.

ing process as well, we can capture an important aspect of amici's goals: influencing the text of the opinions.

In §3, we demonstrate the effectiveness of our approach on vote prediction and perplexity. Furthermore, we present analyses that reveal the persuasiveness of amici and influenceability of justices that are consistent with past findings.

2 Generative Models of SCOTUS

Our approach builds on a series of probabilistic models only recently considered in NLP research. To keep the discussion self-contained, we begin with classical models of votes alone and build up toward our novel contributions.

2.1 Modeling Votes

Ideal point (IP) models are a mainstay in quantitative political science, often applied to voting records to place voters (lawmakers, justices, etc.) in a continuous space. A justice's "ideal point" is a latent variable positioning him in this space. Martin and Quinn (2002) introduced the unidimensional IP model for judicial votes, which posits an IP $\psi_j \in \mathbb{R}$ for each justice j. Often the ψ_j values are interpreted as positions along a liberal-conservative ideological spectrum. Each case i is represented by popularity (a_i) and polarity (b_i) parameters.[3] A probabilistic view of the unidimensional IP model is that justice j votes in favor of case i's petitioner (as opposed to the respondent) with probability

$$p(v_{i,j} = \text{petitioner} \mid \psi_j, a_i, b_i) = \sigma(a_i + b_i\psi_j)$$

where $\sigma(x) = \frac{\exp(x)}{1+\exp(x)}$ is the logistic function. When the popularity parameter a_i is high enough, every justice is more likely to favor the petitioner. The polarity b_i captures the importance of a justice's ideology: polarizing cases (i.e., $|b_i| \gg 0$) push justice j more strongly to the side of the petitioner (if b_i has the same sign as ψ_j) or the respondent (otherwise).

Amici IP models. Sim et al. (2015) introduced a multidimensional IP model that incorporated text from merits and amicus briefs as evidence. They inferred dimensions of IP that are grounded in "topical" space, where topics are learned using latent Dirichlet allocation (Blei et al., 2003). In their proposed model, the merits briefs describe the issues and facts of the case, while amicus briefs were hypothesized to "frame" the facts and potentially influence the outcome of the case. For case i and justice j, the vote probability is

$$\begin{aligned} &p(v_{i,j} = \text{petitioner} \mid \boldsymbol{\psi}_j, \boldsymbol{\theta}_i, \boldsymbol{\Delta}_i, a_i, b_i, \boldsymbol{c}_i) \qquad (1) \\ &= \sigma\Big(a_i + b_i \boldsymbol{\psi}_j^\top \big(\underbrace{\boldsymbol{\theta}_i + \tfrac{1}{|\mathcal{A}_i|}\textstyle\sum_{k\in\mathcal{A}_i} c_i^{s_{i,k}} \boldsymbol{\Delta}_{i,k}}_{\text{case IP}}\big)\Big) \end{aligned}$$

where $\mathcal{A}_i$ is the set of amicus briefs filed on this case, $s_{i,k}$ denotes the side ($\in$ {petitioner, respondent}) supported by the kth brief, and c_i^{p}, and c_i^{r} are the amicus polarities for briefs on either side. The **case IP** is influenced by merits briefs (embedded in $\boldsymbol{\theta}_i$) and by the amicus briefs (embedded in $\boldsymbol{\Delta}_{i,k}$), both of which are rescaled independently by the case discrimination parameters to generate the vote probability. The model assumes that briefs on the same side share a single embedding and that individual briefs on one side influence the vote-specific IP equally.

New IP model: Persuasive amici. Lynch (2004) and others have argued that some amici are more effective than others, with greater influence on justices. We therefore propose a new model which considers amici as individual actors. Starting from Eq. 1, we consider two additional variables: each amicus e's **persuasiveness** ($\pi_e > 0$) and each justice j's **influenceability** ($\chi_j > 0$).[4]

$$\begin{aligned} &p(v_{i,j} = \text{petitioner} \mid \boldsymbol{\psi}_j, \chi_j, \boldsymbol{\theta}_i, \boldsymbol{\Delta}_i, a_i, b_i, \boldsymbol{\pi}) \qquad (2) \\ &= \sigma\Big(a_i + b_i \boldsymbol{\psi}_j^\top \big(\boldsymbol{\theta}_i + \tfrac{\chi_j}{|\mathcal{A}_i|}\textstyle\sum_{k\in\mathcal{A}_i} \bar{\pi}_{i,k} \boldsymbol{\Delta}_{i,k}\big)\Big) \end{aligned}$$

where $\bar{\pi}_{i,k} = \frac{\sum_{e\in\mathcal{E}_{i,k}} \pi_e}{|\mathcal{E}_{i,k}|}$ is the average of their π-values, with $\mathcal{E}_{i,k}$ denoting the set of entities who co-authored the kth amicus brief for case i.

Intuitively, a larger value of χ_j will shift the case IP more towards the contents of the amicus briefs,

[3] This model is also known as a two parameter logistic model in item-response theory (Fox, 2010), where a_i is "difficulty" and b_i is "discrimination."

[4] Note that the amici IP model of Sim et al. (2015), Eq. 1, is a special case of this model where $\chi_j = 1$ and each case has polarity parameters for each side; no information is shared across briefs written by the same amicus-entity for different cases.

thus making the justice seem more "influenced" by amicus. Likewise, briefs co-authored by groups of amici who are more effective (i.e., larger $\bar{\pi}_{i,k}$), will "frame" the case towards their biases. Unlike Sim et al. (2015), we eschew the amicus polarity parameters (c_i) and instead rely on the influenceability and persuasiveness parameters. Furthermore, we note that they performed a post-hoc analysis of amici influence on justices but we do so directly through χ_j.

With appropriate priors on the latent variables, the generative story for votes is:

1. For each topic $t \in \{1, \ldots, T\}$, draw topic-word distributions $\boldsymbol{\phi}_t \sim \text{Dirichlet}(\beta)$.
2. For each justice $j \in \mathcal{J}$, draw justice IP $\boldsymbol{\psi}_j \sim \mathcal{N}(\mathbf{0}, \sigma_J^2\mathbf{I} + \rho\mathbf{1})$[5] and influenceability $\chi_j \sim \log\mathcal{N}(\mathbf{0}, \sigma_I^2\mathbf{I})$.
3. For each amicus-entity $e \in \mathcal{E}$, draw its persuasiveness $\pi_e \sim \log\mathcal{N}(\mathbf{0}, \sigma_P^2\mathbf{I})$.
4. For each case $i \in \mathcal{C}$:

(a) Draw case parameters $a_i, b_i \sim \mathcal{N}(0, \sigma_C^2)$.

(b) Draw topic proportions for merits $\boldsymbol{\theta}_i \sim \text{Dirichlet}(\alpha)$.

(c) For each word $w_{i,n}^{(m)}$ in the merits briefs, draw topic indicators $z_{i,n}^{(m)} \sim \text{Categorical}(\boldsymbol{\theta}_i)$ and $w_{i,n}^{(m)} \sim \text{Categorical}(\boldsymbol{\phi}_{z_{i,n}^{(m)}})$.

(d) For each amicus brief indexed by k:

i. Draw topic proportions $\boldsymbol{\Delta}_{i,k}$ according to a distribution discussed in §2.3.

ii. For each word $w_{i,n}^{(a)}$ in the brief, draw topic indicators $z_{i,k,n}^{(a)} \sim \text{Categorical}(\boldsymbol{\Delta}_{i,k})$ and $w_{i,k,n}^{(a)} \sim \text{Categorical}(\boldsymbol{\phi}_{z_{i,k,n}^{(a)}})$.

(e) For each participating justice $j \in \mathcal{J}_i$, draw vote $v_{i,j}$ according to Eq. 2.

2.2 Modeling Opinions

In most SCOTUS cases, a justice is assigned to author a majority opinion, and justices voting in the majority "join" in the opinion. Justices may author additional opinions concurring or dissenting with the majority, and they may choose to join concurring and dissenting opinions written by others. Here, we extend the IP model of votes to generate the opinions of a case; this marks the second major extension beyond the IP model of Sim et al. (2015).

SCOTUS justices often incorporate language from merits (Feldman, 2016b; Feldman, 2016a) and amicus (Collins et al., 2015; Ditzler, 2011) briefs into their opinions. While amicus briefs are not usually used directly in legal analyses, the background and technical information they provide are often quoted in opinions. As such, we model opinions as a mixture of its justice-authors' topic preferences, topic proportions of the merits briefs ($\boldsymbol{\theta}$), and topic proportions of the amicus briefs ($\boldsymbol{\Delta}$). This can also be viewed as an author-topic model (Rosen-Zvi et al., 2004) where justices, litigants, and groups of amici are all effective authors. To accomplish this, we introduce an explicit switching variable x for each word, which selects between the different sources of topics, to capture the mixture proportions.

Since any justice can author additional opinions explaining the rationale behind their votes, we concatenate all opinions supporting the same side of a case into a single document.[6] However, we note that concurring opinions often contain perspectives that are different from the majority opinion and by concatenating them, we may lose some information about individual justices' styles or preferences. Building on the generative model for votes, the generative story for each case i's two opinions-documents is:

5. For each justice $j \in \mathcal{J}$, draw topics $\boldsymbol{\Gamma}_j \sim \text{Dirichlet}(\alpha)$.
6. For each case $i \in \mathcal{C}$:

(a) For each side $s \in \{\text{petitioner}, \text{respondent}\}$, draw "author"-mixing proportions:

$$\boldsymbol{\tau}_i^s \sim \text{Dirichlet}\left(\begin{bmatrix} p(v_{i,1} = s) \\ \vdots \\ p(v_{i,|\mathcal{J}|} = s) \\ 1 \\ 1 \end{bmatrix}\right) \quad (3)$$

where the last two dimensions are for choosing topics from the merits and amicus briefs, re-

[5] The positive off-diagonal elements of the covariance matrix for justice IPs (ψ_j) orient the issue-specific dimensions in the same direction (i.e., with conservatives at the same end) and provide shrinkage of IP in each dimension to their common mean across dimensions (Lauderdale and Clark, 2014).

[6] Opinions where justices dissent from the majority are concatenated together, and those where justices concur with the majority are concatenated with the majority opinion.

spectively.[7] Intuitively, our model assumes that opinions will incorporate more language from justices who agree with it.

(b) For each side $s \in \{\text{petitioner}, \text{respondent}\}$ and each word $w^{(o)}_{i,s,n}$ in the opinion for side s,

i. Draw $x_{i,s,n} \sim \text{Categorical}(\boldsymbol{\tau}^s_i)$.

ii. If $x_{i,s,n} \in \mathcal{J}_i$, draw $z^{(o)}_{i,s,n} \sim \text{Categorical}(\boldsymbol{\Gamma}_{x_{i,s,n}})$, the justice's topic distribution.

iii. If $x_{i,s,n} = \text{merits}$, draw $z^{(o)}_{i,s,n} \sim \text{Categorical}(\boldsymbol{\theta}_i)$, the merits topic distribution.

iv. If $x_{i,s,n} = \text{amici}$, draw $z^{(o)}_{i,s,n} \sim \text{Categorical}(\boldsymbol{\Delta}^s_i)$, side s's amicus briefs topic distribution.

v. Draw word $w^{(o)}_{i,s,n} \sim \text{Categorical}(\boldsymbol{\phi}_{z^{(o)}_{i,s,n}})$.

Unlike in the Court, where an opinion is mainly authored by a single justice, all the participating justices contribute to an opinion in our generative story, with different proportions. This approach simplifies the computational model and reflects the closed-door nature of discussions held by justices prior to writing their opinions. Our model assumes that justices debate together, and that the arguments are reflected in the final opinions. In future work, we might extend the model to infer an authoring process that separates an initial author from "joiners."

2.3 Amici Utility

Our approach assumes that amici are rational and purposeful decisionmakers who write briefs to influence the outcome of a case; this assumption leads to the design of the distribution over $\boldsymbol{\Delta}$ (generative model step 4(d)i). When writing a brief $\boldsymbol{\Delta}$, an amicus seeks to increase the response to her brief (i.e., votes), while keeping her costs low. We encode her objectives as a utility function, which she aims to maximize with respect to the decision variable $\boldsymbol{\Delta}$:

$$U(\boldsymbol{\Delta}) = R(\boldsymbol{\Delta}) - C(\boldsymbol{\Delta}) \tag{4}$$

where $R(\cdot)$ is the extrinsic response (reward) that an amicus gets from filing brief $\boldsymbol{\Delta}$ and $C(\cdot)$ is the "cost" of filing the brief; dependency on other latent variables is notationally suppressed. When authoring her brief, we assume that the amicus writer has knowledge of the justices (IP and topic preferences), case parameters, and merits, but not the other amici participating in the case.[8]

Amicus curiae are motivated to position themselves (through their briefs) in such a way as to improve the likelihood that their arguments will persuade SCOTUS justices. This is reflected in the way a justice votes or through the language of the opinions. Hence, we investigate two response functions. First, an amicus supporting side s seeks to win votes for s,

$$R^{\text{vote}}(\boldsymbol{\Delta}) = \tfrac{1}{|\mathcal{J}|} \textstyle\sum_{j \in \mathcal{J}} p(v_j = s \mid \ldots), \tag{5}$$

which is the expected number of votes for side s, under the model. This follows Sim et al. (2015).

An alternative is to maximize the (topical) similarity between her brief and the Court's opinion(s) siding with s,

$$R^{\text{opinion}}(\boldsymbol{\Delta}) = 1 - H^2(\boldsymbol{\Delta}, \boldsymbol{\Omega}^s), \tag{6}$$

where $H^2(P, Q) = \frac{1}{2}\|\sqrt{P} - \sqrt{Q}\|_2^2$ is the squared Hellinger (1909) distance between two distributions, and $\boldsymbol{\Omega}^s$ is the expected topic mixture under the model assumptions in §2.2 (which has a closed form). In short, the amicus gains utility by accurately predicting the expected opinion, thereby gaining publicity and demonstrating to members, donors, potential clients, and others that the language of the highly visible SCOTUS opinion was influenced. Both Eqs. 5 and 6 reward amici when justices "agree" with them, for different definitions of agreement.

We assume the cost $C(\boldsymbol{\Delta}) = H^2(\boldsymbol{\Delta}, \boldsymbol{\theta})$, the squared Hellinger distance between the mixture proportions of the amicus brief and merits briefs.[9] The cost term defines the "budget" set of the amicus: briefs cannot be arbitrary text, as there is disutility or

[7] In cases where there are less than nine justices voting, the size of $\boldsymbol{\tau}^{\text{p}}_i$ and $\boldsymbol{\tau}^{\text{r}}_i$ may be smaller.

[8] Capturing strategic amici agents (a petitioner amicus choosing brief topics considering a respondent amicus' brief) would require a game-theoretic model and, we conjecture, would require a much richer representation of policy and goals. That idea is left for future research.

[9] Sim et al. (2015) used a Euclidean distance for cost rather than Hellinger distance, which we believe is a better fit for probability distributions without sacrificing symmetry (cf. KL divergence).

effort required to carefully frame a case, and monetary cost to hiring legal counsel. The key assumption is that framing is costly, while simply matching the merits is cheap (and presumably unnecessary).

Notationally, we use U^{vote} to refer to models where Eq. 5 is in the utility function (in Eq. 4) and U^{opinion} where it is Eq. 6.

Random utility models Recall our assumption that amici are purposeful writers whose briefs are optimized for their utility function. In an ideal setting, the $\boldsymbol{\Delta}$ which we observe will be utility maximizing. We simplify computation by assuming that these amici agents' preferences also contain an idiosyncratic random component that is unobserved to us. This is a common assumption in discrete choice models known as a "random utility model" (McFadden, 1974). We view the utility function as a prior on $\boldsymbol{\Delta}$,

$$p_{\text{util}}(\boldsymbol{\Delta} \mid \ldots) \propto \exp \eta U(\boldsymbol{\Delta}),$$

where our functional equations for utility imply $-1 \leq U(\cdot) \leq 1$. η is a hyperparameter tuned using cross validation. The behavior which we observe (i.e., the amicus' topic mixture proportions) has a likelihood that is proportional to utility.

2.4 Parameter Estimation

The models we described above can be estimated within a Bayesian framework. We decoupled the estimation of the votes model from the opinions model; we first estimate the parameters for the votes model and hold them fixed while we estimate the new latent variables in the opinions model. In our preliminary experiments, we found that estimating parameters for both votes and opinions jointly led to slow mixing and poor predictive performance. Separating the estimation procedure into two stages allows the model to find better parameters for the votes model, which are then fed into the opinions model as priors through the vote probabilities.

We used Metropolis within Gibbs, a hybrid MCMC algorithm, to sample the latent parameters from their posterior distributions (Tierney, 1994).[10] For the Metropolis-Hastings proposal distributions, we used a Gaussian for the case parameters a, b, and justice IPs $\boldsymbol{\psi}$, log-normal distributions for χ and π, and logistic-normal distribution for the variables on the simplex $\boldsymbol{\theta}, \boldsymbol{\Delta}, \boldsymbol{\tau}$, and $\boldsymbol{\Gamma}$. We tuned the hyperparameters of the proposal distributions at each iteration to achieve a target acceptance rate of 15–45%. We used $T = 128$ topics for model and initialized topic proportions $(\boldsymbol{\theta}, \boldsymbol{\Delta})$ and topic-word distributions $(\boldsymbol{\phi})$ using online LDA (Hoffman et al., 2010).

[10] The details of our sampler and hyperparameter settings can be found in §A and §B of the supplementary materials.

3 Experiments

Data. In our experiments, we use SCOTUS cases between 1985–2014; votes and metadata are from Spaeth et al. (2013) and brief texts come from Sim et al. (2015). We concatenate each of the 2,643 cases' merits briefs from both parties to form a single document, where the text is used to infer the representation of the case in topical space ($\boldsymbol{\theta}$; i.e., merits briefs are treated as "facts of the case"). Likewise, opinions supporting the same side of the case (i.e., majority and concurring vs. dissents) were concatenated to form a single document. In our dataset, the opinions are explicitly labeled with the justice who authored them (as well as other justices who decide to "join" it).

As the amicus briefs in the dataset were not explicitly labeled with the side that they support, Sim et al. (2015) built a binary classifier with bag-of-n-gram features that took advantage of cues in the brief content that *strongly* signal the side that the amici supports (e.g., "in support of petitioner"). We used their classifier to label the amici's supporting side. Additionally, we created regular expression rules to identify and standardize amicus authors from the header of briefs. We filtered amici who have participated in fewer than 5 briefs[11] and merged regional chapters of amicus organizations together (i.e., "ACLU of Kansas" and "ACLU of Kentucky" are both labeled "ACLU"). On the other hand, we separated labeled amicus briefs by the U.S. Solicitor General according to the presidential administration when the brief is filed (i.e., an amicus brief filed during Obama's administration will be labeled "USSG-Obama"). The top three amici by number of briefs filed are *American Civil Liberties Union* (463), *Utah* (376), and *National Asso-*

[11] Briefs which have no authors as a result of the filtering process are removed from our dataset. This occurred in about 24% of amicus briefs.

Cases / Votes	2,643 / 23,465
Merits / Amicus briefs	16,416 / 16,303
Opinions	4,187
Phrases	18,207,326

Table 1: Corpus statistics.

ciation of Criminal Defense Lawyers (359).

We represent a document as a bag of n-grams with part of speech tags that follow the simple but effective pattern (Adjective|Cardinal|Noun)+ Noun (Justeson and Katz, 1995). We filter phrases appearing fewer than 100 times or in more than 8,500 documents, obtaining a final set of 48,589 phrase types. Table 1 summarizes the details of our corpus.

Predicting Votes. We quantify the performance of our vote model using 5-fold cross validation and on predicting future votes from past votes. The utility function in the vote model uses the response function in Eq. 5. Due to the specification of IP models, we need the case parameters of new cases to predict the direction of the votes. Gerrish and Blei (2011) accomplished this by using regression on legislative text to predict the case parameters (a, b). Here, we follow a similar approach, fitting ridge regression models on the merits brief topic mixtures $\boldsymbol{\theta}$ to predict a and b for each case.[12] On the held-out test cases, we sampled the mixture proportions for the merits and amicus briefs directly using latent Dirichlet allocation with parameters learned while fitting our vote model. With the parameters from our fitted vote model and ridge regression, we can predict the votes of every justice for every case.

We compared the performance of our model with two strong baselines: (i) a random forest trained on case-centric metadata coded by Spaeth et al. (2013) to make predictions on how justices would vote (Katz et al., 2014) and (ii) Sim et al. (2015)'s amici IP model, which uses amicus briefs and their version of utility; it is a simpler version of our vote model that does not consider the persuasiveness of different amici or the influenceability of different justices. For prediction in Sim et al. (2015), we used the same approach described above to estimate the case parameters a, b, and regressing on amicus brief topics ($\boldsymbol{\Delta}$) instead for amicus polarities c^{p} and c^{r}. Table 2 shows performance on vote prediction.

[12] We tuned the parameters of the regression using 5-fold cross-validation on the training data.

Model	5-fold	2013	2014
Most frequent	0.597	**0.694**	0.650
Random forest	0.651	0.648	0.633
Vote model without U^{vote}	0.661	0.655	0.660
Sim et al. (2015)	0.675	0.658	0.661
Vote model with U^{vote}	**0.685**	0.664	**0.672**

Table 2: Accuracy of vote prediction. There are 70 cases (625 votes) and 69 cases (619 votes) in the 2013 and 2014 test sets, respectively.

We evaluated the models using 5-fold cross validation, as well as on forecasting votes in 2013 and 2014 (trained using data from 1985 to the preceding year). Our model outperformed the baseline models. The improvement in accuracy over Sim et al. (2015) is small; most likely because both models are very similar, the main difference being the parametrization of amicus briefs. In the 2013 test set, the distribution of votes is significantly skewed towards the petitioner (compared to the training data), which resulted in the most frequent class classifier performing much better than everything else. Fig. 1 illustrates our model's estimated ideal points for selected topics.

Predicting Opinions. We also estimated the opinion model using the utility function with response function in Eq. 6. We use perplexity as a proxy to measure the opinion content predictive ability of our model. Perplexity on a test set is commonly used to quantify the generalization ability of probabilistic models and make comparisons among models over the same observation space. For a case with opinion $\boldsymbol{w}$ supporting side s, the perplexity is defined as

$$\exp\left(-\frac{\log p(\boldsymbol{w} \mid s, \ldots)}{N}\right),$$

where N is the number of tokens in the opinion and a lower perplexity indicates better generalization performance. The likelihood term can be approximated using samples from the inference step.

Table 3 shows the perplexity of our model on opinions in the test set. As described in §2.4, we learn the vote model in the first stage before estimating the opinion model. Here, we compare our model against using vote models that do not include U^{vote} to evaluate the sensitivity of our opinion

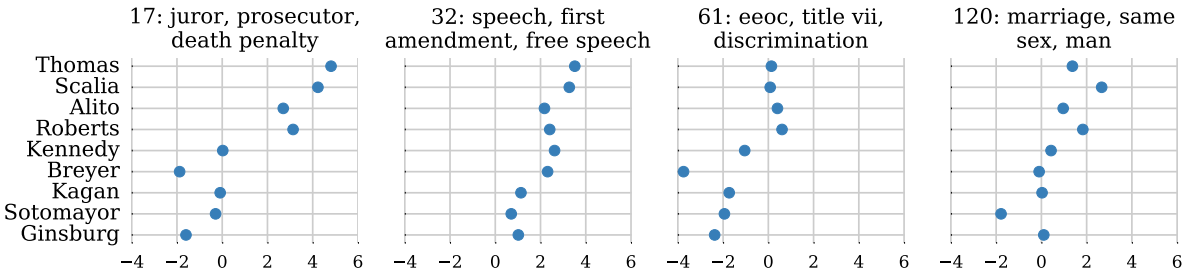

Figure 1: Justices' ideal points for selected topics. Justices whose topic IPs are close to each other are more likely to vote in the same direction on cases involving those topics. The IP estimated by our model is consistent with publicly available knowledge regarding justices' ideological stances on these issues.

model to the vote model parameters. Additionally, we compared against two baselines trained on just the opinions: one using LDA[13] and another using the author-topic model (Rosen-Zvi et al., 2004). For the author-topic model, we treat each opinion as being "authored" by the participating justices, a pseudo-author representing the litigants which is shared between opinions in a case, and a unique amicus author for each side. Our model with U^{opinion} achieves better generalization performance than the simpler baselines, while we do not see significant differences in whether the first stage vote models use U^{vote}. This is not surprising since the vote model's results are similar with or without U^{vote} and it influences the opinion model indirectly through priors and U^{opinion}.

In our model, the latent variable $\mathbf{\Gamma}_j$ captures the proportion of topics that justice j is likely to contribute to an opinion. When j has a high probability of voting for a particular side, our informed prior increases the likelihood that j's topics will be selected for words in the opinion. While $\mathbf{\Gamma}_j$ serves a similar purpose to $\boldsymbol{\psi}_j$ in characterizing j through her ideological positions, $\boldsymbol{\psi}_j$ relies on votes and gives us a "direction" of j's ideological standing, whereas $\mathbf{\Gamma}_j$ is estimated from text produced by the justices and only gives us the "magnitude" of her tendency to author on a particular issue. In Table 4, we identify the top topics in $\mathbf{\Gamma}_j$ by considering the deviation from the mean of all justice's $\mathbf{\Gamma}$, i.e., $\Gamma_{j,k} - \frac{1}{|\mathcal{J}|}\sum_j \Gamma_{j,k}$.

Amici Persuasiveness. The latent variable π_e captures the model's belief about amicus e's brief's effect on the case IP, which we call "persuasiveness." A large π_e indicates that across the dataset, e exerts a larger effect on the case IPs, that is, according to our model, she has a larger impact on the Court's decision than other amici. Fig. 2 is a swarm plot illustrating the distribution of π values for different types of amicus writers.

Model	5-fold	2013	2014
LDA	2.86	2.67	2.63
Author-Topic	2.62	2.36	2.25
Opinion model without U^{opinion}	†2.43	†2.26	†2.13
	2.45	2.27	2.11
Opinion model with U^{opinion}	†2.10	†**1.91**	†1.96
	2.07	1.98	**1.94**

Table 3: Perplexity of Court's opinions ($\times 10^3$). There are 30,133 phrases (98 opinions) and 23,706 phrases (109 opinions) in the 2013 and 2014 test set, respectively. Results marked † are initialized with a vote model U^{vote}.

Our model infers that governmental offices tend to have larger π values than private organizations, especially the U.S. Solicitor General.[14] In fact, Lynch (2004) found through interviews with SCOTUS law clerks that "amicus briefs from the solicitor general are 'head and shoulders' above the rest, and are often considered more carefully than party briefs."

Another interesting observation from Fig. 2 is the low π value for ACLU and ABA, despite being prolific amicus brief filers. While it is tempting to say that amici with low π values are ineffective, we find that there is almost no correlation between π and the proportion of cases where they were on the winning side.[15] Note that our model does not assume that a

[13] We used `scikit-learn`'s LDA module (Pedregosa et al., 2011) which implements the online variational Bayes algorithm (Hoffman et al., 2010).

[14] The average π for *Federal*, *State/Local* and *Others* are 2.35, 1.11, and 0.929 respectively.

[15] The Spearman's ρ between π and the proportion of winning

Table 4: Top three topics contributed to Court opinions for selected justices ($\mathbf{\Gamma}$). The full list can be found in supplementary §C.

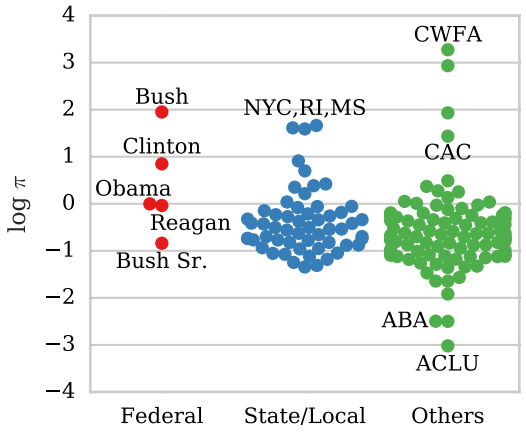

Figure 2: Amici "persuasiveness" by organization type. *Federal* refers to different presidential administration's federal government (and represented by the U.S. Solicitor General) and *State/Local* refers to state and local governments. The abbreviated amici are New York City (NYC), Rhode Island (RI), Mississippi (MS), Concerned Women For America (CWFA), Constitution Accountability Center (CAC), American Bar Association (ABA), and American Civil Liberties Union (ACLU).

"persuasive" amicus tends to win. Instead, an amicus with large π will impact the case IP most, and thus explain a justice's vote or opinion (even dissenting) more than the other components in a case.

Insofar as π explains a vote, we must exercise caution; it is possible that the amicus played no role in the decision-making process and the values of π_e simply reflect our modeling assumptions and/or artifacts of the data. Without entering the minds of SCOTUS justices, or at least observing their closed-door deliberations, it is difficult to measure the influence of amicus briefs on justices' decisions.

Justice Influenceability. The latent variable χ_j measures the relative effect of amicus briefs on justice j's vote IP; when χ_j is large, justice j's vote probability is affected by amicus briefs more. Since χ_j is shared between all cases that a justice participates in, χ_j should correspond to how much they value amicus briefs. Some justices, such as the late Scalia, are known to be dubious of amicus briefs, preferring to leave the task of reading these briefs to their law clerks, who will pick out any notable briefs for them; we would expect Scalia to have a smaller χ than other justices. In Table 5, we compare the χ values of justices with how often they cite an amicus brief in any opinion they wrote (Franze and Anderson, 2015). The χ values estimated by our model are consistent with our expectations.[16]

We note that the χ values correlate considerably with the general ideological leanings of the justices. This might be a coincidence or an inability of the model's specification to discern between ideological extremeness and influenceability.

4 Related Work

The ideal points model was first introduced by Poole and Rosenthal (1985) and has inspired a variety of IP models in SCOTUS (Lauderdale and Clark, 2014; Martin and Quinn, 2002) and Congressional bills (Clinton et al., 2004; Gerrish and Blei, 2011; Heckman and Snyder, 1996). IP has provided a useful framework to characterize voters using roll call information and textual evidence.

We view amicus briefs as "purposeful" texts, where authors are writing to maximize their utility function. This is related to work investigating news media for "slant" to maximize profit (Gentzkow and Shapiro, 2010) and economists choosing research topics maximize certain career outcomes (Jelveh et al., 2015). More generally, extensive literature in

sides is -0.0549. On average, an amicus supports the winning side in 55% of cases. For the ACLU, ABA, CAC, and CWFA, the proportions are 44%, 50%, 47%, and 50% respectively.

[16]The Spearman's ρ between χ_j and citation rates is 0.678.

Justice	χ_j	Citation rate (%)
Sonia Sotomayor	1.590	45
Elena Kagan	0.714	40
Stephen G. Breyer	0.637	38
Ruth B. Ginsburg	0.515	41
John G. Roberts	0.495	42
Anthony M. Kennedy	0.468	42
Samuel A. Alito	0.286	27
Antonin Scalia	0.268	22
Clarence Thomas	0.162	25

econometrics estimates structural utility-based decisions (Berry et al., 1995, *inter alia*).

Researchers have used SCOTUS texts to study authorship (Li et al., 2013), historical changes (Wang et al., 2012), power relationships (Danescu-Niculescu-Mizil et al., 2012; Prabhakaran et al., 2013), and pragmatics (Goldwasser and Daumé, 2014).

5 Conclusion

We presented a random utility model of the Supreme Court that is more comprehensive than earlier work. We considered an individual amicus' persuasiveness and motivations through two different utility functions. On the vote prediction task, our results are consistent with earlier work, and we can infer and compare the relative effectiveness of an individual amicus. Moreover, our opinions model and opinion utility function achieved better generalization performance than simpler methods.

Abstract

Verb Phrase Ellipsis (VPE) is an anaphoric construction in which a verb phrase has been elided. It occurs frequently in dialogue and informal conversational settings, but despite its evident impact on event coreference resolution and extraction, there has been relatively little work on computational methods for identifying and resolving VPE. Here, we present a novel approach to detecting and resolving VPE by using supervised discriminative machine learning techniques trained on features extracted from an automatically parsed, publicly available dataset. Our approach yields state-of-the-art results for VPE detection by improving F1 score by over 11%; additionally, we explore an approach to antecedent identification that uses the Margin-Infused-Relaxed-Algorithm, which shows promising results.

1 Introduction

Verb Phrase Ellipsis (VPE) is an anaphoric construction in which a verbal constituent has been omitted. In English, an instance of VPE consists of two parts: a **trigger**, typically an auxiliary or modal verb, that indicates the presence of a VPE; and an **antecedent**, which is the verb phrase to which the elided element resolves (Bos and Spenader, 2011; Dalrymple et al., 1991). For example, in the sentence, *"The government includes money spent on residential renovation; Dodge does not"*, the trigger *"does"* resolves to the antecedent *"includes money spent on residential renovation"*.

The ability to perform VPE resolution is important for tasks involving event extraction, especially in conversational genres such as informal dialogue where VPE occurs more frequently (Nielsen, 2005). Most current event extraction systems ignore VPE and derive some structured semantic representation by reading information from a shallow dependency parse of a sentence. Such an approach would not only miss many valid links between an elided verb and its arguments, it could also produce nonsensical extractions if applied directly on an auxiliary trigger. In the example above, a naive approach might produce an unhelpful semantic triple such as $(\textit{Dodge}, \textit{agent}, \textit{do})$.

There have been several previous empirical studies of VPE (Hardt, 1997; Nielsen, 2005; Bos and Spenader, 2011; Bos, 2012; Liu et al., 2016). Many previous approaches were restricted to solving specific subclasses of VPE (e.g., VPE triggered by *do* (Bos, 2012)), or have relied on simple heuristics for some or all of the steps in VPE resolution, such as by picking the most recent previous clause as the antecedent.

In this paper, we develop a VPE resolution pipeline which encompasses a broad class of VPEs (Figure 1), decomposed into the following two steps. In the *VPE detection* step, the goal is to determine whether or not a word triggers VPE. The second step, *antecedent identification*, requires selecting the clause containing the verbal antecedent, as well as determining the exact boundaries of the antecedent, which are often difficult to define.

Our contribution is to combine the rich linguistic analysis of earlier work with modern statistical approaches adapted to the structure of the VPE resolution problem. First, inspired by earlier work,

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1734–1743,
Austin, Texas, November 1-5, 2016.

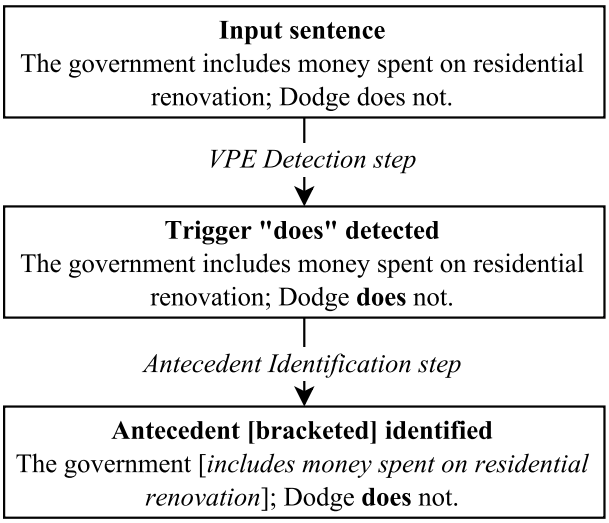

Figure 1: Example of the VPE resolution pipeline on an example found in WSJ file wsj_0036.

our system exploits linguistically informed features specific to VPE in addition to standard features such as lexical features or POS tags. Second, we adapt the Margin-Infused-Relaxed-Algorithm (MIRA) (Crammer et al., 2006), which has been popular in other tasks, such as machine translation (Watanabe et al., 2007) and parsing (McDonald et al., 2005), to antecedent identification. This algorithm admits a partial loss function which allows candidate solutions to overlap to a large degree. This makes it well suited to antecedent identification, as candidate antecedents can overlap greatly as well.

On *VPE detection*, we show that our approach significantly improves upon a deterministic rule-based baseline and outperforms the state-of-the-art system of Liu et al. (2016) by 11%, from 69.52% to 80.78%. For *antecedent identification* we present results that are competitive with the state-of-the-art (Liu et al., 2016). We also present state-of-the-art results with our end-to-end VPE resolution pipeline. Finally, we perform feature ablation experiments to analyze the impact of various categories of features.

2 Related Work

VPE has been the subject of much work in theoretical linguistics (Sag, 1976; Dalrymple et al., 1991, *inter alia*). VPE resolution could have a significant impact on related problems such as event coreference resolution (Lee et al., 2012; Bejan and Harabagiu, 2010; Liu et al., 2014) and event extraction (Ahn, 2006; Kim et al., 2009; Ritter et al., 2012). It has, however, received relatively little attention in the computational literature.

Hardt (1992) engaged in the first study of computational and algorithmic approaches for VPE detection and antecedent identification by using heuristic, linguistically motivated rules. Hardt (1997) extracted a dataset of 260 examples from the WSJ corpus by using an algorithm that exploited null elements in the PTB parse trees. Nielsen (2005) built a dataset that combined sections of the WSJ and BNC; he showed that the more informal settings captured in the BNC corpora show significantly more frequent occurrences of VPE, especially in dialogue excerpts from interviews and plays. Using this dataset, he created a full VPE pipeline from raw input text to a full resolution by replacing the trigger with the intended antecedent[1].

Bos and Spenader (2011) annotated the WSJ for occurrences of VPE. They found over 480 instances of VPE, and 67 instances of the similar phenomenon of *do-so* anaphora. Bos (2012) studied *do*-VPE by testing algorithmic approaches to VPE detection and antecedent identification that utilize Discourse Representation Theory.

Concurrently with the present work, Liu et al. (2016) explored various decompositions of VPE resolution into detection and antecedent identification subtasks, and they corrected the BNC annotations created by Nielsen (2005), which were difficult to use because they depended on a particular set of preprocessing tools. Our work follows a similar pipelined statistical approach. However, we explore an expanded set of linguistically motivated features and machine learning algorithms adapted for each subtask. Additionally, we consider all forms of VPE, including *to*-VPE, whereas Liu et al. only consider modal or light verbs (be, do, have) as candidates for triggering VPE. This represented about 7%

[1] e.g., the resolution of the example in Figure 1 would be "The government includes money spent on residential renovation; Dodge does not [include money spent on residential renovation]". We did not pursue this final step due to the lack of a complete dataset that explicitly depicts the correct grammatical resolution of the VPE.

Auxiliary Type	Example	Frequency
Do	does, done	214 (39%)
Be	is, were	108 (19%)
Have	has, had	44 (8%)
Modal	will, can	93 (17%)
To	to	29 (5%)
So	do so/same[3]	67 (12%)
TOTAL		554

Table 1: Auxiliary categories for VPE and their frequencies in all 25 sections of the WSJ.

of the dataset that they examined.

3 Approach and Data

We divide the problem into two separate tasks: VPE detection (Section 4), and antecedent identification (Section 5). Our experiments use the entire dataset presented in (Bos and Spenader, 2011). For preprocessing, we used CoreNLP (Manning et al., 2014) to automatically parse the raw text of WSJ for feature extraction. We also ran experiments using gold-standard parses; however, we did not find significant differences in our results[2]. Thus, we only report results on automatically generated parses.

We divide auxiliaries into the six different categories shown in Table 1, which will be relevant for our feature extraction and model training process, as we will describe. This division is motivated by the fact that different auxiliaries exhibit different behaviours (Bos and Spenader, 2011). The results we present on the different auxiliary categories (see Tables 2 and 4) are obtained from training a single classifier over the entire dataset and then testing on auxiliaries from each category, with the *ALL* result being the accuracy obtained over all of the test data.

[2]An anonymous reviewer recommended that further experiments could be performed by using the more informative NPs created with NML nodes (Vadas and Curran, 2007) on the gold-standard parsed WSJ.

[3]For example, "John will **go to the store** and Mary will *do the same/likewise/the opposite*". *Do X* anaphora and modals are not technically auxiliary verbs, as noted by the annotators of our dataset (Bos and Spenader, 2011), but for the purposes of this study we generalize them all as auxiliaries while simultaneously dividing them into their correct lexical categories.

4 VPE Detection

The task of VPE detection is structured as a binary classification problem. Given an auxiliary, a, we extract a feature vector f, which is used to predict whether or not the auxiliary is a trigger for VPE. In Figure 1, for example, there is only one auxiliary present, "does", and it is a trigger for VPE. In our experiments, we used a logistic regression classifier.

4.1 Feature Extraction

We created three different sets of features related to the auxiliary and its surrounding context.

Auxiliary. Auxiliary features describe the characteristics of the specific auxiliary, including the following:

- ◇ word identity of the auxiliary
- ◇ lemma of the auxiliary
- ◇ auxiliary type (as shown in Table 1)

Lexical. These features represent:

- ◇ the three words before and after the trigger
- ◇ their part-of-speech (POS) tags
- ◇ their POS bigrams

Syntactic. We devise these features to encode the relationship between the candidate auxiliary and its local syntactic context. These features were determined to be useful through heuristic analysis of VPE instances in a development set. The feature set includes the following binary indicator features (a = the auxiliary):

- ◇ a c-commands[4] a verb
- ◇ a c-commands a verb that comes after it
- ◇ a verb c-commands a
- ◇ a verb *locally*[5] c-commands a
- ◇ a locally c-commands a verb
- ◇ a is c-commanded by "than", "as", or "so"
- ◇ a is preceded by "than", "as", or "so"
- ◇ a is next to punctuation
- ◇ the word "to" precedes a
- ◇ a verb immediately follows a
- ◇ a is followed by "too" or "the same"

[4]A word *A* c-commands another word *B* if *A*'s nearest branching ancestor in the parse tree is an ancestor of B, following the definition of Carnie (2013). We use this term purely to define a syntactic relation between two points in a parse tree.

[5]A word *A* and word *B* share a local structure if they have the same closest S-node ancestor in the parse tree.

4.2 Baseline

As a baseline, we created a rule-based system inspired by Nielsen's (2005) approach to solving VPE detection. The baseline algorithm required significant experimental tuning on the development set because different linguistically hand-crafted rules were needed for each of the six trigger forms. For example, the following rule for *modals* achieved 80% F1-accuracy (see Table 2): "assume VPE is occurring if the modal does not c-command a verb that follows it". The other trigger forms, however, required several layers of linguistic rules. The rules for *be* and *have* triggers were the most difficult to formulate.

4.3 Experiments

We evaluate our models as usual using precision, recall and F1 metric for binary classification. The primary results we present in this section are obtained through 5-fold cross validation over all 25 sections of the automatically-parsed dataset. We use cross validation because the train-test split suggested by Bos and Spenader (2011) could result in highly varied results due to the small size of the dataset (see Table 1). Because the vast majority of auxiliaries do not trigger VPE, we over-sample the positive cases during training. Table 2 shows a comparison between the machine learning technique and a rule-based baseline for the six auxiliary forms. Table 3 shows results obtained from using the same train-test split used by Liu et al. (2016) in order to provide a direct comparison.

Results. Using a standard logistic regression classifier, we achieve an 11% improvement in accuracy over the baseline approach, as can be seen in Table 2. The rule-based approach was insufficient for *be* and *have* VPE, where logistic regression provides the largest improvements. Although we improve upon the baseline by 29%, the accuracy achieved for *be*-VPE is still low; this occurs mainly because: (i) *be* is the most commonly used auxiliary, so the number of negative examples is high compared to the number of positive examples; and, (ii) the analysis of the some of the false positives showed that there may have been genuine cases of VPE that were missed by the annotators of the dataset (Bos and Spenader, 2011). For example, this sentence (in file *wsj_2057*) was missed by the annotators (trigger in bold, antecedent italicized) "Some people tend to ignore that a 50-point move is *less in percentage terms* than it **was** when the stock market was lower."; here it is clear that **was** is a trigger for VPE.

Auxiliary	Baseline	ML	Change
Do	0.83	0.89	+0.06
Be	0.34	0.63	+0.29
Have	0.43	0.75	+0.32
Modal	0.80	0.86	+0.06
To	0.76	0.79	+0.03
So	0.67	0.86	+0.19
ALL	0.71	0.82	+0.11

Table 2: VPE detection results (baseline F1, Machine Learning F1, ML F1 improvement) obtained with 5-fold cross validation.

Test Set Results	P	R	F1
Liu et al. (2016)	**0.8022**	0.6134	0.6952
This work	0.7574	**0.8655**	**0.8078**

Table 3: Results (precision, recall, F1) for VPE detection using the train-test split proposed by Bos and Spenader (2011).

In Table 3, we compare our results to those achieved by Liu et al. (2016) when using WSJ sets 0-14 for training and sets 20-24 for testing. We improve on their overall accuracy by over 11%, due to the 25% improvement in recall achieved by our method. Our results show that oversampling the positive examples in the dataset and incorporating linguistically motivated syntactic features provide substantial gains for VPE detection. Additionally, we consider every instance of the word *to* as a potential trigger, while they do not - this lowers their recall because they miss every gold-standard instance of *to*-VPE. Thus, not only do we improve upon the state-of-the-art accuracy, but we also expand the scope of VPE-detection to include *to*-VPE without causing a significant decrease in accuracy.

5 Antecedent Identification

In this section we assume that we are given a trigger, from which we have to determine the correct antecedent; i.e., in the example in Figure 1, our task would be to identify "includes money spent on res-

idential renovation" as the correct antecedent. Our approach to this problem begins with generating a list of candidate antecedents. Next, we build a feature vector for each candidate by extracting features from the context surrounding the trigger and antecedent. Lastly, we use these features to learn a weight vector by using the Margin-Infused-Relaxed-Algorithm.

5.1 Candidate Generation

We generate a list of candidate antecedents by first extracting all VPs and ADJPs (and all contiguous combinations of their constituents) from the current sentence and the prior one. We then filter these candidates by predefining possible POS tags that an antecedent can start or end with according to the training set's gold standard antecedents. This method generates an average of 55 candidate antecedents per trigger, where triggers in longer sentences cause the creation of a larger number of candidate antecedents due to the larger number of VPs. This strategy accounts for 92% of the gold antecedents on the validation set by head match. We experimented with a less restrictive generation filter, but performance was not improved due to the much larger number of candidate antecedents.

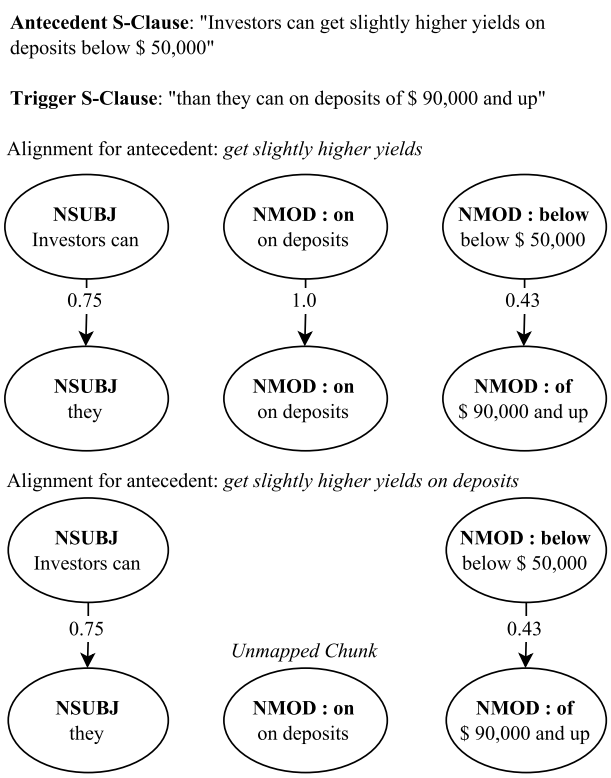

Figure 2: Alignment algorithm example with simplified dependencies.

5.2 Feature Extraction

We construct a feature vector representation for each candidate antecedent; in the example in Figure 1, for example, we would need feature vectors that differentiate between the two potential antecedents "includes money" and "includes money spent on residential renovation".

Alignment. This feature set results from an alignment algorithm that creates a mapping between the S-clause nearest to the trigger, S_t, and the S-clause nearest to the potential antecedent, S_a. The purpose of these features is to represent the parallelism (or lack thereof) between an antecedent's local vicinity with that of the trigger. The creation of this alignment algorithm was motivated by our intuition that the clause surrounding the trigger will have a parallel structure to that of the antecedent, and that an alignment between the two would best capture this parallelism. In the example sentence in Figure 2 (trigger in bold, antecedent italicized) "Investors can *get slightly higher yields* on deposits below $50,000 than they **can** on deposits of $90,000 and up" a simple observation of parallelism is that both the trigger and the correct antecedent are followed by the phrase "on deposits".

Formally, for each $S \in \{S_a, S_t\}$, we extract the dependencies in S as chunks of tokens, where each dependency chunk d_i contains all tokens between its governor and dependent (whichever comes first). Next, for each $d_i \in S_a$, if d_i contains any tokens that belong to the antecedent, delete those tokens. Similarly, for each $d_i \in S_t$, delete any token in d_i that belongs to T. We then perform a bipartite matching to align the $d_i \in S_t$ to the $d_j \in S_a$, where each edge's weight is determined by a scoring function $s(d_i, d_j)$. The scoring function we use considers the F1-similarity between the lemmas, POS-tags, and words shared between the two chunks, as well as whether or not the chunks share the same dependency name.

In the example in Figure 2 we can see that the correct antecedent, "*get slightly higher yields*", has a stronger alignment than the incorrect one, "*get slightly higher yields on deposits*". This occurs because we remove the candidate antecedent from its S-clause before creating the chunks; this leaves three nodes for the correct antecedent which map to the three nodes of the trigger's S-clause. However, this process only leaves two nodes for the incorrect candidate antecedent, thus causing one chunk to be unmapped, thus creating a weaker alignment.

We then use this mapping to generate a feature vector for the antecedent, which contains: the minimum, maximum, average, and standard deviation of the scores between chunks in the mapping; the number and percentage of unmapped chunks; the dependencies that have (and have not) been mapped to; the dependency pairs that were mapped together; and the minimum, maximum, average, and standard deviation of the cosine-similarity between the average word embedding of the words in a chunk between each d_i, d_j pair in the mapping.

NP Relation. These features compare the Noun Phrase (NP) closest to the antecedent to the NP closest to the trigger. This is motivated by an observation of many instances of VPE where it is often the case that the entity preceding the trigger is either repeated, similar, or corefers to the entity preceding the antecedent. The relationship between each *NP* is most significantly represented by features created with pre-trained *word2vec* word embeddings (Mikolov et al., 2013). For each NP, and for each word in the NP, we extract its pre-trained word embedding and then average them all together. We then use the cosine similarity between these two vectors as a feature.

Syntactic. Syntactic features are based on the relationship between the candidate antecedent's parse tree with that of the trigger. This feature set includes the following features, with the last three being influenced by Hardt's (1997) "preference factors" (a = candidate antecedent, t = trigger):

- ◇ if a's first word is an auxiliary
- ◇ if a's head (i.e., first main verb) is an auxiliary
- ◇ the POS tag of a's first and last words
- ◇ the frequency of each POS tag in the antecedent
- ◇ the frequency of each phrase (i.e., NP, VP, ADJP, etc.) in a's sentence and t's sentence
- ◇ if "than", "as", or "so" is between a and t
- ◇ if the word before a has the same POS-tag or lemma as t
- ◇ if a word in a c-commands a word in t
- ◇ if a's first or last word c-commands the trigger
- ◇ *Be-Do Form:* if the lemma of the token preceding a is *be* and the t's lemma is *do*
- ◇ *Recency:* distance between a and t and the distance between the t's nearest VP and a
- ◇ *Quotation:* if t is between quotation marks and similarly for a

Matching. This last feature set was influenced by the features described by Liu et al. (2016). We only use the "Match" features described by them; namely: whether the POS-tags, lemmas, or words in a two-token window before the start of the antecedent exactly match the two before the trigger; and whether the POS-tag, lemma, or word of the ith token before the antecedent equals that of the i-1th token before the trigger (for $i \in \{1, 2, 3\}$, where $i = 1$ considers the trigger itself).

5.3 Training Algorithm - MIRA

Since many potential antecedents share relatively similar characteristics, and since we have many features and few examples, we use the Margin-Infused-Relaxed-Algorithm (MIRA) in order to identify the most likely potential antecedent. MIRA maximizes the margin between the best candidate and the rest of the potential antecedents according to a loss function. It has been used for tasks with similar characteristics, such as statistical machine translation (Watanabe et al., 2007).

The training algorithm begins with a random initialization of the weight vector w. The training set contains triggers, each trigger's candidate antecedents, and their gold standard antecedents; it is reshuffled after each training epoch. We find the K highest-scoring potential antecedents, $a_1, \ldots, a_k$, according to the current weight value. A learning rate parameter determines how much we retain the new weight update with respect to the previous weight vector values.

MIRA defines the update step of the standard online training algorithm: it seeks to learn a weight

vector that, when multiplied with a feature vector f_i, gives the highest score to the antecedent that is most similar to the gold standard antecedent, a_*. This is posed as an optimization problem:

$$\begin{aligned} \underset{w_i}{\text{minimize}} \quad & \|w_i - w_{i-1}\| + C \sum_{k}^{K} \xi_k \\ \text{subject to} \quad & w_i \cdot a_* - w_i \cdot a_k + \xi_k \geq L(a_*, a_k), \\ & k = 1, \ldots, K \end{aligned} \tag{1}$$

Here, L is the loss function that controls the margin between candidates and the gold standard; it is defined as the evaluation metric proposed by Bos and Spenader (2011) (described in Section 5.5).

The ξ are slack variables and $C \geq 0$ is a hyper-parameter that controls the acceptable margin. This problem is solved by converting it to its Lagrange dual form[6].

5.4 Baseline Algorithm

The baseline we created was motivated by Bos's (2012) baseline algorithm: given a trigger, return as the antecedent the nearest VP that does not include the trigger. This is a naïve approach to antecedent identification because it does not consider the relationship between the context surrounding the antecedent and the context surrounding the trigger.

5.5 Experiments

We evaluate our results following the proposed metrics of Bos and Spenader (2011), as do Liu et al. (2016). Accuracy for antecedent identification is computed according to n = the number of correctly identified tokens between the candidate antecedent and the gold standard antecedent. Precision is n divided by the length of the candidate antecedent, recall is n divided by the length of the correct antecedent, and accuracy is the harmonic mean of precision and recall. For MIRA, final results are determined by choosing the weight vector that achieved the best performance on a validation set that is split off from part of the training set, as calculated after each update step.

[6]In this study, the dual form was implemented by hand using Gurobi's python API (Gurobi Optimization Inc., 2015).

have	0.39	0.61	+0.22
to	0.03	0.58	+0.55
ALL	0.36	0.65	+0.29

Table 4: Results (baseline accuracy, MIRA accuracy, accuracy improvement) for antecedent identification; obtained with 5-fold cross validation.

End-to-end Results	P	R	F1
Liu et al. (2016)	**0.5482**	0.4192	0.4751
This work	0.4871	**0.5567**	**0.5196**

Table 5: End-to-end results (precision, recall, F1) using the train-test split proposed by Bos and Spenader (2011).

MIRA has several hyper-parameters that were tuned through a grid search over the validation set. The most crucial parameters were the learning rate α, and C, while the value of K did not cause significant changes in accuracy.

Results. In Table 4, we see that MIRA improves upon the baseline with a 29% increase in overall accuracy. MIRA provides significant gains for each form of VPE, although there is room for improvement, especially when identifying the antecedents of *do-so* triggers.

Liu et al. (2016) achieve an accuracy of 65.20% with their joint resolution model for antecedent identification when using the train-test split proposed by Bos and Spenader (2011); our model achieves 62.20% accuracy. However, their experimental design was slightly different than ours — they only considered antecedents of triggers detected by their oracle trigger detection method, while we use all gold-standard triggers, meaning our results are not directly comparable to theirs. Our cross validated results (65.18% accuracy) paint a better picture of the quality of our model because the small size of the dataset (554 samples) can cause highly varied results.

Excluded	P	R	F1
Auxiliary	0.7982	0.7611	0.7781
Lexical	0.6937	0.8408	0.7582
Syntactic	0.7404	0.7330	0.7343
NONE	0.8242	0.8120	0.8170

Table 6: Feature ablation results (feature set excluded, precision, recall, F1) on VPE detection; obtained with 5-fold cross validation.

Features Excluded	Accuracy
Alignment	0.6511
NP Relation	0.6428
Syntactic	0.5495
Matching	0.6504
NONE	0.6518

Table 7: Feature ablation results (feature set excluded, precision, recall, F1) on antecedent identification; obtained with 5-fold cross validation.

In Table 5 we present end-to-end results obtained from our system when using the triggers detected by our VPE detection model (see Section 4). We compare these results to the end-to-end results of the best model of Liu et al. (2016). Following Liu et al., we assign partial credit during end-to-end evaluation in the following way: for each correctly detected (true positive) trigger, the Bos and Spenader (2011) antecedent evaluation score between the trigger's predicted antecedent and its gold antecedent is used (as opposed to a value of 1). As can be seen from Table 5, we trade about 6 points of precision for 14 points of recall, thus improving state-of-the-art end-to-end accuracy from 47.51% to 51.96%.

6 Feature Ablation Studies

We performed feature ablation experiments in order to determine the impact that the different feature sets had on performance.

Trigger Detection. In Table 6 we can see that the syntactic features were essential for obtaining the best results, as can be seen by the 8.3% improvement, from 73.4% to 81.7%, obtained from including these features. This shows that notions from theoretical linguistics can prove to be invaluable when approaching the problem of VPE detection and that extracting these features in related problems may improve performance.

Antecedent Identification. Table 7 presents the results from a feature ablation study on antecedent identification. The most striking observation is that the alignment features do not add any significant improvement in the results. This is either because there simply is not an inherent parallelism between the trigger site and the antecedent site, or because the other features represent the parallelism adequately without necessitating the addition of the alignment features. The heuristic syntactic features provide a large (10%) accuracy improvement when included. These results show that a dependency-based alignment approach to feature extraction does not represent the parallelism between the trigger and antecedent as well as features based on the lexical and syntactic properties of the two.

7 Conclusion and Future Work

We presented an approach for the tasks of Verb Phrase Ellipsis detection and antecedent identification that leverages features informed both by theoretical linguistics and NLP, and employs machine learning methods to build VPE detection and antecedent identification tools using these features. Our results show the importance of distinguishing VPE triggers from each other, and highlight the importance of using the notion of c-command for both tasks.

For VPE detection, we improve upon the accuracy of the state-of-the-art system by over 11%, from 69.52% to 80.78%. For antecedent identification, our results significantly improve upon a baseline algorithm and we present results that are competitive with the state-of-the-art, as well as state-of-the-art results for an end-to-end system. We also expand the scope of previous state-of-the-art by including the detection and resolution of *to*-VPE, thus building a system that encompasses the entirety of the Bos and Spenader (2011) VPE dataset.

In future work, we would like to further inves-

tigate other margin-based optimizations similar to MIRA, but perhaps even more resilient to overfitting. We also seek to improve the antecedent identification approach by extracting stronger features.

Abstract

We introduce two first-order graph-based dependency parsers achieving a new state of the art. The first is a consensus parser built from an ensemble of independently trained greedy LSTM transition-based parsers with different random initializations. We cast this approach as minimum Bayes risk decoding (under the Hamming cost) and argue that weaker consensus within the ensemble is a useful signal of difficulty or ambiguity. The second parser is a "distillation" of the ensemble into a single model. We train the distillation parser using a structured hinge loss objective with a novel cost that incorporates ensemble uncertainty estimates for each possible attachment, thereby avoiding the intractable cross-entropy computations required by applying standard distillation objectives to problems with structured outputs. The first-order distillation parser matches or surpasses the state of the art on English, Chinese, and German.

1 Introduction

Neural network dependency parsers achieve state of the art performance (Dyer et al., 2015; Weiss et al., 2015; Andor et al., 2016), but training them involves gradient descent on non-convex objectives, which is unstable with respect to initial parameter values. For some tasks, an **ensemble** of neural networks from different random initializations has been found to improve performance over individual models (Sutskever et al., 2014; Vinyals et al., 2015, *inter alia*). In §3, we apply this idea to build a first-order graph-based (FOG) ensemble parser (Sagae and Lavie, 2006) that seeks consensus among 20 randomly-initialized stack LSTM parsers (Dyer et al., 2015), achieving nearly the best-reported performance on the standard Penn Treebank Stanford dependencies task (94.51 UAS, 92.70 LAS).

We give a probabilistic interpretation to the ensemble parser (with a minor modification), viewing it as an instance of **minimum Bayes risk** inference. We propose that disagreements among the ensemble's members may be taken as a signal that an attachment decision is difficult or ambiguous.

Ensemble parsing is not a practical solution, however, since an ensemble of N parsers requires N times as much computation, plus the runtime of finding consensus. We address this issue in §5 by **distilling** the ensemble into a **single** FOG parser with discriminative training by defining a new *cost function*, inspired by the notion of "soft targets" (Hinton et al., 2015). The essential idea is to derive the cost of each possible attachment from the ensemble's division of votes, and use this cost in discriminative learning. The application of distilliation to structured prediction is, to our knowledge, new, as is the idea of empirically estimating cost functions.

The distilled model performs almost as well as the ensemble consensus and much better than (i) a strong LSTM FOG parser trained using the conventional Hamming cost function, (ii) recently published strong LSTM FOG parsers (Kiperwasser and Goldberg, 2016; Wang and Chang, 2016), and (iii) many higher-order graph-based parsers (Koo and Collins, 2010; Martins et al., 2013; Le and Zuidema, 2014). It represents a new state of the art for graph-based dependency parsing for English, Chinese, and

Austin, Texas, November 1-5, 2016.

German. The code to reproduce our results is publicly available.[1]

2 Notation and Definitions

Let $\boldsymbol{x} = \langle x_1, \ldots, x_n \rangle$ denote an n-length sentence. A dependency parse for $\boldsymbol{x}$, denoted $\boldsymbol{y}$, is a set of tuples (h, m, ℓ), where h is the index of a head, m the index of a modifier, and ℓ a dependency label (or relation type). Most dependency parsers are constrained to return $\boldsymbol{y}$ that form a directed tree.

A first-order graph-based (**FOG**; also known as "arc-factored") dependency parser exactly solves

$$\hat{\boldsymbol{y}}(\boldsymbol{x}) = \arg\max_{\boldsymbol{y} \in \mathcal{T}(\boldsymbol{x})} \underbrace{\sum_{(h,m) \in \boldsymbol{y}} s(h, m, \boldsymbol{x})}_{S(\boldsymbol{y}, \boldsymbol{x})}, \quad (1)$$

where $\mathcal{T}(\boldsymbol{x})$ is the set of directed trees over $\boldsymbol{x}$, and s is a local scoring function that considers only a single dependency arc at a time. (We suppress dependency labels; there are various ways to incorporate them, discussed later.) To define s, McDonald et al. (2005a) used hand-engineered features of the surrounding and in-between context of x_h and x_m; more recently, Kiperwasser and Goldberg (2016) used a bidirectional LSTM followed by a single hidden layer with non-linearity.

The exact solution to Eq. 1 can be found using a minimum (directed) spanning tree algorithm (McDonald et al., 2005b) or, under a projectivity constraint, a dynamic programming algorithm (Eisner, 1996), in $O(n^2)$ or $O(n^3)$ runtime, respectively. We refer to parsing with a minimum spanning tree algorithm as **MST parsing**.

An alternative that runs in linear time is **transition-based** parsing, which recasts parsing as a sequence of actions that manipulate auxiliary data structures to incrementally build a parse tree (Nivre, 2003). Such parsers can return a solution in a faster $O(n)$ asymptotic runtime. Unlike FOG parsers, transition-based parsers allow the use of scoring functions with history-based features, so that attachment decisions can interact more freely; the best performing parser at the time of this writing employ neural networks (Andor et al., 2016).

[1] https://github.com/adhigunasurya/distillation_parser.git

Let $h_{\boldsymbol{y}}(m)$ denote the parent of x_m in $\boldsymbol{y}$ (using a special null symbol when m is the root of the tree), and $h_{\boldsymbol{y'}}(m)$ denotes the parent of x_m in the predicted tree $\boldsymbol{y'}$. Given two dependency parses of the same sentence, $\boldsymbol{y}$ and $\boldsymbol{y'}$, the **Hamming cost** is

$$C_H(\boldsymbol{y}, \boldsymbol{y'}) = \sum_{m=1}^{n} \begin{cases} 0 & \text{if } h_{\boldsymbol{y}}(m) = h_{\boldsymbol{y'}}(m) \\ 1 & \text{otherwise} \end{cases}$$

This cost underlies the standard dependency parsing evaluation scores (unlabeled and labeled attachment scores, henceforth UAS and LAS). More generally, a **cost function** C maps pairs of parses for the same sentence to non-negative values interpreted as the cost of mistaking one for the other, and a **first-order cost function** (FOC) is one that decomposes by attachments, like the Hamming cost.

Given a cost function C and a probabilistic model that defines $p(\boldsymbol{y} \mid \boldsymbol{x})$, **minimum Bayes risk** (MBR) decoding is defined by

$$\begin{aligned} \hat{\boldsymbol{y}}_{\text{MBR}}(\boldsymbol{x}) &= \arg\min_{\boldsymbol{y} \in \mathcal{T}(\boldsymbol{x})} \sum_{\boldsymbol{y'} \in \mathcal{T}(\boldsymbol{x})} p(\boldsymbol{y'} \mid \boldsymbol{x}) \cdot C(\boldsymbol{y}, \boldsymbol{y'}) \\ &= \arg\min_{\boldsymbol{y} \in \mathcal{T}(\boldsymbol{x})} \mathbb{E}_{p(\boldsymbol{Y} \mid \boldsymbol{x})}[C(\boldsymbol{y}, \boldsymbol{Y})]. \end{aligned} \quad (2)$$

Under the Hamming cost, MBR parsing equates algorithmically to FOG parsing with $s(h, m, \boldsymbol{x}) = p((h, m) \in \boldsymbol{Y} \mid \boldsymbol{x})$, the posterior marginal of the attachment under p. This is shown by linearity of expectation; see also Titov and Henderson (2006).

Apart from MBR decoding, cost functions are also used for *discriminative training* of a parser. For example, suppose we seek to estimate the parameters $\boldsymbol{\theta}$ of scoring function $S_{\boldsymbol{\theta}}$. One approach is to minimize the structured hinge loss of a training dataset $\mathcal{D}$ with respect to $\boldsymbol{\theta}$:

$$\begin{aligned} \min_{\boldsymbol{\theta}} \sum_{(\boldsymbol{x}, \boldsymbol{y}) \in \mathcal{D}} [&- S_{\boldsymbol{\theta}}(\boldsymbol{y}, \boldsymbol{x}) \\ &+ \max_{\boldsymbol{y'} \in \mathcal{T}(\boldsymbol{x})} \big(S_{\boldsymbol{\theta}}(\boldsymbol{y'}, \boldsymbol{x}) + C(\boldsymbol{y'}, \boldsymbol{y}) \big)] \end{aligned} \quad (3)$$

Intuitively, this amounts to finding parameters that separate the model score of the correct parse from any wrong parse by a distance proportional to the cost of the wrong parse. With regularization, this is equivalent to the structured support vector machine

(Taskar et al., 2005; Tsochantaridis et al., 2005), and if $S_{\boldsymbol{\theta}}$ is (sub)differentiable, many algorithms are available. Variants have been used extensively in training graph-based parsers (McDonald et al., 2005b; Martins et al., 2009), which typically make use of Hamming cost, so that the inner $\max$ can be solved efficiently using FOG parsing with a slightly revised local scoring function:

$$s'(h, m, \boldsymbol{x}) = s(h, m, \boldsymbol{x}) + \begin{cases} 0 & \text{if } (h, m) \in \boldsymbol{y} \\ 1 & \text{otherwise} \end{cases} \quad (4)$$

Plugging this into Eq. 1 is known as **cost-augmented** parsing.

3 Consensus and Minimum Bayes Risk

Despite the recent success of neural network dependency parsers, most prior works exclusively report single-model performance. Ensembling neural network models trained from different random starting points is a standard technique in a variety of problems, such as machine translation (Sutskever et al., 2014) and constituency parsing (Vinyals et al., 2015). We aim to investigate the benefit of ensembling independently trained neural network dependency parsers by applying the parser ensembling method of Sagae and Lavie (2006) to a collection of N strong neural network base parsers.

Here, each base parser is an instance of the greedy, transition-based parser of Dyer et al. (2015), known as the stack LSTM parser, trained from a different random initial estimate. Given a sentence $\boldsymbol{x}$, the consensus FOG parser (Eq. 1) defines score $s(h, m, \boldsymbol{x})$ as the number of base parsers that include the attachment (h, m), which we denote $votes(h, m)$.[2] An example of this scoring function with an ensemble of 20 models is shown in Figure 1 We assign to dependency (h, m) the label most frequently selected by the base parsers that attach m to h.

Next, note that if we let $s(h, m, \boldsymbol{x}) = votes(h, m)/N$, this has no effect on the parser (we have only scaled by a constant factor). We can therefore view s as a posterior marginal, and the ensemble parser as an MBR parser (Eq. 2).

[2]An alternative to building an ensemble of stack LSTM parsers in this way would be to average the softmax decisions at each timestep (transition), similar to Vinyals et al. (2015).

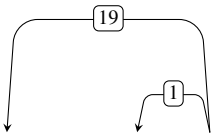

Figure 1: Our ensemble's votes (20 models) on an ambiguous PP attachment of *with*. The ensemble is nearly but not perfectly unanimous in selecting *saw* as the head.

Model	UAS	LAS	UEM
Andor et al. (2016)	**94.61**	**92.79**	-
$N = 1$ (stack LSTM)	93.10	90.90	47.60
ensemble, $N = 5$, MST	93.91	91.94	50.12
ensemble, $N = 10$, MST	94.34	92.47	52.07
ensemble, $N = 15$, MST	94.40	92.57	51.86
ensemble, $N = 20$, MST	94.51	92.70	**52.44**

Table 1: PTB-SD task: ensembles improve over a strong greedy baseline. UEM indicates unlabeled exact match.

Experiment. We consider this approach on the Stanford dependencies version 3.3.0 (De Marneffe and Manning, 2008) Penn Treebank task. As noted, the base parsers instantiate the greedy stack LSTM parser (Dyer et al., 2015).[3]

Table 1 shows that ensembles, even with small N, strongly outperform a single stack LSTM parser. Our ensembles of greedy, locally normalized parsers perform comparably to the best previously reported, due to Andor et al. (2016), which uses a beam (width 32) for training and decoding.

4 What is Ensemble Uncertainty?

While previous works have already demonstrated the merit of ensembling in dependency parsing (Sagae and Lavie, 2006; Surdeanu and Manning, 2010), usually with diverse base parsers, we consider whether the posterior marginals estimated by $\hat{p}((h, m) \in \boldsymbol{Y} \mid \boldsymbol{x}) = votes(h, m)/N$ can be interpreted. We conjecture that disagreement among base parsers about where to attach x_m (i.e., uncertainty in the posterior) is a sign of difficulty or am-

[3]We use the standard data split (02–21 for training, 22 for development, 23 for test), automatically predicted part-of-speech tags, same pretrained word embedding as Dyer et al. (2015), and recommended hyperparameters; `https://github.com/clab/lstm-parser`, each with a different random initialization; this differs from past work on ensembles, which often uses different base model architectures.

Sentence: It will **go** for **work** ranging from refinery **modification** to **changes** in the distribution **system**, *including* the way service stations **pump** fuel into cars.

x_h	posterior	new cost	Hamming
go	0.143	0.143	1
work	0.095	0.191	1
modification	0.190	0.096	1
changes	**0.286**	**0.000**	**0**
system	0.095	0.191	1
pump	0.190	0.096	1
stations	0.000	0.286	1

Table 2: An ambiguous sentence from the training set and the posteriors[4] of various possible parents for *including*. The last two columns are, respectively, the contributions to the distillation cost C_D (explained in §5.1, Eq. 5) and the standard Hamming cost C_H. The most probable head under the ensemble is *changes*, which is also the correct answer.

biguity. If this is true, then the ensemble provides information about which confusions are more or less reasonable—information we will exploit in our distilled parser (§5).

A complete linguistic study is out of scope here; instead, we provide a motivating example before empirically validating our conjecture. Table 2 shows an example where there is considerable disagreement among base parsers over the attachment of a word (*including*). We invite the reader to attempt to select the correct attachment and gauge the difficulty of doing so, before reading on.

Regardless of whether our intuition that this is an inherently difficult and perhaps ambiguous case is correct, it is uncontroversial to say that the words in the sentence not listed, which received zero votes (e.g., both instances of *the*), are obviously implausible attachments.

Our next idea is to transform ensemble uncertainty into a new estimate of cost—a replacement for the Hamming cost—and use it in discriminative training of a single FOG parser. This allows us to distill what has been learned by the ensemble into a single model.

5 Distilling the Ensemble

Despite its state of the art performance, our ensemble requires N parsing calls to decode each sentence. To reduce the computational cost, we introduce a method for "distilling" the ensemble's knowledge into a single parser, making use of a novel **cost function** to communicate this knowledge from the ensemble to the distilled model. While models that combine the outputs of other parsing models have been proposed before (Martins et al., 2008; Nivre and McDonald, 2008; Zhang and Clark, 2008, *inter alia*), these works incorporated the scores or outputs of the baseline parsers as **features** and as such require running the first-stage models at test-time. Creating a cost function from a data analysis procedure is, to our knowledge, a new idea.

The idea is attractive because cost functions are model-agnostic; they can be used with any parser amenable to discriminative training. Further, only the training procedure changes; parsing at test time does not require consulting the ensemble at all, avoiding the costly application of the N parsers to new data, unlike model combination techniques like stacking and beam search.

Distilling an ensemble of classifiers into one simpler classifer that behaves similarly is due to Bucilă et al. (2006) and Hinton et al. (2015); they were likewise motivated by a desire to create a simpler model that was cheaper to run at test time. In their work, the ensemble provides a probability distribution over labels for each input, and this predicted distribution serves as the training target for the distilled model (a sum of two cross entropies objective is used, one targeting the empirical training distribution and the other targeting the ensemble's posterior distribution). This can be contrasted with the supervision provided by the training data alone, which conventionally provides a single correct label for each instance. These are respectively called "soft" and "hard" targets.

We propose a novel adaptation of the soft target idea to the structured output case. Since a sentence

[4] In §3, we used 20 models. Since those 20 models were trained on the whole training set, they cannot be used to obtain the uncertainty estimates on the training set, where the example sentence in Table 2 comes from. Therefore we trained a new ensemble of 21 models from scratch with five-way jackknifing. The same jackknifing setting is used in the distillation parser (§6).

Sentence: John **saw** the **woman** *with* a telescope

x_h	soft	hard
John	0.0	0
saw	**0.95**	**1**
the	0.0	0
woman	0.05	0
a	0.0	0
telescope	0.0	0

Table 3: Example of soft targets (taken from our 20-model ensemble's uncertainty on the sentence) and hard targets (taken from the gold standard) for possible parents of *with*. The soft target corresponds with the posterior (second column) in Table 2, but the hard target differs from the Hamming cost (last column of Table 2) since the hard target assigns a value of 1 to the correct answer and 0 to all others (the reverse is true for Hamming cost).

has an exponential (in its length) number of parses, representing the posterior distribution over parses predicted by the ensemble is nontrivial. We solve this problem by taking a single parse from each model, representing the N-sized ensemble's parse distribution using N samples.

Second, rather than considering uncertainty at the level of complete parse trees (which would be analogous to the classification case) or larger structures, we instead consider uncertainty about *individual* attachments, and seek to "soften" the attachment targets used in training the parser. An illustration for the prepositional phrase attachment ambiguity in Fig. 1, taken from the ensemble output for the sentence, is shown in Table 3. Soft targets allow us to encode the notion that mistaking *woman* as the parent of *with* is less bad than attaching *with* to *John* or *telescope*. Hard targets alone do not capture this information.

5.1 Distillation Cost Function

The natural place to exploit this additional information when training a parser is in the cost function. When incorporated into discriminative training, the Hamming cost encodes hard targets: the correct attachment should receive a higher score than all incorrect ones, with the same margin. Our distillation cost function aims to reduce the cost of decisions that—based on the ensemble uncertainty—appear to be more difficult, or where there may be multiple plausible attachments.

Let $\pi(h, m) =$

$$1 - \hat{p}((h, m) \in \boldsymbol{Y} \mid \boldsymbol{x}) = \frac{N - votes(h, m)}{N}.$$

Our new cost function is defined by $C_D(\boldsymbol{y}, \boldsymbol{y'}) =$

$$\begin{aligned} &\textstyle\sum_{m=1}^{n} \max\left\{0, \pi(h_{\boldsymbol{y'}}(m), m) - \pi(h_{\boldsymbol{y}}(m), m)\right\} \\ &= \textstyle\sum_{m=1}^{n} \max\left\{0, \hat{p}(h_{\boldsymbol{y}}(m), m) - \hat{p}(h_{\boldsymbol{y'}}(m), m)\right\}. \end{aligned} \quad (5)$$

Recall that $\boldsymbol{y}$ denotes the correct parse, according to the training data, and $\boldsymbol{y'}$ is a candidate parse.

This function has several attractive properties:

1. When a word x_m has more than one plausible (according to the ensemble) but incorrect (according to the annotations) attachment, each one has a diminished cost (relative to Hamming cost and all implausible attachments).
2. The correct attachment (according to the gold-standard training data) always has zero cost since $h_{\boldsymbol{y}}(m) = h_{\boldsymbol{y'}}(m)$ and Eq. 5 cancels out.
3. When the ensemble is confident, cost for its choice(s) is lower than it would be under Hamming cost—even when the ensemble is wrong. This means that we are largely training the distilled parser to simulate the ensemble, including mistakes and correct predictions. This encourages the model to replicate the state of the art ensemble performance.
4. Further, when the ensemble is perfectly confident and correct, every incorrect attachment has a cost of 1, just as in Hamming cost.
5. The cost of any attachment is bounded above by the proportion of votes assigned to the correct attachment.

One way to understand this cost function is to imagine that it gives the parser more ways to achieve a zero-cost[5] attachment. The first is to correctly attach a word to its correct parent. The second is to predict a parent that the ensemble prefers to the correct parent, i.e., $\pi(h_{\boldsymbol{y'}}(m), m) < \pi(h_{\boldsymbol{y}}(m), m)$. Any other decision will incur a non-zero cost that is

[5]It is important to note the difference between cost (Eq. 5) and loss (Eq. 3).

proportional to the implausibility of the attachment, according to the ensemble. Hence the model is supervised both by the hard targets in the training data annotations and the soft targets from the ensemble.

While it may seem counter-intuitive to place zero cost on an incorrect attachment, recall that the *cost* is merely a margin that must separate the scores of parses containing correct and incorrect arcs. In contrast, the *loss* (in our case, the structured hinge loss) is the "penalty" the learner tries to minimize while training the graph-based parser, which depends on both the *cost* and *model score* as defined in Equation 3. When an incorrect arc is preferred by the ensemble over the gold arc (hence assigned a cost/margin of 0), the model will still incur a loss if $s(h_{\boldsymbol{y}}(m), m, \boldsymbol{x}) < s(h_{\boldsymbol{y'}}(m), m, \boldsymbol{x})$. In other words, the score of *any* incorrect arc (including those strongly preferred by the ensemble) cannot be higher than the score of the gold arc.

The learner only incurs 0 loss if $s(h_{\boldsymbol{y}}(m), m, \boldsymbol{x}) \geq s(h_{\boldsymbol{y'}}(m), m, \boldsymbol{x})$. This means that the gold score and the predicted score can have a margin of 0 (i.e., have the same score and incur no loss) when the ensemble is highly confident of that prediction, but the score of the correct parse cannot be lower regardless of how confident the ensemble is (hence the objective does not encourage incorrect trees at the expense of gold ones).

In the example in Table 2, we show the (additive) contribution to the distillation cost by each attachment decision (column labeled "new cost"). Note that more plausible attachments according to the ensemble have a lower cost than less plausible ones (e.g., the cost for *modification* is less than *system*, though both are incorrect). While in the last line *stations* received no votes in the ensemble (implausible attachment), its contribution to the cost is bounded by the proportion of votes for correct attachment. The intuition is that, when the ensemble is not certain of the correct answer, it should not assign a large cost to implausible attachments. In contrast, Hamming cost would assign a cost of 1 (column labeled "Hamming") in all incorrect cases.

5.2 Distilled Parser

Our distilled parser is trained discriminatively with the structured hinge loss (Eq. 3). This is a natural choice because it makes the cost function explicit and central to learning.[6] Further, because our ensemble's posterior gives us information about each attachment individually, the cost function we construct can be first-order, which simplifies training with exact inference.

This approach to training a model is well-studied for a FOG parser, but not for a transition-based parser, which is comprised of a collection of classifiers trained to choose good sequences of transitions—not to score whole trees for good attachment accuracy. Transition-based approaches are therefore unsuitable for our proposed distillation cost function, even though they are asymptotically faster. We proceed with a FOG parser (with Eisner's algorithm for English and Chinese, and MST for German since it contains a considerable number of non-projective trees) as the distilled model.

Concretely, we use a bidirectional LSTM followed by a hidden layer of non-linearity to calculate the scoring function $s(h, m, \boldsymbol{x})$, following Kiperwasser and Goldberg (2016) with minor modifications. The bidirectional LSTM maps each word x_i to a vector $\bar{\mathbf{x}}_i$ that embeds the word in context (i.e., $\boldsymbol{x}_{1:i-1}$ and $\boldsymbol{x}_{i+1:n}$). Local attachment scores are given by:

$$s(h, m, \boldsymbol{x}) = \mathbf{v}^\top \tanh\left(\mathbf{W}[\bar{\mathbf{x}}_h; \bar{\mathbf{x}}_m] + \mathbf{b}\right) \quad (6)$$

where the model parameters are $\mathbf{v}$, $\mathbf{W}$, and $\mathbf{b}$, plus the bidirectional LSTM parameters. We will refer to this parsing model as **neural FOG**.

Our model architecture is nearly identical to that of Kiperwasser and Goldberg (2016), with two primary differences. The first difference is that we fix the pretrained word embeddings and compose them with learned embeddings and POS tag embeddings (Dyer et al., 2015), allowing the model to simultaneously leverage pretrained vectors and learn a task-specific representation.[7] Unlike Kiperwasser and Goldberg (2016), we did not observe any degradation by incorporating the pretrained vectors. Second,

[6] Alternatives that do not use cost functions include probabilistic parsers, whether locally normalized like the stack LSTM parser used within our ensemble, or globally normalized, as in Andor et al. (2016); cost functions can be incorporated in such cases with minimum risk training (Smith and Eisner, 2006) or softmax margin (Gimpel and Smith, 2010).

[7] To our understanding, Kiperwasser and Goldberg (2016) initialized with pretrained vectors and backpropagated during training.

we apply a per-epoch learning rate decay of 0.05 to the Adam optimizer. While the Adam optimizer automatically adjusts the global learning rate according to past gradient magnitudes, we find that this additional per-epoch decay consistently improves performance across all settings and languages.

6 Experiments

We ran experiments on the English PTB-SD version 3.3.0, Penn Chinese Treebank (Xue et al., 2002), and German CoNLL 2009 (Hajič et al., 2009) tasks.

Experimental settings. We used the standard splits for all languages. Like Chen and Manning (2014) and Dyer et al. (2015), we use predicted tags with the Stanford tagger (Toutanova et al., 2003) for English and gold tags for Chinese. For German we use the predicted tags provided by the CoNLL 2009 shared task organizers. All models were augmented with pretrained structured-skipgram (Ling et al., 2015) embeddings; for English we used the Gigaword corpus and 100 dimensions, for Chinese Gigaword and 80, and for German WMT 2010 monolingual data and 64.

Hyperparameters. The hyperparameters for neural FOG are summarized in Table 4. For the Adam optimizer we use the default settings in the CNN neural network library.[8] Since the ensemble is used to obtain the uncertainty on the training set, it is imperative that the stack LSTMs do not overfit the training set. To address this issue, we performed five-way jackknifing of the training data for each stack LSTM model to obtain the training data uncertainty under the ensemble. To obtain the ensemble uncertainty on each language, we use 21 base models for English (see footnote 4), 17 for Chinese, and 11 for German.

Speed. One potential drawback of using a quadratic or cubic time parser to distill an ensemble of linear-time transition-based models is speed. Our FOG model is implemented using the same CNN library as the stack LSTM transition-based parser. On the same single-thread CPU hardware, the distilled MST parser[9] parses 20 sentences per second without any pruning, while a single stack LSTM model is only three times faster at 60 sentences per second. Running an ensemble of 20 stack LSTMs is at least 20 times slower (without multi-threading), not including consensus parsing. In the end, the distilled parser is more than ten times faster than the ensemble pipeline.

Bi-LSTM dimension	100
Bi-LSTM layers	2
POS tag embedding	12
Learned word embedding	32
Hidden Layer Units	100
Labeler Hiden Layer Units	100
Optimizer	Adam
Learning rate decay	0.05

Table 4: Hyperparameters for the distilled FOG parser. Both the model architecture and the hyperparameters are nearly identical with Kiperwasser and Goldberg (2016). We apply a per-epoch learning rate decay to the Adam optimizer, which consistently improves performance across all datasets.

Accuracy. All scores are shown in Table 5. First, consider the neural FOG parser trained with Hamming cost (C_H in the second-to-last row). This is a very strong benchmark, outperforming many higher-order graph-based and neural network models on all three datasets. Nonetheless, training the same model with distillation cost gives consistent improvements for all languages. For English, we see that this model comes close to the slower ensemble it was trained to simulate. For Chinese, it achieves the best published scores, for German the best published UAS scores, and just after Bohnet and Nivre (2012) for LAS.

Effects of Pre-trained Word Embedding. As an ablation study, we ran experiments on English without pre-trained word embedding, both with the Hamming and distillation costs. The model trained with Hamming cost achieved 93.1 UAS and 90.9 LAS, compared to 93.6 UAS and 91.1 LAS for the model with distillation cost. This result further showcases the consistent improvements from using the distillation cost across different settings and languages.

We conclude that "soft targets" derived from ensemble uncertainty offer useful guidance, through the distillation cost function and discriminative training of a graph-based parser. Here we consid-

Table 5: Dependency parsing performance on English, Chinese, and German tasks. The "P?" column indicates the use of pretrained word embeddings. Reranking/blend indicates that the reranker score is interpolated with the base model's score. Note that previous works might use different predicted tags for English. We report accuracy without punctuation for English and Chinese, and with punctuation for German, using the standard evaluation script in each case. We only consider systems that do not use additional training data. The best overall results are indicated with bold (this was achieved by the ensemble of greedy stack LSTMs in Chinese and German), while the best non-ensemble model is denoted with an underline. The † sign indicates the use of predicted tags for Chinese in the original publication, although we report accuracy using gold Chinese tags based on private correspondence with the authors.

ered a FOG parser, though future work might investigate any parser amenable to training to minimize a cost-aware loss like the structured hinge.

7 Related Work

Our work on ensembling dependency parsers is based on Sagae and Lavie (2006) and Surdeanu and Manning (2010); an additional contribution of this work is to show that the normalized ensemble votes correspond to MBR parsing. Petrov (2010) proposed a similar model combination with random initializations for phrase-structure parsing, using products of constituent marginals. The local optima in his base model's training objective arise from latent variables instead of neural networks (in our case).

Model distillation was proposed by Bucilă et al. (2006), who used a single neural network to simulate a large ensemble of classifiers. More recently, Ba and Caruana (2014) showed that a single shallow neural network can closely replicate the performance of an ensemble of deep neural networks in phoneme recognition and object detection. Our work is closer to Hinton et al. (2015), in the sense that we do not simply *compress* the ensemble and hit the "soft target," but also the "hard target" at the same time[10]. These previous works only used model compression and distillation for classification; we extend the work to a structured prediction problem (dependency parsing).

Täckström et al. (2013) similarly used an ensemble of other parsers to guide the prediction of a seed model, though in a different context of "ambiguity-aware" ensemble training to re-lexicalize a transfer model for a target language. We similarly use an ensemble of models as a supervision for a sin-

[10]Our cost is zero when the correct arc is predicted, regardless of what the soft target thinks, something a compression model without gold supervision cannot do.

gle model. By incorporating the ensemble uncertainty estimates in the cost function, our approach is cheaper, not requiring any marginalization during training. An additional difference is that we learn from the gold labels ("hard targets") rather than only ensemble estimates on unlabeled data.

Kim and Rush (2016) proposed a distillation model at the sequence level, with application in sequence-to-sequence neural machine translation. There are two primary differences with this work. First, we use a global model to distill the ensemble, instead of a sequential one. Second, Kim and Rush (2016) aim to distill a larger model into a smaller one, while we propose to distill an ensemble instead of a single model.

8 Conclusions

We demonstrate that an ensemble of 20 greedy stack LSTMs (Dyer et al., 2015) can achieve state of the art accuracy on English dependency parsing. This approach corresponds to minimum Bayes risk decoding, and we conjecture that the arc attachment posterior marginals quantify a notion of uncertainty that may indicate difficulty or ambiguity. Since running an ensemble is computationally expensive, we proposed discriminative training of a graph-based model with a novel cost function that *distills* the ensemble uncertainty. Deriving a cost function from a statistical model and extending distillation to structured prediction are new contributions. This distilled model, trained to simulate the slower ensemble parser, improves over the state of the art on Chinese and German.

LSTM Shift-Reduce CCG Parsing

Wenduan Xu
Computer Laboratory
University of Cambridge
wx217@cam.ac.uk

Abstract

We describe a neural shift-reduce parsing model for CCG, factored into four unidirectional LSTMs and one bidirectional LSTM. This factorization allows the linearization of the complete parsing history, and results in a highly accurate greedy parser that outperforms all previous beam-search shift-reduce parsers for CCG. By further deriving a globally optimized model using a task-based loss, we improve over the state of the art by up to 2.67% labeled F1.

1 Introduction

Combinatory Categorial Grammar (CCG; Steedman, 2000) parsing is challenging due to its so-called "spurious" ambiguity that permits a large number of non-standard derivations (Vijay-Shanker and Weir, 1993; Kuhlmann and Satta, 2014). To address this, the *de facto* models resort to chart-based CKY (Hockenmaier, 2003; Clark and Curran, 2007), despite CCG being naturally compatible with shift-reduce parsing (Ades and Steedman, 1982). More recently, Zhang and Clark (2011) introduced the first shift-reduce model for CCG, which also showed substantial improvements over the long-established state of the art (Clark and Curran, 2007).

The success of the shift-reduce model (Zhang and Clark, 2011) can be tied to two main contributing factors. First, without any feature locality restrictions, it is able to use a much richer feature set; while intensive feature engineering is inevitable, it has nevertheless delivered an effective and conceptually simpler alternative for both parameter estimation and inference. Second, it couples beam search with global optimization (Collins, 2002; Collins and Roark, 2004; Zhang and Clark, 2008), which makes it less prone to search errors than fully greedy models (Huang et al., 2012).

In this paper, we present a neural architecture for shift-reduce CCG parsing based on long short-term memories (LSTMs; Hochreiter and Schmidhuber, 1997). Our model is inspired by Dyer et al. (2015), in which we explicitly linearize the complete history of parser states in an incremental fashion by requiring no feature engineering (Zhang and Clark, 2011; Xu et al., 2014), and no atomic feature sets (Chen and Manning, 2014). However, a key difference is that we achieve this linearization without relying on any additional control operations or compositional tree structures (Socher et al., 2010; Socher et al., 2011; Socher et al., 2013), both of which are vital in the architecture of Dyer et al. (2015). Crucially, unlike the sequence-to-sequence transduction model of Vinyals et al. (2015), which primarily conditions on the input words, our model is sensitive to all aspects of the parsing history, including arbitrary positions in the input.

As another contribution, we present a global LSTM parsing model by adapting an expected F-measure loss (Xu et al., 2016). As well as naturally incorporating beam search during training, this loss optimizes the model towards the final evaluation metric (Goodman, 1996; Smith and Eisner, 2006; Auli and Lopez, 2011b), allowing it to learn shift-reduce action sequences that lead to parses with high expected F-scores. We further show the globally optimized model can be leveraged with greedy inference, resulting in a deterministic parser as accurate

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1754–1764,
Austin, Texas, November 1-5, 2016.

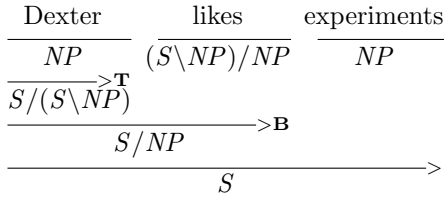

Figure 1: A CCG derivation, in which each point corresponds to the result of a shift-reduce action. In this example, composition (**B**) and application (>) are re actions, and type-raising (**T**) is a un action.

as its beam-search counterpart.

On standard CCGBank tests, we clearly outperform all previous shift-reduce CCG parsers; and by combining the parser with an attention-based LSTM supertagger (§4), we obtain further significant improvements (§5).

2 Shift-Reduce CCG Parsing

CCG is strongly lexicalized by definition. A CCG grammar extracted from CCGBank (Hockenmaier and Steedman, 2007) contains over 400 lexical types and over 1,500 non-terminals (Clark and Curran, 2007), which is an order of magnitude more than those of a typical CFG parser. This lexicalized nature raises another unique challenge for parsing—any parsing model for CCG needs to perform lexical disambiguation. This is true even in the approach of Fowler and Penn (2010), in which a context-free cover grammar extracted from CCGBank is used to parse CCG. Indeed, as noted by Auli and Lopez (2011a), the search problem for CCG parsing is equivalent to finding an optimal derivation in the weighted intersection of a regular language (generated by the supertagger) and a mildly context-sensitive language (generated by the parser), which can quickly become expensive.

The shift-reduce paradigm (Aho and Ullman, 1972; Yamada and Matsumoto, 2003; Nivre and Scholz, 2004) applied to CCG (Zhang and Clark, 2011) presents a more elegant solution to this problem by allowing the parser to conduct lexical assignment "incrementally" as a complete parse is being built by the decoder. This is not possible with a chart-based parser, in which complete derivations must be built first. Therefore, a shift-reduce parser is able to consider a much larger set of categories per word for a given input, achieving higher lexical assignment accuracy than the C&C parser (Clark and Curran, 2007), even with the same supertagging model (Zhang and Clark, 2011; Xu et al., 2014).

In our parser, we follow this strategy and adopt the Zhang and Clark (2011) style shift-reduce transition system, which assumes a set of lexical categories has been assigned to each word using a supertagger (Bangalore and Joshi, 1999; Clark and Curran, 2004). Parsing then proceeds by applying a sequence of actions to transform the input maintained on a *queue*, into partially constructed derivations, kept on a *stack*, until the queue and available actions on the stack are both exhausted. At each time step, the parser can choose to *shift* (sh) one of the lexical categories of the front word onto the stack, and remove that word from the queue; *reduce* (re) the top two subtrees on the stack using a CCG rule, replacing them with the resulting category; or take a *unary* (un) action to apply a CCG type-raising or type-changing rule to the stack-top element. For example, the deterministic sequence of shift-reduce actions that builds the derivation in Fig.1 is: sh $\Rightarrow NP$, un $\Rightarrow S/(S\backslash NP)$, sh $\Rightarrow (S\backslash NP)/NP$, re $\Rightarrow S/NP$, sh $\Rightarrow NP$ and re $\Rightarrow S$, where we use $\Rightarrow$ to indicate the CCG category produced by an action.[1]

3 LSTM Shift-Reduce Parsing

3.1 LSTM

Recurrent neural networks (RNNs; e.g., see Elman, 1990) are factored into an input layer $\mathbf{x}_t$ and a hidden state (layer) $\mathbf{h}_t$ with recurrent connections, and they can be represented by the following recurrence:

$$\mathbf{h}_t = \Phi_\theta(\mathbf{x}_t, \mathbf{h}_{t-1}), \quad (1)$$

where $\mathbf{x_t}$ is the current input, $\mathbf{h}_{t-1}$ is the previous hidden state and Φ is a set of affine transformations parametrized by θ. Here, we use a variant of RNN referred to as LSTMs, which augment Eq. 1 with a cell state, $\mathbf{c}_t$, s.t.

$$\mathbf{h}_t, \mathbf{c}_t = \Phi_\theta(\mathbf{x}_t, \mathbf{h}_{t-1}, \mathbf{c}_{t-1}). \quad (2)$$

Compared with conventional RNNs, this extra facility gives LSTMs more persistent memories over

[1] Our parser models normal-form derivations (Eisner, 1996) in CCGBank. However, unlike Zhang and Clark (2011), derivations are not restricted to be normal-form during inference.

longer time delays and makes them less susceptible to the vanishing gradient problem (Bengio et al., 1994). Hence, they are better at modeling temporal events that are arbitrarily far in a sequence.

Several extensions to the vanilla LSTM have been proposed over time, each with a modified instantiation of Φ_θ that exerts refined control over e.g., whether the cell state could be reset (Gers et al., 2000) or whether extra connections are added to the cell state (Gers and Schmidhuber, 2000). Our instantiation is as follows for all LSTMs:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{ix}\mathbf{x}_t + \mathbf{W}_{ih}\mathbf{h}_{t-1} + \mathbf{W}_{ic}\mathbf{c}_{t-1} + \mathbf{b}_i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}_{fx}\mathbf{x}_t + \mathbf{W}_{fh}\mathbf{h}_{t-1} + \mathbf{W}_{fc}\mathbf{c}_{t-1} + \mathbf{b}_f) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \\
&\quad \mathbf{i}_t \odot \tanh(\mathbf{W}_{cx}\mathbf{x}_t + \mathbf{W}_{ch}\mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{ox}\mathbf{x}_t + \mathbf{W}_{oh}\mathbf{h}_{t-1} + \mathbf{W}_{oc}\mathbf{c}_t + \mathbf{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t),
\end{aligned}$$

where σ is the sigmoid activation and $\odot$ is the element-wise product.

In addition to unidirectional LSTMs that model an input sequence $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{n-1}$ in a strict left-to-right order, we also use bidirectional LSTMs (Graves and Schmidhuber, 2005) (BLSTMs), which read the input from both directions with two independent LSTMs. At each step, the forward hidden state $\mathbf{h}_t$ is computed using Eq. 2 for $t = (0, 1, \ldots, n-1)$; and the backward hidden state $\hat{\mathbf{h}}_t$ is computed similarly but from the reverse direction for $t = (n-1, n-2, \ldots, 0)$. Together, the two hidden states at each step t capture both past and future contexts, and the representation for each $\mathbf{x}_t$ is obtained as the concatenation $[\mathbf{h}_t; \hat{\mathbf{h}}_t]$.

3.2 Embeddings

The neural network model employed by Chen and Manning (2014), and followed by a number of other parsers (Weiss et al., 2015; Zhou et al., 2015; Ambati et al., 2016; Andor et al., 2016; Xu et al., 2016) allows higher-order feature conjunctions to be automatically discovered from a set of dense feature embeddings. However, a set of atomic feature templates, which are only sensitive to contexts from the top few elements on the stack and queue are still needed to dictate the choice of these embeddings. Instead, we dispense with such templates and seek to design a model that is sensitive to both local and non-local contexts, on both the stack and queue.

input: $w_0 \ldots w_{n-1}$

axiom: $0 : (0, \epsilon, \beta, \phi)$

goal: $2n - 1 + \mu : (n, \delta, \epsilon, \Delta)$

$$\frac{t : (j, \delta, x_{w_j}|\beta, \Delta)}{t+1 : (j+1, \delta|x_{w_j}, \beta, \Delta)} \quad (\mathsf{sh}; 0 \le j < n)$$

$$\frac{t : (j, \delta|s_1|s_0, \beta, \Delta)}{t+1 : (j, \delta|x, \beta, \Delta \cup \langle x \rangle))} \quad (\mathsf{re}; s_1 s_0 \to x)$$

$$\frac{t : (j, \delta|s_0, \beta, \Delta)}{t+1 : (j, \delta|x, \beta, \Delta)} \quad (\mathsf{un}; s_0 \to x)$$

Figure 2: The shift-reduce deduction system. For the sh deduction, x_{w_j} denotes an available lexical category for w_j; for re, $\langle x \rangle$ denotes the set of dependencies on x.

Consequently, embeddings represent atomic input units that are added to our parser and are preserved throughout parsing. In total we use four types of embeddings, namely, word, CCG category, POS and action, where each has an associated look-up table that maps a string of that type to its embedding. The look-up table for words is $\mathcal{L}_w \in \mathbb{R}^{k \times |w|}$, where k is the embedding dimension and $|w|$ is the size of the vocabulary. Similarly, we have look-up tables for CCG categories, $\mathcal{L}_c \in \mathbb{R}^{l \times |c|}$, for the three types of actions, $\mathcal{L}_a \in \mathbb{R}^{m \times 3}$, and for POS tags, $\mathcal{L}_p \in \mathbb{R}^{n \times |p|}$.

3.3 Model

Parser. Fig. 2 shows the deduction system of our parser.[2] We denote each parse item as $(j, \delta, \beta, \Delta)$, where j is the positional index of the word at the front of the queue, δ is the stack (with its top element s_0 to the right), and β is the queue (with its top element w_j to the left) and Δ is the set of CCG dependencies realized for the input consumed so far. Each item is also associated with a step indicator t, signifying the number of actions applied to it and the goal is reached in $2n - 1 + \mu$ steps, where μ is the total number of un actions. We also define each action in our parser as a 4-tuple $(\tau_t, c_t, w_{c_t}, p_{w_{c_t}})$, where $\tau_t \in \{\mathsf{sh}, \mathsf{re}, \mathsf{un}\}$ for $t \ge 1$, c_t is the resulting category of τ_t, and w_{c_t} is the head word attached to

[2] We assume greedy inference unless otherwise stated.

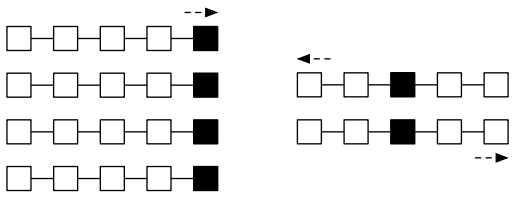

Figure 3: An example representation for a parse item at time step t, with the 4 unidirectional LSTMs (left) and the bidirectional LSTM (right). The shaded cells on the left represent $\boldsymbol{\delta}_t = [\mathbf{h}_t^{\text{U}}; \mathbf{h}_t^{\text{V}}; \mathbf{h}_t^{\text{X}}; \mathbf{h}_t^{\text{Y}}]$ (Eq. 3); and the shaded cells on the right represent $\mathbf{w}_j = [\mathbf{h}_j^{\text{W}}; \hat{\mathbf{h}}_j^{\text{W}}]$.

c_t with $p_{w_{c_t}}$ being its POS tag.[3]

LSTM model. LSTMs are designed to handle time-series data, in a purely sequential fashion; and we try to exploit this fact by completely linearizing all aspects of the parsing history. Concretely, we factor the model as five LSTMs, comprising four unidirectional ones, denoted as U, V, X and Y, and an additional BLSTM, denoted as W (Fig. 3). Before parsing each sentence, we feed W with the complete input (padded with a special embedding $\perp$ as the end of sentence token); and we use $\mathbf{w}_j = [\mathbf{h}_j^{\text{W}}; \hat{\mathbf{h}}_j^{\text{W}}]$ to represent w_j in subsequent steps.[4] We also add $\perp$ to the other 4 unidirectional LSTMs as initialization.

Given this factorization, the stack representation for a parse item $(j, \delta, \beta, \Delta)$ at step t, for $t \geq 1$, is obtained as

$$\boldsymbol{\delta}_t = [\mathbf{h}_t^{\text{U}}; \mathbf{h}_t^{\text{V}}; \mathbf{h}_t^{\text{X}}; \mathbf{h}_t^{\text{Y}}], \tag{3}$$

and together with $\mathbf{w}_j$, $[\boldsymbol{\delta}_t; \mathbf{w}_j]$ gives a representation for the parse item. For the axiom item, we represent it as $[\boldsymbol{\delta}_0; \mathbf{w}_0]$, where $\boldsymbol{\delta}_0 = [\mathbf{h}_\perp^{\text{U}}; \mathbf{h}_\perp^{\text{V}}; \mathbf{h}_\perp^{\text{X}}; \mathbf{h}_\perp^{\text{Y}}]$ is a representation for its stack.

Each time the parser applies an action $(\tau_t, c_t, w_{c_t}, p_{w_{c_t}})$, we update the model by adding the embedding of τ_t, denoted as $\mathcal{L}_a(\tau_t)$, onto U, and adding the other three embeddings of the action 4-tuple, namely $\mathcal{L}_c(c_t)$, $\mathcal{L}_w(w_{c_t})$ and $\mathcal{L}_p(p_{w_{c_t}})$, onto V, X and Y respectively.

To predict the next action, we first derive an action hidden layer $\mathbf{b}_t$, by passing the parse item representation $[\boldsymbol{\delta}_t; \mathbf{w}_j]$ through an affine transformation, s.t.

$$\mathbf{b}_t = f(\mathbf{B}[\boldsymbol{\delta}_t; \mathbf{w}_j] + \mathbf{r}), \tag{4}$$

where $\mathbf{B}$ is a parameter matrix of the model, $\mathbf{r}$ is a bias vector and f is a ReLU non-linearity (Nair and Hinton, 2010). Then we apply another affine transformation (with $\mathbf{A}$ as the weights and $\mathbf{s}$ as the bias) to $\mathbf{b}_t$:

$$\mathbf{a}_t = f(\mathbf{A}\mathbf{b}_t + \mathbf{s}),$$

and obtain the probability of the i^{th} action in $\mathbf{a}_t$ as

$$p(\tau_t^i | \mathbf{b}_t) = \frac{\exp\{\mathbf{a}_t^i\}}{\sum_{\tau_t^k \in \mathcal{T}(\delta_t, \beta_t)} \exp\{\mathbf{a}_t^k\}},$$

where $\mathcal{T}(\delta_t, \beta_t)$ is the set of feasible actions for the current parse item, and $\tau_t^i \in \mathcal{T}(\delta_t, \beta_t)$.

3.4 Derivations and Dependency Structures

Our model naturally linearizes CCG derivations "incrementally" following their post-order traversals. As such, the four unidirectional LSTMs always have the same number of steps; and at each step, the concatenation of their hidden states (Eq. 3) represents a point in a CCG derivation (i.e., an action 4-tuple). Due to the large amount of flexibility in how dependencies are realized in CCG (Hockenmaier, 2003; Clark and Curran, 2007), and in line with most existing CCG parsing models, including dependency models, we have chosen to model CCG derivations, rather than dependency structures.[5] We also hypothesize that tree structures are not necessary for the current model, since they are already implicit in the linearized derivations; and similarly, we have found the action embeddings to be nonessential (§5.2).

3.5 Training

As a baseline, we first train a greedy model, in which we maximize the log-likelihood of each target action in the training data. More specifically, let $(\tau_1^g, \ldots, \tau_{T_n}^g)$ be the gold-standard action sequence for a training sentence n, a cross-entropy criterion is used to obtain the error gradients, and for each sentence, training involves minimizing

$$L(\theta) = -\log \prod_{t=1}^{T_n} p(\tau_t^g | \mathbf{b}_t) = -\sum_{t=1}^{T_n} \log p(\tau_t^g | \mathbf{b}_t),$$

where θ is the set of all parameters in the model.

[3] In case of multiple heads, we always choose the first one.

[4] Word and POS embeddings are concatenated at each input position j, for $0 \leq j < n$; and $\mathbf{w}_n = [\mathbf{h}_\perp^{\text{W}}; \hat{\mathbf{h}}_\perp^{\text{W}}]$.

[5] Most CCG dependency models (e.g., see Clark and Curran (2007) and Xu et al. (2014)) model CCG derivations with dependency features.

As other greedy models (e.g., see Chen and Manning (2014) and Dyer et al. (2015)), our greedy model is *locally* optimized, and suffer from the label bias problem (Andor et al., 2016). A partial solution to this is to use beam search at test time, thereby recovering higher scoring action sequences that would otherwise be unreachable with fully greedy inference. In practice, this has limited effect (Table 2), and a number of more principled solutions have been recently proposed to derive *globally* optimized models during training (Watanabe and Sumita, 2015; Weiss et al., 2015; Zhou et al., 2015; Andor et al., 2016). Here, we extend our greedy model into a global one by adapting the expected F-measure loss of Xu et al. (2016). To our best knowledge, this is the first attempt to train a globally optimized LSTM shift-reduce parser.

Let $\theta = \{\mathbf{U}, \mathbf{V}, \mathbf{X}, \mathbf{Y}, \mathbf{W}, \mathbf{B}, \mathbf{A}\}$ be the weights of the baseline greedy model,[6] we initialize the weights of the global model, which has the same architecture as the baseline, to θ, and we reoptimize θ in multiple training epochs as follows:

1. Pick a sentence x_n from the training set, decode it with beam search, and generate a k-best list of output parses with the *current* θ, denoted as $\Lambda(x_n)$.[7]

2. For each parse y_i in $\Lambda(x_n)$, compute its sentence-level F1 using the set of dependencies in the Δ field of its parse item. In addition, let $|y_i|$ be the total number of actions that derived y_i and $s_\theta(y_i^j)$ be the softmax action score of the j^{th} action, given by the LSTM model. Compute the log-linear score of its action sequence as $\rho(y_i) = \sum_{j=1}^{|y_i|} \log s_\theta(y_i^j)$.

3. Compute the negative expected F1 objective (defined below) for x_n and minimize it using stochastic gradient descent (maximizing expected F1). Repeat these three steps for the remaining sentences.

[6] We use boldface letters to designate the weights of the corresponding LSTMs, and omit bias terms for brevity.

[7] As in Xu et al. (2016), we did not preset k, and found $k = 11.06$ on average with a beam size of 8 that we used for this training.

More formally, the loss $J(\theta)$, is defined as

$$\begin{aligned} J(\theta) &= -\text{XF1}(\theta) \\ &= -\sum_{y_i \in \Lambda(x_n)} p(y_i|\theta)\text{F1}(\Delta_{y_i}, \Delta_{x_n}^G), \end{aligned}$$

where $\text{F1}(\Delta_{y_i}, \Delta_{x_n}^G)$ is the sentence level F1 of the parse derived by y_i, with respect to the gold-standard dependency structure $\Delta_{x_n}^G$ of x_n; $p(y_i|\theta)$ is the normalized probability score of the action sequence y_i, computed as

$$p(y_i|\theta) = \frac{\exp\{\gamma\rho(y_i)\}}{\sum_{y \in \Lambda(x_n)} \exp\{\gamma\rho(y)\}},$$

where γ is a parameter that sharpens or flattens the distribution (Tromble et al., 2008).[8] Different from the maximum-likelihood objective, XF1 optimizes the model on a sequence level and towards the final evaluation metric, by taking into account all action sequences in $\Lambda(x_n)$.

4 Attention-Based LSTM Supertagging

In addition to the size of the label space, supertagging is difficult because CCG categories can encode long-range dependencies and tagging decisions frequently depend on non-local contexts. For example, in *He went to the zoo with a cat*, a possible category for *with*, $(S\backslash NP)\backslash(S\backslash NP)/NP$, depends on the word *went* further back in the sentence.

Recently a number of RNN models have been proposed for CCG supertagging (Xu et al., 2015; Lewis et al., 2016; Vaswani et al., 2016; Xu et al., 2016), and such models show dramatic improvements over non-recurrent models (Lewis and Steedman, 2014b). Although the underlying models differ in their exact architectures, all of them make each tagging decision using only the hidden states at the current input position, and this imposes a potential bottleneck in the model. To mitigate this, we generalize the attention mechanisms of Bahdanau et al. (2015) and Luong et al. (2015), and adapt them to supertagging, by allowing the model to explicitly use hidden states from more than one input positions for tagging each word. Similar to Bahdanau et al. (2015) and Luong et al. (2015), a key feature in

[8] We found $\gamma = 1$ to be a good choice during development.

our model is a soft alignment vector that weights the relative importance of the considered hidden states.

For an input sentence $w_0, w_1, \ldots, w_{n-1}$, we consider $\mathbf{w}_t = [\mathbf{h}_t; \hat{\mathbf{h}}_t]$ (§3.1) to be the representation of the t^{th} word ($0 \leq t < n$, $\mathbf{w}_t \in \mathbb{R}^{2d \times 1}$), given by a BLSTM with a hidden state size d for both its forward and backward layers.[9] Let k be a context window size hyperparameter, we define $\mathbf{H}_t \in \mathbb{R}^{2d \times (k-1)}$ as

$$\mathbf{H}_t = [\mathbf{w}_{t-\lfloor k/2 \rfloor}, \ldots, \mathbf{w}_{t-1}, \mathbf{w}_{t+1}, \ldots, \mathbf{w}_{t+\lfloor k/2 \rfloor}],$$

which contains representations for all words in the size k window except $\mathbf{w}_t$. At each position t, the attention model derives a context vector $\mathbf{c}_t \in \mathbb{R}^{2d \times 1}$ (defined below) from $\mathbf{H}_t$, which is used in conjunction with $\mathbf{w}_t$ to produce an attentional hidden layer:

$$\mathbf{x}_t = f(\mathbf{M}[\mathbf{c}_t; \mathbf{w}_t] + \mathbf{m}), \tag{5}$$

where f is a ReLU non-linearity, $\mathbf{M} \in \mathbb{R}^{g \times 4d}$ is a learned weight matrix, $\mathbf{m}$ is a bias term, and g is the size of $\mathbf{x}_t$. Then $\mathbf{x}_t$ is used to produce another hidden layer (with $\mathbf{N}$ as the weights and $\mathbf{n}$ as the bias):

$$\mathbf{z}_t = \mathbf{N}\mathbf{x}_t + \mathbf{n},$$

and the predictive distribution over categories is obtained by feeding $\mathbf{z}_t$ through a softmax activation.

In order to derive the context vector $\mathbf{c}_t$, we first compute $\mathbf{b}_t \in \mathbb{R}^{(k-1) \times 1}$ from $\mathbf{H}_t$ and $\mathbf{w}_t$ using $\boldsymbol{\alpha} \in \mathbb{R}^{1 \times 4d}$, s.t. the i^{th} entry in $\mathbf{b}_t$ is

$$\mathbf{b}_t^i = \boldsymbol{\alpha}[\mathbf{w}_{T[i]}; \mathbf{w}_t],$$

for $i \in [0, k-1)$, $T = [t-\lfloor k/2 \rfloor, \ldots, t-1, t+1, \ldots, t+\lfloor k/2 \rfloor]$; and $\mathbf{c}_t$ is derived as follows:

$$\mathbf{a}_t = \text{softmax}(\mathbf{b}_t),$$
$$\mathbf{c}_t = \mathbf{H}_t \mathbf{a}_t,$$

where $\mathbf{a}_t$ is the alignment vector. We also experiment with two types of attention reminiscent of the *global* and *local* models in Luong et al. (2015), where the first attends over all input words ($k = n$) and the second over a local window.

It is worth noting that two other works have concurrently tackled supertagging with BLSTM models. In Vaswani et al. (2016), a language model layer is added on top of a BLSTM, which allows embeddings of previously predicted tags to propagate through and influence the pending tagging decision. However, the language model layer is only effective when both scheduled sampling for training (Bengio et al., 2015) and beam search for inference are used. We show our attention-based models can match their performance, with only standard training and greedy decoding. Additionally, Lewis et al. (2016) presented a BLSTM model with two layers of stacking in each direction; and as an internal baseline, we show a non-stacking BLSTM without attention can achieve the same accuracy.

[9] Unlike in the parsing model, POS tags are excluded.

5 Experiments

Dataset and baselines. We conducted all experiments on CCGBank (Hockenmaier and Steedman, 2007) with the standard splits.[10] We assigned POS tags with the C&C POS tagger, and used 10-fold jackknifing for both POS tagging and supertagging. All parsers were evaluated using F1 over labeled CCG dependencies.

For supertagging, the baseline models are the RNN model of Xu et al. (2015), the bidirectional RNN (BRNN) model of Xu et al. (2016), and the BLSTM supertagging models in Vaswani et al. (2016) and Lewis et al. (2016). For parsing experiments, we compared with the global beam-search shift-reduce parsers of Zhang and Clark (2011) and Xu et al. (2014). One neural shift-reduce CCG parser baseline is Ambati et al. (2016), which is a beam-search shift-reduce parser based on Chen and Manning (2014) and Weiss et al. (2015); and the others are the RNN shift-reduce models in Xu et al. (2016). Additionally, the chart-based C&C parser was included by default.

Model and training parameters.[11] All our LSTM models are non-stacking with a single layer.[12] For the supertagging models, the LSTM

[10] Training: Sections 02-21 (39,604 sentences). Development: Section 00 (1,913 sentences). Test: Section 23 (2,407 sentences).

[11] We implemented all models using the CNN toolkit: `https://github.com/clab/cnn`.

[12] The BLSTMs have a single layer in each direction. We experimented with 2 layers in all models during development and found negligible improvements.

Model	Dev	Test
C&C	91.50	92.02
Xu et al. (2015)	93.07	93.00
Xu et al. (2016)	93.49	93.52
Lewis et al. (2016)	94.1	94.3
Vaswani et al. (2016)	94.08	-
Vaswani et al. (2016) +LM +beam	94.24	94.50
BLSTM	94.11	94.29
BLSTM-local	**94.31**	**94.46**
BLSTM-global	94.22	94.42

Table 1: 1-best supertagging results on both the dev and test sets. BLSTM is the baseline model without attention; BLSTM-local and -global are the two attention-based models.

hidden state size is 256, and the size of the attentional hidden layer ($\mathbf{x}_t$, Eq. 5) is 200. All parsing model LSTMs have a hidden state size of 128, and the size of the action hidden layer ($\mathbf{b}_t$, Eq. 4) is 80.

Pretrained word embeddings for all models are 100-dimensional (Turian et al., 2010), and all other embeddings are 50-dimensional. We also pretrained CCG lexical category and POS embeddings on the concatenation of the training data and a Wikipedia dump parsed with C&C.[13] All other parameters were uniformly initialized in $\pm\sqrt{6/(r+c)}$, where r and c are the number of rows and columns of a matrix (Glorot and Bengio, 2010).

For training, we used plain non-minibatched stochastic gradient descent with an initial learning rate $\eta_0 = 0.1$ and we kept iterating in epochs until accuracy no longer increases on the dev set. For all models, a learning rate schedule $\eta_e = \eta_0/(1+\lambda e)$ with $\lambda = 0.08$ was used for $e \geq 11$. Gradients were clipped whenever their norm exceeds 5. Dropout training as suggested by Zaremba et al. (2014), with a dropout rate of 0.3, and an ℓ_2 penalty of 1×10^{-5}, were applied to all models.

5.1 Supertagging Results

Table 1 summarizes 1-best supertagging results. Our baseline BLSTM model without attention achieves the same level of accuracy as Lewis et al. (2016) and the baseline BLSTM model of Vaswani et al. (2016). Compared with the latter, our hidden state size is 50% smaller (256 vs. 512).

For training and testing the local attention model (BLSTM-local), we used an attention window size of 5 (tuned on the dev set), and it gives an improvement of 0.94% over the BRNN supertagger (Xu et al., 2016), achieving an accuracy on par with the beam-search (size 12) model of Vaswani et al. (2016) that is enhanced with a language model. Despite being able to consider wider contexts than the local model, the global attention model (BLSTM-global) did not show further gains, hence we used BLSTM-local for all parsing experiments below.

[13] We used the gensim word2vec toolkit: https://radimrehurek.com/gensim/.

5.2 Parsing Results

All parsers we consider use a supertagger probability cutoff β to prune categories less likely than β times the probability of the best category in a distribution: for the C&C parser, it uses an *adaptive* strategy to backoff to more relaxed β values if no spanning analysis is found given an initial β setting; for all the shift-reduce parsers, fixed β values are used without backing off. Since β determines the derivation space of a parser, it has a large impact on the final parsing accuracy.

For the maximum-likelihood greedy model, we found using a small β value (bigger ambiguity) for training significantly improved accuracy, and we chose $\beta = 1 \times 10^{-5}$ (5.22 categories per word with jackknifing) via development experiments. This reinforces the findings in a number of other CCG parsers (Clark and Curran, 2007; Auli and Lopez, 2011a; Zhang and Clark, 2011; Lewis and Steedman, 2014a; Xu et al., 2014): even though a more relaxed β increases ambiguity, it leads to more accurate models at test time. On the other hand, we found using smaller β values at test time led to significantly better results (Table 2). And this observation differs from the beam-search models which use the same β value for both training and testing.

Table 4: Parsing results on the dev (Section 00) and test (Section 23) sets with 100% coverage, with all LSTM models using the BLSTM-local supertagging model. All experiments using auto POS. CAT (lexical category assignment accuracy). LSTM-greedy is the full greedy parser.

The greedy model. Table 3 shows the dev set results for all greedy models, where the four types of embeddings, that is, word (w), CCG category (c), action (a) and POS (p), are gradually introduced. The full model LSTM-w+c+a+p surpasses all previous shift-reduce models (Table 4), achieving a dev set accuracy of 86.56%. Category embeddings (LSTM-w+c) yielded a large gain over using word embeddings alone (LSTM-w); action embeddings (LSTM-w+c+a) provided little improvement, but further adding POS embeddings (LSTM-w+c+a+p) gave noticeable recall (+0.61%) and F1 improvements (+0.36%) over LSTM-w+c. Fig. 4a shows the learning curves, where all models converged in under 30 epochs.

The XF1 model. Table 4 also shows the results for the XF1 models (LSTM-XF1), which use all four types of embeddings. We used a beam size of 8, and a β value of 0.06 for both training and testing (tuned on the dev set); and training took 12 epochs to converge (Fig. 4b), with an F1 of 87.45% on the dev set. Decoding the XF1 model with greedy inference only slightly decreased recall and F1, and this resulted in a highly accurate deterministic parser. On the test set, our XF1 greedy model gives +2.67% F1 improvement over the greedy model in Xu et al. (2016); and the beam-search XF1 model achieves an F1 improvement of +1.34% compared with the XF1 model of Xu et al. (2016).

LSTM-XF1 (beam = 1)	89.85	85.51	87.62
LSTM-XF1 (beam = 8)	89.81	85.81	87.76

Table 6: Comparison of our XF1 models with chart-based parsers on the test set. $\star$ denotes a tri-trained model and $*$ indicates a different POS tagger.

Effect of the supertagger. To isolate the parsing model from the supertagging model, we first experimented with the BRNN supertagging model as in Xu et al. (2016) for both training and testing the full greedy LSTM parser. Using this supertagger, we still achieved the highest F1 (85.86%) on the dev set (LSTM-BRNN, Table 5) in comparison with all previous shift-reduce models; and an improvement of 1.42% F1 over the greedy model of Xu et al. (2016) was obtained on the test set (Table 4). We then experimented with using the baseline BLSTM supertagging model for parsing (LSTM-BLSTM), and observed the attention-based setup (LSTM-greedy) outperformed it, despite the attention-based supertagger (BLSTM-local) did not give better multi-tagging accuracy. We owe this to the fact that very tight β cutoff values—resulting in almost deterministic supertagging decisions on average—are required by the parser during inference; for instance, BLSTM-local has an average ambiguity of 1.09 on the dev set with $\beta = 0.06$.[14]

Comparison with chart-based models. For completeness and to put our results in perspective, we compare our XF1 models with other CCG parsers in the literature (Table 6): Xu et al. (2015) is the log-linear C&C dependency hybrid model with an RNN supertagger front-end; Lewis et al. (2016) is an LSTM supertagger-factored parser using the A* CCG parsing algorithm of Lewis and Steedman (2014a); Vaswani et al. (2016) combine a BLSTM supertagger with a new version of the C&C parser (Clark et al., 2015) that uses a max-violation percetrpon, which significantly improves over the original C&C models; and finally, a global recursive neural network model with A* decoding (Lee et al., 2016). We note that all these alternative models—with the exception of Xu et al. (2015) and Lewis et al. (2016)—use structured training that accounts for violations of the gold-standard, and we conjecture further improvements for our model are possible by incorporating such mechanisms.[15]

6 Conclusion

We have presented an LSTM parsing model for CCG, with a factorization allowing the linearization of the complete parsing history. We have shown that this simple model is highly effective, with results outperforming all previous shift-reduce CCG parsers. We have also shown global optimization benefits an LSTM shift-reduce model; and contrary to previous findings with the averaged percetpron (Zhang and Clark, 2008), we empirically demonstrated beam-search inference is not necessary for our globally optimized model. For future work, a natural direction is to explore integrated supertagging and parsing in a single neural model (Zhang and Weiss, 2016).

An Evaluation of Parser Robustness for Ungrammatical Sentences

Abstract

For many NLP applications that require a parser, the sentences of interest may not be well-formed. If the parser can overlook problems such as grammar mistakes and produce a parse tree that closely resembles the correct analysis for the intended sentence, we say that the parser is *robust*. This paper compares the performances of eight state-of-the-art dependency parsers on two domains of ungrammatical sentences: learner English and machine translation outputs. We have developed an evaluation metric and conducted a suite of experiments. Our analyses may help practitioners to choose an appropriate parser for their tasks, and help developers to improve parser robustness against ungrammatical sentences.

1 Introduction

Previous works have shown that, in general, parser performances degrade when applied to out-of-domain sentences (Gildea, 2001; McClosky et al., 2010; Foster, 2010; Petrov et al., 2010; Foster et al., 2011). If a parser performs reasonably well for a wide range of out-of-domain sentences, it is said to be *robust* (Bigert et al., 2005; Kakkonen, 2007; Foster, 2007).

Sentences that are ungrammatical, awkward, or too casual/colloquial can all be seen as special kinds of out-of-domain sentences. These types of sentences are commonplace for NLP applications, from product reviews and social media analysis to intelligent language tutors and multilingual processing. Since parsing is an essential component for many applications, it is natural to ask: Are some parsers more robust than others against sentences that are not well-formed? Previous works on parser evaluation that focused on accuracy and speed (Choi et al., 2015; Kummerfeld et al., 2012; McDonald and Nivre, 2011; Kong and Smith, 2014) have not taken ungrammatical sentences into consideration.

In this paper, we report a set of empirical analyses of eight leading dependency parsers on two domains of ungrammatical text: English-as-a-Second Language (ESL) learner text and machine translation (MT) outputs. We also vary the types of training sources; the parsers are trained with the Penn Treebank (to be comparable with other studies) and Tweebank, a treebank on tweets (to be a bit more like the test domain) (Kong et al., 2014).

The main contributions of the paper are:

- a metric and methodology for evaluating ungrammatical sentences without referring to a gold standard corpus;
- a quantitative comparison of parser accuracy of leading dependency parsers on ungrammatical sentences; this may help practitioners to select an appropriate parser for their applications; and
- a suite of robustness analyses for the parsers on specific kinds of problems in the ungrammatical sentences; this may help developers to improve parser robustness in the future.

2 Evaluation of Parser Robustness

Parser evaluation for ungrammatical texts presents some domain-specific challenges. The typical approach to evaluate parsers is to compare parser out-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1765–1774,
Austin, Texas, November 1-5, 2016.

puts against manually annotated gold standards. Although there are a few small semi-manually constructed treebanks on learner texts (Geertzen et al., 2013; Ott and Ziai, 2010) or tweets (Daiber and van der Goot, 2016), their sizes make them unsuitable for the evaluation of parser robustness. Moreover, some researchers have raised valid questions about the merit of creating a treebank for ungrammatical sentences or adapting the annotation schema (Cahill, 2015; Ragheb and Dickinson, 2012).

A "gold-standard free" alternative is to compare the parser output for each problematic sentence with the parse tree of the corresponding correct sentence. Foster (2004) used this approach over a small set of ungrammatical sentences and showed that parser's accuracy is different for different types of errors. A limitation of this approach is that the comparison works best when the differences between the problematic sentence and the correct sentence are small. This is not the case for some ungrammatical sentences (especially from MT systems). Another closely-related approach is to semi-automatically create treebanks from artificial errors. For example, Foster generated artificial errors to the sentences from the Penn Treebank for evaluating the effect of error types on parsers (Foster, 2007). In another work, Bigert et al. (2005) proposed an unsupervised evaluation of parser robustness based on the introduction of artificial spelling errors in error-free sentences. Kakkonen (2007) adapted a similar method to compare the robustness of four parsers over sentences with misspelled words.

Our proposed evaluation methodology is similar to the "gold-standard free" approach; we compare the parser output for an ungrammatical sentence with the automatically generated parse tree of the corresponding correct sentence. In the next section, we discuss our evaluation metric to address the concerns that some ungrammatical sentences may be very different from their corrected versions. This allows us to evaluate parsers with more realistic data that exhibit a diverse set of naturally occurring errors, instead of artificially generated errors or limited error types.

3 Proposed Evaluation Methodology

For the purpose of robustness evaluation, we take the automatically produced parse tree of a well-formed sentence as "gold-standard" and compare the parser output for the corresponding problematic sentence against it. Even if the "gold-standard" is not perfectly correct in absolute terms, it represents the norm from which parse trees of problematic sentences diverge: if a parser were robust against ungrammatical sentences, its output for these sentences should be similar to its output for the well-formed ones.

Determining the evaluation metric for comparing these trees, however, presents another challenge. Since the words of the ungrammatical sentence and its grammatical counterpart do not necessarily match (an example is given in Figure 1), we cannot use standard metrics such as Parseval (Black et al., 1991). We also cannot use adapted metrics for comparing parse trees of unmatched sentences (e.g., Sparseval (Roark et al., 2006)), because these metrics consider all the words regardless of the mismatches (extra or missing words) between two sentences. This is a problem for comparing ungrammatical sentences to grammatical ones because a parser is unfairly penalized when it assigns relations to extra words and when it does not assign relations to missing words. Since a parser cannot modify the sentence, we do not want to penalize these extraneous or missing relations; on the other hand, we do want to identify cascading effects on the parse tree due to a grammar error. For the purpose of evaluating parser robustness against ungrammatical sentences, we propose a modified metric in which the dependencies connected to unmatched (extra or missing) error words are ignored. A more formal definition is as follows:

- *Shared dependency* is a mutual dependency between two trees;
- *Error-related dependency* is a dependency connected to an extra word[1] in the sentence;
- *Precision* is (# of shared dependencies) / (# of dependencies of the ungrammatical sentence -

[1]The extra word in the ungrammatical sentences is an unnecessary word error, and the extra word in the grammatical sentence is a missing word error.

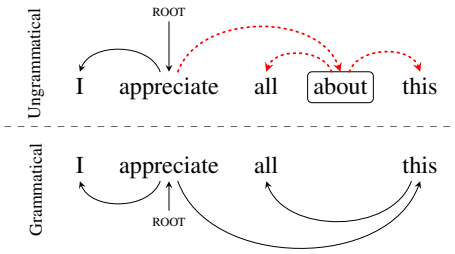

Figure 1: Example of evaluating robustness of an ungrammatical sentence (top) dependency parse tree with its corresponding grammatical sentence (bottom).

# of error-related dependencies of the ungrammatical sentence);

- *Recall* is (# of shared dependencies) / (# of dependencies of the grammatical sentence - # of error-related dependencies of the grammatical sentence); and
- *Robustness* F_1 is the harmonic mean of precision and recall.

Figure 1 shows an example in which the ungrammatical sentence has an unnecessary word, "about", so the three dependencies connected to it are counted as error-related dependencies. The two shared dependencies between the trees result in a precision of $2/(5-3) = 1$, recall of $2/(4-0) = 0.5$, and Robustness F_1 of 66%.

4 Experimental Setup

Our experiments are conducted over a wide range of dependency parsers that are trained on two different treebanks: Penn Treebank (PTB) and Tweebank. We evaluate the robustness of parsers over two datasets that contain ungrammatical sentences: writings of English-as-a-Second language learners and machine translation outputs. We choose datasets for which the corresponding correct sentences are available (or easily reconstructed).

4.1 Parsers

Our evaluation is over eight state-of-the-art dependency parsers representing a wide range of approaches. We use the publicly available versions of each parser with the standard parameter settings.

Malt Parser (Nivre et al., 2007)[2] A greedy transition-based dependency parser. We use LIBLINEAR setting in the learning phase.

Mate Parser v3.6.1 (Bohnet, 2010)[3] A graph-based dependency parser that uses second-order maximum spanning tree.

MST Parser (McDonald and Pereira, 2006)[4] A first-order graph-based parser that searches for maximum spanning trees.

Stanford Neural Network Parser (SNN) (Chen and Manning, 2014)[5] A transition-based parser that uses word embeddings. We use pre-trained word embeddings from Collobert et al. (2011) as recommended by the authors.

SyntaxNet (Andor et al., 2016)[6] A transition-based neural network parser. We use the globally normalized training of the parser with default parameters.

Turbo Parser v2.3 (Martins et al., 2013)[7] A graph-based dependency parser that uses dual decomposition algorithm with third-order features.

Tweebo Parser (Kong et al., 2014)[8] An extension of the Turbo Parser specialized to parse tweets. Tweebo Parser adds a new constraint to the Turbo Parser's integer linear programming to ignore some Twitter tokens from parsing, but also simultaneously uses these tokens as parsing features.

Yara Parser (Rasooli and Tetreault, 2015)[9] A transition-based parser that uses beam search training and dynamic oracle.

4.2 Data

We train all the parsers using two treebanks and test their robustness over two ungrammatical datasets.

4.2.1 Parser Training Data

Penn Treebank (PTB) We follow the standard splits of Penn Treebank, using section 2-21 for training, section 22 for development, and section 23 for

testing. We transform bracketed sentences from PTB into dependency formats using Stanford Basic Dependency representation (De Marneffe et al., 2006) from Stanford parser v3.6. We assign POS tags to the training data using Stanford POS tagger (Toutanova et al., 2003) with ten-way jackknifing (with 97.3% accuracy).

Tweebank Tweebank is a Twitter dependency corpus annotated by non-experts containing 929 tweets (Kong et al., 2014). Kong et al. (2014) used 717 of tweets for training and 201 for test[10]. We follow the same split in our experiments. We use pretrained POS tagging model of Kong et al. (2014) (with 92.8% accuracy) over the tweets.

The elements in tweets that have no syntactic function (such as hashtags, URLs and emoticons) are annotated as unselected tokens (no tokens as the heads). In order to be able to use Tweebank in other parsers, we link the unselected tokens to the wall symbol (i.e. root as the heads). This assumption will generate more arcs from the root, but since we use the same evaluation setting for all the parsers, the results are comparable. We evaluate the accuracy of the trained parser on Tweebank with the unlabeled attachment F_1 score (same procedure as Kong et al. (2014)).

4.2.2 Robustness Test Data

To test the robustness of parsers, we choose two datasets of ungrammatical sentences for which their corresponding correct sentences are available. For a fair comparison, we automatically assign POS tags to the test data. When parsers are trained on PTB, we use the Stanford POS tagger (Toutanova et al., 2003). When parsers are trained on Tweebank, we coarsen POS tags to be compatible with the Twitter POS tags using the mappings specified by Gimpel et al. (2011).

English-as-a-Second Language corpus (ESL) For the ungrammatical sentences, we use the First Certificate in English (FCE) dataset (Yannakoudakis et al., 2011) that contains the writings of English as a second language learners and their corresponding error corrections. Given the errors and their corrections, we can easily reconstruct the corrected version of each ungrammatical ESL sentence. From this corpus, we randomly select 10,000 sentences with at least one error; there are 4954 with one error; 2709 with two errors; 1290 with three; 577 with four; 259 with five; 111 with six; and 100 with 7+ errors.

Machine Translation corpus (MT) Machine translation outputs are another domain of ungrammatical sentences. We use the LIG (Potet et al., 2012) which contains 10,881 and LISMI's TRACE corpus[11] which contains 6,693 French-to-English machine translation outputs and their human post-editions. From these corpora, we randomly select 10,000 sentences with at least edit distance one (upon words) with their human-edited sentence. The distribution of the number of sentences with their edit distances from 1 to 10+ is as follows (beginning with 1 edit distance and ending with 10+): 674; 967; 1019; 951; 891; 802; 742; 650; 547; and 2752.

4.3 Evaluation Metric

In the robustness evaluation metric (Section 3), shared dependencies and error-related dependencies are detected based on alignments between words in the ungrammatical and grammatical sentences. We find the alignments in the FCE and MT data in a slightly different way. In the FCE dataset, in which the error words are annotated, the grammatical and ungrammatical sentences can easily be aligned. In the MT dataset, we use the TER (Translation Error Rate) tool (default settings)[12] to find alignments.

In our experiments, we present unlabeled robustness F_1 micro-averaged across the test sentences. We consider punctuations when parsers are trained with the PTB data, because punctuations can be a source of ungrammaticality. However, we ignore punctuations when parsers are trained with the Tweebank data, because punctuations are not annotated in the tweets with their dependencies.

5 Experiments

The experiments aim to address the following questions given separate training and test data:

1. How do parsers perform on erroneous sentences? (Section 5.1)

[10] github.com/ikekonglp/TweeboParser/tree/master/Tweebank

Table 1: Parsers' performance in terms of accuracy and robustness. The best result in each column is given in bold, and the worst result is in italics.

2. To what extent is each parser negatively impacted by the increase in the number of errors in sentences? (Section 5.2)

3. To what extent is each parser negatively impacted by the interactions between multiple errors? (Section 5.3)

4. What types of errors are more problematic for parsers? (Section 5.4)

5.1 Overall Accuracy and Robustness

The overall performances of all parsers are shown in Table 1. Note that the Tweebo Parser's performance is not trained on the PTB because it is a specialization of the Turbo Parser, designed to parse tweets. Table 1 shows that, for both training conditions, the parser that has the best robustness score in the ESL domain has also high robustness for the MT domain. This suggests that it might be possible to build robust parsers for multiple ungrammatical domains. The training conditions do matter – Malt performs better when trained from Tweebank than from the PTB. In contrast, Tweebank is not a good fit with the neural network parsers due to its small size. Moreover, SNN uses pre-trained word embeddings, and 60% of Tweebank tokens are missing.

Next, let us compare parsers within each train/test configuration for their relative robustness. When trained on the PTB, all parsers are comparably robust on ESL data, while they exhibit more differences on the MT data, and, as expected, everyone's performance is much lower because MT errors are more diverse than ESL errors. We expected that by training on Tweebank, parsers will perform better on ESL data (and maybe even MT data), since Tweebank is arguably more similar to the test domains than the PTB; we also expected Tweebo to outperform others. The results are somewhat surprising. On the one hand, the highest parser score increased from 93.72% (Turbo trained on PTB) to 94.36% (Malt trained on Tweebank), but the two neural network parsers performed significantly worse, most likely due to the small training size of Tweebank. Interestingly, although SyntaxNet has the lowest score on ESL, it has the highest score on MT, showing promise in its robustness.

5.2 Parser Robustness by Number of Errors

To better understand the overall results, we further breakdown the test sentences by the number of errors each contains. Our objectives are: (1) to observe the speed with which the parsers lose their robustness as the sentences become more error-prone; (2) to determine whether some parsers are more robust than others when handling noisier data.

Figure 2 presents four graphs, plotting robustness F_1 scores against the number of errors for all parsers under each train/test configuration. In terms of the parsers' general degradation of robustness, we observe that: 1) parsing robustness degrades faster with the increase of errors for the MT data than the ESL data; 2) training on the PTB led to a more similar behavior between the parsers than when training on Tweebank; 3) training on Tweebank does help some parsers to be more robust against many errors.

In terms of relative robustness between parsers,

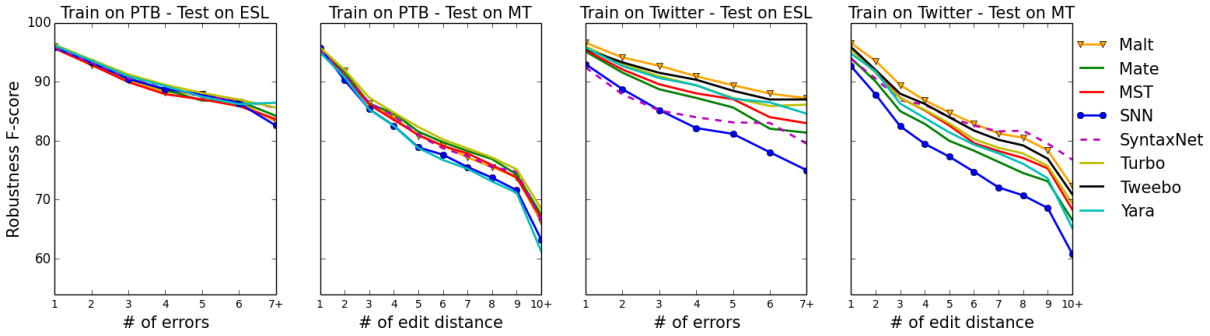

Figure 2: Variation in parser robustness as the number of errors in the test sentences increases.

we observe that Malt, Turbo, and Tweebo parsers are more robust than others given noisier inputs. The SNN parser is a notable outlier when trained on Tweebank due to insufficient training examples.

5.3 Impact of Error Distances

This experiment explores the impact of the interactivity of errors. We assume that errors have more interaction if they are closer to each other, and less interaction if they are scattered throughout the sentence. We define "near" to be when there is at most 1 word between errors and "far" to be when there are at least 6 words between errors. We expect all parsers to have more difficulty on parsing sentences when their errors have more interaction, but how do the parsers compare against each other? We conduct this experiment using a subset of sentences that have exactly three errors; we compare parser robustness when these three errors are near each other with the robustness when the errors are far apart.

Table 2 presents the results as a collection of shaded bars. This aims to give an at-a-glance visualization of the outcomes. In this representation, all parsers with the same train data and *test domain* (including both the *near* and *far* sets) are treated as one group. The top row specifies the lowest score of all parsers on both test sets; the bottom row specifies the highest score. The shaded area of each bar indicates the *relative robustness* of each parser with respect to the lowest and highest scores of the group. An empty bar indicates that it is the least robust (corresponding to the lowest score in the top row); a fully shaded bar means it is the most robust (corresponding to the highest score in the bottom row). Consider the left-most box, in which parsers trained on PTB and tested on ESL are compared. In this group[13], Yara (near) is the least robust parser with a score of $F_1 = 87.3\%$, while SNN (far) is the most robust parser with a score of $F_1 = 93.4\%$; as expected, all parsers are less robust when tested on sentences with near errors than far errors, but they do exhibit relative differences: Turbo parser seems most robust in this setting. Turbo parser's lead in handling error interactivity holds for most of the other train/test configurations as well; the only exception is for Tweebank/MT, where SyntaxNet and Malt are better. Compared to ESL data, near errors in MT data are more challenging for all parsers; when trained on PTB, most are equally poor, except for Yara, which has the worst score (79.1%), even though it has the highest score when the errors are far apart (91.5%). Error interactivity has the most effect on Yara parser in all but one train/test configuration (Tweebank/ESL).

5.4 Impact of Error Types

In the following experiments, we examine the impact of different error types. To remove the impact due to interactivity between multiple errors, these studies use a subset of sentences that have only one error. Although all parsers are fairly robust for sentences containing one error, our focus here is on the relative performances of parsers over different error types: We want to see whether some error types are more problematic for some parsers than others.

5.4.1 Impact of grammatical error types

The three main grammar error types are replacement (a word need replacing), missing (a word missing), and unnecessary (a word is redundant). Our

[13] As previously explained, Tweebo is not trained on PTB, so it has no bars associated with it.

goal is to see whether different error types have different effect on parsers. If yes, is there a parser that is more robust than others?

As shown in Table 3, replacement errors are the least problematic error type for all the parsers; on the other hand, missing errors are the most difficult error type for parsers. This finding suggests that a preprocessing module for correcting missing and unnecessary word errors may be helpful in the parsing pipeline.

5.4.2 Impact of error word category

Another factor that might affect parser performances is the class of errors; for example, we might expect an error on a preposition to have a higher impact (since it is structural) than an error on an adjective. We separate the sentences into two groups: error occurring on an open- or closed-class word. We expect closed-class errors to have a stronger negative impact on the parsers because they contain function words such as determiners, pronouns, conjunctions and prepositions.

Table 4 shows results. As expected, closed-class errors are generally more difficult for parsers. But when parsers are trained on PTB and tested on MT, there are some exceptions: Turbo, Mate, MST and Yara parsers tend to be more robust on closed-class errors. This result corroborates the importance of building grammar error correction systems to handle closed-class errors such as preposition errors.

5.4.3 Impact of error semantic role

An error can be either in a verb role, an argument role, or no semantic role. We extract semantic role of the error by running Illinoise semantic role labeler (Punyakanok et al., 2008) on corrected version of the

Table 5: Parser robustness on sentences with one error where the error occurs on a word taking on a verb role, an argument role, or a word with no semantic role.

sentences. We then obtain the role of the errors using alignments between ungrammatical sentence and its corrected counterpart.

Table 5 shows the average robustness of parsers when parsing sentences that have one error. For parsers trained on the PTB data, handling sentences with argument errors seem somewhat easier than those with other errors. For parsers trained on the Tweebank, the variation in the semantic roles of the errors does not seem to impact parser performance; each parser performs equally well or poorly across all roles; comparing across parsers, Malt seems particularly robust to error variations due to semantic roles.

6 Conclusions and Recommendations

In this paper, we have presented a set of empirical analyses on the robustness of processing ungrammatical text for several leading dependency parsers, using an evaluation metric designed for this purpose. We find that parsers indeed have different responses to ungrammatical sentences of various types. We recommend practitioners to examine the range of ungrammaticality in their input data (whether it is more like tweets or has grammatical errors like ESL writings). If the input data contains text more similar to tweets (e.g. containing URLs and emoticons), Malt or Turbo parser may be good choices. If the input data is more similar to the machine translation outputs; SyntaxNet, Malt, Tweebo and Turbo parser are good choices.

Our results also suggest that some preprocessing steps may be necessary for ungrammatical sentences, such as handling redundant and missing word errors. While there are some previous works on fixing the unnecessary words in the literature (Xue and Hwa, 2014), it is worthy to develop better NLP methods for catching and mitigating the missing word errors prior to parsing. Finally, this work corroborate the importance of building grammar error correction systems for handling closed-class er-

rors such as preposition errors.

Neural Shift-Reduce CCG Semantic Parsing

Dipendra K. Misra and **Yoav Artzi**

Abstract

We present a shift-reduce CCG semantic parser. Our parser uses a neural network architecture that balances model capacity and computational cost. We train by transferring a model from a computationally expensive log-linear CKY parser. Our learner addresses two challenges: selecting the best parse for learning when the CKY parser generates multiple correct trees, and learning from partial derivations when the CKY parser fails to parse. We evaluate on AMR parsing. Our parser performs comparably to the CKY parser, while doing significantly fewer operations. We also present results for greedy semantic parsing with a relatively small drop in performance.

1 Introduction

Shift-reduce parsing is a class of parsing methods that guarantees a linear number of operations in sentence length. This is a desired property for practical applications that require processing large amounts of text or real-time response. Recently, such techniques were used to build state-of-the-art syntactic parsers, and have demonstrated the effectiveness of deep neural architectures for decision making in linear-time dependency parsing (Chen and Manning, 2014; Dyer et al., 2015; Andor et al., 2016; Kiperwasser and Goldberg, 2016). In contrast, semantic parsing often relies on algorithms with polynomial number of operations, which results in slow parsing times unsuitable for practical applications. In this paper, we apply shift-reduce parsing to semantic parsing. Specifically, we study transferring a learned Combinatory Categorial Grammar (CCG; Steedman, 1996, 2000) from a dynamic-programming CKY model to a shift-reduce neural network architecture.

We focus on the feed-forward architecture of Chen and Manning (2014), where each parsing step is a multi-class classification problem. The state of the parser is represented using simple feature embeddings that are passed through a multilayer perceptron to select the next action. While simple, the capacity of this model to capture interactions between primitive features, instead of relying on sparse complex features, has led to new state-of-the-art performance (Andor et al., 2016). However, applying this architecture to semantic parsing presents learning and inference challenges.

In contrast to dependency parsing, semantic parsing corpora include sentences labeled with the system response or the target formal representation, and omit derivation information. CCG induction from such data relies on latent-variable techniques and requires careful initialization (e.g., Zettlemoyer and Collins, 2005, 2007). Such feature initialization does not directly transfer to a neural network architecture with dense embeddings, and the use of hidden layers further complicates learning by adding a large number of latent variables. We focus on data that includes sentence-representation pairs, and learn from a previously induced log-linear CKY parser. This drastically simplifies learning, and can be viewed as bootstrapping a fast parser from a slow one. While this dramatically narrows down the number of parses per sentence, it does not eliminate ambiguity. In our experiments, we often get multiple correct parses, up to 49K in some cases. We also observe that the CKY parser generates no parses for

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1775–1786,
Austin, Texas, November 1-5, 2016.

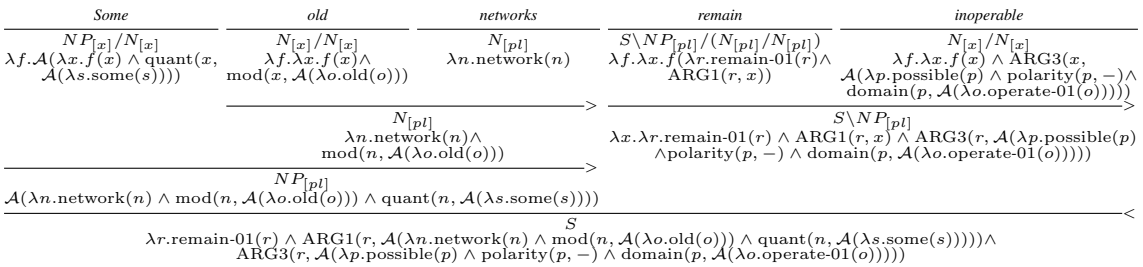

Figure 1: Example CCG tree with five lexical entries, three forward applications (>) and a backward application (<).

a significant number of training sentences. Therefore, we propose an iterative algorithm that automatically selects the best parses for training at each iteration, and identifies partial derivations for best-effort learning, if no parses are available.

CCG parsing largely relies on two types of actions: using a lexicon to map words to their categories, and combining categories to acquire the categories of larger phrases. In most semantic parsing approaches, the number of operations is dominated by the large number of categories available for each word in the lexicon. For example, the lexicon in our experiments includes 1.7M entries, resulting in an average of 146, and up to 2K, applicable actions. Additionally, both operations and parser state have complex structures, for example including both syntactic and semantic information. Therefore, unlike in dependency parsing (Chen and Manning, 2014), we can not treat action selection as multi-class classification, and must design an architecture that can accommodate a varying number of actions. We present a network architecture that considers a variable number of actions, and emphasizes low computational overhead per action, instead focusing computation on representing the parser state.

We evaluate on Abstract Meaning Representation (AMR; Banarescu et al., 2013) parsing. We demonstrate that our modeling and learning contributions are crucial to effectively commit to early decisions during parsing. Somewhat surprisingly, our shift-reduce parser provides equivalent performance to the CKY parser used to generate the training data, despite requiring significantly fewer operations, on average two orders of magnitude less. Similar to previous work, we use beam search, but also, for the first time, report greedy CCG semantic parsing results at a relatively modest 9% decrease in performance, while the source CKY parser with a beam of one demonstrates a 71% decrease. While we focus on semantic parsing, our learning approach makes no task-specific assumptions and has potential for learning efficient models for structured prediction from the output of more expensive ones.[1]

2 Task and Background

Our goal is to learn a function that, given a sentence x, maps it to a formal representation of its meaning z with a linear number of operations in the length of x. We assume access to a training set of N examples $\mathcal{D} = \{(x^{(i)}, z^{(i)})\}_{i=1}^{N}$, each containing a sentence $x^{(i)}$ and a logical form $z^{(i)}$. Since $\mathcal{D}$ does not contain complete derivations, we instead assume access to a CKY parser learned from the same data. We evaluate performance on a test set $\{(x^{(i)}, z^{(i)})\}_{i=1}^{M}$ of M sentences $x^{(i)}$ labeled with logical forms $z^{(i)}$. While we describe our approach in general terms, we apply our approach to AMR parsing and evaluate on a common benchmark (Section 6).

To map sentences to logical forms, we use CCG, a linguistically-motivated grammar formalism for modeling a wide-range of syntactic and semantic phenomena (Steedman, 1996, 2000). A CCG is defined by a lexicon Λ and sets of unary $\mathcal{R}_u$ and binary $\mathcal{R}_b$ rules. In CCG parse trees, each node is a category. Figure 1 shows a CCG tree for the sentence *Some old networks remain inoperable*. For example, $S\backslash NP_{[pl]}/(N_{[pl]}/N_{[pl]})$: $\lambda f.\lambda x.f(\lambda r.\text{remain-01}(r) \wedge \text{ARG1}(r, x))$ is the category of the verb *remain*. The syntactic type $S\backslash NP_{[pl]}/(N_{[pl]}/N_{[pl]})$ indicates that two arguments are expected: first an adjective $N_{[pl]}/N_{[pl]}$ and then a plural noun phrase $NP_{[pl]}$. The final syntactic type will be S. The forward slash / indicates the argument is expected on the right, and the backward slash \ indicates it is expected on the left. The syntactic attribute pl is used to express the plural-

[1]The source code and pre-trained models are available at `http://www.cs.cornell.edu/~dkm/ccgparser`.

ity constraint of the verb. The simply-typed lambda calculus logical form in the category represents semantic meaning. The typing system includes atomic types (e.g., entity e, truth value t) and functional types (e.g., $\langle e, t\rangle$ is the type of a function from e to t). In the example category above, the expression on the right of the colon is a $\langle\langle\langle e,t\rangle,\langle e,t\rangle\rangle,\langle e,\langle e,t\rangle\rangle\rangle$-typed function expecting first an adjectival modifier and then an ARG1 modifier. The conjunction $\wedge$ specifies the roles of remain-01. The lexicon Λ maps words to CCG categories. For example, the lexical entry $remain \vdash S\backslash NP_{[pl]}/(N_{[pl]}/N_{[pl]}) : \lambda f.\lambda x.f(\lambda r.\text{remain-01}(r) \wedge \text{ARG1}(r,x))$ pairs the example category with *remain*. The parse tree in the figure includes four binary operations: three forward applications ($>$) and a backward application ($<$).

3 Neural Shift Reduce Semantic Parsing

Given a sentence $x = \langle x_1, \ldots, x_m\rangle$ with m tokens x_i and a CCG lexicon Λ, let $\textsc{Gen}(x;\Lambda)$ be a function that generates CCG parse trees. We design GEN as a shift-reduce parser, and score decisions using embeddings of parser states and candidate actions.

3.1 Shift-Reduce Parsing for CCG

Shift-reduce parsers perform a single pass of the sentence from left to right to construct a parse tree. The parser configuration[2] is defined with a stack and a buffer. The stack contains partial parse trees, and the buffer the remainder of the sentence to be processed. Formally, a parser configuration c is a tuple $\langle\sigma,\beta\rangle$, where the stack σ is a list of CCG trees $[s_l \cdots s_1]$, and the buffer β is a list of tokens from x to be processed $[x_i \cdots x_m]$.[3] For example, the top-left of Figure 2 shows a parsing configuration with two partial trees on the stack and two words on the buffer (*remain* and *inoperable*).

Parsing starts with the configuration $\langle[], [x_1 \cdots x_m]\rangle$, where the stack is empty and the buffer is initialized with x. In each parsing step, the parser either consumes a word from the buffer and pushes a new tree to the stack, or applies a parsing rule to the trees at the top of the stack. For simplicity, we apply CCG rules to trees, where a rule is applied to the root categories of the argument trees to create a new tree with the arguments as children. We treat lexical entries as trees with a single node. There are three types of actions:[4]

$$\begin{aligned}
\textsc{Shift}(l, \langle\sigma, x_i|\cdots|x_j|\beta\rangle) &= \langle\sigma|g,\beta\rangle \\
\textsc{Binary}(b, \langle\sigma|s_2|s_1,\beta\rangle) &= \langle\sigma|b(s_2,s_1),\beta\rangle \\
\textsc{Unary}(u, \langle\sigma|s_1,\beta\rangle) &= \langle\sigma|u(s_1),\beta\rangle \quad .
\end{aligned}$$

Where $b \in \mathcal{R}_b$ is a binary rule, $u \in \mathcal{R}_u$ is a unary rule, and l is a lexical entry $x_i, \ldots x_j \vdash g$ for the tokens x_i,...,x_j and CCG category g. SHIFT creates a tree given a lexical entry for the words at the top of the buffer, BINARY applies a binary rule to the two trees at the head of the stack, and UNARY applies a unary rule to the tree at head of the stack. A configuration is terminal when no action is applicable.

Given a sentence x, a derivation is a sequence of action-configuration pairs $\langle\langle c_1, a_1\rangle, \ldots, \langle c_k, a_k\rangle\rangle$, where action a_i is applied to configuration c_i to generate configuration c_{i+1}. The result configuration c_{k+1} is of the form $\langle[s],[]\rangle$, where s represents a complete parse tree, and the logical form z at the root category represents the meaning of the complete sentence. Following previous work with CKY parsing (Zettlemoyer and Collins, 2005), we disallow consecutive unary actions. We denote the set of actions allowed from configuration c as $\mathcal{A}(c)$.

3.2 Model

Our goal is to balance computation and model capacity. To recover a rich representation of the configuration, we use a multilayer perceptron (MLP) to create expressive interactions between a small number of simple features. However, since we consider many possible actions in each step, computing activations for multiple hidden layers for each action is prohibitively expensive. Instead, we opt for a computationally-inexpensive action representation computed by concatenating feature embeddings. Figure 2 illustrates our architecture.

Given a configuration c, the probability of an action a is:

$$p(a \mid c) = \frac{\exp\{\phi(a,c)\mathbf{W}_b\mathcal{F}(\xi(c))\}}{\sum_{a'\in\mathcal{A}(c)}\exp\{\phi(a',c)\mathbf{W}_b\mathcal{F}(\xi(c))\}} \quad ,$$

[2] We use the terms *parser configuration* and *parser state* interchangeably.

[3] The head of the stack σ is the right-most entry, and the head of the buffer β is the left-most entry.

[4] We follow the standard notation of $L|x$ indicating a list with all the entries from L and x as the right-most element.

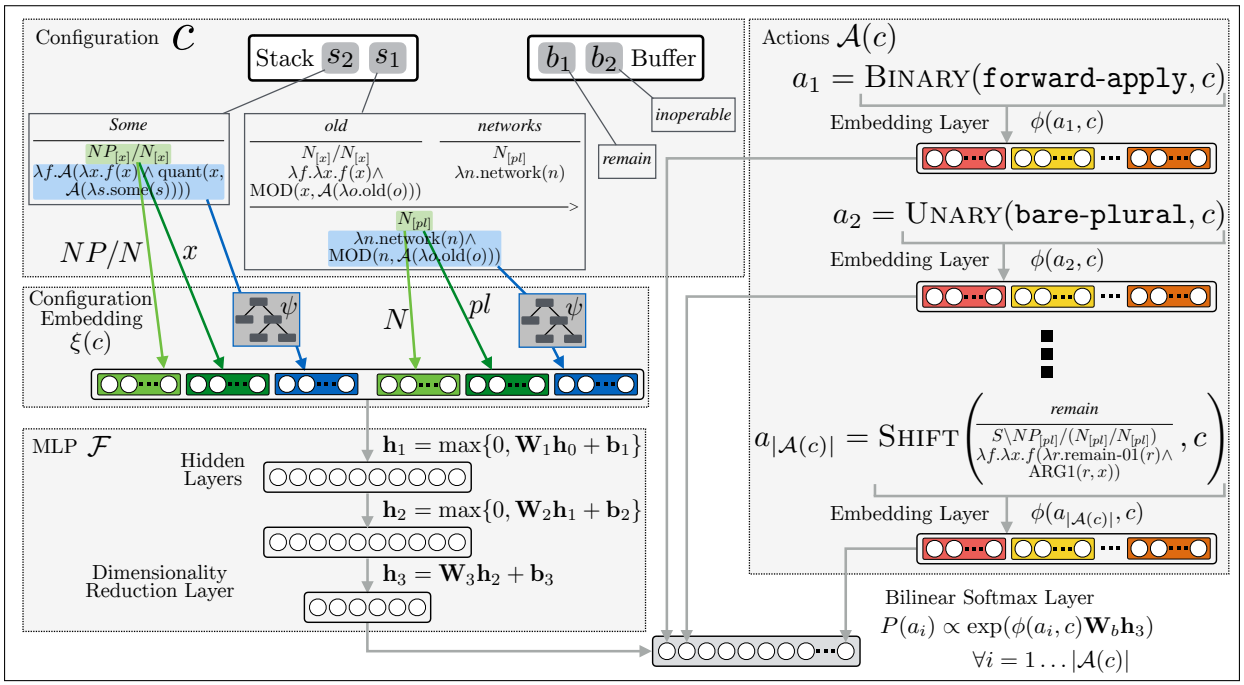

Figure 2: Illustration of scoring the next action given the configuration c when parsing the sentence *Some old networks remain inoperable*. Embeddings of the same feature type are colored the same. The configuration embedding $\xi(c)$ is a concatenation of syntax embeddings (green) and the logical form embedding (blue; computed by ψ) for the top entries in the stack. We then pass $\xi(c)$ through the MLP $\mathcal{F}$. Given the actions $\mathcal{A}(c)$, we compute the embeddings $\phi(a_i, c)$, $i = 1 \ldots |\mathcal{A}(c)|$. The actions and MLP representation are combined with a bilinear softmax layer. The number of concatenated vectors and stack elements used is for illustration. The details are described in Section 3.2.

where $\phi(a, c)$ is the action embedding, $\xi(c)$ is the configuration embedding, and $\mathcal{F}$ is an MLP. $\mathbf{W}_b$ is a bilinear transformation matrix. Given a sentence x and a sequence of action-configuration pairs $\langle\langle c_1, a_1\rangle, \ldots, \langle c_k, a_k\rangle\rangle$, the probability of a CCG tree y is

$$p(y \mid x) = \prod_{i=1\ldots k} p(a_i \mid c_i) \ .$$

The probability of a logical form z is then

$$p(z \mid x) = \sum_{y \in \mathcal{Y}(z)} p(y \mid x) \ ,$$

where $\mathcal{Y}(z)$ is the set of CCG trees with the logical form z at the root.

MLP Architecture $\mathcal{F}$ We use a MLP with two hidden layers parameterized by $\{\mathbf{W}_1, \mathbf{W}_2, \mathbf{b}_1, \mathbf{b}_2\}$ with a ReLu non-linearity (Glorot et al., 2011). Since the output of $\mathcal{F}$ influences the dimensionality of $\mathbf{W}_b$, we add a linear layer parameterized by $\mathbf{W}_3$ and $\mathbf{b}_3$ to reduce the dimensionality of the configuration, thereby reducing the dimensionality of $\mathbf{W}_b$.

Configuration Embedding $\xi(c)$ Given a configuration $c = \langle[s_l \cdots s_1], [x_i \cdots x_m]\rangle$, the input to $\mathcal{F}$ is a concatenation of syntactic and semantic embeddings, as illustrated in Figure 2. We concatenate embeddings from the top three trees in the stack s_1, s_2, s_3.[5] When a feature is not present, for example when the stack or buffer are too small, we use a tunable null embedding.

Given a tree on the stack s_j, we define two syntactic features: *attribute set* and *stripped syntax*. The attribute feature is created by extracting all the syntactic attributes of the root category of s_j. The stripped syntax feature is the syntax of the root category without the syntactic attributes. For example, in Figure 2, we embed the stripped category N and attribute pl for s_1, and NP/N and x for s_2. The attributes are separated from the syntax to reduce sparsity, and the interaction between them is computed by $\mathcal{F}$. The sparse features are converted to dense embeddings using a lookup table and concatenated. In addition, we also embed the logical form at the root of s_j. Figure 3 illustrates the recursive embedding function ψ.[6] Using a recursive function to embed logical forms is computationally intensive. Due to strong correlation between sentence length and logical form complexity, this computation increases

[5] For simplicity, the figure shows only the top two trees.

[6] The algorithm is provided in the supplementary material.

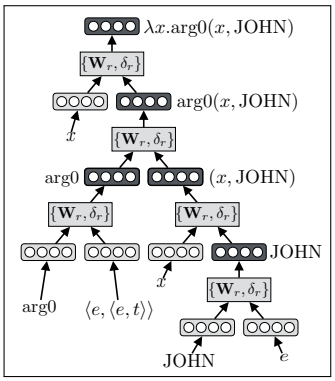

Figure 3: Illustration of embedding the logical form $\lambda x.\text{arg0}(x, \text{JOHN})$ with the recursive embedding function ψ. In each level in ψ, the children nodes are combined with a single-layer neural network parameterized by $\mathbf{W}_r$, δ_r, and the $\tanh$ activation function. Computed embeddings are in dark gray, and embeddings from lookup tables are in light gray. Constants are embedded by combining name and type embeddings, literals are unrolled to binary recursive structures, and lambda terms are combinations of variable type and body embeddings. For example, JOHN is embedded by combining the embeddings of its name and type, the literal $\text{arg0}(x, \text{JOHN})$ is recursively embedded by first embedding the arguments (x, JOHN) and then combining the predicate, and the lambda term is embedded to create the embedding of the entire logical form.

the cost of configuration embedding by a factor linear in sentence length. In Section 6, we experiment with including this option, balancing between potential expressivity and speed.

Action Embedding $\phi(a, c)$ Given an action $a \in \mathcal{A}(c)$, and the configuration c, we generate the action representation by computing sparse features, converting them to dense embeddings via table lookup, and concatenating. If more than one feature of the same type is triggered, we average their embeddings. When no features of a given type are triggered, we use a tunable placeholder embedding instead. The features include all the features used by Artzi et al. (2015), including all conjunctive features, as well as properties of the action and configuration, such as the POS tags of tokens on the buffer.[7]

Discussion Our use of an MLP is inspired by Chen and Manning (2014). However, their architecture is designed to handle only a fixed number of actions, while we observe varying number of actions. Therefore, we adopt a probabilistic model similar to Dyer et al. (2015) to effectively combine the benefits of the two approaches.[8] We factorize the exponent in our objective into action $\phi(a, c)$ and configuration $\mathcal{F}(\xi(c))$ embeddings. While every parse step involves a single configuration, the number of actions is significantly higher. With the goal of minimizing the amount of computation per action, we use simple concatenation only for action embedding. However, this requires retaining sparse conjunctive action features since they are never combined through hidden layers similar to configuration features.

3.3 Inference

To compute the set of parse trees $\textsc{Gen}(x; \Lambda)$, we perform beam search to recover the top-k parses. The beam contains configurations. At each step, we expand all configurations with all actions, and keep only the top-k new configurations. To promote diversity in the beam, given two configurations with the same *signature*, we keep only the highest scoring one. The signature includes the previous configuration in the derivation, the state of the buffer, and the root categories of all stack elements. Since all features are computed from these elements, this optimization does not affect the max-scoring tree. Additionally, since words are assigned structured categories, a key problem is unknown words or word uses. Following Zettlemoyer and Collins (2007), we use a two-pass parsing strategy, and allow skipping words controlled by the term γ in the second pass. The term γ is added to the exponent of the action probability when words are skipped. See the supplementary material for the exact form.

Complexity Analysis The shift-reduce parser processes the sentence from left to right with a linear number of operations in sentence length. We define an operation as applying an action to a configuration. Formally, the number of operations for a sentence of length m is bounded by $O(4mk(|\lambda| + |\mathcal{R}_b| + |\mathcal{R}_u|))$, where $|\lambda|$ is the number of lexical entries per token, k is the beam size, $\mathcal{R}_b$ is the set of binary rules, and $\mathcal{R}_u$ the set of unary rules. In comparison, the number of operations for the CKY parser, where an operation is applying a rule to a single cell or two adjacent cells in the chart, is bounded by $O(m|\lambda| + m^3k^2|\mathcal{R}_b| + m^2b|\mathcal{R}_u|)$. For sentence

[7] See the supplementary material for feature details.

[8] We experimented with an LSTM parser similar to Dyer et al. (2015). However, performance was not competitive. This direction remains an important avenue for future work.

length 25, the mean in our experiments, the shift-reduce parser performs 100 time fewer operations. See the supplementary material for the full analysis.

4 Learning

We assume access to a training set of N examples $\mathcal{D} = \{(x^{(i)}, z^{(i)})\}_{i=1}^{N}$, each containing a sentence $x^{(i)}$ and a logical form $z^{(i)}$. The data does not include information about the lexical entries and CCG parsing operations required to construct the correct derivations. We bootstrap this information from a learned parser. In our experiments we use a learned dynamic-programming CKY parser. We transfer the lexicon Λ directly from the input parser, and focus on estimating the parameters θ, which include feature embeddings, hidden layer matrices, and bias terms. The main challenge is learning from the noisy supervision provided by the input parser. In our experiments, the CKY parser fails to correctly parse 40% of the training data, and returns on average 147 max-scoring correct derivations for the rest. We propose an iterative algorithm that treats the choice between multiple parse trees as latent, and effectively learns from partial analysis when no correct derivation is available.

The learning algorithm (Algorithm 1) starts by processing the data using the CKY parser (lines 3 - 4). For each sentence $x^{(i)}$, we collect the max-scoring CCG trees with $z^{(i)}$ at the root. The CKY parser often contains many correct parses with identical scores, up to 49K parses per sentence. Therefore, we randomly sample and keep up to 1K trees. This process is done once, and the algorithm then runs for T iterations. At each iteration, given the sets of parses from the CKY parser $\mathcal{Y}$, we select the max-probability parse according to our current parameters θ (line 10) and add all the shift-reduce decisions from this parse to $\mathcal{D}_A$ (line 12), the action data set that we use to estimate the parameters. We approximate the $\arg\max$ with beam search using an oracle computed from the CKY parses.[9] CONFGEN aggregates the configuration-action pairs from the highest scoring derivation. Parse selection depends on θ and this choice will gradually converge as the parameters improve. The action data set is used to compute the ℓ_2-regularized negative log-likelihood objective

[9] Our oracle is non-deterministic and incomplete (Goldberg and Nivre, 2013).

Algorithm 1 The learning algorithm.

Input: Training set $\mathcal{D} = \{(x^{(i)}, z^{(i)})\}_{i=1}^{N}$, learning rate μ, regularization parameter ℓ_2, and number of iterations T.

Definitions: GENMAXCKY(x, z) returns the set of max-scoring CKY parses for x with z at the root. SCORE(y, θ) scores a tree y according to the parameters θ (Section 3.2). CONFGEN(x, y) is the sequence of action-configuration pairs that generates y given x (Section 3.1). BP$(\Delta_{\mathcal{J}})$ takes the objective $\mathcal{J}$ and back-propagates the error $\nabla\mathcal{J}$ through the computation graph for the sample used to compute the objective. ADAGRAD(Δ) applies a per-feature learning rate to the gradient Δ (Duchi et al., 2011).

Output: Model parameters θ.

```
1:  » Get trees from CKY parser.
2:  Y ← []
3:  for i = 1 to N do
4:      Y[i] = GENMAXCKY(x^(i), z^(i))
5:  for t = 1 to T do
6:      » Pick max-scoring trees and create action dataset.
7:      D_A = ∅
8:      for i = 1 to N do
9:          if Y[i] ≠ ∅ then
10:             A ← CONFGEN(x^(i),
11:                     arg max_{y∈Y[i]} SCORE(y, θ))
12:             for ⟨c, a⟩ ∈ A do
13:                 D_A ← D_A ∪ {⟨c, a⟩}
14:     » Back-propagate the loss through the network.
15:     for ⟨c, a⟩ ∈ D_A do
16:         J =def − log p(a | c) + (ℓ2/2) θ^T θ
17:         Δ ← BP(∇J)
18:         θ ← θ − μ ADAGRAD(Δ)
19: return θ
```

$\mathcal{J}$ (line 16) and back-propagate the error to compute the gradient (line 17). We use AdaGrad (Duchi et al., 2011) to update the parameters θ (line 18).

4.1 Learning from Partial Derivations

The input parser often fails to generate correct parses. In our experiments, this occurs for 40% of the training data. In such cases, we can obtain a forest of partial parse trees $\mathcal{Y}_p$. Each partial tree $y \in \mathcal{Y}_p$ corresponds to a span of tokens in the sentence and is scored by the input parser. In practice, the spans are often overlapping. Our goal is to generate high quality configuration-action pairs $\langle c, a \rangle$ from $\mathcal{Y}_p$. These pairs will be added to $\mathcal{D}_A$ for training. While extracting actions a is straightforward, generating configurations c requires reconstructing the stack σ from an incomplete forest of partial trees $\mathcal{Y}_p$. Figure 4 illustrates our proposed process. Let CKYSCORE(y) be the CKY score of the partial tree y. To reconstruct σ, we select non-overlapping par-

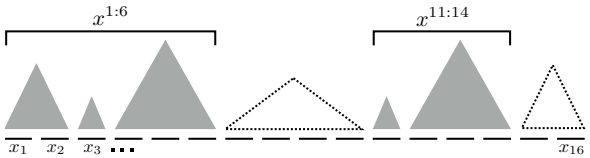

Figure 4: Partial derivation selection for learning (Section 4.1). The dotted triangles represent skipped spans in the sentence, where no high quality partial trees were found. Dark triangles represent the selected partial trees. We identify two contiguous spans, 1-6 and 11-14, and generate two synthetic sentences for training: the tokens are treated as complete sentences and actions and stack state are generated from the partial trees.

tial trees Y that correspond to the entire sentence by solving $\arg\max_{Y \subseteq \mathcal{Y}_p} \text{CKYSCORE}(y)$ under two constraints: (a) no two trees from Y correspond to overlapping tokens, and (b) for each token in x, there exists $y \in Y$ that corresponds to it. We solve the $\arg\max$ using dynamic programming. The generated set Y approximates an intermediate state of a shift-reduce derivation. However, $\mathcal{Y}_p$ often does not contain high quality partial derivation for all spans. To skip low quality partial trees and spans that have no trees, we generate empty trees y_e for every span, where $\text{CKYSCORE}(y_e) = 0$, and add them to $\mathcal{Y}_p$. If the set of selected partial trees Y includes empty trees, we divide the sentence to separate examples and ignore these parts. This results in partial and approximate stack reconstruction. Finally, since $\mathcal{Y}_P$ is noisy, we prune from it partial trees with a root that does not match the syntactic type for this span from an automatically generated CCGBank (Hockenmaier and Steedman, 2007) syntactic parse.

Our complete learning algorithm alternates between epochs of learning with complete parse trees and learning with partial derivations. In epochs where we use partial derivations, we use a modified version of Algorithm 1, where lines 9-10 are updated to use the above process.

5 Related work

Our approach is inspired by recent results in dependency parsing, specifically by the architecture of Chen and Manning (2014), which was further developed by Weiss et al. (2015) and Andor et al. (2016). Dyer et al. (2015) proposed to encode the parser state using an LSTM recurrent architecture, which has been shown generalize well between languages (Ballesteros et al., 2015; Ammar et al., 2016). Our network architecture combines ideas from the two threads: we use feature embeddings and a simple MLP to score actions, while our probability distribution is similar to the LSTM parser.

The majority of CCG approaches for semantic parsing rely on CKY parsing with beam search (e.g., Zettlemoyer and Collins, 2005, 2007; Kwiatkowski et al., 2010, 2011; Artzi and Zettlemoyer, 2011, 2013; Artzi et al., 2014; Matuszek et al., 2012; Kushman and Barzilay, 2013). Semantic parsing with other formalisms also often relied on CKY-style algorithms (e.g., Liang et al., 2009; Kim and Mooney, 2012). With a similar goal to ours, Berant and Liang (2015) designed an agenda-based parser. In contrast, we focus on a method with linear number of operations guarantee.

Following the work of Collins and Roark (2004) on learning for syntactic parsers, Artzi et al. (2015) proposed an early update procedure for inducing CCG grammars with a CKY parser. Our partial derivations learning method generalizes this method to parsers with global features.

6 Experimental Setup

Task and Data We evaluate on AMR parsing with CCG. AMR is a general-purpose meaning representation, which has been used in multiple tasks (Pan et al., 2015; Liu et al., 2015; Sawai et al., 2015; Garg et al., 2016), We use the newswire portion of AMR Bank 1.0 release (LDC2014T12), which displays some of the fundamental challenges in semantic parsing, including long newswire sentences with a broad array of syntactic and semantic phenomena. We follow the standard train/dev/test split of 6603/826/823 sentences. We evaluate with the SMATCH metric (Cai and Knight, 2013). Our parser is incorporated into the two-stage approach of Artzi et al. (2015). The approach includes a bi-directional and deterministic conversion between AMR and lambda calculus. Distant references, for example such as introduced by pronouns, are represented using Skolem IDs, globally-scoped existentially-quantified unique IDs. A derivation includes a CCG tree, which maps the sentence to an *underspecified logical form*, and a constant mapping, which maps underspecified elements to their fully specified form. The key to the approach is the underspecified logical forms, where distant references and most relations are not fully specified, but instead represented

AMR	Underspecified Logical Form	Logical Form
$(c/\text{conclude-02}$	$\mathcal{A}_1(\lambda c.\text{conclude-02}(c) \wedge$	$\mathcal{A}_1(\lambda c.\text{conclude-02}(c) \wedge$
:ARG0 (l/lawyer)	$\text{ARG0}(c, \mathcal{A}_2(\lambda l.\text{lawyer}(l))) \wedge$	$\text{ARG0}(c, \mathcal{A}_2(\lambda l.\text{lawyer}(l))) \wedge$
:ARG1 $(a/\text{argument}$	$\text{ARG1}(c, \mathcal{A}_3(\lambda a.\text{argument}(a) \wedge$	$\text{ARG1}(c, \mathcal{A}_3(\lambda a.\text{argument}(a) \wedge$
:poss $l)$	$\text{poss}(a, \mathcal{R}(\textbf{ID}))))) \wedge$	$\text{poss}(a, \mathcal{R}(2)))) \wedge$
:time $(l2/late))$	$\textbf{REL}(c, \mathcal{A}_4(\lambda l2.late(l2))))$	$\text{time}(c, \mathcal{A}_4(\lambda l2.late(l2))))$

Figure 5: AMR for the sentence *the lawyer concluded his arguments late*. In Artzi et al. (2015), The AMR (left) is deterministically converted to the logical form (right). The underspecified logical form is the result of the first stage, CCG parsing, and contains two placeholders (bolded): ID for a reference, and REL for a relation. To generate the final logical form, the second stage resolves ID to the identifier of the *lawyer* (2), and REL to the relation time. We focus on a model for the first stage and use an existing model for the second stage.

as placeholders. Figure 5 shows an example AMR, its lambda calculus conversion, and its underspecified logical form. (Artzi et al., 2015) use a CKY parser to identify the best CCG tree, and a factor graph for the second stage. We integrate our shift-reduce parser into the two-stage setup by replacing the CKY parser. We use the same CCG configuration and integrate our parser into the join probabilistic model. Formally, given a sentence x, the probability of an AMR logical form z is

$$p(z \mid x) = \sum_u p(z \mid u, x) \sum_{y \in \mathcal{Y}(u)} p(y \mid x) \ ,$$

where u is an underspecified logical form, $\mathcal{Y}(u)$ is the set of CCG trees with u at the root. We use our shift-reduce parser to compute $p(y \mid x)$ and use the pre-trained model from Artzi et al. (2015) for $p(z \mid u, x)$. Following Artzi et al. (2015), we disallow configurations that will not result in a valid AMR, and design a heuristic post-processing technique to recover a single logical form from terminal configurations that include multiple disconnected partial trees on the stack. We use the recovery technique when no complete parses are available.

Tools We evaluate with the SMATCH metric (Cai and Knight, 2013). We use EasyCCG (Lewis and Steedman, 2014) for CCGBank categories (Section 4.1). We implement our system using Cornell SPF (Artzi, 2016), and the deeplearning4j library.[10] The setup of Artzi et al. (2015) also includes the Illinois NER (Ratinov and Roth, 2009) and Stanford CoreNLP POS Tagger (Manning et al., 2014).

Parameters and Initialization We minimize our loss on a held-out 10% of the training data to tune our parameters, and train the final model on the full data. We set the number of epochs $T = 3$, regularization coefficient $\ell_2 = 10^{-6}$, learning rate $\mu = 0.05$, skipping term $\gamma = 1.0$. We set the dimensionality of feature embeddings based on the vocabulary size of the feature type. The exact dimensions are listed in the supplementary material. We use 65 ReLU units for $\mathbf{h}_1$ and $\mathbf{h}_2$, and 50 units for $\mathbf{h}_3$. We initialize θ with the initialization scheme of Glorot and Bengio (2010), except the bias term for ReLu layers, which we initialize to 0.1 to increase the number of active units on initialization. During test, we use the vector $\mathbf{0}$ as embedding for unseen features. We use a beam of 512 for testing and 2 for CONFGEN (Section 4).

Table 2: Test SMATCH results.[12]

Model Ensemble For our final results, we marginalize the output over three models $\mathcal{M}$ using $p(z \mid x, \theta, \Lambda) = \frac{1}{|M|} \sum_{m \in \mathcal{M}} p(z \mid m, x, \theta, \Lambda)$.

7 Results

Table 1 shows development results. We trained each model three times and report the best performance. We observed a variance of roughly 0.5 in these runs. We experimented with different features for configuration embedding and with removing learning with partial derivations (Section 4.1). The com-

plete model gives the best single-model performance of 65.3 F1 SMATCH, and we observe the benefits for semantic embeddings and learning from partial derivations. Using partial derivations allowed us to learn 370K more features, 22% of observed embeddings. We also evaluate ensemble performance. We observe an overall improvement in performance. However, with multiple models, the benefit of using semantic embeddings vanishes. This result is encouraging since semantic embeddings can be expensive to compute if the logical form grows with sentence length. We also provide results for running a shift-reduce log-linear parser $p(a \mid c) \propto \exp\{\mathbf{w}^T \phi_{\text{CKY}}(a, c)\}$ using the input CKY model. We observe a significant drop in performance, which demonstrates the overall benefit of our architecture.

Figure 6 shows the development performance of our best performing ensemble model for different beam sizes. The performance decays slowly with decreasing beam size. Surprisingly, our greedy parser achieves 59.77 SMATCH F1, while the CKY parser with a beam of 1 achieves only 19.2 SMATCH F1 (Table 1). This allows our parser to trade-off a modest drop in accuracy for a significant improvement in runtime.

Table 2 shows the test results using our best performing model (ensemble with syntax features). We compare our approach to the CKY parser of Artzi et al. (2015) and JAMR (Flanigan et al., 2014).[11,12] We also list the results of Wang et al. (2015b), who demonstrated the benefit of auxiliary analyzers and is the current state of the art.[13] Our performance is comparable to the CKY parser of (Artzi et al., 2015), which we use to bootstrap our system. This demonstrates the ability of our parser to match the performance of a dynamic-programming parser, which executes significantly more operations per sentence.

Finally, Figure 7 shows our parser runtime relative to sentence length. In this analysis, we focus on runtime, and therefore use a single model.

[11] JAMR results are taken from Artzi et al. (2015).

[12] Pust et al. (2015), Flanigan et al. (2014), and Wang et al. (2015b) report results on different sections of the corpus. These results are not comparable to ours.

[13] Our goal is to study the effectiveness of our model transfer approach and architecture. Therefore, we avoid using any resources used in (Wang et al., 2015b) that are not used in the CKY parser we compare to.

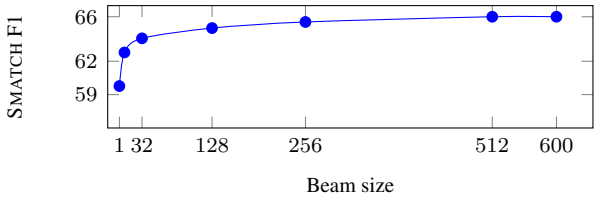

Figure 6: The effect of beam size on model performance.

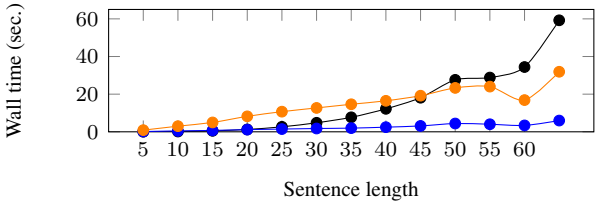

Figure 7: Wall-time performance of shift reduce parser with only syntax features (blue), with syntax and semantic features (orange) and the CKY parser of Artzi et al. (2015) (black).

We compare two versions of our system, including and excluding semantic embeddings, and the CKY parser of Artzi et al. (2015). We run both parsers with 16 cores and 122GB memory. The shift-reduce parser is three times faster on average, and up to ten times faster on long sentences. Since our parser is currently using CPUs, future work focused on GPU porting is likely to see further improvements.

8 Conclusion

Our parser design emphasizes a balance between model capacity and the ability to combine atomic features against the computational cost of scoring actions. We also design a learning algorithm to transfer learned models and learn neural network models from ambiguous and partial supervision. Our model shares many commonalities with transition-based dependency parsers. This makes it a good starting point to study the effectiveness of other dependency parsing techniques for semantic parsing, for example global normalization (Andor et al., 2016) and bidirectional LSTM feature representations (Kiperwasser and Goldberg, 2016).

Syntactic Parsing of Web Queries

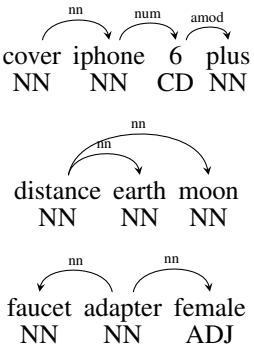
Abstract

Syntactic parsing of web queries is important for query understanding. However, web queries usually do not observe the grammar of a written language, and no labeled syntactic trees for web queries are available. In this paper, we focus on a query's clicked sentence, i.e., a well-formed sentence that i) contains all the tokens of the query, and ii) appears in the query's top clicked web pages. We argue such sentences are semantically consistent with the query. We introduce algorithms to derive a query's syntactic structure from the dependency trees of its clicked sentences. This gives us a web query treebank without manual labeling. We then train a dependency parser on the treebank. Our model achieves much better UAS (0.86) and LAS (0.80) scores than state-of-the-art parsers on web queries.

1 Introduction

Syntactic analysis is important in understanding a sentence's grammatical constituents, parts of speech, syntactic relations, and semantics. In this paper, we are concerned with the syntactic structure of a short text. The challenge is that short texts, for example, web queries, do not observe grammars of written languages (e.g., users often overlook capitalization, function words, and word order when creating a web query), and applying parsers trained on standard treebanks on queries leads to poor results.

Syntactic structures are valuable for query understanding. Consider the following web queries and their syntactic structures we would like to construct:



The syntactic structure of query `cover iphone 6 plus` tells us that the head token is `cover`, indicating its intent is to shop for the cover of an iphone, instead of iphones. With this knowledge, search engines show ads of iphone covers instead of iphones. For `distance earth moon`, the head is `distance`, indicating its intent is to find the distance between the earth and the moon. For `faucet adapter female`, the intent is to find a female faucet adapter. In summary, correctly identifying the head of a query helps identify its intent, and correctly identifying the modifiers helps rewrite the query (e.g., dropping non-essential modifiers).

Syntactic parsing of web queries is challenging for at least two reasons. First, grammatical signals from function words and word order are not available. Query `distance earth moon` is missing function words *between* (preposition), *and* (coordinator), and *the* (determiner) in conveying the intent

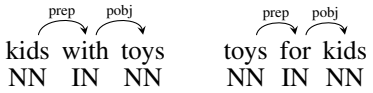
distance between the earth and the moon. Also, it is likely that queries {`distance earth moon`, `earth moon distance`, `earth distance moon`, $\cdots$} have the same intent, which means they should have the same syntactic structure. Second, there is no labeled dependency trees (treebank) for web queries, nor is there a standard for constructing such dependency trees. It will take a tremendous amount of time and effort to come up with such a standard and a treebank for web queries.

In this paper, we propose an end-to-end solution from treebank construction to syntactic parsing for web queries. Our model achieves a UAS of 0.830 and an LAS of 0.747 on web queries, which is dramatic improvement over state-of-the-art parsers trained from standard treebanks.

2 Our Approach

The biggest challenge of syntactic analysis of web queries is that they do not contain sufficient grammatical signals required for parsing. Indeed, web queries can be very ambiguious. For example, `kids toys` may mean either `toys for kids` or `kids with toys`, for which the dependency relationships between `toys` and `kids` are totally opposite.

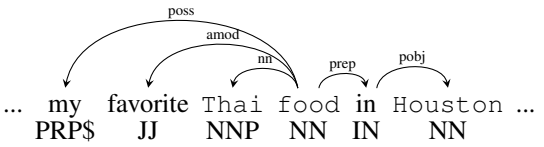


In view of this, why is syntactic parsing of web queries a legitimate problem? We have shown some example syntactic structures for 3 queries in Section 1. How do we know they are the correct syntactic structures for the queries? We answer these questions here.

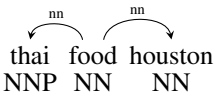
2.1 Derive syntax from semantics

In many cases, humans can easily determine the syntax of a web query because its intent is easy to understand. For example, for `toys kids`, we are pretty sure as a web query, its intent is to look for toys for kids, instead of the other way around. Thus, `toys` should be the head of the query, and `kids` should be its modifier. In other words, when the semantics of a query is understood, we can often recover its syntax.

We may then manually annotate web queries. Specifically, given a query, a human annotator forms a sentence that is consistent with the meaning he comes up for the query. Then, from the sentence's syntactic structure (which is well understood and can be derived by a parser), the annotator derives the syntactic structure of the query. For example, for query `thai food houston`, the annotator may formulate the following sentence:



Then we may project the dependency tree of the sentence to the query:



The above approach has two issues. First, `food` and `houston` are not directly connected in the dependency tree of the sentence. We connected them in the query, but in general, it is not trivial to infer synatx of the query from sentences in a consistent way. There is no linguistic standard for doing this. Second, annotation is very costly. A treebank project takes years to accomplish.

2.2 Semantics of a web query

To avoid human annotation, we derive syntactic understanding of the query from semantic understanding of the query. Our goal is to decide for any two tokens $x, y \in q$, whether there is a dependency arc between x and y, and if yes, what the dependency is.

Context-free signals. One approach to determine the dependency between x and y is to directly model $P(e|x, y)$, where e denotes the dependency ($x \rightarrow y$ or $x \leftarrow y$). It is context-free because we do not condition on the query where x and y appear in.

To acquire $P(e|x, y)$, we may consider annotated corpora such as Google's syntactic ngram (Goldberg and Orwant, 2013). For any x and y, we count the number of times that x is a dependent of y in the corpus. One disadvantage of this approach is that web queries and normal text differ significantly in distribution. Another approach (Wang et al., 2014) is to use search log to estimate $P(e|x, y)$, where x and y are nouns. Specifically, we find queries of pattern x PREP y, where PREP is a preposition {of, in, for, at, on, with, $\cdots$}. We have $P(x \rightarrow y|x, y) =$

$\frac{n_{x,y}}{n_{x,y}+n_{y,x}}$ where $n_{x,y}$ denotes the number of times pattern x PREP y appears in the search log. The disadvantage is that the simple pattern only gives dependency between two nouns.

Context-sensitive signals. The context-free approach has two major weaknesses: (1) It is risky to decide the dependency between two tokens without considering the context. (2) Context-free signals do not reveal the type of dependency, that is, it does not reveal the linguistic relationship between the head and the modifier.

To take context into consideration, which means estimating $P(e|x, y, q)$ for any two tokens $x, y \in q$, we are looking at the problem of building a parser for web queries. This requires a training dataset (a treebank). In this work, we propose to automatically create such a treebank. The feasibility is centered on the following assumption: The intent of q is contained in or consistent with the semantics of its **clicked sentences**. We call sentence s a clicked sentence of q if i) s appears in a top clicked page for q, and ii) s contains all tokens in q. For instance, assume sentence $s =$ "`... my favorite Thai food in Houston ...`" appears in one of the most frequently clicked pages for query $q =$ `thai food houston`, then s is a clicked sentence of q. It follows from the above assumption that the dependency between any two tokens in q are likely to be the same as the dependency between their corresponding tokens in s. This allows to create a treebank if we can project the dependency from sentences to queries. However, since x and y may not be directly connected by a dependency edge in s, we need a method to derive the dependency between $x, y \in q$ from the (indirect) dependency between $x, y \in s$. We propose such a method in Section 3.

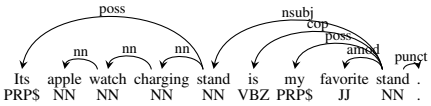
3 Treebank for Web Queries

We create a web query treebank by projecting dependency from clicked sentences to queries.

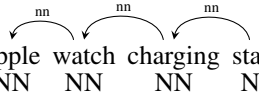
3.1 Inferring a dependency tree

A query q may have multiple clicked sentences. We describe here how we project dependency to q from such a sentence s. We describe how we aggregate dependencies from multiple sentences in Sec 3.2.

Under our assumption, each token $x \in q$ must appear in sentence s. But x may appear multiple times in s (especially when x is a function word). As an example, for query `apple watch stand`, we may get the following sentence:



Sentence s contains token `stand` twice, but only one subtree contains each token in q exactly once.



We use the following heuristics to derive a dependency tree for query q from sentence s.

1. Let T_s denote all the subtrees of the dependency tree of s.
2. Find the minimum subtree $t \in T_s$ such that each $x \in q$ has one and only one match $x' \in t$.
3. Derive dependency tree $t_{q,s}$ for q from t as follows. For any two tokens x and y in q:
   (a) if there is an edge from x' to y' in t, we create a same edge from x to y in $t_{q,s}$.
   (b) if there is a path[1] from x' to y' in t, we create an edge from x to y in $t_{q,s}$, and label it temporarily as *dep*.

We note the following. First, we argue that if the dependency tree of s has a subtree that contains each token in q once and only once, then it is very likely that the subtree expresses the same semantics as the query. On the other hand, if we cannot find such a subtree, it is an indication that we cannot derive reasonable dependency information from the sentence.

Second, it's possible x' and y' are not connected directly in s but through one or more other tokens. Thus, we do not know the label of the derived edge. We will decide on the label in Sec 3.3.

Third, we want to know whether it is meaningful to connect x and y in q while x' and y' are not directly connected in s. We evaluated a few hundreds

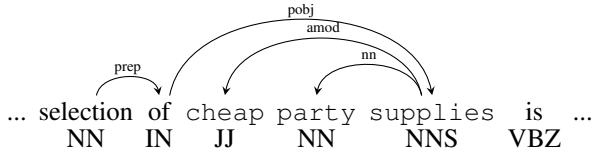
[1] A path consists of edges of the same direction.

of query-sentence pairs. Among the cases where dependency trees for queries can be derived successfully, we found that x' and y' are connected in 5 possible ways (Table 1). We describe them in details next.

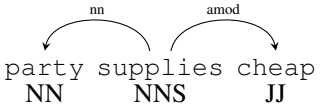
directly connected	46%
connected via function words	24%
connected via modifiers	24%
connected via a head noun	4%
connected via a verb	2%

Table 1: Dependency Projection

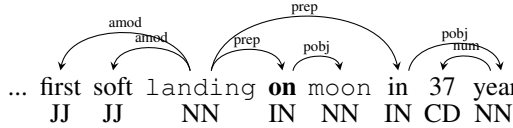
Directly connected. In this case, we copy the edge and its label directly. Consider query `party supplies cheap`'s clicked sentence below:



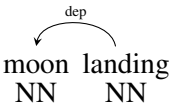
Here both (`party`, `supplies`) and (`supplies`, `cheap`) are directly connected. The query inherits the dependencies, but note that tokens `supplies` and `cheap` have different word orders in q and s:



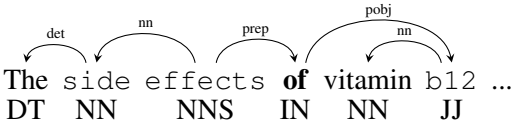
Connected via function words. It is quite common prepositions are omitted in a query. Consider query `moon landing`'s clicked sentence:



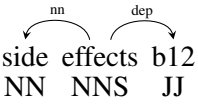
We can derive the following dependency tree:



For query `side effects b12`, suppose we have the following sentence:



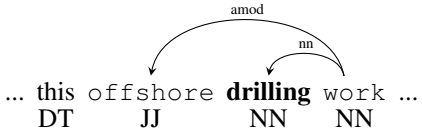
The derived dependency tree should be:



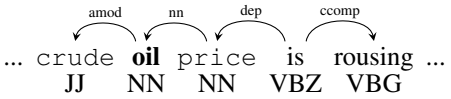
For these two cases, we need to introduce a derived edge for the query, which will be resolved later to a specific dependency label.

Connected via modifiers. Many web queries are noun compounds. Their clicked sentences may have more modifiers. Depending on the bracketing, we may or may not have direct dependencies.

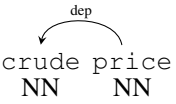
For `offshore work` and its clicked sentence below, missing `drilling` in the query does not cause any problem: `offshore` and `work` are still directly connected in the dependency tree.



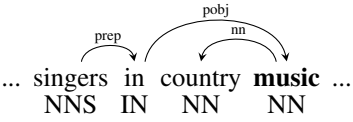
But not for `crude price` and its clicked sentence. Still, there is a path: `crude` ← `oil` ← `price`.



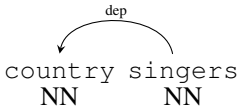
In this case, we create a dependency between `crude` and `oil` in the query and give it a temporary label *dep*. We will resolve it to a specific label later.



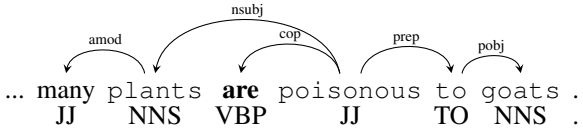
Connected via a head noun. In some cases, the head of a noun compound is missing. Consider `country singers` and its clicked sentence:



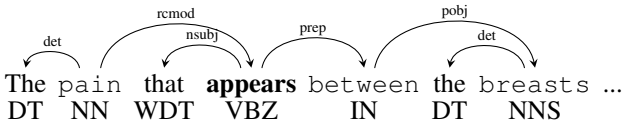
Clearly they mean the same thing, but the head (`music`) of the noun compound is missing in the query. Still, a path exists from `singers` to `country`, and we create a dependency:



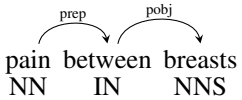
Connected via a verb. One common case is the omission of copular verbs. Consider `plants poisonous to goats` and its clicked sentence:



Here, the missing `are` does not cause any problem. But for query `pain between breasts` and its clicked sentence:



we need to introduce a derived edge, and it leads to:



3.2 Inferring a unique dependency tree

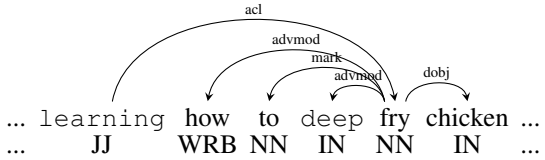
A query corresponds to multiple clicked sentences. From each sentence, we derive a dependency tree. These dependency trees may not be the same, because i) dependency parsing for sentences is not perfect; ii) queries are ambiguous; or iii) some queries do not have well-formed clicked sentences.

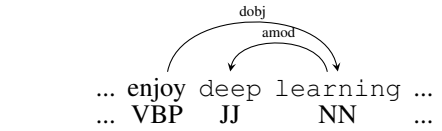
To choose a unique dependency tree for a query q, we define a scoring function f to measure the quality of a dependency tree t_q derived from q's clicked sentence s:

$$f(t_q, s) = \sum_{(x \to y) \in t_q} -\alpha dist(x, y) + \log \frac{count(x \to y)}{count(x \leftarrow y)} \quad (1)$$

where $(x \to y)$ is an edge in the tree t_q, $count(x \to y)$ is the occurrence count of the edge $x \to y$ in the entire query dataset, $dist(x, y)$ is the distance of words x and y on the original sentence parsing tree, and α is a parameter to adjust the importance between the two measures (its value is empirically determined).

The first term of the scoring function measures the *compactness* of the query tree. Consider two clicked sentences for query `deep learning`:





In the first sentence, `deep` and `learning` are indirectly connected through `fry` so the total distance measure is 2. In the second query, the distance is 1. Therefore, query aligned with the second sentence is better than the first sentence.

The second term of the scoring function measures the *global consistency* among head modifier directions. For a word pair (x, y), if in the dataset, the number of edges $x \to y$ dominates the number of edges $x \leftarrow y$, then the latter is likely to be incorrect.

One important thing to note is word order. Word order may influence the head-modifier relations between two words. For example, `child of` and `of child` should definitely have different head-modifier relations. Therefore, we treat two words of different order as two different word pairs.

Table 2 shows some examples of conflicting dependency edges and their corresponding occurrence count in queries and sentences.

Correct	Wrong	Query	Sentence
side ← effects	side → effects	1110:1	11257:17
benefits → of	benefits ← of	144:63	5228:0
Full ← Movie	Full → Movie	128:5	1585:27
coconut ← oil	coconut → oil	91:10	1507:46
credit ← card	credit → card	96:2	4394:60

Table 2: Examples of globally inconsistent head modifier relations

3.3 Label refinement

In Section 3.1, some dependencies are derived with a placeholder label *dep*. Before we use the data to train a parser, we must resolve *dep* to a true label, otherwise they introduce inconsistency in the training data. For example, consider a simple query `crude price`. From clicked sentences that contain `crude oil price`, we de-

rive crude$\xleftarrow{\text{dep}}$price, but from those that contain crude price, we derive crude$\xleftarrow{\text{amod}}$price.

To resolve *dep*, we resort to majority vote first. For any $x \xleftarrow{\text{dep}} y$, we count the occurrence of $x \xleftarrow{\text{label}} y$ in the training data for each concrete label. If the frequency of a certain label is dominating by a predetermined threshold (10 times more frequent than any other label), then we resolve *dep* to that label.

With our training data, the above process is able to resolve about 90% dependencies. We can simply discard queries that contain unresolvable dependencies. However, such queries still contain useful information, for example, the direction of this edge, and the directions and labels of all the other edges. We develop a bootstrapping method to preserve such useful information. First, we train a parser on data without *dep* labels. This skips about 10% queries in our experiments. Second, we use the parser to predict the unknown label. If the prediction is consistent with the annotation except for the *dep* label, we use the predicted label. Third, we add the resolved queries into the training data and train a final parser. Experiments show the bootstrapping approach improves the quality of the parser.

4 Dependency Parsing

We train a parser from the web query treebank data. We also try to incorporate context-free head-modifier signals into parsing. To make it easier to incorporate such signals, we adopt a neural network approach to train our POS tagger and parser.

4.1 Neural network POS tagger and parser

We first train a neural network POS tagger for web queries. For each word in the sentence, we construct features out of a fixed context window centered at that word. The features include the word itself, case (whether the first letter, any letter, or every letter in the word, is in uppercase), prefix, and suffix (we recognize a pre-defined set of prefixes and suffixes, for the rest we use a special token "UNK"). For the word feature, we use pre-trained word2vec embeddings. For word case and prefix/suffix, we use random initialization for the embeddings. The accuracy of the trained POS tagger is similar to that of (Ganchev et al., 2012), which outperforms POS taggers trained on PTB data.

Buffer features
$b_1.wt$, $b_2.wt$, $b_3.wt$
Stack features
$s_1.wt$, $s_2.wt$, $s_3.wt$
Tree features
$lc_1(s_1).wtl$, $lc_2(s_1).wtl$, $rc_1(s_1).wtl$, $rc_2(s_1).wtl$
$lc_1(lc_1(s_1)).wtl$, $rc_1(rc_1(s_1)).wtl$
$lc_1(s_2).wtl$, $lc_2(s_2).wtl$, $rc_1(s_2).wtl$, $rc_2(s_2).wtl$
$lc_1(lc_1(s_2)).wtl$, $rc_1(rc_1(s_2)).wtl$

Table 3: The feature templates. $s_i(i = 1, 2, ...)$ denote the i^{th} top element of the stack, $b_i(i = 1, 2, ...)$ denote the i^{th} element on the buffer, $lc_k(s_i)$ and $rc_k(s_i)$ denote the kth leftmost and rightmost children of s_i, w denotes words, t denotes POS tag, l denotes label.

We use the arc standard transition based dependency parsing system (Nivre, 2004). The architecture of the neural network dependency parser is similar to that of (Chen and Manning, 2014) designed for parsing sentences. The features used in parsing are shown in Table 3.

4.2 Context free features

In Section 2.2, we discussed context-free signals $P(e|x, y)$ and context-sensitive signals $P(e|x, y, q)$. Previous work (Wang et al., 2014) uses context-free signals for syntactic analysis of a query. Our approach outperforms the context-free approach.

An interesting question is, will context-free signals further improve our approach? The rationale is that although context-sensitive signals $P(e|x, y, q)$ are more accurate in predicting the dependency between x and y, such signals are also very sparse. Do context-free signals $P(e|x, y)$ provide backoff information in parsing?

It is not straightforward to include $P(e|x, y)$ in the neural network model. The head-modifier relations $P(e|x, y)$ may exist between any pair of tokens in the input query. Essentially, it is a pairwise graphical model and it is difficult to directly incorporate the signals in transition based dependency parsing.

We treat context-free signals as *prior knowledge*. We train head-modifier embeddings for each token, and use such embeddings as pre-trained embeddings. Specifically, we use an approach similar to training word2vec embeddings but focusing on head

modifier relationships instead of co-occurrence relationships. More specifically, we train an one hidden layer neural network classifier to determine whether two words have head-modifier relations. The input of the neural network is the concatenation of the embeddings of two words. The output is whether the two words form a proper head-modifier relationship. We obtain a large set of head-modifier data from text corpus by mining "h PREP m" pattern in search log where h and m are nouns. Then, for each known head modifier pair h and m, we use (h, m) as positive example and (m, h) as negative example. For each word, we also choose a few random words as negative examples. During the training process, the gradients are back propagated to the word embeddings. After training, the embeddings should contain sufficient information to recover head modifier relations between any word pairs.

But we did not observe improvement over the existing neural network that are trained on context sensitive treebank data alone. The head-modifier embeddings has about 3% advantage in UAS over randomized embeddings. However, using pretrained word2vec embeddings, we also achieve 3% advantage. Thus, it seems that context-sensitive signals plus the generalizing power of embeddings contain all the context-free signals already.

5 Experiments

In this section, we start with some case studies. Then we describe data and compare models.

In experiments, we use the standard UAS (unlabeled attachment score) and LAS (labeled attachment score) score for measuring the quality of dependency parsing. They are calculated as:

$$UAS = \frac{\#\ correct\ arc\ directions}{\#\ total\ arcs} \quad (2)$$

$$LAS = \frac{\#\ correct\ arc\ directions\ and\ labels}{\#\ total\ arcs} \quad (3)$$

5.1 Case Study

We compare dependency trees produced by our QueryParser and Stanford Parser (Chen and Manning, 2014) for some web queries (Stanford Parser is trained from the standard PTB treebank). Table 4 shows that Stanford Parser heavily relies on grammar signals such as function words and word order, while QueryParser relies more on the semantics of the query. For instance, in the 1st example, QueryParser identifies `toys` as the head, regardless of the word order, while Stanford parser always assumes the last token as the head. In the 2nd example, the semantics of the query is a school (`vanguard school`) at a certain location (`lake wales`). QueryParser captures the semantics and correctly identifies `school` as the head (root) of the query, while Stanford parser treats the entire query as a single noun compound (likely inferred from the POS tags).

5.2 Clicked Sentences

For training data, we use one-month Bing query log (between July 25, 2015 and August 24, 2015). From the log, we obtain web query q and its top clicked URLs $\{url_1, url_2, ..., url_m\}$. From the urls, we retrieve the clicked HTML document, and find sentences $\{s_1, s_2, ..., s_n\}$ that contain all words (regardless to their order of occurrence) in q. Then we extract query-sentence tuples $(q, s, count)$ to serve as our training data to generate a web query treebank. The size (# of distinct query-sentence pairs) of the raw clicked sentences is 390,225,806.

5.3 Web Query Treebank

We evaluate the 3 steps of treebank generation. After each step, we sample 100 queries from the result and manually compute their UAS and LAS scores. We also count the number of total query instances in each step. The results are shown in Table 5.

- **Inferring a dependency tree**: For each (query, sentence) pair, we project dependency from the sentence to the query. The number of instances shown in Table 5 are the input number of (query, sentence) pairs. It shows that we obtain dependency trees for only 31% of the queries, while the rest do not satisfy our filtering criterion. This however is not a concern. By sacrificing recall in this process, we ensure high precision. Given that query log is large, precision is more important.

- **Inferring a unique dependency tree**: In this step, we group (query, sentence) pairs by unique queries. Using the method in Section

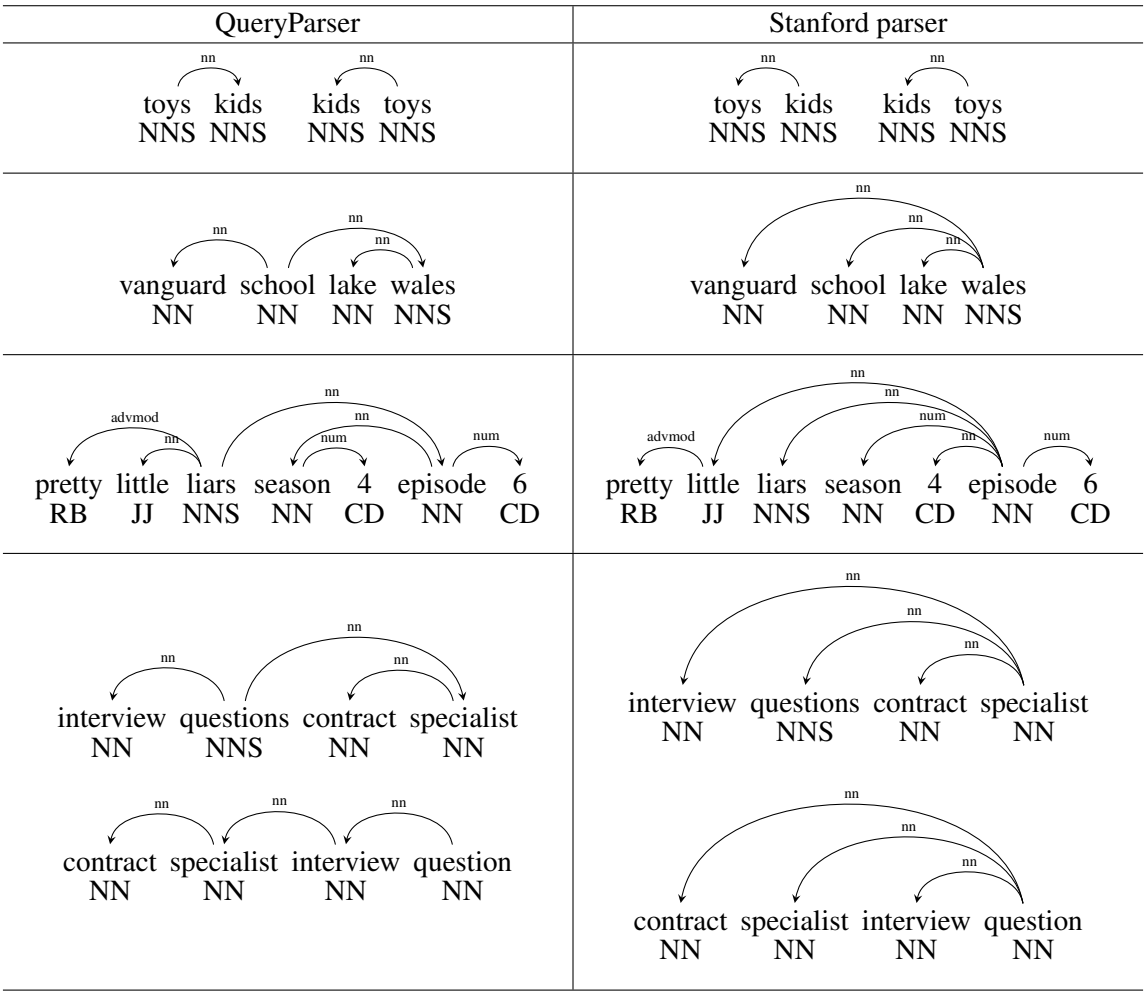


Table 4: Case study of parsers.

3.2, each group produces one or zero dependency trees. The number of instances in Table 5 corresponds to the number of different query groups. The overall success rate is high. This is expected as the filtering process uses majority voting, and we already have high precision parsing trees after the first step.

- **Label refinement**: Dependency labels are refined using the methodology in Section 3.3. It shows that with majority voting and bootstraping, we are able to keep all the input.

5.4 Parser Performance

We compare QueryParser against three state-of-the-art parsers: Stanford parser, which is a transition based dependency parser based on neural network, MSTParser (McDonald et al., 2005), which is a graph based dependency parser based on minimum spanning tree algorithms, and LSTMParser (Dyer et al., 2015), which is a transition based dependency parser based on stack long short-term memory cells. Here, QueryParser is trained from our web query treebank, while Stanford Parser and MSTParser are trained from standard PTB treebanks.

For comparison, we manually labeled 1,000 web queries to serve as a ground truth dataset[2]. We produce POS tags for the queries using our neural network POS tagger. To specifically measure the ability of QueryParser in parsing queries with no explicit syntax structure, we split the entire dataset **All** into two parts: **NoFunc** and **Func**, which correspond to queries without any function word, and queries with at least one function word. The number of queries

[2]https://github.com/wishstudio/queryparser

Step	Total Instances	Produced Instances	Success Rate	UAS	LAS
Inferring a dependency tree	3986300	1229860	31%	0.906	0.851
Inferring a unique tree	716261	680857	95%	0.910	0.851
Label refinement	680857	680857	100%	0.917	0.855

Table 5: Training dataset generation statistics

System	**All** (n=1000)		**NoFunc** (n=900)		**Func** (n=100)	
	UAS	LAS	UAS	LAS	UAS	LAS
Stanford	0.694	0.602	0.670	0.568	0.834	0.799
MSTParser	0.699	0.616	0.683	0.691	0.799	0.766
LSTMParser	0.700	0.608	0.679	0.578	0.827	0.790
QueryParser + label refinement	0.829	0.769	0.824	0.761	0.858	0.818
QueryParser + word2vec	0.843	0.788	0.843	0.784	0.838	0.812
QueryParser + label refinement + word2vec	**0.862**	**0.804**	**0.858**	**0.795**	**0.883**	**0.854**

Table 6: Parsing performance on web queries

of the two datasets are 900 and 100, respectively.

Table 6 shows the results. We use 3 versions of QueryParser. The first two use random word embedding for initialization, and the first one does not use label refinement. From the results, it can be concluded that QueryParser consistently outperformed competitors on query parsing task. Pretrained word2vec embeddings improve performance by 3-5 percent, and the postprocess of label refinement also improves the performance by 1-2 percent.

Table 6 also shows that conventional depencency parsers trained on sentence dataset relies much more on the syntactic signals in the input. While Stanford parser and MSTParser have similar performance to our parser on **Func** dataset, the performance drops significantly on **All** and **NoFunc** dataset, when the majority of input has no function words.

6 Related Work

Some recent work (Ganchev et al., 2012; Barr et al., 2008) investigated the problem of syntactic analysis for web queries. However, current study is mostly at postag rather than dependency tree level. Barr et al. (2008) showed that applying taggers trained on traditional corpora on web queries leads to poor results. Ganchev et al. (2012) propose a simple, efficient procedure in which part-of-speech tags are transferred from retrieval-result snippets to queries at training time. But they do not reveal syntactic structures of web queries.

More work has focused on resolving simple relations or structures in queries or short texts, particularly entity-concept relations (Shen et al., 2006; Wang et al., 2015; Hua et al., 2015), entity-attribute relations (Pasca and Van Durme, 2007; Lee et al., 2013), head-modifier relations (Bendersky et al., 2010; Wang et al., 2014). Such relations are important but not enough. The general dependency relations we focus on is an important addition to query understanding.

On the other hand, there is extensive work on syntactic analysis of well-formed sentences (De Marneffe et al., 2006). Recently, a lot of work (Collobert et al., 2011; Vinyals et al., 2015; Chen and Manning, 2014; Dyer et al., 2015) started using neural network for this purpose. In this work, we use similar neural network architecture for web queries.

7 Conclusion

Syntactic analysis of web queries is extremely important as it reveals actional signals to many downstream applications, including search ranking, ads matching, etc. In this work, we first acquire well-formed sentences that contain the semantics of the query, and then infer the syntax of the query from the sentences. This essentially creates a treebank for web queries. We then train a neural network dependency parser from the treebank. Our experiments show that we achieve significant improvement over traditional parsers on web queries.

Abstract

Sequences found at the beginning of TV shows help the audience absorb the essence of previous episodes, and grab their attention with upcoming plots. In this paper, we propose a novel task, text recap extraction. Compared with conventional summarization, text recap extraction captures the duality of summarization and plot contingency between adjacent episodes. We present a new dataset, *TVRecap*, for text recap extraction on TV shows. We propose an unsupervised model that identifies text recaps based on plot descriptions. We introduce two contingency factors, *concept coverage* and *sparse reconstruction*, that encourage recaps to prompt the upcoming story development. We also propose a multi-view extension of our model which can incorporate dialogues and synopses. We conduct extensive experiments on *TVRecap*, and conclude that our model outperforms summarization approaches.

1 Introduction

According to a study by FX Networks, in U.S., the total number of ongoing scripted TV series hit a new high of 409 on broadcast, cable, and streaming in 2015[1]. Such a large number indicates there are more shows than anyone can realistically watch. To attract prospective audiences as well as help current viewers recall the key plot when airing new episodes, some TV shows add a clip montage, which is called a recap sequence, at the beginning of new episodes or seasons. Recaps not only help the audience absorb the essence of previous episodes, but also grab people's attention with upcoming plots. However, creating those recaps for every newly aired episode is labor-intensive and time-consuming. To our advantage, there are many textual scripts freely available online which describe the events and actions happening during the TV show episodes[2]. These textual scripts contain *plot descriptions* of the events, *dialogues* of the actors, and sometimes also the *synopsis* summarizing the whole episode.

These abundant textual resources enable us to study a novel, yet challenging task: automatic text recap extraction, illustrated in Figure 1. The goal of text recap extraction is to identify segments from scripts which both summarize the current episode and prompt the story development of the next episode. This unique task brings new technical challenges as it goes beyond summarizing prior TV episodes, by introducing a concept of plot contingency to the upcoming TV episode. It differs from conventional summarization techniques which do not consider the interconnectivity between neighboring episodes. Text recaps should capture the duality of summarization and plot contingency between neighboring episodes. To our knowledge, no dataset exists to study this research topic.

In this paper, we present an unsupervised model to automatically extrapolate text recaps of TV shows from plot descriptions. Since we assume recaps should cover the main plot of the current episode and also prompt the story development of the next episode, our model jointly optimizes these two ob-

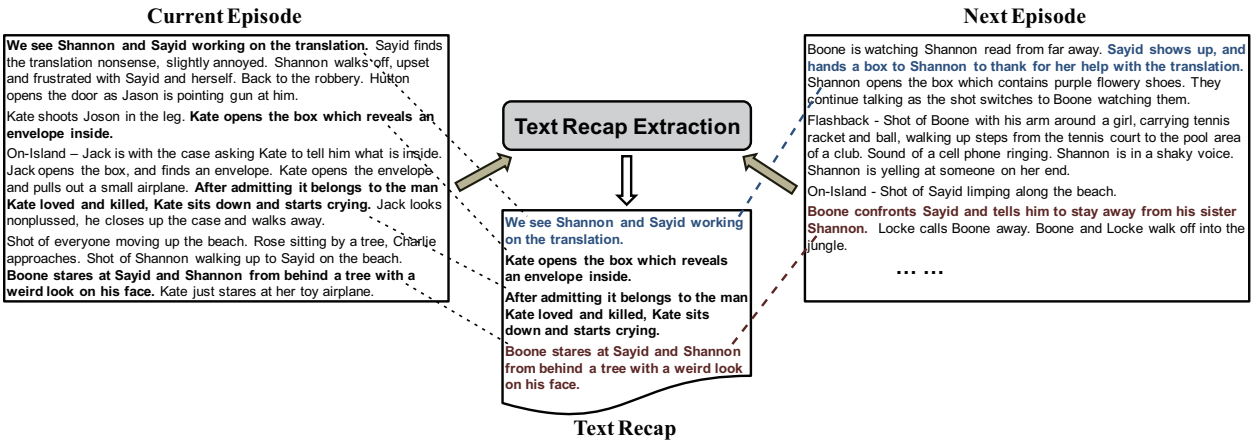

Figure 1: Illustration of text recap extraction. The system extracts sentences from the current episode. The text recap sentences in black summarize the current episode, while colored sentences motivate the next episode.

jectives. To summarize the current episode, our model exploits coverage-based summarization techniques. To connect to the next episode, we devise two types of plot contingency factors between adjacent episodes. These factors implement the coverage and reconstruction assumptions to the next episode. We also show how our model can be extended to integrate dialogues and synopses when available.

We introduce a new dataset[3], named *TVRecap* for text recap extraction which consists of TV series with textual scripts, including descriptions, dialogues and synopses. The dataset enables us to study whether contingency-based methods which exploit relationships between adjacent episodes can improve summarization-based methods.

The rest of this paper is organized as follows. In Section 2, we discuss related work and the motivation for our work. In Section 3, we introduce our new dataset for text recap extraction. Section 4 explains our proposed model for text recap extraction, and Section 5 expands the model by incorporating synopses and dialogues. In Section 6 and 7, we present our experimental results and analyses, and finally conclude our work in Section 8.

2 Related Work

In this section, we discuss three related research topics. Text summarization is an relevant task that aims to create a summary that retains the most important points of the original document. Then we discuss the evaluation metrics of text summarization. Finally, we discuss the video description which is complementary to our work.

Generic Text Summarization Alogrithms Text summarization is widely explored in the news domain (Hong and Nenkova, 2014; McKeown, 2005). Generally, there are two approaches: *extractive* and *abstractive* summarization.

Extractive summarization forms a summary by choosing the most representative sentences from the original corpus. The early system LEAD (Wasson, 1998) was pioneering work. It selected leading text of the document as the summary, and was applied in news searching to help online customers focus their queries on the beginning of news documents. He et al. (2012) assumed that summarization should consist of sentences that could best reconstruct the original document. They modeled relationship among sentences by forming an optimization problem. Moreover, Sipos et al. (2012) and Lin and Bilmes (2010) studied multi-document summarization using coverage-based methods. Among them, Lin and Bilmes (2010) proposed to approximate the optimal solution of a class of functions by exploiting submodularity.

Abstractive summarization automatically create new sentences. For example, compared with the sentence-level analysis in extractive summarization, Bing et al. (2015) explored fine-grained syntactic units, i.e. noun/verb phrases, to represent concepts in input documents. The informative phrases were

[3] http://multicomp.cs.cmu.edu

then used to generate sentences.

In this paper, we generalize the idea of text summarization to text recap extraction. Instead of summarizing a given document or collection, our model emphasizes plot contingency with the next episode.

Summarization Applications Summarization techniques are not restricted to informative resources (e.g. news), applications in broader areas are gaining attention (Aparício et al., 2016). As the prevailance of online forums, Misra et al. (2015) developed tools to recognize arguments from opinionated conversations, and group them across discussions. In entertainment industry, Sang and Xu (2010) proposed a character-based movie summarization approach by incorporating scripts into movie analysis. Moreover, recent applications include multimedia artifact generation (Figueiredo et al., 2015), music summarization (Raposo et al., 2015) and customer satisfaction analysis (Roy et al., 2016).

Video Description Generating video descriptions is a task that studies automatic generation of natural language that describes events happening in video clips. Most work uses sequential learning for encoding temporal information and language generation (Guadarrama et al., 2013; Rohrbach et al., 2013, 2015; Donahue et al., 2015). Our work is complementary to video description: the large number of unlabeled videos can be utilized to train end-to-end recap extraction system when video description models can properly output textual descriptions.

Contributions of This Paper In contrast with prior work, the main contributions of this paper are:
(1) We propose a novel problem, text recap extraction for TV series. Our task aims to identify segments from scripts which both summarize the current episode and prompt the story development of the upcoming episode;
(2) We propose an unsupervised model for text recap extraction from descriptions. It models the episode contingency through two factors, next episode summarization and sparse reconstruction;
(3) We introduce a new dataset for TV show recap extraction, where descriptions, dialogues and synopses are provided.

3 The TVRecap Dataset

We collected a new dataset, called *TVRecap*, for text recap extraction on TV series. We gathered and processed scripts, subtitles and synopses from websites[4] as components to build our model upon. We also established ground truth to help future research on this challenging topic. *TVRecap* includes all seasons from the widely-known show "*Lost*" with a total of 106 episodes. Statistics of our dataset are shown in Table 1.

	# sent.	avg. # sent.	# words	avg. # w./s.
description	14,686	138.5	140,684	9.57
dialogue	37,714	355.8	284,514	7.54
synopsis	453	4.27	7,868	17.36
recap	619	17.19	5,892	9.52

Table 1: Statistics of *TVRecap*.

This section describes how textual scripts and synopses are processed, and how we automatically define the ground truth of text recap annotations.

Descriptions, Dialogues and Synopses A script for one TV series episode is a sequence of dialogues interleaved with descriptions (marked by square brackets). We automatically split the script into descriptions and dialogues. For each episode, We also downloaded the synopsis, a human-written paragraph summarizing the main plot of the episode. Figure 2 shows examples of a script and a synopsis from our *TVRecap* dataset.

LOCKE: Two players. Two sides. One is light... one is dark. Walt, do you want to know a secret?

[*Claire writing in her diary. Jin approaches and offers her some urchin. She shakes her head, but then gives in and takes some.*]

CLAIRE: No. Thank you. No, it's okay. [*Jin keeps insisting*] No, really. Okay. Thanks.

(a) Script: containing descriptions and dialogues.

Boone steals the decreasing water supply in a misguided attempt to help everyone, but the survivors turn on him. A sleep-deprived Jack chases after what appears to be his deceased father in the forests and eventually discovers caves with fresh water. Jack comes to terms with his role as leader. In flashbacks, Jack goes to Australia to retrieve his deceased father.

(b) Synopsis.

Figure 2: Example of a script (including descriptions and dialogues) and a synopsis.

[4] `http://lostpedia.wikia.com/` and `https://www.wikipedia.org/`

All plot descriptions and dialogues are time-aligned automatically using the subtitle files[5]. We first aligned the dialogue sentences from the script with the subtitle files which contain time-stamps (in milliseconds) of the spoken dialogues. Then we estimated time-stamps of description sentences using surrounding dialogues.

Since descriptions sometimes contain words not relevant to the event, we manually post-processed all descriptions and recap sentences as follows: (1) remove trivial sentences such as "*music on*", (2) remove introductory terms like "*Shot of*", (3) complete missing grammatical components (like omitted subjects) of sentences when possible.

Text Recap Annotations The goal of our ground truth annotation is to identify the text descriptions associated with the TV show recap. We performed this annotation task in three steps.

First, we automatically extracted the recap sequence, which is a montage of important scenes from previous episodes to inform viewers of what has happened in the show, from the TV show video. These recap sequences, if available, are always shown at the beginning of TV episodes. We automatically separated video recap sequences from full-length video files by detecting a lengthy appearance of black frames in the first several minutes of the episode. Second, we located the frames of the recap sequences in the videos of previous episodes, and recorded their time-stamps. Finally, the recap annotations are automatically identified by comparing the video time-stamps with the text description time-stamps. A description is annotated as part of the recap if at least 4 frames from the video recap are present during this description.

4 Our Text Recap Extraction Model

In our Text Recap Extraction Model (TREM), we assume a good text recap should have two characteristics: (a) it covers the main plot of the current episode, and (b) it holds plot contingency with the next episode. Under the first assumption, the text recap can be seen as a summarization that retains the most important plots. Under assumption (b), the text recap should capture the connections between two consecutive episodes.

[5] http://www.tvsubtitles.net/

Formally, the system is given E episodes from a specific TV show, where each episode contains textual descriptions. We define these descriptions as $D = \{D^1, \cdots, D^E\}$, where D^i is the set of descriptions of episode i. D^i is composed of descriptive sentences as $D^i = \{d^i_1, \cdots, d^i_{|D^i|}\}$, where d^i_j is the j-th sentence. The goal of our task is to find text recaps $R = \{R^1, \cdots, R^{E-1}\}$ where the components of R^i are selected from D^i with a length budget (constraint on the number of sentences) $|R^i| \leq K$.

In our TREM model, the text recap R^i of the i-th episode is optimized by:

$$\begin{aligned} \max_{R^i \subset D^i} \quad & \mathcal{F}(R^i) = \mathcal{S}(R^i, D^i) + \mathcal{M}(R^i, D^{i+1}) \\ \text{s.t} \quad & |R^i| \leq K, \end{aligned} \tag{1}$$

where $\mathcal{S}(R^i, D^i)$ measures how well R^i summarizes D^i, and $\mathcal{M}(R^i, D^{i+1})$ quantifies the level of connectivity between the text recap of the current episode and the plot description of the next episode. By using $\mathcal{M}(\cdot,\cdot)$, we expect to produce text recaps with better plot contingency with the upcoming story.

In the following sections, we demonstrate in details: (1) the definition of the summarization function $\mathcal{S}(\cdot,\cdot)$; (2) two factors that derive the contingency function $\mathcal{M}(\cdot,\cdot)$ based on different hypotheses.

4.1 Plot Summarization

In this section, we discuss the summarization component of our model's objective function. Our model is inspired by the coverage-based summarization (Lin and Bilmes, 2010), whose key idea is to find a proxy that approximates the information overlap between the summary and the original document. In this work, any text is assumed to be represented by a set of "*concepts*" using weights to distinguish their importance. To be more specific, a *concept* is defined as a noun/verb/adjective or noun/verb phrase. In terms of *concepts*, we define the summarization term $\mathcal{S}(R^i, D^i)$ as follows:

$$\mathcal{S}(R^i, D^i) = \sum_{c \in \mathcal{C}(D^i)} z(c, D^i) \max_{r \in R^i} w(c, r), \tag{2}$$

where $\mathcal{C}(D^i) = \{c' | c' \in d^i_j, \forall d^i_j \in D^i\}$ is the concept set of D^i, and $z(c, D^i)$ measures the importance of c in D^i. We use Term Frequency Inverse

Document Frequency (TF-IDF) (Salton and Buckley, 1988) to calculate $z(c, D^i)$. Finally, $w(c, r)$ denotes the relatedness of a concept c to a sentence r.

We use Word2Vec (Mikolov et al., 2013) vectors as the semantic representation of concepts, and define $w(c, r)$ as:

$$w(c, r) = |c| \cdot \max_{c' \in r} \cos(\mathbf{c}, \mathbf{c}'), \tag{3}$$

where bold notations are the Word2Vec representations of c and c'. Note that if c is a phrase, $\mathbf{c}$ is mean pooled by the embeddings of its component words. $|c|$ is the number of words in c.

4.2 Plot Contingency

We model plot contingency on the concept level as well as on the sentence level. Therefore, the component $\mathcal{M}(\cdot, \cdot)$ is decomposed into two factors:

$$\begin{aligned}\mathcal{M}(R^i, D^{i+1}) =& \lambda_s \mathcal{M}_s(R^i, D^{i+1}) + \\ & \lambda_r \mathcal{M}_r(R^i, D^{i+1}).\end{aligned} \tag{4}$$

where $\mathcal{M}_s(R^i, D^{i+1})$ measures how well R^i can summarize the next episode D^{i+1} and $\mathcal{M}_r(R^i, D^{i+1})$ is the factor that quantify the ability of R^i to reconstruct D^{i+1}. $\lambda_s, \lambda_r \geq 0$ are coefficients for $\mathcal{M}_s(\cdot, \cdot)$ and $\mathcal{M}_r(\cdot, \cdot)$ respectively. In the following sections, we define and explain these two factors in details.

4.2.1 Concept Coverage

Following the coverage assumption of Section 4.1, we argue that the text recap should also cover important concepts from the next episode. Therefore, the first contingency factor can be defined in the same form as the summarization component where D^i's in Equation 2 are replaced by D^{i+1}'s:

$$\mathcal{M}_s(R^i, D^{i+1}) = \sum_{c \in \mathcal{C}(D^{i+1})} z(c, D^{i+1}) \max_{r \in R^i} w(c, r). \tag{5}$$

4.2.2 Sparse Reconstruction

As events happening in the current episode can have an impact on the next episode, there exist hidden connections between the descriptive sentences in D^i and D^{i+1}. To be more specific, assuming descriptive sentences from D^{i+1} are dependent on a few sentences in D^i, we aim to infer such hidden contingency. Here we assume that sentence d_j^{i+1} is related to a small number of sentences in D^i.

Let $\boldsymbol{\alpha}_j^{i+1} \in \mathbb{R}^{|D^i|}$ be the indicator that determines which sentences in D^i prompt d_j^{i+1}, and $\mathbf{W}$ be the matrix that transforms these contingent sentences to the embedding space of d_j^{i+1}. Intuitively, our model learns $\mathbf{W}$ by assuming each sentence in D^{i+1} can be reconstructed by contingent sentences from D^i:

$$\mathbf{d}_j^{i+1} \approx \mathbf{W}\mathbf{D}^i \boldsymbol{\alpha}_j^{i+1}, \tag{6}$$

In the equation, we first convert every description sentence to its distributed representation using the pre-trained skip-thought model proposed by Kiros et al. (2015). The sentence embedding is denoted in bold (e.g. $\mathbf{d}_j^i$ for sentence d_j^i). $\mathbf{D}^i = [\mathbf{d}_1^i; \cdots; \mathbf{d}_{|D^i|}^i]$ stacks the vector representations of all sentences in D^i, and $\boldsymbol{\alpha}_j^{i+1}$ linearly combines the contingent sentences.

We propose to jointly optimize $\boldsymbol{\alpha}_j^{i+1}$ and $\mathbf{W}$ by:

$$\begin{aligned}\min_{\{\boldsymbol{\alpha}^{i+1}\}_{i=1}^{E-1}, \mathbf{W}} & \sum_{i,j} \big(\|\mathbf{W}\mathbf{D}^i \boldsymbol{\alpha}_j^{i+1} - \mathbf{d}_j^{i+1}\|_2^2 \\ & + \gamma \|\boldsymbol{\alpha}_j^{i+1}\|_1 \big) + \theta \|\mathbf{W}\|_F^2,\end{aligned} \tag{7}$$

where we denote $\boldsymbol{\alpha}^{i+1} = [\boldsymbol{\alpha}_1^{i+1}; \cdots; \boldsymbol{\alpha}_{|D^{i+1}|}^{i+1}]$. We impose sparsity constraint on $\boldsymbol{\alpha}_j^{i+1}$ with L_1 norm such that only a small fraction of sentences in D^i will be linked to d_j^{i+1}. γ and θ are coefficients of the regularization terms.

Given the optimal $\mathbf{W}^*$ from Equation 7, our main objective is to identify the subset of descriptions in D^i that best capture the contingency between D^i and D^{i+1}. The reconstruction contingency factor can be defined as:

$$\mathcal{M}_r(R^i, D^{i+1}) = \sum_{d \in D^{i+1}} \max_{r \in R^i} \mathbf{r}^\intercal \mathbf{W}^* \mathbf{d}. \tag{8}$$

4.3 Optimization

In this section, we describe our approach to optimize the main objective function expressed in Equations 1 and 7.

Finding an efficient algorithm to optimize a set function like Equation 1 is often challenging. However, it can be easily shown that the objective function of Equation 1 is submodular, since all its components $\mathcal{S}(R^i, D^i), \mathcal{M}_s(R^i, D^{i+1})$ and

$\mathcal{M}_r(R^i, D^{i+1})$ are submodular with respect to R^i. According to Lin and Bilmes (2011), there exists a simple greedy algorithm for monotonic submodular function maximization where the solution is guaranteed to be close to the real optimum. Specifically, if we denote R^i_{greedy} as the approximation optimized by greedy algorithm and R^{i*} as the best possible solution, then $\mathcal{F}(R^i_{greedy}) \geq (1 - \frac{1}{e}) \cdot \mathcal{F}(R^{i*})$, where $\mathcal{F}(\cdot)$ is the objective function of Equation 1 and $e \approx 2.718$ denotes the natural constant. The greedy approach is shown in Algorithm 1.

Algorithm 1 Text Recap Extraction

Input: Vectorized sentence representations $\{\mathbf{D}^i\}_{i=1}^E$, parameters $\lambda_s, \lambda_r, \theta, \gamma$, budget K, optimal $\mathbf{W}^*$ for Equation 7.
Output: Text recaps $\{R^i\}_{i=1}^E$.

```
for i = 1, ..., E
    Initialize R^i ← ∅;
    REPEAT
        r* ← arg max F(R^i ∪ {r});
        R^i ← R^i ∪ {r*};
    UNTIL |R^i| ≥ K
end
```

Algorithm 1 requires the optimal $\mathbf{W}^*$ learned from the adjacent episode pairs in Equation 7. We utilize the algorithm that iteratively updates $\mathbf{W}$ and $\boldsymbol{\alpha}$ given the current solution. At each iteration, each variable ($\mathbf{W}$ or $\{\boldsymbol{\alpha}^{i+1}\}$) is updated by fixing the other. At t-th iteration, $\mathbf{W}^{(t)}$ is computed as the solution of ridge regression (Hoerl and Kennard, 1970):

$$\mathbf{W}^{(t)} = \mathbf{D}\mathbf{X}^\intercal(\mathbf{X}\mathbf{X}^\intercal + \theta\mathbf{I})^{-1}, \tag{9}$$

where $\mathbf{D}$ and $\mathbf{X}$ stack all $\mathbf{d}_j^{i+1}$ and $\mathbf{x}_j^{i+1} \triangleq \mathbf{D}^i\boldsymbol{\alpha}_j^{i+1}, \forall i = 1, \cdots, E-1, j = 1, \cdots, |D^i|$. Fixing $\mathbf{W}$, each $\boldsymbol{\alpha}_j^{i+1}$ can be solved separately by general sparse coding algorithms as stated in Mairal et al. (2009). Algorithm 2 shows the optimization process of Equation 7.

5 Multi-View Recap Extraction

In addition to plot descriptions, there are also dialogues and plot synopses available for TV shows. Descriptions, dialogues and synopses can be seen as three different views of the same TV show episode.

Algorithm 2 Reconstruction Matrix Optimization

Input: Vectorized sentence representations $\{\mathbf{D}^i\}_{i=1}^E$, θ and γ.
Output: Contingency matrix $\mathbf{W}$.

```
Initialize W^(0) ← I and α_j^{i+1(0)} ← 0, ∀i, j;
Initialize iteration step t ← 0;
REPEAT
    t ← t + 1;
    W^(t) is updated according to Equation 9;
    ∀i, j, α_j^{i+1,(t)} ← sparse_coding(W^(t));
UNTIL ||W^(t) − W^(t−1)||_F^2 ≤ ε
```

Previously, we build TREM using plot descriptions. In this section, we expand our TREM model to incorporate plot synopses and dialogues. We define text synopses and dialogues as $S = \{S^1, \cdots, S^E\}$ and $T = \{T^1, \cdots, T^E\}$, where S^i and T^i are the set of sentences from synopses and dialogues of the i-th episode.

Dialogues In TV shows, a lot of useful information is presented via actors' dialogues which motivates us to extend our TREM model to include dialogues. Both views can be used to identify recap segments which are assumed to be summative and contingent. Denote the neighboring dialogues of R^i as $N(R^i) = \{t \in T^i \big| \exists r \in R^i, \text{ s.t. } |\text{time}(t) - \text{time}(r)| < \delta\}$, we extend the optimization objective (Equation 1) into:

$$\begin{aligned}\mathcal{F}(R^i) = &\big(\mathcal{S}(R^i, D^i) + \mathcal{S}(N(R^i), T^i)\big) \\ &+ \big(\mathcal{M}(R^i, D^{i+1}) + \mathcal{M}(N(R^i), T^{i+1})\big).\end{aligned} \tag{10}$$

Synopses Since a synopsis is a concise summary of each episode, we can treat plot summarization as text alignment where R^i is assumed to match the content of S^i. Therefore, the summarization term can be redefined by substituting D^i with S^i:

$$\mathcal{S}(R^i, S^i) = \sum_{c \in \mathcal{C}(S^i)} z(c, S^i) \max_{r \in R^i} w(c, r). \tag{11}$$

Similarly, the contingency component can be modified to include connections from synopses to detailed descriptions. For Equation 8, we substitute

	ROUGE-1	ROUGE-2	ROUGE-SU4
ILP-Ext (Banerjee et al., 2015)	0.308	0.112	0.091
ILP-Abs (Banerjee et al., 2015)	0.361	0.158	0.120
Our approach TREM	**0.405**	**0.207**	**0.148**
w/o SR	0.393	0.189	0.144
w/o CC	0.383	0.171	0.132
w/o SR&CC (summarization only)	0.374	0.168	0.129

Table 2: Experimental results on different methods using descriptions. Contingency-based methods generally outperforms summarization-based methods.

D^{i+1} to S^{i+1} where our model only focuses on high-level storyline:

$$\mathcal{M}_r(R^i, S^{i+1}) = \sum_{s \in S^{i+1}} \max_{r \in R^i} \mathbf{r}^\intercal \mathbf{W}^* \mathbf{s}. \quad (12)$$

6 Experimental Setup

We designed our experiments to evaluate whether our TREM model, by considering contingency between adjacent episodes, can achieve better results than summarization techniques. Furthermore, we want to examine how each contingency factor as proposed in Section 4.2 contributes to the system performance. As our model can integrate multiple views, we want to dissect the effects of using different combinations of three views.

6.1 Comparison Models

To answer the research questions presented above, we compare the following methods in our experiments.

– **ILP-Ext** and **ILP-Abs** (Banerjee et al., 2015): This summarizer generates sentences by optimizing the integer linear programming problem in which the information content and linguistic quality are defined. Both extractive and abstractive implementations are used in our experiments.

– **TREM**: Our TREM model proposed in Section 4 extracts sentences that can both summarize the current episode and prompt the next episode with two contingency factors.

– **TREM w/o SR**: The TREM model without the sparse reconstruction factor proposed in Section 4.2.2.

– **TREM w/o CC**: The TREM model without the concept coverage factor proposed in Section 4.2.1.

– **TREM w/o SR&CC**: The summarization-only TREM model without contingency factors. In the rest of the paper, we also call it as **TREM-Summ**.

– **Multi-view TREM**: The augmented TREM model with descriptions, dialogues and synopses as proposed in Section 5. Different views and combinations will be tested in our experiments.

6.2 Methodology

Using *TVRecap*, we measure the quality of generated sentences following the standard metrics in the summarization community, ROUGE (Lin and Hovy, 2003).

For the purpose of evaluation, we defined a development and a test set, by randomly selecting 18 adjacent pairs of episodes from all seasons. These episodes were selected to have at least two recap description sentences. The remaining 70 episodes were only used during the learning process of $\mathbf{W}$. After tuning hyper-parameters on development set, we report the comparison results on the test set.

7 Results and Discussion

7.1 Overall Results

Table 2 shows our experimental results comparing TREM and baseline models using descriptions.

In general, contingency-based methods (TREM, TREM w/o SR and TREM w/o CC) outperform summarization-based methods. Our contingency assumptions are verified as adding CC and SC both improve TREM with summarization component only. Moreover, the best result is achieved by the complete TREM model with both contingency factors. It suggests that these two factors, modeling word-level summarization and sentence-level reconstruction, are complementary.

From the summarization-based methods, we can see that our TREM-Summ gets higher ROUGE scores than two ILP approaches. Additionally, we

Target sentence from next episode	Sentences with highest reconstruction value from current episode
Kate is putting water bottles in a pack.	We see three bottles of water. They go into a room with a body bag on a gurney. Kate is going through clothes, as Claire approaches.
Locke is with his knife case, holding a pencil, sitting by a fire.	Boone is coming up to camp and sees Locke sitting by a fire. Locke throws a knife into the ground, just out of Boone's reach. Boone quickly cuts through the ropes and starts running.
In another part of the temple grounds, Miles and Hurley are playing Tic-Tac-Toe by placing leaves in a grid of sticks on the ground.	John contemplates the fabric swatches he is holding. On the beach, Frank covers Locke's body with a tarp. Helen closes the door and brings the case inside to the kitchen.

Table 3: A case study on sparse reconstruction as proposed in Section 4.2.2. Sentences in the first column are reconstructed by sentences in the second column. The first two examples successfully captures related sentences, while the third example fails.

note that the performance of ILP-Ext is poor. This is because ILP-Ext tends to output short sentences, while ROUGE is a recall-oriented measurement.

Model	Current	Next	R-1	R-2	R-SU4
TREM-Summ	des	-	0.374	0.168	0.129
	syn	-	0.369	0.163	0.121
	dial	-	0.354	0.138	0.115
	des+syn	-	0.384	0.172	0.132
	des+dial	-	0.386	0.168	0.135
TREM	des	des	0.405	0.207	0.148
	des	syn	**0.411**	**0.219**	**0.154**
	des	dial	0.375	0.158	0.127
	des	des+syn	0.409	0.210	**0.154**
	des	des+dial	0.395	0.177	0.142

Table 4: Comparison of views in summarization-only TREM and full TREM with contingency factors. "*des*", "*syn*", and "*dial*" are abbreviated for description, synopses and dialogues.

7.2 Multi-view Comparison

As shown in Table 4, The second study examines the effect of different views in both types of methods using the TREM model. In single-view summarization, TREM-Summ with descriptions outperforms methods based on the other two views. In terms of hybrid of views, only ROUGE-1 is significantly improved, while ROUGE-2 and ROUGE-SU4, which focus more on semantic consistency, have little improvement.

In contingency-based methods, we keep the current episode represented as descriptions which obtain the best performance in single-view summarization, and change the views of the next episode. Comparing the model using descriptions with the one fusing descriptions and synopses, we can see that simply adding views does not guarantee higher ROUGE scores. In both TREM-Summ and full TREM, dialogue is inferior to others. It might be because dialogues contain too many trivial sentences. Synopses, however, are relatively short, but provide key plots to summarize the story, and hence achieve the best ROUGE scores.

7.3 Qualitative Study on Sparse Reconstruction

In this section, we give some examples to illustrate the process of sparse reconstruction. Equation 7 assumes that each descriptive sentence can be reconstructed by a few sentences from the previous episode. Table 3 shows three examples of sentences with their top-3 reconstructive sentences, which are defined by values in the indicator vector $\boldsymbol{\alpha}_j^{i+1}$.

7.4 Limitations and Future Work

TREM restrains the contingency within adjacent episodes. However, storylines sometimes proceed through multiple episodes. In our model, with more connectivity terms $\mathcal{M}(R^i, D^j)$ where $i < j$, we can develop more general system with longer dependencies.

While our model and dataset are appropriate for text recap extraction and algorithm comparison, this task can be further applied to multimedia settings, where visual or acoustic information can be included. Therefore, in future work, we plan to expand our work to broader applications where interconnectivity between consecutive instances is crucial, such as educational lectures, news series and book chapters. Specifically, TREM can be integrated with video description results to get an end-to-end system that produces video recaps.

8 Conclusion

In this paper, we explore a new problem of text recap extraction for TV shows. We propose an unsupervised model that identifies recap segments from multiple views of textual scripts. To facilitate the study of this new research topic, we create a dataset called *TVRecap*, which we test our approach on. From the experimental results, we conclude that contingency-based methods improve summarization-based methods at ROUGE measurements by exploiting plot connection between adjacent episodes.

On- and Off-Topic Classification and Semantic Annotation of User-Generated Software Requirements

Markus Dollmann and **Michaela Geierhos**
Heinz Nixdorf Institute
University of Paderborn
Fürstenallee 11, 33102 Paderborn, Germany
{dollmann|geierhos}@hni.upb.de

Abstract

Users prefer natural language software requirements because of their usability and accessibility. When they describe their wishes for software development, they often provide off-topic information. We therefore present REaCT[1], an automated approach for identifying and semantically annotating the on-topic parts of requirement descriptions. It is designed to support requirement engineers in the elicitation process on detecting and analyzing requirements in user-generated content. Since no lexical resources with domain-specific information about requirements are available, we created a corpus of requirements written in controlled language by instructed users and uncontrolled language by uninstructed users. We annotated these requirements regarding predicate-argument structures, conditions, priorities, motivations and semantic roles and used this information to train classifiers for information extraction purposes. REaCT achieves an accuracy of 92% for the on- and off-topic classification task and an F_1-measure of 72% for the semantic annotation.

1 Introduction

"Requirements are what the software product, or hardware product, or service, or whatever you intend to build, is meant to do and to be" (Robertson and Robertson, 2012). This intuitive description of requirements has one disadvantage. It is as vague as a requirement that is written by an untrained user. More generally, functional requirements define what a product, system or process, or a part of it is meant to do (Robertson and Robertson, 2012; Vlas and Robinson, 2011). Due to its expressiveness, natural language (NL) became a popular medium of communication between users and developers during the requirement elicitation process (de Almeida Ferreira and da Silva, 2012; Mich et al., 2004). Especially in large ICT projects, requirements, wishes, and ideas of up to thousands of different users have to be grasped (Castro-Herrera et al., 2009). For this purpose, requirement engineers collect their data, look for project-relevant concepts and summarize the identified technical features. However, this hand-crafted aggregation and translation process from NL to formal specifications is error-prone (Goldin and Berry, 1994). Since people are getting tired and unfocused during this monotonous work, the risk of information loss increases. Hence, this process should be automated as far as possible to support requirement engineers.

In this paper, we introduce our approach to identify and annotate requirements in user-generated content. We acquired feature requests for open source software from SourceForge[2], specified by (potential) users of the software. We divided these requests into off-topic information and (on-topic) requirements to train a binary text classifier. This allows an automated identification of new requirements in user-generated content. In addition, we collected requirements in controlled language from the NFR corpus[3] and from web pages with user-story explanations. We annotated the semantically rele-

Austin, Texas, November 1-5, 2016.

vant parts of the acquired requirements for information extraction purposes. This will support requirements engineers on requirement analysis and enables a further processing such as disambiguation or the resolution of incomplete expressions.

This paper is structured as follows: In Section 2, we discuss the notion of requirements. Then we provide an overview of previous work (Section 3), before we introduce lexical resources necessary for our method (Section 4). The approach itself is presented in Section 5 before it is evaluated in Section 6. Finally, we conclude this work in Section 7.

2 The Nature of Requirements

Requirement engineers and software developers have to meet users' wishes in order to create new software products. Such descriptions of software functionalities can be expressed in different ways: For example, by using controlled languages or formal methods, clarity and completeness can be achieved. But non-experts can hardly apply them and therefore do not belong to the user group. For this reason, users are encouraged to express their individual requirements for the desired software application in NL in order to improve user acceptance and satisfaction (Firesmith, 2005). In general, software requirements are expressed through active verbs such as *"to calculate"* or *"to publish"* (Robertson and Robertson, 2012). In this work, we distinguish requirements expressed in NL between controlled and uncontrolled language.

A controlled language is a subset of NL, which is characterized by a restricted grammar and/or limited vocabulary (Yue et al., 2010). Requirements in controlled language do not suffer from ambiguity, redundancy and complexity (Yue et al., 2010). That is why these recommendations lead to a desirable input for text processing. Robertson and Robertson (2012) therefore recommend specifying each requirement in a single sentence with one verb. Furthermore, they suggest the following start of record *"The [system/product/process] shall ..."*, which focuses on the functionality and keeps the active form of a sentence. An example therefore is *"The system shall display the Events in a graph by time."* Another type of controlled requirements are user stories. They follow the form *"As a [role], I want [something] so that [benefit]"* and describe software functionalities from the user's perspective (Cohn, 2004). Compared to the previous ones, they do not focus on the technical implementation but concentrate on the goals and resulting benefits. An example therefore is *"As a Creator, I want to upload a video from my local machine so that any users can view it."*

We also consider uncontrolled language in this work because requirements are usually specified by users that have not been instructed for any type of formulation. Requirements in uncontrolled language do not stick to grammar and/or orthographic rules and may contain abbreviations, acronyms or emoticons. There is no restriction how to express oneself. An example therefore is *"Hello, I would like to suggest the implementation of expiration date for the master password :)"*.

In the following, the word "requirement" is used for a described functionality. We assume that its textualization is written within a single English sentence. Requirements are specified in documents like the *Software Requirements Specification* (SRS). We refer to SRS and other forms (e.g. e-mails, memos from workshops, transcripts of interviews or entries in bug-trackers) as requirement documentations.

3 Previous Work

It is quite common that requirement engineers elicit requirements together with users in interviews, group meetings, or by using questionnaires (Mich, 1996). Researchers developed (semi-) automated and collaborative approaches to support requirement engineers in this process (Ankori and Ankori, 2005; Castro-Herrera et al., 2009). Besides the elicitation in interaction with the users, an identification of requirements from existing sources is possible. For example, John and Dörr (2003) used documentations from related products to derive requirements for a new product. Vlas and Robinson (2011) used unstructured, informal, NL feature requests from the platform SourceForge to collect requirements for open source software. They presented a rule-based method to identify and classify requirements according to the quality criteria of the *McCall's Quality Model* (McCall, 1977). Analogous to their work, we want to automatically detect requirements in user-generated content. While they applied a rule-based

method, we plan to identify requirements in user-generated content with a machine learning approach. Since those approaches automatically identify patterns for this classification task, we expect a higher recall and more reliable results.

Goldin and Berry (1994) identified so-called abstractions (i.e. relevant terms and concepts related to a product) of elicited requirements for a better comprehension of the domain and its restrictions. Their tool *AbstFinder* is based on the idea that the significance of terms and concepts is related to the number of mentions in the text. However, in some cases, there is only a weak correlation between the term frequencies and their relevance in documents. This problem can be reduced by a statistical corpus analysis, when the actual term frequency is similar to the expected (Sawyer et al., 2002; Gacitua et al., 2011). This approach eliminates corpus specific stopwords and misleading frequent terms. In our work, we intent to perform a content analysis of the previously detected requirements. However, instead of only identifying significant terms and concepts, we capture the semantically relevant parts of requirements such as conditions, motivations, roles or actions (cf. Figure 1).

In addition to the identification of abstractions, there are methods to transform NL requirements into graphical models (e.g. in *Unified Modeling Language*) (Harmain and Gaizauskas, 2003; Ambriola and Gervasi, 2006; Körner and Gelhausen, 2008). A systematic literature review, done by Yue et al. (2010), aims at the modeling of requirements by comparing transformation techniques in such models. Unlike those techniques, we aim to keep the expressive aspect of the original textual requirements and semantically annotate them for filtering purposes. These results can be further used for different NLP tasks such as disambiguation, resolution of vagueness or the compensation of underspecification.

The semantic annotation task of this work is similar to semantic role labeling (SLR). According to Jurafsky and Martin (2015), the goal of SLR is understanding events and their participants, especially being able to answer the question *who did what to whom* (and perhaps also *when and where*). In this work, we seek to adapt this goal to the requirements domain, where we want to answer the question *what actions should be done by which component* (and perhaps also *who wants to perform that action*, *are there any conditions*, *what is the motivation for performing this action* and *is there a priority assigned to the requirement*).

4 Gathering and Annotation of Controlled and Uncontrolled Requirements

There are benchmarks comparing automated methods for requirement engineering (Tichy et al., 2015). However, none of the published datasets is sufficient to train a text classifier, since annotated information is missing. For our purposes, we need a data set with annotated predicate-argument structures, conditions, priorities, motivations and semantic roles. We therefore created a semantically annotated corpus by using the categories shown in Figure 1, which represent all information bits of a requirement. Since the approach should be able to distinguish between (on-topic) requirements and off-topic comments, we acquired software domain-specific off-topic sentences, too.

Therefore, we acquired requirements in controlled language from the system's and the user's perspective. While requirements from the system's perspective are describing technical software functionalities, the requirements from the user's perspective express wishes for software, to fulfill user needs. For instance, the NFR corpus[4] covers the system's perspective of controlled requirements specifications. It consists of 255 functional and 370 non-functional requirements whereof we used the functional subset to cover the system's perspective. Since we could not identify any requirement corpus that describes a software at user's request, we acquired 304 user stories from websites and books that describe how to write user stories.

However, these requirements in controlled language have not the same characteristics as uncontrolled requirements descriptions. For the acquisition of uncontrolled requirements, we adapted the idea of Vlas and Robinson (2011) that is based on feature requests gathered from the open-source software platform SourceForge[5]. These feature requests

[4] https://terapromise.csc.ncsu.edu/repo/requirements/nfr/nfr.arff

[5] https://sourceforge.net

are created by users that have not been instructed for any type of formulation. Since these requests do not only contain requirements, we split them into sentences and manually classified them in requirements and off-topic information. Here, we consider social communication, descriptions of workflows, descriptions of existing software features, feedback, salutations, or greetings as off-topic information. In total, we gathered 200 uncontrolled on-topic sentences (i.e. requirements) and 492 off-topic ones.

Then we analyzed the acquired requirements in order to identify the different possible semantic categories to annotate their relevant content in our requirements corpus (cf. Figure 1):

- **component**
  - refinement of component
- **action**
  - argument of action
- condition
- priority
- motivation
- role
- **object**
  - refinement of object
- **sub-action**
  - argument of sub-action
- sub-priority
- sub-role
- **sub-object**
  - refinement of sub-object

Figure 1: Semantic categories in our software requirements corpus used for annotation purposes

The categories *component* or *role*, *action* and *object* are usually represented by subject, predicate and object of a sentence. In general, a description refers to a *component*, either to a product or system itself or to a part of the product/system. *Actions* describe what a component should accomplish and affect. Actions have an effect on *Objects*. The authors of the requirements can refine the description of components and objects, which is covered by the categories *refinement of component* and *refinement of object*. For each action, users can set a certain *priority*, describe their *motivation* for a specific functionality, state *conditions*, and/or even define some semantic *roles*. Apart from the component and the object, additional arguments of the action (predicate of a sentence) are annotated with *argument of action*. In some cases, requirements contain sub-requirements in subordinate clauses. The annotators took this into account when using the predefined sub-categories. An example of an annotated requirement is shown in Figure 2.

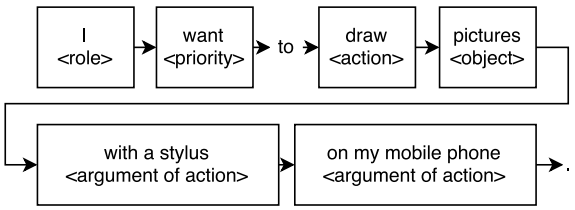

Figure 2: Annotated requirement sample

Two annotators independently labeled the categories in the requirements. We define one of the annotation set as gold standard and the other as candidate set. We will use the gold standard for training and testing purposes in Section 5 and 6 and the candidate set for calculating an inter-annotator agreement. In total, our gold standard consists of 3,996 labeled elements (i.e. clauses, phrases, and even modality). The frequency distribution is shown in Table 1.

Semantic Category	CR	UR	Total
component	241	84	325
refinement of component	6	16	22
action	526	204	730

Table 1: Number of annotated elements per category in our gold standard (CR=controlled requirements, UR=uncontrolled requirements)

The inter-annotator agreement in multi-token annotations is commonly evaluated by using F_1-score (Chinchor, 1998). The two annotators achieve an agreement of 80%, whereby the comparison was invoked from the gold standard.

Many information extraction tasks use the IOB encoding[6] for annotation purposes. When using the IOB encoding, the first token of an element is split into its head (first token) and its tail (rest of the element). That way, its boundaries are labeled with B (begin) and I (inside). This allows separating successive elements of the same category. Thus, we use the IOB encoding during the annotation step. However, we want to discuss a drawback of this notation: When applying text classification approaches in information extraction tasks with IOB encoding, the number of classes reduplicates and this reduces the amount of training data per class. During our annotation process, successive elements of the same semantic category only occurred in the case of *argument of the action* and *argument of the sub-action*. When we disregard the IOB encoding, we can easily split up (sub-)actions by keywords such as *"in"*, *"by"*, *"from"*, *"as"*, *"on"*, *"to"*, *"into"*, *"for"*, and *"through"*. So if we use IO encoding, it can be easily transformed to the IOB encoding. The only difference between IOB and IO encoding is that it does not distinguish between the head and tail of an element and therefore does not double the number of classes.

5 REaCT – A Two-Stage Approach

Requirement documentations are the input of our system. Figure 3 illustrates the two-stage approach divided in two separate classification tasks. First, we apply an on-/off-topic classification to decide whether a sentence is a requirement or irrelevant for the further processing (cf. Section 5.1). Then, the previously identified requirements were automatically annotated (Section 5.2). As a result, we get filtered and semantically annotated requirements in XML or JSON.

The models for on-/off-topic classification and semantic annotation are trained on the gathered requirements (cf. Section 4). We split up the gold standard on sentence level in a ratio of 4:1 in a training set of 607 requirements and test set of 152 requirements. Furthermore, we used 10-fold cross validation on the training set for algorithm configuration and feature engineering (cf. Section 5.1 and Section 5.2). Finally, our approach is evaluated on the test set (cf. Section 6).

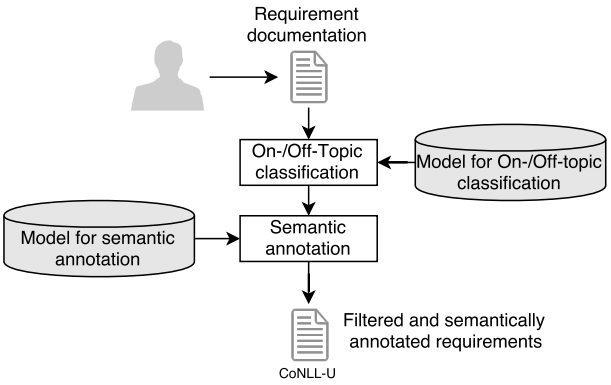

Figure 3: Processing pipeline of the two-stage approach

5.1 On-/Off-Topic Classification Task

User requirement documentations often contain off-topic information. Therefore, we present a binary text classification approach that distinguishes between requirements and off-topic content. Thus, we trained different classification algorithms and tested them using various features and parameter settings. We compared the results to select the best algorithm together with its best-suited parameter values and features.

5.1.1 Features

To differentiate requirements from off-topic content, the sentences will be transformed in numerical feature vectors using a bag-of-words approach with different settings[7]. The features for the transformation are listed along with their possible parameter settings in Table 2. We can choose whether the feature should be taken from word or character n-grams (a.1). For both versions, the unit can range between $[n, m]$ (a.2), which can be specified by parameters. Here, we consider all combinations of $n = [1, 5]$ and $m = [1, 5]$ (where $m \geq n$). If the feature should be build from word n-grams, stopword detection is possible (a.3). Additionally, terms can be ignored that reach a document frequency below or above a given

[6] I (inside), O (outside) or B (begin) of an element

[7] Parameters; to be chosen during algorithm configuration

threshold (e.g. domain-specific stopwords) (a.4 and a.5). Another threshold can be specified to only consider the top features ordered by term frequency (a.6). Besides, it is possible to re-weight the units in the bag-of-words model in relation to the inverse document frequency (IDF) (a.7). Moreover, the frequency vector can be reduced to binary values (a.8), so that the bag-of-words model only contains information about the term occurrence but not about its calculated frequency. We also consider the length of a sentence as feature (b). Furthermore, the frequency of the part-of-speech (POS) tags (c) and the dependencies between the tokens (d) can be added to the feature vector[8]. These two features are optional (c.1 and d.1). This set of features covers the domain-specific characteristics and should enable the identification of the requirements.

#	Feature/Parameter	Possible Values
a	Bag of words	
a.1	analyzer	word, char
a.2	ngram_range	(1,1),(1,2), ...,(5,5)
a.3	stop_words	True, False
a.4	max_df	[0,8,1,0]
a.5	min_df	[0.0,0.5]
a.6	max_features	int or None
a.7	use_idf	True, False
a.8	binary	True, False
b	Length of the sentence	
c	Dependencies	
c.1	use_dep	True, False
d	Part of speech	
d.1	use_pos	True, False

Table 2: Features for on-/off-topic classification together with their corresponding parameters

5.1.2 Selected Algorithms

We selected the following algorithms from the *scikit-learn* library[9] for binary classification: decision tree (`DecisionTreeClassifier`), Naive Bayes (`BernoulliNB` and `MultionmialNB`), support vector machine (`SVC` and `NuSVC`) as well as ensemble methods (`BaggingClassifier`, `RandomForestClassifier`, `ExtraTreeClassifier` and `AdaBoostClassifier`). Finally, after evaluating these algorithms, we chose the best one for the classification task (cf. Section 6).

5.2 Semantic Annotation Task

For each identified requirement, the approach should annotate the semantic components (cf. Figure 1). Here, we use text classification techniques on token level for information extraction purposes. The benefit is that these techniques can automatically learn rules to classify data from the annotated elements (cf. Section 4). Each token will be assigned to one of the semantic categories presented in Figure 1 or the additional class *O* (outside according IOB notation).

We decided in favor of IO encoding during classification to reduce the drawback described in Section 4. We finally convert the classification results into the IOB encoding by labeling the head of each element as begin and the tail as inside. By using the keywords listed in Section 4 as separators, we further distinguish the beginning and the inner parts of arguments.

5.2.1 Features

In the second classification step, we had to adapt the features to token level. The goal of feature engineering is to capture the characteristics of the tokens embedded in their surrounding context. We divided the features in four groups: orthographic and semantic features of the token, contextual features, and traceable classification results.

Orthographic features of a token are its graphematic representation (a) and additional flags that decide if a token contains a number (b), is capitalized (c), or is somehow uppercased (d) (cf. Table 3). For the graphematic representation, we can choose between the token or the lemma (a.1). Another orthographic feature provides information about the length of the token (e). Furthermore, we can use the pre- and suffix characters of the token as features (f and g). Their lengths are configurable (f.1 and g.1).

[8] We use spaCy (`https://spacy.io`) for POS tagging and dependency parsing

[9] `http://scikit-learn.org`

#	Feature/Parameter	Possible Values
a	Graphematic representation	
a.1	use_lemma	True, False
b	Token contains a number	
c	Token is capitalized	
d	Token is somehow uppercased	
e	Length of the token	
f	Prefix of the token	
f.1	length_prefix	[0,5]
g	Suffix of the token	
g.1	length_suffix	[0,5]

Table 3: Orthographic features for semantic annotation

Furthermore, we consider the relevance (h), the POS tag (i) and the WordNet ID of a token (j) as its semantic features (cf. Table 4). By checking the stopword status of a token, we can decide about its relevance. Besides, the POS tag of each token is used as feature. When applying the POS information, we can choose between the *Universal Tag Set*[10] (consisting of 17 POS tags) and the *Penn Treebank Tag Set*[11] (including of 36 POS tags) (i.1). Another boolean feature tells us whether the token appears in *WordNet*[12]. We use this feature as indicator for component or object identification.

#	Feature/Parameter	Possible Values
h	Relevance	
i	Part-of-speech tag	
i.1	extended_tagset	True, False
j	WordNet ID	

Table 4: Semantic features for semantic annotation

As contextual features, we use sentence length (k), index of the token in the sentence (l), as well as the tagging and dependency parsing information of the surrounding tokens (m, n and o) (cf. Table 5). Thus, the POS tags sequences of the n previous and the next m token are considered, where n and m are defined during algorithm configuration (l.1 and n.1). Moreover, it can be specified if each POS tag should be stored as a single feature or should be concatenated (e.g. NOUN+VERB+NOUN) (l.2 and n.2).

#	Feature/Parameter	Possible Values
k	Sentence length	
l	Index of the token	
m	Previous part-of-speech tags	
l.1	n_pos_prev	[0,15]
l.2	conc_prev_pos	True, False
n	Subsequent part-of-speech tags	
n.1	n_pos_succ	[0,15]
n.2	conc_succ_pos	True, False
o	Dependencies	

Table 5: Contextual features for semantic annotation

The classification task is carried out from left to right in the sentence. This enables the consideration of previous classification results (cf. Table 6). We implemented two slightly different variants that can be combined on demand: Firstly, we can define a fixed number of previous classification results as independent or concatenated features (i.e. a sliding window (p)). Secondly, the number of token already assigned to a particular class may be a valuable information (q). This is especially of interest for the hierarchical structure of the categories: For instance, a *sub-object* should only occur if an *object* has already been identified. These two features are optional (p.1 and q.1). The size of the sliding window will be specified during algorithm configuration (p.2).

#	Feature/Parameter	Possible Values
p	Sliding windows	
p.1	conc_prev_labels	True, False
p.2	window_size	[0,10]
q	Number of previous labels per category	
q.1	use_prev_labels	True, False

5.2.2 Selected Algorithms

In addition to the classifiers we already used in the on-/off-topic classification task, we considered three sequential learning algorithms: conditional random fields (`FrankWolfeSSVM`) from the *PyStruct*-library[13], multinomial hidden markov model (`MultinomialHMM`) as well as structured perceptron from the *seqlearn*-library[14]. We could not estimate feasible parameter settings for the `NuSVC` classifier, so that this classifier was ignored. We chose the algorithm with the best results on the test set for annotating the requirements (cf. Section 6).

6 Evaluation

As mentioned in Section 5, the data was separated in a ratio of 4:1 in a training and a test set. We trained all classifiers on the training set with their defined settings from the automated algorithm configuration. Subsequently, we evaluated these classifiers on the test set. Our results are shown in Table 7 that lists the accuracy for the best classifier per algorithm family of the on-/off-topic classification task. The `ExtraTreeClassifier` performs best on the test data with an accuracy of 92%. The accuracy was calculated with the following formula:

$$accuracy = \frac{\#true\ positives + \#true\ negatives}{\#classified\ requirements}$$

The `ExtraTreeClassifier` is an implementation of *Extremely Randomized Trees* (Geurts et al., 2006). We achieved the best result when using character n-grams as features in the model with a fixed length of 4. Thereby, we considered term occurrence instead of term frequency and IDF. Before creating the bag-of-words model, the approach removes stopwords. Furthermore, the frequency of the POS tags and their dependencies are used as features. In total, the `ExtraTreeClassifier` used 167 estimators based on entropy in the ensemble (algorithm-specific parameters).

[13] `https://pystruct.github.io`

[14] `https://github.com/larsmans/seqlearn`

Classifier	Accuracy
AdaBoostClassifier	0.87
ExtraTreeClassifier	0.92
MultinomialNB	0.89
NuSVC	0.90

Table 7: Accuracy of best classifiers per algorithm family in the on-/off-topic classification task after algorithm configuration

Table 8 shows the values for precision, recall, and F_1 of the `ExtraTreeClassifier`. In brief, the introduced approach detects requirements in user-generated content with an average F_1-score of 91%.

Class	Precision	Recall	F_1
off-topic info	0.94	0.85	0.89
requirements	0.89	0.96	0.93
Avg.	0.92	0.91	0.91

Table 8: Evaluation results for the on-/off-topic classification with the `ExtraTreeClassifier`

Table 9 provides an overview of the results of the semantic annotation task. To determine the F_1-score, the agreement of the predicted and the a priori given annotations is necessary to count an element as true positive.

Again, the `ExtraTreeClassifier` achieves the best F_1-score of 72%. We gained the best results by using 171 randomized decision trees based on entropy (algorithm-specific parameters). As features, we took the POS tags from *Universal Tag Set* for the twelve previous and the three following tokens. Traceable classification results are taken into account by a sliding window of size 1. Besides, we validate if a class label has already been assigned. For each considered token, the four prefix and the two suffix characters as well as the graphematic representation of the token are applied as features.

The sequential learning algorithms (`FrankWolfeSSVM`, `MultinomialHMM` and `StructuredPerceptron`) perform worse than the other classifiers. We assume that this is due to the small amount of available training data. However, the methods depending on decision trees, especially the ensemble methods (`RandomForestClassifier`, `Bagging-`

Classifier and ExtraTreeClassifier), perform significantly better.

Classifier	F_1
AdaBoostClassifier	0.33
ExtraTreeClassifier	0.72
FrankWolfeSSVM	0.50
MultinomialNB	0.64
SVC	0.70

Table 9: F_1-scores of best classifiers per algorithm family in the semantic annotation task after algorithm configuration

In Table 10, we provide detailed results achieved with the ExtraTreeClassifier for the different semantic categories. The recognition of main aspects (component, action and object) reached F_1-scores of 73%, 80% and 68%. The semantic categories, that have only a few training examples, are more error-prone (e.g. sub-action or sub-object).

Semantic Category	Precision	Recall	F_1
component	0.71	0.75	0.73
ref. of component	0.17	0.14	0.15
action	0.78	0.82	0.80
arg. of action	0.49	0.62	0.54
condition	0.88	0.61	0.72
priority	0.96	0.96	0.96
motivation	0.67	0.29	0.40
role	0.93	0.86	0.89
object	0.63	0.74	0.68
ref. of object	0.69	0.51	0.59
sub-action	0.46	0.44	0.45
arg. of sub-action	0.33	0.29	0.31
sub-priority	0.44	0.57	0.50
sub-role	0.40	0.80	0.53
sub-object	0.35	0.33	0.34
ref. of sub-object	0.67	0.33	0.44
Avg.	0.72	0.73	0.73

7 Conclusion and Future Work

Requirement engineers and software developers have to meet users' wishes to create new software products. The goal of this work was to develop a system that can identify and analyze requirements expressed in natural language. These are written by users unlimited in their way of expression. Our system REaCT achieves an accuracy of 92% in distinguishing between on- and off-topic information in the user-generated requirement descriptions. The text classification approach for semantic annotation reaches an F_1-score of 72% – a satisfying result compared to the inter-annotator agreement of 80%. One possibility to improve the quality of the semantic annotation is to expand the training set. Especially the sequential learning techniques need more training data. Besides, this would have a positive impact on those semantic categories that only contain a small number of annotated elements.

Developers and requirement engineers can facilely identify requirements written by users for products in different scenarios by applying our approach. Moreover, the semantic annotations are useful for further NLP tasks. User-generated software requirements adhere to the same quality standards as software requirements that are collected and revised by experts: They should be complete, unambiguous and consistent (Hsia et al., 1993). Since there was no assistant system to check the quality for many years (Hussain et al., 2007) we plan to extend the provided system in order to provide some quality analysis of the extracted information. We have already developed concepts to generate suggestions for non-experts, how to complete or clarify their requirement descriptions (Geierhos et al., 2015). Based on these insights, we want to implement a system for the resolution of vagueness and incompleteness of NL requirements.

Acknowledgments

Special thanks to our colleagues Frederik S. Bäumer and David Kopecki for their support during the semantic annotation of the requirements. This work was partially supported by the German Research Foundation (DFG) within the Collaborative Research Centre „On-The-Fly Computing“ (SFB 901).

Abstract

Existing work on detecting deceptive reviews primarily focuses on feature engineering and applies off-the-shelf supervised classification algorithms to the problem. Then, one real challenge would be to manually recognize plentiful ground truth spam review data for model building, which is rather difficult and often requires domain expertise in practice. In this paper, we propose to exploit the relatedness of multiple review spam detection tasks and readily available unlabeled data to address the scarcity of labeled opinion spam data. We first develop a multi-task learning method based on logistic regression (MTL-LR), which can boost the learning for a task by sharing the knowledge contained in the training signals of other related tasks. To leverage the unlabeled data, we introduce a graph Laplacian regularizer into each base model. We then propose a novel semi-supervised multi-task learning method via Laplacian regularized logistic regression (SMTL-LLR) to further improve the review spam detection performance. We also develop a stochastic alternating method to cope with the optimization for SMTL-LLR. Experimental results on real-world review data demonstrate the benefit of SMTL-LLR over several well-established baseline methods.

1 Introduction

Nowadays, more and more individuals and organizations have become accustomed to consulting user-generated reviews before making purchases or online bookings. Considering great commercial benefits, merchants, however, have tried to hire people to write undeserving positive reviews to promote their own products or services, and meanwhile to post malicious negative reviews to defame those of their competitors. The fictitious reviews and opinions, which are deliberately created in order to promote or demote targeted entities, are known as *deceptive opinion spam* (Jindal and Liu, 2008; Ott et al., 2011).

By formulating deceptive opinion spam detection as a classification problem, existing work primarily focuses on extracting different types of features and applies off-the-shelf supervised classification algorithms to the problem (Jindal and Liu, 2008; Ott et al., 2011; Feng et al., 2012; Chen and Chen, 2015). Then, one weakness of previous work lies in the demand of manually recognizing a large amount of ground truth review spam data for model training. Unlike other forms of spamming activities, such as email or web spam, deceptive opinion spam, which has been deliberately written to sound authentic, is more difficult to be recognized by manual read. In an experiment, three undergraduate students were (randomly) invited to identify spam reviews from nonspam ones in hotel domain. As shown in Table 1, their average accuracy is merely 57.3% (Ott et al., 2011). Then, given a limited set of labeled review data for a domain, e.g., hotel, it is almost impossible to build a robust classification model for detecting deceptive spam reviews in reality.

In this work, we deal with the problem of detecting a textual review as *spam* or not, i.e., *nonspam*. We consider each deceptive review spam detection problem within each domain, e.g., detecting

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1817–1826,
Austin, Texas, November 1-5, 2016.

	Judge-1	Judge-2	Judge-3
Accuracy	61.9%	56.9%	53.1%
F-spam	48.7%	30.3%	43.6%
F-nonspam	69.7%	68.8%	59.9%

Table 1: Performance of human judges for review spam detection in hotel domain (Ott et al., 2011), where F-spam/F-nonspam means F-score for spam/nonspam label.

spam hotel/restuarnt reviews from hotel/restaurnat domain, to be a different task. Previous studies have empirically shown that learning multiple related tasks simultaneously can significantly improve performance relative to learning each task independently, especially when only a few labeled data per task are available (Caruana, 1997; Bakker and Heskes, 2003; Argyriou et al., 2006). Thus, given the limited labeled review data for each domain, we formulate the review spam detection tasks for multiple domains, e.g., hotel, restaurant, and so on, as a multi-task learning problem.

We develop a multi-task learning method via logistic regression (MTL-LR) to address the problem. One key advantage of the method is that it allows to boost the learning for one review spam detection task by leveraging the knowledge contained in the training signals of other related tasks. Then, there is often a large quantity of review data freely available online. In order to leverage the unlabeled data, we introduce a graph Laplacian regularizer into each base logistic regression model. We extend MTL-LR, and propose a novel semi-supervised multi-task learning model via Laplacian regularized logistic regression (SMTL-LLR) to further boost the review spam detection performance under the multi-task learning setting. Moreover, to cope with the optimization problem for SMTL-LLR, we also develop a stochastic alternating optimization method, which is computationally efficient.

To the best of our knowledge, this is the first work that generalizes opinion spam detection from independent single-task learning to symmetric multi-task learning setting. By symmetric, we mean that the setting seeks to improve the performance of all learning tasks simultaneously. In this sense, it is different from transfer learning (Pan and Yang, 2010), where the objective is to improve the performance of a target task using information from source tasks. Under this new setting, we can exploit the commonality shared by related review spam detection tasks as well as readily available unlabeled data, and then alleviate the scarcity of labeled spam review data. Experimental results on real-world review data demonstrate the superiority of SMTL-LLR over several representative baseline methods.

The rest of this paper is organized as follows. Section 2 presents related work. Section 3 introduces the proposed methods and stochastic alternating optimization algorithm. Then, in Section 4, we present the experimental results in detail, and conclude this paper in Section 5.

2 Related Work

Previous work typically formulates deceptive opinion spam detection as a classification problem, and then presents different types of features to train supervised classification algorithms for the problem. Jindal and Liu (2008) first studied opinion spam detection problem. They built the ground truth review data set by treating the duplicate reviews in a given corpus as spam reviews and the rest as nonspam reviews. They presented review, product, and reviewer related features, and then trained logistic regression (LR) model on the features for finding fake review spam. Ott et al. (2011) created the ground truth review data via a crowd-sourcing service called Amazon Mechanical Turk[1]. They presented three different types of features for opinion spam detection, i.e., genre identification features, psycholinguistic deception features, and standard n-gram text features. They found that the supervised support vector machines (SVM) trained on the textual n-gram features can achieve good performance. Feng et al. (2012) presented syntactic stylometry features and trained SVM model for deception detection, while Chen and Chen (2015) built the SVM classifier on a diversity of features, such as content and thread features, for opinion spam detection in web forum. In addition, Li et al. (2014) employed a feature-based additive model to explore the general rule for deceptive opinion spam detection. Generally, in order to build robust supervised review spam detection models, we have to manually recognize large-scale ground truth spam data. But this could be very ex-

[1]https://www.mturk.com

pensive, and often requires domain expertise.

Though a large amount of unlabeled review data are freely available online, very limited work has been done on developing semi-supervised methods for review spam detection. Li et al. (2011) used a two-view co-training method (Blum and Mitchell, 1998) for semi-supervised learning to identify fake review spam. One limitation of the work is that it needs additional reviewer information when building model. Given a corpus of textual reviews, the reviewer related view may not be always available in reality. Moreover, the co-training method is not intrinsically geared to learning from the unlabeled review data, instead, simply makes use of the unlabeled reviews within a fully supervised learning framework, negating the semi-supervised learning benefit. For some particular scenarios, the available training data could be only a partially labeled set of positive examples, e.g., spam reviews, and a large set of unlabeled reviews. Positive unlabeled learning (PU) (De Comite et al., 1999; Liu et al., 2002) may be then used for deceptive review spam detection (Hernandez et al., 2013). However, this clearly contrasts with our problem, where our training data contains a complete labeled set of positive (spam) and negative (nonspam) reviews besides the unlabeled set of review data.

In addition, instead of detecting spam reviews directly, considerable efforts have been made to recognize review spammers, i.e., online users who have written spam reviews. Lim et al. (2010) studied different types of spamming behavioral indicators, and then used a regression method on the indicators for finding review spammers. Wang et al. (2012) investigated the relationships among reviewers, reviews, and stores, and developed a social review graph based method to identify online store spammers. Mukherjee et al. (2013) developed an author spamicity Bayesian model to exploit the observed behavioral footprints for spammer detection. In reality, a group of online users may work together to create spam reviews. Mukherjee et al. (2012) developed a group spam ranking algorithm to detect spammer groups.

Multi-task learning is a learning paradigm that seeks to boost generalization performance by learning a task together with other tasks at the same time while using a shared representation (Caruana, 1997). Most majority of existing work on multi-task learning does not infer actual task relations from training data automatically, instead, they typically make the assumptions that the relations are existent or are given as prior knowledge (Thrun and O'Sullivan, 1996; Bakker and Heskes, 2003; Evgeniou and Pontil, 2004; Argyriou et al., 2006; Liu et al., 2009). To better fit the multi-task learning model to real-world data, Zhang and Yeung (2010) proposed a convex regularization formulation named multi-task relation learning (MTRL), which can learn real relationships between tasks under a multi-task learning framework.

In this work, we focus on detecting online deceptive review spam. We formulate review spam detection for multiple domains (e.g., hotel and restaurant) as a multi-task learning problem. Following the convex framework of MTRL, we first develop a multi-task learning method via logistic regression (MTL-LR). We employ logistic regression as base classification model, because: 1) It is a robust model that does not have configuration parameters to tune; 2) It can be straightforwardly extended, and be efficiently trained using convex optimization techniques (Hoi et al., 2006; Minka, 2003); and 3) It has been shown effective for large-scale text classification and fake review detection problems (Hoi et al., 2006; Jindal and Liu, 2008). Then, to leverage the large volume of unlabeled review data, we extend the base logistic regression model, and incorporate a graph Laplacian regularizer into it. We thus develop a new semi-supervised multi-task learning paradigm via Laplacian regularized logistic regression, which is able to further boost the performance for review spam detection.

3 Methodology

3.1 Multi-task Learning via Logistic Regression

Given m review domains $\mathcal{D}_1, \ldots, \mathcal{D}_m$, we accordingly have m review spam detection tasks $\mathcal{T}_1, \ldots, \mathcal{T}_m$, which share a common feature space with d dimensions. For the task $\mathcal{T}_i$ in the domain $\mathcal{D}_i$, there is a small labeled set of l_i review examples $\mathcal{L}_i = \{(\mathbf{x}_1^i, y_1^i), \ldots, (\mathbf{x}_{l_i}^i, y_{l_i}^i)\}$, where $\mathbf{x}_j^i \in \mathbb{R}^d$ is the vectorial representation of the review j in the labeled set $\mathcal{L}_i$, and $y_j^i \in \{+1, -1\}$ refers to the *spam*

(+1) or *nonspam* (−1) label of the review.

When there is only one review spam detection task, for example, $\mathcal{T}_i$, we can use logistic regression (LR) model to learn a supervised classifier based on the labeled set $\mathcal{L}_i$. The objective function of LR for single-task learning is

$$P^i_{LR}(\mathbf{w}_i) = \frac{1}{l_i}\sum_{j=1}^{l_i}\ln(1+\exp(-y^i_j\mathbf{w}_i^\top\mathbf{x}^i_j)) + \frac{\lambda}{2}\|\mathbf{w}_i\|^2,$$

where $\mathbf{w}_i \in \mathbb{R}^d$, $\lambda > 0$ refers to regularization parameter.

Once the model is learned from solving the optimization problem, given a test review instance $\mathbf{x}_{j'}$ of the task $\mathcal{T}_i$, we can employ the model to predict it as *spam*, i.e., $\hat{y}_{j'} = 1$, with probability

$$Prob(\hat{y}_{j'} = 1) = \frac{1}{1+\exp(-\mathbf{w}_i^\top\mathbf{x}^i_{j'})}.$$

Now we have m review spam detection tasks for multiple domains, and we would learn m supervised classification models simultaneously. To achieve this, we introduce a covariance matrix Ω to represent the correlations among the m review spam detection tasks, where Ω_{ij} refers to the relation/covariance between a pair of tasks $\mathcal{T}_i$ and $\mathcal{T}_j$. Since Ω is a task covariance matrix, we require it to satisfy the constraint $\Omega \succeq 0$, i.e., positive semidefinite. We also restrict $Tr(\Omega) = 1$ without of loss of generality, since for any covariance matrix $Tr(\Sigma) \neq 1$, we can use $\frac{\Sigma}{Tr(\Sigma)}$ as Ω. If the covariance matrix is given as prior knowledge, then we introduce a supervised multi-task learning (MTL) framework via logistic regression as follows

$$P^\Omega_{MTL}(\mathbf{W}) = \sum_{i=1}^{m}\frac{1}{l_i}\sum_{j=1}^{l_i}\ln(1+\exp(-y^i_j\mathbf{w}_i^T\mathbf{x}^i_j)) + \frac{\lambda}{2}Tr(\mathbf{W}\mathbf{W}^\mathbf{T}) + \frac{\beta}{2}Tr(\mathbf{W}\mathbf{\Omega}^{-1}\mathbf{W}^T),$$

where $\mathbf{W} = (\mathbf{w}_1, \ldots, \mathbf{w}_m)$, and $\beta > 0$ is a regularization parameter.

Under this multi-task learning setting, the first term refers to the sum of all the average empirical loss, the second term refers to the regularizer used to avoid over-fitting, and the last term is introduced to leverage the shared knowledge from multiple learning tasks according to their relationships.

In reality, the covariance matrix may be not provided a priori. We then present the following multi-task learning model, which can learn the model parameters W and Ω automatically from training review data

$$P_{MTL}(\mathbf{W}, \mathbf{\Omega}) = \sum_{i=1}^{m}\frac{1}{l_i}\sum_{j=1}^{l_i}\ln(1+\exp(-y^i_j\mathbf{w}_i^T\mathbf{x}^i_j)) + \frac{\lambda}{2}Tr(\mathbf{W}\mathbf{W}^\mathbf{T}) + \frac{\beta}{2}Tr(\mathbf{W}\mathbf{\Omega}^{-1}\mathbf{W}^T)$$
$$s.t. \quad \mathbf{\Omega} \succeq 0, \quad Tr(\mathbf{\Omega}) = 1,$$

If we have only one review spam detection task, i.e., $m = 1$, then it is straightforward to verify that the above multi-task learning formulation would be reduced to single-task objective function of logistic regression.

3.2 Semi-supervised Multi-task Learning via Laplacian Regularized Logistic Regression

Generally, for a given review domain $\mathcal{D}_i$, there is a large set of unlabeled reviews $\mathcal{U}_i = \{\mathbf{x}^i_{l_i+1}, \ldots, \mathbf{x}^i_{n_i}\}$ in addition to the labeled review set $\mathcal{L}_i$. Then, for each review spam detection task $\mathcal{T}_i$, we constracut a weighted neighborhood graph $\mathcal{G}_i = (V_i, E_i)$ based on both labeled and unlabeled review sets $\mathcal{L}_i$ and $\mathcal{U}_i$. V refers to the set of data points, each of which stands for a review example $\mathbf{x}^i_j$ ($j : 1, \ldots, n_i$) from either $\mathcal{L}_i$ or $\mathcal{U}_i$. E refers to the set of weighted edges. Specifically, if a review example/point $\mathbf{x}^i_j$ is among the K nearest neighbors of the review point $\mathbf{x}^i_k$, we put an edge linking the two examples, and vice versa. We also assign an adjacent weight score s^i_{jk} to the edge, which represents the similarity or closeness between the two reviews. Once the neighborhood graph $\mathcal{G}_i$ has been built for each task, a Laplacian regularizer can be then constrcted on the graph to extend the regular logistic regression model.

Considering the similarity matrix S_i that corresponds to the graph $\mathcal{G}_i$ for the task $\mathcal{T}_i$, it is expected that a good model would also minimize the follow-

ing objective

$$\sum_{jk} s^i_{jk}(\mathbf{w}_i^\top \mathbf{x}^i_j - \mathbf{w}_i^\top \mathbf{x}^i_k)^2,$$

This objective implies that $\mathbf{w}_i^\top \mathbf{x}^i_j$ should be close to $\mathbf{w}_i^\top \mathbf{x}^i_k$ if the similarity s^i_{jk} is large. The objective can be simplified as

$$\begin{aligned}&\sum_{jk} s^i_{jk}(\mathbf{w}_i^\top \mathbf{x}^i_j - \mathbf{w}_i^\top \mathbf{x}^i_k)^2\\ &= \mathrm{Tr}(\mathbf{w}_i^\top X_i(D_i - S_i)X_i^\top \mathbf{w}_i)\\ &= \mathrm{Tr}(\mathbf{w}_i^\top X_i L_i X_i^\top \mathbf{w}_i),\end{aligned}$$

where $D_i = diag(D^i_{jj})$ is a diagonal matrix, $D^i_{jj} = \sum_k s^i_{jk}$, and $L_i = D_i - S_i$ refers to the graph Laplacian matrix.

Then, given both labeled review set $\mathcal{L}_i$ and unlabeled set $\mathcal{U}_i$ for the task T_i, we extend the basic logistic regression by incorporating the graph Laplacian regularizer into its learning framework, and develop a new semi-supervised Laplacian regularized logistic regression (LLR) model. The objective function of LLR for semi-supervised single-task learning is given below

$$\begin{aligned}&P^i_{LLR}(\mathbf{w}_i)\\ &= \frac{1}{l_i}\sum_{j=1}^{l_i} \ln(1+\exp(-y^i_j \mathbf{w}_i^\top \mathbf{x}^i_j))\\ &+\frac{\lambda}{2}\|\mathbf{w}_i\|^2 + \frac{\gamma}{2}\mathrm{Tr}(\mathbf{w}_i^\top X_i L_i X_i^\top \mathbf{w}_i),\end{aligned}$$

where $\lambda > 0$ and $\gamma > 0$ are regularization parameters.

The semi-supervised formulation of LLR balances several desires. The first term is used to minimize the loss of the model on the labeled review data, the second term is used to minimize the complexity of the model, and the last term refers to the Laplacian regularizer, which is introduced to make the prediction of the model smooth on the whole review data set.

Next, based on the objective function of the above LLR model, we extend the supervised multi-task learning framework, and propose a novel semi-supervised multi-task learning paradigm via Laplacian regularized logistic regression (SMTL-LLR) as follows

$$\begin{aligned}&P_{SMTL}(\mathbf{W}, \mathbf{\Omega})\\ &= \sum_{i=1}^{m}\frac{1}{l_i}\sum_{j=1}^{l_i}\ln(1+\exp(-y^i_j \mathbf{w}_i^T \mathbf{x}^i_j))\\ &+\frac{\lambda}{2}Tr(\mathbf{W}\mathbf{W}^\top) + \frac{\beta}{2}Tr(\mathbf{W}\mathbf{\Omega}^{-1}\mathbf{W}^\top)\\ &+\frac{\gamma}{2}\sum_{i=1}^{m}\frac{1}{n_i}Tr(\mathbf{w}_i^T X_i L_i X_i^T \mathbf{w}_i)\\ &s.t., \quad \mathbf{\Omega} \succeq 0, \quad Tr(\mathbf{\Omega}) = 1.\end{aligned}$$

Under this new semi-supervised unified framework, our proposed SMTL-LLR model can leverage the large amount of unlabeled review data in addition to the labeled ones to learn multiple review spam detection models simultaneously, and then, what is learned for one task can help other related tasks be learned better. In contrast, previous single-task learning based review spam detection models, which are trained independently, and are typically built on a limited set of labeled review data, cannot benefit from this.

3.3 Stochastic Alternating Method

There are two parameters $\mathbf{W}$ and Ω in the objective function of the proposed SMTL-LLR model. It is not easy to optimize the objective function against the two parameters at the same time. We then develop a stochastic alternating method to cope with the optimization problem for SMTL-LLR, i.e., alternatively updating one parameter by fixing the other. In particular, we initialize $\mathbf{W}$ with the values randomly chosen from $[0, 1]$, and initialize $\mathbf{\Omega}$ as a diagonal matrix, where $\mathbf{\Omega}_{ii} = \frac{1}{m}$. For each iteration, the key update steps for the two parameters are described as follows

- *Step 1*: Update $\mathbf{W}$ while $\mathbf{\Omega}$ is fixed.

$$\mathbf{W} \leftarrow \operatorname*{argmin}_{\mathbf{W}} P_{SMTL}(\mathbf{W}, \mathbf{\Omega})$$

- *Step 2*: Update $\mathbf{\Omega}$ while $\mathbf{W}$ is fixed.

$$\Omega \leftarrow \operatorname*{argmin}_{\Omega} P_{SMTL}(\mathbf{W}, \mathbf{\Omega})$$

3.3.1 Updating W While Fixing Ω

For *Step 1* of the alternating optimization method, we introduce a stochastic gradient descent method to efficiently update the parameter $\mathbf{W}$, while Ω is fixed. Formally, given a learning task T_i, we randomly choose a subset or mini-batch of reviews $A_b^i = \{(\mathbf{x}_j^i, y_j^i)|j \in [l_i]\}$ from the labeled set $\mathcal{L}_i$ in a particular iteration, where $[l_i]$ denotes $\{1, \ldots, l_i\}$ and $|A_b^i| = r \ll l_i$. Based on the subset of labeled reviews A_b^i, we can construct an unbiased estimate of the objective function

$$\begin{aligned}
&P_{SMTL}(\mathbf{W}, \mathbf{\Omega}, \{A_b^i\}_{i=1}^m) \\
&= \sum_{i=1}^{m} \frac{1}{r} \sum_{j \in A_b^i} \ln(1 + \exp(-y_j^i \mathbf{w}_i^T \mathbf{x}_j^i)) \\
&+ \frac{\lambda}{2} Tr(\mathbf{W}\mathbf{W}^{\mathbf{T}}) + \frac{\beta}{2} Tr(\mathbf{W}\mathbf{\Omega}^{-1}\mathbf{W}^T) \\
&+ \frac{\gamma}{2} \sum_{i=1}^{m} \frac{1}{n_i} Tr(\mathbf{w}_i^T X_i L_i X_i^T \mathbf{w}_i)
\end{aligned}$$

We can then obtain an unbiased stochastic gradient of the objective

$$\begin{aligned}
&\nabla_{\mathbf{W}} P_{SMTL}(\mathbf{W}, \mathbf{\Omega}, \{A_b^i\}_{i=1}^m) \\
&= [\mathbf{g}_b^1, \ldots, \mathbf{g}_b^m] + \lambda \mathbf{W} + \beta \mathbf{W}\Omega^{-1} \\
&+ [\gamma \frac{1}{n_1} X_1 L_1 X_1^T \mathbf{w}_1, \ldots, \gamma \frac{1}{n_m} X_m L_m X_m^T \mathbf{w}_m],
\end{aligned}$$

where

$$\mathbf{g}_b^i = \frac{1}{r} \sum_{j \in A_b^i} \frac{-y_j^i \mathbf{x}_j^i}{1 + \exp(y_j^i \mathbf{w}_i^T \mathbf{x}_j^i)}.$$

Next, the model parameter $\mathbf{W}$ can be updated via stochastic gradient descent method

$$\mathbf{W}_{t+\frac{1}{2}} = \mathbf{W}_t - \eta_t \nabla_{\mathbf{W}} P_{SMTL}(\mathbf{W}, \mathbf{\Omega}, \{A_b^i\}_{i=1}^m)$$

where $\eta_t > 0$ refers to learning rate in iteration *t*.

Note that, after each update step for the parameter $\mathbf{W}$, we perform a scaling process by forcing the solution

$$\|\mathbf{W}_{t+1}\|_F \leq \sqrt{2m \ln(2)/\lambda},$$

and then have the following update rule

$$\mathbf{W}_{t+1} = \min(1, \frac{\sqrt{2m \ln(2)/\lambda}}{\|\mathbf{W}_{t+\frac{1}{2}}\|_F}) \mathbf{W}_{t+\frac{1}{2}}.$$

We provide a straightforward theoretical analysis, which shows an upper bound of the norm of the optima solution $\mathbf{W}_*$, and explains why we perform the above scaling step. Using the fact that

$$P_{SMTL}(\mathbf{W}_*) \leq P_{SMTL}(0),$$

we thus have

$$\begin{aligned}
\frac{\lambda}{2} \|\mathbf{W}_*\|_F^2 &\leq P_{SMTL}(\mathbf{W}_*) \\
&\leq P_{SMTL}(0) = m \ln(2).
\end{aligned}$$

The fist inequality is guaranteed by

$$\ln(1 + \exp(-y_j^i \mathbf{w}_i^\top \mathbf{x}_j^i)) > 0,$$

$$Tr(\mathbf{W}\mathbf{\Omega}^{-1}\mathbf{W}^\top) \geq 0,$$

and

$$\mathrm{Tr}(\mathbf{w}_i^\top X_i L_i X_i^\top \mathbf{w}_i) \geq 0.$$

3.3.2 Updating Ω While Fixing W

The second step of the stochastic alternating method is equivalent to solving the following optimization problem

$$\begin{aligned}
&\min_{\Omega} \ Tr(W\Omega^{-1}W^\top) \\
&s.t., \ \mathbf{\Omega} \succeq 0, \ Tr(\mathbf{\Omega}) = 1.
\end{aligned}$$

This convex formulation enjoys the following closed-form solution (Zhang and Yeung, 2010)

$$\mathbf{\Omega} = \frac{(\mathbf{W}^\top \mathbf{W})^{\frac{1}{2}}}{Tr((\mathbf{W}^\top \mathbf{W})^{\frac{1}{2}})}.$$

It is obviously observed that Ω models the correlations between each pair of the tasks or the models.

Algorithm 1 summarizes the stochastic alternating optimization method for SMTL-LLR. Given labeled and unlabeled review data for multiple review domains, we run the algorithm for P alternating loops. Within each loop p, we update the model parameter $\mathbf{W}$ for T iterations via stochastic gradient descent method, where *B* is number of mini-batches; after that, we update the task covariance matrix $\mathbf{\Omega}$ once based on new $\mathbf{W}$. The procedure is performed iteratively until it is converged. Then, multiple optimized review spam detection models and task covariance matrix would be learned finally.

Algorithm 1 Stochastic Alternating Method

Input:
Labeled and unlabeled review data for multiple tasks
Initial learning rate η_0, hyper-parameter δ
Regularization parameters λ, β, γ
Initialization:
Initialize $\mathbf{W}$ with values randomly chosen from [0, 1]
Initialize $\mathbf{\Omega} = diag(1/m, \ldots, 1/m)$
for $p = 1, \ldots, P$ **do**
  $\widetilde{\mathbf{W}}_1 = \mathbf{W}$
  for $t = 1, \ldots, T$ **do**
    Learning rate $\eta_t = \frac{\eta_0}{1+\eta_0 \delta t}$
    Randomly shuffle reviews in the training set
    for $b = 1, \ldots, B$ **do**
      Compute $\nabla_{\mathbf{W}} P_{SMTL}(\mathbf{W}, \mathbf{\Omega}, \{A_b^i\}_{i=1}^m)$
      Update $\widetilde{\mathbf{W}}_{t+\frac{1}{2}} = \widetilde{\mathbf{W}}_t$
        $-\eta_t \nabla_{\mathbf{W}} P_{SMTL}(\mathbf{W}, \mathbf{\Omega}, \{A_b^i\}_{i=1}^m)$
      $\widetilde{\mathbf{W}}_{t+1} = \min(1, \frac{\sqrt{2m\ln(2)/\lambda}}{\|\widetilde{\mathbf{W}}_{t+\frac{1}{2}}\|_F}) \widetilde{\mathbf{W}}_{t+\frac{1}{2}}$
    end for
  end for
  Update $\mathbf{W} = \widetilde{\mathbf{W}}_{T+1}$
  Update $\mathbf{\Omega} = \frac{(\mathbf{W}^\top \mathbf{W})^{\frac{1}{2}}}{Tr((\mathbf{W}^\top \mathbf{W})^{\frac{1}{2}})}$
end for
Output: $\mathbf{W}$ and $\mathbf{\Omega}$

In addition, we also rely on the stochastic alternating method to optimize the proposed MTL-LR method. Differently, we need to remove all the terms related to unlabeled data, i.e., discarding the Laplacian regularization term from the objective function and gradient.

4 Experiments

In this section, we evaluate the proposed multi-task learning methods MTL-LR and SMTL-LLR for review spam detection, and demonstrate the improved effectiveness of the methods over other well-established baselines.

4.1 Data Sets

Due to big challenge in manually recognizing deceptive reviews, there are limited benchmark opinion spam data in this field. We used three ground truth data sets from the review domains, *doctor*[2], *hotel*[3], and *restaurant*[4], respectively, to evaluate the proposed methods, which were created by following the similar rules used in (Ott et al., 2011). Then, for each ground truth review data set, we randomly collected a large number of unlabeled reviews (10,000), which were written about the same entities or domain. Table 2 shows some data statistics, where the last column computes the ratio of labeled reviews to unlabeled ones.

	Spam/Nonspam	Unlabeled	Ratio
Doctor	200/200	10,000	4.0%
Hotel	300/300	10,000	6.0%
Restaurant	200/200	10,000	4.0%

Table 2: Some statistics of review data sets.

4.2 Experimental Setup

We followed previous work (Mihalcea and Strapparava, 2009; Ott et al., 2011), and leveraged text unigram and bigram term-frequency features to train our models for review spam detection. This problem setting is quite useful, for example, when user behavior data are sparse or even not available in practical applications.

Supervised classification models, such as logistic regression (LR) and support vector machines (SVM), have been used to identify fake review spam (Jindal and Liu, 2008; Ott et al., 2011). We compared our methods with the two models. Semi-supervised positive-unlabeled (PU) learning was employed for review spam detection, then we chose one representative PU learning method (Liu et al., 2002) to evaluate our models. We did not compare our methods with the two-view co-training method, which was used for fake review detection (Li et al., 2011), because the *reviewer view* data are not available in the ground truth review sets. Instead, we selected a well-known semi-supervised transductive SVM (TSVM) (Joachims, 1999) to evaluate our models. Different from the proposed methods, we trained each of above baselines in a single domain, because they are single-task learning methods. Moreover, we also compared our methods with one well-established multi-task learning baseline MTRL (Zhang and Yeung, 2010), which has not been used

[2]https://www.ratemds.com

[3]https://www.tripadvisor.com

[4]http://www.yelp.com

for review spam detection problem.

It is important to specify appropriate values for the parameters in the proposed methods. In our setting, we used the learning rates η_t that asymptotically decrease with iteration numbers (Bottou, 2012). Following previous work (Ott et al., 2011; Chen and Chen, 2015), we conducted five-fold cross-validation experiments, and determined the values of the regularization and hyper parameters via a grid-search method.

4.3 Experimental Results

Table 3 reports the spam and nonspam review detection accuracy of our methods SMTL-LLR and MTL-LR against all other baseline methods. In terms of 5% significance level, the differences between SMTL-LLR and the baseline methods are considered to be statistically significant.

	Doctor	Hotel	Restaurant	Average
SMTL-LLR	85.4%	88.7%	87.5%	87.2%
MTL-LR	83.1%	86.7%	85.7%	85.2%
MTRL	82.0%	85.4%	84.7%	84.0%
TSVM	80.6%	84.2%	83.8%	82.9%
LR	79.8%	83.5%	83.1%	82.1%
SVM	79.0%	83.5%	82.9%	81.8%
PU	68.5%	75.4%	74.0%	72.6%

Table 3: Spam and nonspam review detection results in the doctor, hotel, and restaurant review domains.

Under symmetric multi-task learning setting, our methods SMTL-LLR and MTL-LR outperform all other baselines for identifying spam reviews from nonspam ones. MTL-LR achieves the average accuracy of 85.2% across the three domains, which is 3.1% and 3.4% better than LR and SVM trained in the single task learning setting, and 1.2% higher than MTRL. Training with a large quantity of unlabeled review data in addition to labeled ones, SMTL-LLR improves the performance of MTL-LR, and achieves the best average accuracy of 87.2% across the domains, which is 3.2% better than that of MTRL, and is 4.3% better than TSVM, a semi-supervised single task learning model. PU gives the worst performance, because learning only with partially labeled positive review data (spam) and unlabeled data may not generalize as well as other methods.

4.4 Performance versus Unlabeled Data Size

Figure 1 plots SMTL-LLR accuracy versus unlabeled data sizes from *0* to *10,000*, where *0* corresponds to using only labeled data to build the model, i.e., MTL-LR. Note that we first randomly sampled *2,000* unlabeled reviews to build the first set, and then created the second set by appending another randomly selected set of *2,000* reviews to the previous one. We repeated the process until all the unlabeled review data sets were created.

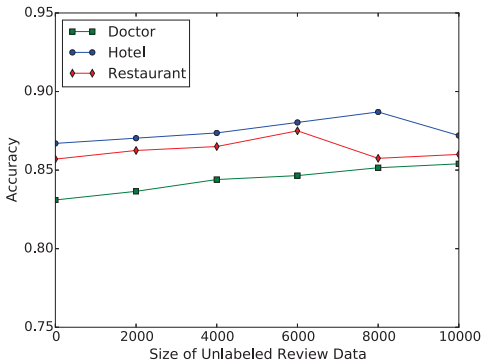

Figure 1: Accuracy versus Unlabeled Data Size.

We observed that learning from unlabeled reviews does help to boost the performance of MTL-LR, which was trained with labeled data alone. The performance of SMTL-LLR improves when training with more and more unlabeled review data. This is because the useful patterns learned from unlabeled data perhaps supports SMTL-LLR to generalize better. But continuing to learn from much more unlabeled reviews may even harm the performance. One explanation is that appending more unlabeled data may also incur noisy information to learning process. Interestingly, the performance of SMTL-LLR keeps increasing on the doctor domain, when training with more and more unlabeled reviews up to *10,000*. From above observations, we conclude that an elaborately selected set of high-quality unlabeled review data may help SMTL-LLR to learn better.

4.5 Task Correlation

Based on the covariance matrix (Ω) learned from the review spam detection tasks, we obtained the correlation between each pair of tasks for doctor, hotel, and restaurant domains, as shown in Table 4. The review spam detection tasks are highly correlated with each other for hotel and restaurant domains (0.772).

This is reasonable due to the large amount of commonality shared between the two domains. We can see that the tasks are also positively correlated between hotel and doctor, as well as between doctor and restaurant domains.

	Doctor	Hotel	Restaurant
Doctor	1.0	0.688	0.638
Hotel	0.688	1.0	0.772
Restaurant	0.638	0.772	1.0

Table 4: Task correlations.

4.6 Shared Text Features among Tasks

Table 5 lists top weighted shared text features among the review spam detection tasks for doctor, hotel, and restaurant domains. Generally, review spammers demonstrate similar motivations when creating deceptive review spam, i.e., promoting their own products/services or defaming those of their competitors. Though different aspects or entities can be commented on across different domains, we find that many features or expressions are indeed shared among the three review domains. As we know, deceptive reviewers normally write up reviews for making money, thus they prefer choosing exaggerated language in their lies, no matter which domains they are working with. As shown in the first row for spam category, they tend to exaggerate their sentiments using the words like "definitely", "sure", "highly", and so on.

In contrast, truthful reviewers contribute reviews for sharing their true feelings or personal anecdotes. They are willing to write up detailed factual experiences, for example, about the doctors they visited or delicious foods they enjoyed. Their reviews thus tend to contain language patterns in past tense, such as "went", "did", and "took" shown in the second row.

5 Conclusions

We have coped with the problem of detecting deceptive review spam. Given the limited labeled review data for individual domains, we formulated it as a multi-task learning problem. We first developed a multi-task learning method via logistic regression (MTL-LR), which allows to boost the learning for one task by sharing the knowledge contained in the training signals of other related tasks. To leverage the unlabeled data, we introduced a graph Laplacian regularizer into each base model, and proposed a semi-supervised multi-task learning model via Laplacian regularized logistic regression (SMTL-LLR). Moreover, to deal with the optimization problem, we developed a stochastic alternating method. Experimental results on real-world review data demonstrated the superiority of SMTL-LLR over several well-established baseline methods.

Labels	Features
Spam	staff, friendly,comfortable, really, right, experience, best, way, amazing, check, away, staff friendly, definitely, sure, highly recommend
Nonspam	good, just, like, went, did, people, excellent, took, wonderful, things, day, fantastic, know, going, nice

Table 5: Top weighted shared text features for spam/nonspam category across the three review domains.

For future work, we plan to create much more ground truth review data from other review domains and different applications like forums or microblogs, and further test our proposed models for deceptive opinion spam detection. We also plan to incorporate our model into a practical opinion mining system, in this way, more reliable opinion and sentiment analysis results can be then expected.

Regularizing Text Categorization with Clusters of Words

Abstract

Regularization is a critical step in supervised learning to not only address overfitting, but also to take into account any prior knowledge we may have on the features and their dependence. In this paper, we explore state-of-the-art structured regularizers and we propose novel ones based on clusters of words from LSI topics, word2vec embeddings and graph-of-words document representation. We show that our proposed regularizers are faster than the state-of-the-art ones and still improve text classification accuracy. Code and data are available online[1].

1 Introduction

Harnessing the full potential in text data has always been a key task for the NLP and ML communities. The properties hidden under the inherent high dimensionality of text are of major importance in tasks such as text categorization and opinion mining.

Although simple models like bag-of-words manage to perform well, the problem of overfitting still remains. Regularization as proven in Chen and Rosenfeld (2000) is of paramount importance in Natural Language Processing and more specifically language modeling, structured prediction, and classification. In this paper we build upon the work of Yogatama and Smith (2014b) who introduce prior knowledge of data as a regularization term. One of the most popular structured regularizers, the group lasso (Yuan and Lin, 2006), was proposed to avoid large L2 norms for groups of weights.

[1] https://goo.gl/mKqvro

In this paper, we propose novel linguistic structured regularizers that capitalize on the clusters learned from texts using the word2vec and graph-of-words document representation, which can be seen as group lasso variants. The extensive experiments we conducted demonstrate these regularizers can boost standard bag-of-words models on most cases tested in the task of text categorization, by imposing additional unused information as bias.

2 Background & Notation

We place ourselves in the scenario where we consider a prediction problem, in our case text categorization, as a loss minimization problem, i. e. we define a loss function $\mathcal{L}(\boldsymbol{x}, \boldsymbol{\theta}, y)$ that quantifies the loss between the prediction $h_{\boldsymbol{\theta},b}(\boldsymbol{x})$ of a classifier parametrized by a vector of feature weights $\boldsymbol{\theta}$ and a bias b, and the true class label $y \in \boldsymbol{\mathcal{Y}}$ associated with the example $\boldsymbol{x} \in \boldsymbol{\mathcal{X}}$. Given a training set of N data points $\{(\boldsymbol{x}^i, y^i)\}_{i=1...N}$, we want to find the optimal set of feature weights $\boldsymbol{\theta}^*$ such that:

$$\boldsymbol{\theta}^* = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \underbrace{\sum_{i=1}^{N} \mathcal{L}(\boldsymbol{x}^i, \boldsymbol{\theta}, y^i)}_{\textbf{empirical risk}} \tag{1}$$

In the case of logistic regression with binary predictions ($\boldsymbol{\mathcal{Y}} = \{-1, +1\}$), $h_{\boldsymbol{\theta},b}(\boldsymbol{x}) = \boldsymbol{\theta}^\top \boldsymbol{x} + b$ and $\mathcal{L}(\boldsymbol{x}, \boldsymbol{\theta}, y) = e^{-y h_{\boldsymbol{\theta},b}(\boldsymbol{x})}$ (log loss).

2.1 Regularization

Only minimizing the empirical risk can lead to overfitting, that is, the model no longer learns the underlying pattern we are trying to capture but fits the

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1827–1837,
Austin, Texas, November 1-5, 2016.

noise contained in the training data and thus results in poorer generalization (e. g., lower performances on the test set). For instance, along with some feature space transformations to obtain non-linear decision boundaries in the original feature space, one could imagine a decision boundary that follows every quirk of the training data. Additionally, if two hypothesis lead to similar low empirical risks, one should select the "simpler" model for better generalization power, simplicity assessed using some measure of model complexity.

Loss+Penalty Regularization takes the form of additional constraints to the minimization problem, i. e. a budget on the feature weights, which are often relaxed into a penalty term $\Omega(\boldsymbol{\theta})$ controlled via a Lagrange multiplier λ. We refer to the book of Boyd and Vandenberghe (2004) for the theory behind convex optimization. Therefore, the overall expected risk (Vapnik, 1991) is the weighted sum of two components: the empirical risk and a regularization penalty term, expression referred to as "Loss+Penalty" by Hastie et al. (2009). Given a training set of N data points $\{(\boldsymbol{x}^i, y^i)\}_{i=1\dots N}$, we now want to find the optimal set of feature weights $\boldsymbol{\theta}^*$ such that:

$$\boldsymbol{\theta}^* = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \underbrace{\underbrace{\sum_{i=1}^{N} \mathcal{L}(\boldsymbol{x}^i, \boldsymbol{\theta}, y^i)}_{\textbf{empirical risk}} + \underbrace{\lambda\Omega(\boldsymbol{\theta})}_{\textbf{penalty term}}}_{\textbf{expected risk}} \quad (2)$$

L_1 and L2 regularization The two most used penalty terms are known as L_1 regularization, a. k. a. *lasso* (Tibshirani, 1996), and L2 regularization, a. k. a. *ridge* (Hoerl and Kennard, 1970) as they correspond to penalizing the model with respectively the L_1 and L2 norm of the feature weight vector $\boldsymbol{\theta}$:

$$\boldsymbol{\theta}^* = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \sum_{i=1}^{N} \mathcal{L}(\boldsymbol{x}^i, \boldsymbol{\theta}, y^i) + \lambda \sum_{j=1}^{p} |\boldsymbol{\theta}_j| \quad (3)$$

$$\boldsymbol{\theta}^* = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \sum_{i=1}^{N} \mathcal{L}(\boldsymbol{x}^i, \boldsymbol{\theta}, y^i) + \lambda \sum_{j=1}^{p} \boldsymbol{\theta}_j{}^2 \quad (4)$$

Prior on the feature weights L_1 (resp. L2) regularization can be interpreted as adding a Laplacian (resp. Gaussian) prior on the feature weight vector. Indeed, given the training set, we want to find the most likely hypothesis $h^* \in \boldsymbol{\mathcal{H}}$, i. e. the one with *maximum a posteriori* probability:

$$\begin{aligned}
h^* &= \underset{h\in\boldsymbol{\mathcal{H}}}{\operatorname{argmax}} \left(\mathbb{P}(h|\{(\boldsymbol{x}^i, y^i)\}_{i=1\dots N})\right) \\
&= \underset{h\in\boldsymbol{\mathcal{H}}}{\operatorname{argmax}} \left(\frac{\mathbb{P}(\{y^i\}_i|\{\boldsymbol{x}^i\}_i, h)\,\mathbb{P}(h|\{\boldsymbol{x}^i\}_i)}{\mathbb{P}(\{y^i\}_i|\{\boldsymbol{x}^i\}_i)}\right) \\
&= \underset{h\in\boldsymbol{\mathcal{H}}}{\operatorname{argmax}} \left(\mathbb{P}(\{y^i\}_i|\{\boldsymbol{x}^i\}_i, h)\,\mathbb{P}(h|\{\boldsymbol{x}^i\}_i)\right) \\
&= \underset{h\in\boldsymbol{\mathcal{H}}}{\operatorname{argmax}} \left(\mathbb{P}(\{y^i\}_i|\{\boldsymbol{x}^i\}_i, h)\,\mathbb{P}(h)\right) \quad (5) \\
&= \underset{h\in\boldsymbol{\mathcal{H}}}{\operatorname{argmax}} \left(\prod_{i=1}^{N} \left(\mathbb{P}(y^i|\boldsymbol{x}^i, h)\right)\mathbb{P}(h)\right) \quad (6) \\
&= \underset{h\in\boldsymbol{\mathcal{H}}}{\operatorname{argmax}} \left(\sum_{i=1}^{N} \left(\log \mathbb{P}(y^i|\boldsymbol{x}^i, h)\right) + \log \mathbb{P}(h)\right) \\
&= \underset{h\in\boldsymbol{\mathcal{H}}}{\operatorname{argmin}} \left(\underbrace{\sum_{i=1}^{N} \left(-\log \mathbb{P}(y^i|\boldsymbol{x}^i, h)\right)}_{\textbf{empirical risk}} \underbrace{- \log \mathbb{P}(h)}_{\textbf{penalty term}}\right)
\end{aligned}$$

For the derivation, we assumed that the hypothesis h does not depend on the examples alone (Eq. 5) and that the N training labeled examples are drawn from an i.i.d. sample (Eq. 6). In that last form, we see that the loss function can be interpreted as a negative log-likelihood and the regularization penalty term as a negative log-prior over the hypothesis. Therefore, if we assume a multivariate Gaussian prior on the feature weight vector of mean vector $\mathbf{0}$ and covariance matrix $\Sigma = \sigma^2 I$ (i. e. independent features of same prior standard deviation σ), we do obtain the L2 regularization:

$$\mathbb{P}(h) = \frac{1}{\sqrt{(2\pi)^p|\Sigma|}} e^{-\frac{1}{2}\boldsymbol{\theta}^\top\Sigma^{-1}\boldsymbol{\theta}} \quad (7)$$

$$\begin{aligned}
\Rightarrow -\log \mathbb{P}(h) &= \frac{1}{2\sigma^2}\boldsymbol{\theta}^\top I\boldsymbol{\theta} + \frac{p}{2}\log(2\pi\sigma) \\
&\overset{\text{argmax}}{=} \lambda\|\boldsymbol{\theta}\|_2{}^2, \quad \lambda = \frac{1}{2\sigma^2} \quad (8)
\end{aligned}$$

And similarly, if we assume a multivariate Laplacian prior on the feature weight vector (i. e. $\boldsymbol{\theta}_i \sim Laplace(0, \frac{1}{\lambda})$), we obtain L_1-regularization. In practice, in both cases, the priors basically mean that we expect weights around 0 on average. The main difference between L_1 and L2 regularization is that the Laplacian prior will result in explicitly setting some feature weights to 0 (feature sparsity) while the Gaussian prior will only result in reducing their values (shrinkage).

2.2 Structured regularization

In L_1 and L2 regularizations, features are considered as independent, which makes sense without any additional prior knowledge. However, similar features have similar weights in the case of linear classifiers – equal weights for redundant features in the extreme case – and therefore, if we have some prior knowledge on the relationships between features, we should include that information for better generalization, i. e. include it in the regularization penalty term. Depending on how the similarity between features is encoded, e. g., through sets, trees (Kim and Xing, 2010; Liu and Ye, 2010; Mairal et al., 2010) or graphs (Jenatton et al., 2010), the penalization term varies but in any case, we take into account the structure between features, hence the "structured regularization" terminology. It should not be confused with "structured prediction" where this time the outcome is a structured object as opposed to a scalar (e. g., a class label) classically.

Group lasso Bakin (1999) and later Yuan and Lin (2006) proposed an extension of L_1 regularization to encourage groups of features to either go to zero (as a group) or not (as a group), introducing *group* sparsity in the model. To do so, they proposed to regularize with the $L_{1,2}$ norm of the feature weight vector:

$$\Omega(\boldsymbol{\theta}) = \lambda \sum_g \lambda_g \|\boldsymbol{\theta}_g\|_2 \tag{9}$$

where $\boldsymbol{\theta}_g$ is the subset of feature weights restricted to group g. Note that the groups can be overlapping (Jacob et al., 2009; Schmidt and Murphy, 2010; Jenatton et al., 2011; Yuan et al., 2011) even though it makes the optimization harder.

2.3 Learning

In our case we use a logistic regression loss function in order to integrate our regularization terms easily.

$$\mathcal{L}(x, \boldsymbol{\theta}, y) = \log(1 + \exp(-y\boldsymbol{\theta}^T x)) \tag{10}$$

It is obvious that the framework can be extended to other loss functions (e. g., hinge loss).

For the case of structured regularizers, there exist a plethora of optimization methods such group lasso. Since our tasks involves overlapping groups, we select the method of Yogatama and Smith (2014b).

Algorithm 1 ADMM for overlapping group-lasso

Require: augmented Lagrangian variable ρ, regularization strengths λ_{glas} and λ_{las}

1: **while** update in weights not small **do**
2: $\quad \boldsymbol{\theta} = \underset{\boldsymbol{\theta}}{\operatorname{argmin}}\, \Omega_{las}(\boldsymbol{\theta}) + \mathcal{L}(\boldsymbol{\theta}) + \frac{\rho}{2} \sum_{i=1}^{V} N_i(\boldsymbol{\theta}_i - \mu_i)^2$
3: $\quad$ **for** $g = 1$ to G **do**
4: $\quad\quad \mathrm{v}_g = \mathrm{prox}_{\Omega_{glas}, \frac{\lambda_g}{\rho}}(z_g)$
5: $\quad$ **end for**
6: $\quad u = u + \rho(\mathrm{v} - M\boldsymbol{\theta})$
7: **end while**

Their method uses the alternating directions method of multipliers (Hestenes, 1969; Powell, 1969).

Now given the lasso penalty for each feature and the group lasso regularizer, the problem becomes:

$$\min_{\boldsymbol{\theta}, \mathrm{v}} \Omega_{las}(\boldsymbol{\theta}) + \Omega_{glas}(\mathrm{v}) + \sum_{d=1}^{D} \mathcal{L}(x_d, \boldsymbol{\theta}, y_d) \tag{11}$$

so that $\mathbf{v} = M\boldsymbol{\theta}$, where $\mathbf{v}$ is a copy-vector of $\boldsymbol{\theta}$. The copy-vector $\mathbf{v}$ is needed because the group-lasso regularizer contains overlaps between the used groups. M is an indicator matrix of size $L \times V$, where L is the sum of the total sizes of all groups, and its ones show the link between the actual weights $\boldsymbol{\theta}$ and their copies $\mathbf{v}$. Following Yogatama and Smith (2014b) a constrained optimization problem is formed, that can be transformed to an augmented Lagrangian problem:

$$\Omega_{las}(\boldsymbol{\theta}) + \Omega_{glas}(\mathrm{v}) + \mathcal{L}(\boldsymbol{\theta}) + \mathrm{u}^\top(\mathrm{v} - M\boldsymbol{\theta}) + \frac{\rho}{2}\|\mathrm{v} - M\boldsymbol{\theta}\|_2^2 \tag{12}$$

Essentially, the problem becomes the iterative update of $\boldsymbol{\theta}$, v and u:

$$\min_{\boldsymbol{\theta}} \Omega_{las}(\boldsymbol{\theta}) + \mathcal{L}(\boldsymbol{\theta}) + \mathrm{u}^\top M\boldsymbol{\theta} + \frac{\rho}{2}\|\mathrm{v} - M\boldsymbol{\theta}\|_2^2 \tag{13}$$

$$\min_{\mathrm{v}} \Omega_{glas}(\mathrm{v}) + \mathrm{u}^\top \mathrm{v} + \frac{\rho}{2}\|\mathrm{v} - M\boldsymbol{\theta}\|_2^2 \tag{14}$$

$$\mathrm{u} = \mathrm{u} + \rho(\mathrm{v} - M\boldsymbol{\theta}) \tag{15}$$

Convergence Yogatama and Smith (2014b) proved that ADMM for sparse overlapping group lasso converges. It is also shown that a good approximate solution is reached in a few tens of iterations. Our experiments confirm this as well.

3 Structured Regularization in NLP

In recent efforts there are results to identify useful structures in text that can be used to enhance the effectiveness of the text categorization in a NLP context. Since the main regularization approach we are going to use are variants of the group lasso, we are interested on prior knowledge in terms of groups/clusters that can be found in the training text data. These groups could capture either semantic, or syntactic structures that affiliate words to communities. In our work, we study both semantic and syntactic properties of text data, and incorporate them in structured regularizer. The grouping of terms is produced by either LSI or clustering in the word2vec or graph-of-words space.

3.1 Statistical regularizers

In this section, we present *statistical* regularizers, i. e. with groups of words based on co-occurrences, as opposed to *syntactic* ones (Mitra et al., 1997).

Network of features Sandler et al. (2009) introduced regularized learning with networks of features. They define a graph G whose edges are non-negative with larger weights indicating greater similarity. Conversely, a weight of zero means that two features are not believed a priori to be similar. Previous work (Ando and Zhang, 2005; Raina et al., 2006; Krupka and Tishby, 2007) shows such similarities can be inferred from prior domain knowledge and statistics computed on unlabeled data.

The weights of G are mapped in a matrix P, where $P_{ij} \geq 0$ gives the weight of the directed edge from vertex i to vertex j. The out-degree of each vertex is constrained to sum to one, $\sum_j P_{ij} = 1$, so that no feature "dominates" the graph.

$$\Omega_{network}(\boldsymbol{\theta}) = \lambda_{net} \sum \boldsymbol{\theta}_k^\top M \boldsymbol{\theta}_k \qquad (16)$$

where $M = \alpha(I-P)^\top(I-P)+\beta I$. The matrix M is symmetric positive definite, and therefore it possesses a Bayesian interpretation in which the weight vector $\boldsymbol{\theta}$, is *a priori* normally distributed with mean zero and covariance matrix $2M^{-1}$. However, preliminary results show poorer performance compared to structured regularizers in larger datasets.

Sentence regularizer Yogatama and Smith (2014b) proposed to define groups as the sentences in the training dataset. The main idea is to define a group $d_{d,s}$ for every sentence s in every training document d so that each group holds weights for occurring words in its sentence. Thus a word can be a member of one group for every distinct (training) sentence it occurs in. The regularizer is:

$$\Omega_{sen}(\boldsymbol{\theta}) = \sum_{d=1}^{D} \sum_{s=1}^{S_d} \lambda_{d,s} \|\boldsymbol{\theta}_{d,s}\|_2 \qquad (17)$$

where S_d is the number of sentences in document d.

Since modern text datasets typically contain thousands of sentences and many words appear in more than one sentence, the sentence regularizer could potentially lead to thousands heavily overlapping groups. As stated in the work of Yogatama and Smith (2014b), a rather important fact is that the regularizer will force all the weights of a sentence, if it is recognized as irrelevant. Respectively, it will keep all the weights of a relevant sentence, even though the group contains unimportant words. Fortunately, the problem can be resolved by adding a lasso regularization (Friedman et al., 2010).

3.2 Semantic regularizers

In this section, we present *semantic* regularizers that define groups based on how semantically close words are.

LDA regularizer Yogatama and Smith (2014a) considered topics as another type of structure. It is obvious that textual data can contain a huge number of topics and especially topics that overlap each other. Again the main idea is to penalize weights for words that co-occur in the same topic, instead of treating the weight of each word separately.

Having a training corpus, topics can be easily extracted with the help of the latent Dirichlet allocation (LDA) model (Blei et al., 2003). In our experiments, we form a group by extracting the n most probable words in a topic. We note that the extracted topics can vary depending the text preprocessing methods we apply on the data.

LSI regularizer Latent Semantic Indexing (LSI) can also be used in order to identify topics or groups and thus discover correlation between terms (Deerwester et al., 1990). LSI uses singular value decomposition (SVD) on the document-term matrix to

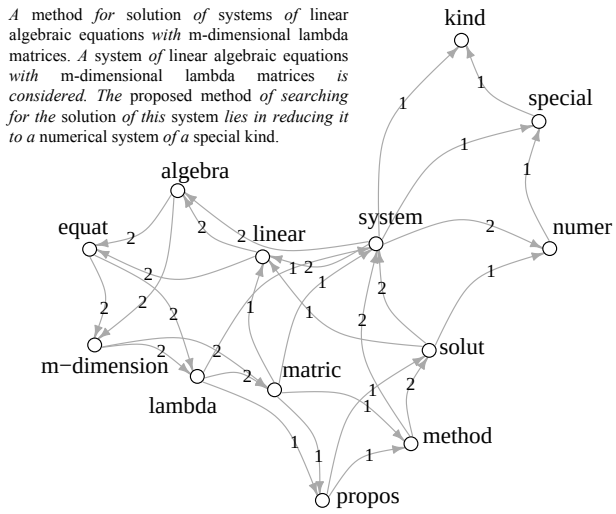

Figure 1: A Graph-of-words example.

identify latent variables that link co-occurring terms with documents. The main basis behind LSI is that words being used in the same contexts (i. e. the documents) tend to have similar meanings. We used LSI as a baseline and compare it with other standard baselines as well as other proposed structured regularizers. In our work we keep the top 10 words which contribute the most in a topic.

The regularizer for both LDA and LSI is:

$$\Omega_{LDA,LSI}(\boldsymbol{\theta}) = \sum_{k=1}^{K} \lambda \|\boldsymbol{\theta}_k\|_2 \qquad (18)$$

where K is the number of topics.

3.3 Graphical regularizers

In this section we present our proposed regularizers based on graph-of-words and word2vec. Essentially the word2vec space can be seen as a large graph where nodes represent terms and edges similarities between them.

Graph-of-words regularizer Following the idea of the network of features, we introduce a simpler and faster technique to identify relationships between features. We create a big collection graph from the training documents, where the nodes correspond to terms and edges correspond to co-occurrence of terms in a sliding window. We present a toy example of a graph-of-words in Figure 1.

A critical advantage of graph-of-words is that it easily encodes term dependency and term order (via edge direction). The strength of the dependence between two words can also be captured by assigning a weight to the edge that links them.

Graph-of-words was originally an idea of Mihalcea and Tarau (2004) and Erkan and Radev (2004) who applied it to the tasks of unsupervised keyword extraction and extractive single document summarization. Rousseau and Vazirgiannis (2013) and Malliaros and Skianis (2015) showed it performs well in the tasks of information retrieval and text categorization. Notably, the former effort ranked nodes based on a modified version of the PageRank algorithm.

Community detection on graph-of-words Our goal is to identify groups or communities of words. Having constructed the collection-level graph-of-words, we can now apply community detection algorithms (Fortunato, 2010).

In our case we use the Louvain method, a community detection algorithm for non-overlapping groups described in the work of Blondel et al. (2008). Essentially it is a fast modularity maximization approach, which iteratively optimizes local communities until we reach optimal global modularity given some perturbations to the current community state. The regularizer becomes:

$$\Omega_{gow}(\boldsymbol{\theta}) = \sum_{c=1}^{C} \lambda \|\boldsymbol{\theta}_c\|_2 \qquad (19)$$

where c ranges over the C communities. Thus $\boldsymbol{\theta}_c$ corresponds to the sub-vector of $\boldsymbol{\theta}$ such that the corresponding features are present in the community c. Note that in this case we do not have overlapping groups, since we use a non-overlapping version of the algorithm.

As we observe that the collection-level graph-of-words does not create well separated communities of terms, overlapping community detection algorithms, like the work of Xie et al. (2013) fail to identify “good" groups and do not offer better results.

Word2vec regularizer Mikolov et al. (2013) proposed the word2vec method for learning continuous vector representations of words from large text datasets. Word2vec manages to capture the actual meaning of words and map them to a multi-dimensional vector space, giving the possibility of

applying vector operations on them. We introduce another novel regularizer method, by applying unsupervised clustering algorithms on the word2vec space.

Clustering on word2vec Word2vec contains millions of words represented as vectors. Since word2vec succeeds in capturing semantic similarity between words, semantically related words tend to group together and create large clusters that can be interpreted as "topics".

In order to extract these groups, we use a fast clustering algorithm such as K-Means (Macqueen, 1967) and especially Minibatch K-means. The regularizer is:

$$\Omega_{word2vec}(\boldsymbol{\theta}) = \sum_{k=1}^{K} \lambda \|\boldsymbol{\theta}_k\|_2 \qquad (20)$$

where K is the number of clusters we extracted from the word2vec space.

Clustering these semantic vectors is a very interesting area to study and could be a research topic by itself. The actual clustering output could vary as we change the number of clusters we are trying to identify. In this paper we do not focus on optimizing the clustering process.

4 Experiments

We evaluated our structured regularizers on several well-known datasets for the text categorization task. Table 1 summarizes statistics about the ten datasets we used in our experiments.

4.1 Datasets

Topic categorization. From the 20 Newsgroups[2] dataset, we examine four binary classification tasks. We end up with binary classification problems, where we classify a document according to two related categories: comp.sys: ibm.pc.hardware vs. mac.hardware; rec.sport: baseball vs. hockey; sci: med vs. space and alt.atheism vs. soc.religion.christian. We use the 20NG dataset from Python.

Sentiment analysis. The sentiment analysis datasets we examined include movie reviews (Pang and Lee, 2004; Zaidan and Eisner, 2008)[3], floor speeches by U.S. Congressmen deciding "yea"/"nay" votes on the bill under discussion (Thomas et al., 2006)[3] and product reviews from Amazon (Blitzer et al., 2007)[4].

Table 1: Descriptive statistics of the datasets

4.2 Experimental setup

As features we use unigram frequency concatenated with an additional unregularized bias term. We reproduce standard regularizers like lasso, ridge, elastic and state-of-the-art structured regularizers like sentence, LDA as baselines and compare them with our proposed methods.

For LSI, LDA and word2vec we use the gensim package (Řehůřek and Sojka, 2010) in Python. For the learning part we used Matlab and specifically code by Schmidt et al. (2007).

We split the training set in a stratified manner to retain the percentage of classes. We use 80% of the data for training and 20% for validation.

All the hyperparameters are tuned on the development dataset, using accuracy as the evaluation criterion. For lasso and ridge regularization, we choose λ from $\{10^{-2}, 10^{-1}, 1, 10, 10^{2}\}$. For elastic net, we perform grid search on the same set of values as ridge and lasso experiments for λ_{rid} and λ_{las}. For the LDA, LSI, sentence, graph-of-words (GoW), word2vec regularizers, we perform grid search on the same set of values as ridge and lasso experiments for the ρ, λ_{glas}, λ_{las} parameters. In the case we get the same accuracy on the development data, the model with the highest sparsity is selected. For

Table 3: Fraction (in %) of non-zero feature weights in each model for each dataset: the smaller, the more compact the model.

LDA we set the number of topics to 1000 and we keep the 10 most probable words of each topic as a group. For LSI we keep 1000 latent dimensions and we select the 10 most significant words per topic. For the clustering process on word2vec we ran Minibatch-Kmeans for max 2000 clusters. For each word belonging to a cluster, we also keep the top 5 or 10 nearest words so that we introduce overlapping groups. The intuition behind this is that words can be part of multiple “concepts" or topics, thus they can belong to many clusters.

4.3 Results

In Table 2 we report the results of our experiments on the aforementioned datasets, and we distinguish our proposed regularizers LSI, GoW, word2vec with underlining. Our results are inline and confirm that of (Yogatama and Smith, 2014a) showing the advantages of using structured regularizers in the text categorization task. The group based regularizers perform systematically better than the baseline ones.

We observe that the word2vec clustering based regularizers performs very well - achieving best performance for three out of the ten data sets while it is quite fast with regards to execution time as it appears in Table 3 (i. e. it is four to ten times faster than the sentence based one).

The LSI based regularization, proposed for the first time in this paper, performs surprisingly well as it achieves the best performance for three of the ten datasets. This is somehow interpreted by the fact that this method extracts the inherent dimensions that best represent the different semantics of the documents - as we see as well in the anecdotal

examples in Table 6, 7, 8. This method proves as well very fast as it appears in Table 5 (i.e. it is three to sixty times faster than the sentence based one).

The GoW based regularization although very fast, did not outperform the other methods (while it has a very good performance in general). It remains to be seen whether a more thorough parameter tuning and community detection algorithm selection would improve further the accuracy of the method.

In Table 3 we present the feature space sizes retained by each of the regularizers for each dataset. As expected the lasso regularizer sets the vast majority of the features' weights to zero, and thus a very sparse feature space is generated. This fact has as a consequence the significant decrease in accuracy performance. Our proposed structured regularizers

managed to perform better in most of the cases, introducing more sparse models compared to the state-of-the-art regularizers.

4.4 Time complexity

Although certain types of structured regularizers improve significantly the accuracy and address the problem of overfitting, they require a notable amount of time in the learning process.

As seen in Yogatama and Smith (2014b), a considerable disadvantage is the need of search for the optimal hyperparameters: λ_{glas}, λ_{lasso} , and ρ, whereas standard baselines like lasso and ridge only have one hyperparameter and elastic net has two.

Parallel grid search can be critical for finding the optimal set of hyperparameters, since there is no dependency on each other, but again the process can be very expensive. Especially for the case of the sentence regularizer, the process can be extremely slow due to two factors. First, the high number of sentences in text data. Second, sentences consist of heavily overlapping groups, that include words reappearing in one or more sentences. On the contrary, as it appears on Table 4, the number of clusters in the clustering based regularizers is significantly smaller than that of the sentences - and definitely controlled by the designer - thus resulting in much faster computation. The update of $\mathbf{v}$ still remains time consuming for small datasets, even with parallelization.

Our proposed structured regularizers are considerably faster in reaching convergence, since they of-

fer a smaller number of groups with less overlapping between words. For example, on the computer subset of the 20NG dataset, learning models with the best hyperparameter value(s) for lasso, ridge, and elastic net took 7, 1.4, and 0.8 seconds, respectively, on an Intel Xeon CPU E5-1607 3.00 GHz machine with 4 cores and 128GB RAM. Given the best hyperparameter values the LSI regularizer takes 6 seconds to converge, the word2vec regularizer takes 10 seconds to reach convergence, the graph-of-words takes 4 seconds while the sentence regularizer requires 43 seconds. Table 5 summarizes required learning time on 20NG datasets.

We also need to consider the time needed to extract the groups. For word2vec, Minibatch K-means requires 15 minutes to cluster the pre-trained vectors by Google. The clustering is executed only once. Getting the clusters of words that belong to the vocabulary of each dataset requires 20 minutes, but can be further optimized. Finding also the communities in the graph-of-words approach with the Louvain algorithm, is very fast and requires a few minutes depending on the size and structure of the graph.

In Tables 6, 7, 8 we show examples of our proposed regularizers-removed and -selected groups (in v) in the science subset of the 20NG dataset. Words with weights (in w) of magnitude greater than 10^{-3} are highlighted in red (sci.med) and blue (sci.space).

5 Conclusion & Future Work

This paper proposes new types of structured regularizers to improve not only the accuracy but also the efficiency of the text categorization task. We mainly focused on how to find and extract semantic and syntactic structures that lead to sparser feature spaces and therefore to faster learning times. Overall, our results demonstrate that linguistic prior knowledge in the data can be used to improve categorization performance for baseline bag-of-words models, by mining inherent structures. We only considered logistic regression because of its interpretation for L2 regularizers as Gaussian prior on the feature weights and following Sandler et al. (2009), we considered a non-diagonal covariance matrix for L2 based on word similarity before moving to group lasso as presented in the paper. We are not expecting a significant change in results with different loss functions as the proposed regularizers are not log loss specific.

Future work could involve a more thorough investigation on how to create and cluster graphs, i. e. covering weighted and/or signed cases. Finding better clusters in the word2vec space is also a critical part. This is not only restricted in finding the best number of clusters but what type of clusters we are trying to extract. Gaussian Mixture Models (McLachlan and Basford, 1988) could be applied in order to capture overlapping groups at the cost of high complexity. Furthermore, topical word embeddings (Liu et al., 2015) can be considered for regularization. This approach could enhance the regularization on topic specific datasets. Additionally, we plan on exploring alternative regularization algorithms diverging from the group-lasso method.

Abstract

We introduce an online popularity prediction and tracking task as a benchmark task for reinforcement learning with a combinatorial, natural language action space. A specified number of discussion threads predicted to be popular are recommended, chosen from a fixed window of recent comments to track. Novel deep reinforcement learning architectures are studied for effective modeling of the value function associated with actions comprised of *interdependent* sub-actions. The proposed model, which represents dependence between sub-actions through a bi-directional LSTM, gives the best performance across different experimental configurations and domains, and it also generalizes well with varying numbers of recommendation requests.

1 Introduction

This paper is concerned with learning policies for sequential decision-making tasks, where a system takes actions given options characterized by natural language with the goal of maximizing a long-term reward. More specifically, we consider tasks with a combinatorial action space, where each action is a set of multiple interdependent sub-actions. The problem of a combinatorial natural language action space arises in many applications. For example, in real-time news feed recommendation, a user may want to read diverse topics of interest, and an action (i.e. recommendation) from the computer agent would consist of a set of news articles that are not all similar in topics (Yue and Guestrin, 2011). In advertisement placement, an action is a selection of several ads to display, and bundling with complementary products might receive higher click-through-rate than displaying all similar popular products.

In this work, we consider Reddit popularity prediction, which is similar to newsfeed recommendation but different in two respects. First, our goal is not to make recommendations based on an individual's preferences, but instead based on the anticipated long-term interest level of a broad group of readers from a target community. Second, we try to predict rather than detect popularity. Unlike individual interests, community interest level is not often immediately clear; there is a time lag before the level of interest starts to take off. Here, the goal is for the recommendation system to identify and track written documents (e.g. news articles, comments in discussion forum threads, or scientific articles) in real time – attempting to identify hot updates before they become hot to keep the reader at the leading edge. The premise is that the user's bandwidth is limited, and only a limited number of things can be recommended out of several possibilities. In our experimental work, we use discussion forum text, where the recommendations correspond to recent posts or comments, assessing interest based on community response as observed in "likes" or other positive reactions to those comments. For training purposes, we can use community response measured at a time much later than the original post or publication. This problem is well-suited to the reinforcement learning paradigm, since the reward (the level of community uptake or positive response) is not immediately known, so the system needs to learn a mechanism for estimating future reactions. Different from

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1838–1848,
Austin, Texas, November 1-5, 2016.

typical reinforcement learning, the action space is combinatorial since an action corresponds to a set of comments (sub-actions) chosen from a larger set of candidates. A sub-action is a written comment (or document, for another variant of this task).

Two challenges associated with this problem include the potentially high computational complexity of the combinatorial action space and the development of a framework for estimating the long-term reward (the Q-value in reinforcement learning) from a combination of sub-actions characterized by natural language. Here, we focus on the second problem, exploring different deep neural network architectures in an effort to efficiently account for the potential redundancy and/or temporal dependency of different sub-actions in relation to the state space. We sidestep the computational complexity issue (for now) by working with a task where the number of combinations is not too large and by further reducing costs by random sampling.

There are two main contributions in this paper. First, we propose a novel reinforcement learning task with both states and combinatorial actions defined by natural language,[1] which is introduced in section 2. This task, which is based on comment popularity prediction using data from the Reddit discussion forum, can serve as a benchmark in social media recommendation and trend spotting. The second contribution is the development of a novel deep reinforcement learning architecture for handling a combinatorial action space associated with natural language. Prior work related to both the task and deep reinforcement learning is reviewed in section 3, Details for the new models and baseline architectures are described in section 4. Experimental results in section 5 show the proposed methods outperform baseline models and that a bidirectional LSTM is effective for characterizing the combined utility of sub-actions. A brief summary of findings and open questions are in section 6.

2 Popularity Prediction and Tracking

Our experiments are based on Reddit[2], one of the world's largest public discussion forums. On Reddit, registered users initiate a post and people respond with comments, either to the original post or one of its associated comments. Together, the comments and the original post form a discussion tree, which grows as new comments are contributed. It has been show that discussions tend to have a hierarchical topic structure (Weninger et al., 2013), i.e. different branches of the discussion reflect narrowing of higher level topics. Reddit discussions are grouped into different domains, called subreddits, according to different topics or themes. Depending on the popularity of the subreddit, a post can receive hundreds of comments.

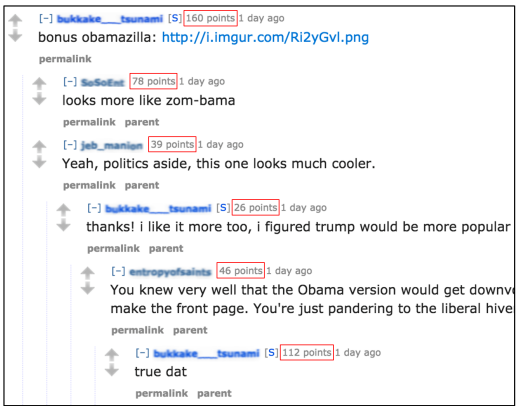

Figure 1: A snapshot of the top of a Reddit discussion tree, where karma scores are shown in red boxes.

Comments (and posts) are associated with positive and negative votes (i.e., likes and dislikes) from registered users that are combined to get a *karma score*, which can be used as a measure for popularity. An example of the top of a Reddit discussion tree is given in Figure 1. The scores in red boxes mark the current karma (popularity) of each comment, and it is quite common that a lower karma comment (e.g. "Yeah, politics aside, this one looks much cooler", compared to "looks more like zom-bama") will lead to more children and popular comments in the future (e.g. "true dat"). Note that the karma scores are dynamic, changing as readers react to the evolving discussion and eventually settling down as the discussion trails off. In a real-time comment recommendation system, the eventual karma of a comment is not immediately available, so prediction of popularity is based on the text in the comment in the context of prior comments in the subtree and other comments in the current time window.

[1] Simulator code and Reddit discussion identifiers are released at `https://github.com/jvking/reddit-RL-simulator`

[2] `http://www.reddit.com`

Popularity prediction and tracking in the Reddit setting is used in this paper for studying reinforcement learning to model long-term rewards in a combinatorial action space. At each time step, the state corresponds to the collection of comments previously recommended. The system aims at automatically picking a few lines of the discussion to follow from the new set of comments in a given window, which is a combinatorial action. Thread popularity tracking can be thought of as a proxy task for news or scientific article recommendation. It has the advantages that "documents" (comments) are relatively short and that the long-term reward can be characterized by Reddit voting scores, which makes this task easier to work with for algorithm development than these larger related tasks.

In this work, we only consider new comments associated with the threads of the discussion that we are currently following to limit the number of possible sub-actions at each time step and with the assumption that prior context is needed to interpret the comments. In other words, the new recommendation should focus on comments that are in the subtrees of previously recommended comments. (A variant relaxing this restriction is suggested in the conclusion section.) Typically, one would expect some interdependencies between comments made in the same window if they fall under the same subtree, because they correspond to a reply to the same parent. In addition, there may be some temporal dependency, since one sub-action may be a comment on the other. These dependencies will affect the combined utility of the sub-actions.

According to our experiments, the performance is significantly worse when we learn a myopic policy compared to reinforcement learning with the same feature set. This shows that long-term dependency indeed matters, as illustrated in Figure 1. This serves as a justification that reinforcement learning is an appropriate approach for modeling popularity of a discussion thread.

3 Related Work

There is a large body of work on reinforcement learning. Among those of most interest here are deep reinforcement learning methods that leverage neural networks because of their success in handling large discrete state/action spaces. Early work such as TD-gammon used a neural network to approximate the state value function (Tesauro, 1995). Recent advances in deep learning (LeCun et al., 2015; Deng and Yu, 2014; Hinton et al., 2012; Krizhevsky et al., 2012; Sordoni et al., 2015) inspired significant progress by combining deep learning with reinforcement learning (Mnih et al., 2015; Silver et al., 2016; Lillicrap et al., 2016; Duan et al., 2016). In natural language processing, reinforcement learning has been applied successfully to dialogue systems that generate natural language and converse with a human user (Scheffler and Young, 2002; Singh et al., 1999; Wen et al., 2016). There has also been interest in mapping text instructions to sequences of executable actions and extracting textual knowledge to improve game control performance (Branavan et al., 2009; Branavan et al., 2011).

Recently, Narasimhan et al. (2015) studied the task of text-based games with a deep Q-learning framework. He et al. (2016) proposed to use a separate deep network for handling natural language actions and to model Q-values via state-action interaction. Nogueira and Cho (2016) have also proposed a goal-driven web navigation task for language-based sequential decision making. Narasimhan et al. (2016) applied reinforcement learning for acquiring and incorporating external evidence to improve information extraction accuracy. The study that we present with Reddit popularity tracking differs from these other text-based reinforcement learning tasks in that the language in both state and action spaces is unconstrained and quite rich.

Dulac-Arnold et al. (2016) also investigated a problem of large discrete action spaces. A Wolpertinger architecture is proposed to reduce computational complexity of evaluating all actions. While a combinatorial action space can be large and discrete, their method does not directly apply in our case, because the possible actions are changing over different states. In addition, our work differs in that its focus is on modeling the combined action-value function rather than on reducing computational complexity. Other work that targets a structured action space includes: an actor-critic algorithm, where actions can have real-valued parameters (Hausknecht and Stone, 2016); and the factored Markov Decision Process (MDP) (Guestrin et al., 2001; Sallans and

Hinton, 2004), with certain independence assumptions between a next-state component and a sub-action. As for a bandits setting, Yue and Guestrin (2011) considered diversification of multi-item recommendation, but their methodology is limited to using linear approximation with hand-crafted features.

The task explored in our paper – detecting and tracking popular threads in a discussion – is somewhat related to topic detection and tracking (Allan, 2012; Mathioudakis and Koudas, 2010), but it differs in that the goal is not to track topics based on frequency, but rather based on reader response. Thus, our work is more closely related to popularity prediction for social media and online news. These studies have explored a variety of definitions (or measurements) of popularity, including: the volume of comments in response to blog posts (Yano and Smith, 2010) and news articles (Tasgkias et al., 2009; Tatar et al., 2011), the number of Twitter shares of news articles (Bandari et al., 2012), the number of reshares on Facebook (Cheng et al., 2014) and retweets on Twitter (Suh et al., 2010; Hong et al., 2011; Tan et al., 2014; Zhao et al., 2015), the rate of posts related to a source rumor (Lukasik et al., 2015), and the difference in the number of reader up and down votes on posts and comments in Reddit discussion forums (Lakkaraju et al., 2013; Jaech et al., 2015). An advantage of working with the Reddit data is that both positive and negative reactions are accounted for in the karma score. Of the prior work on Reddit, the task explored here is most similar to (Jaech et al., 2015) in that it involves choosing relatively high karma comments (or threads) from a time-limited set rather than directly predicting comment (or post) karma. Prior work on popularity prediction used supervised learning; this is the first work that frames tracking hot topics in social media with deep reinforcement learning.

4 Characterizing a combinatorial action space

4.1 Notation

In this sequential decision making problem, at each time step t, the agent receives a text string that describes the state $s_t \in \mathcal{S}$ (i.e., "state-text") and picks a text string that describes the action $a_t \in \mathcal{A}$ (i.e., "action-text"), where $\mathcal{S}$ and $\mathcal{A}$ denote the state and action spaces, respectively. Here, we assume a_t is chosen from a set of given candidates. In our case both $\mathcal{S}$ and $\mathcal{A}$ are described by natural language. Given the state-text and action-texts, the agent aims to select the best action in order to maximize its long-term reward. Then the environment state is updated $s_{t+1} = s'$ according to a probability $p(s'|s, a)$, and the agent receives a reward r_{t+1} for that particular transition. We define the action-value function (i.e. the Q-function) $Q(s, a)$ as the expected return starting from s and taking the action a:

$$Q(s,a) = \mathbb{E}\left\{\sum_{l=0}^{+\infty} \gamma^l r_{t+1+l} | s_t = s, a_t = a\right\}$$

where $\gamma \in (0, 1)$ denotes a discount factor. The Q-function associated with an optimal policy can be found by the Q-learning algorithm (Watkins and Dayan, 1992):

$$Q(s_t,a_t) \leftarrow Q(s_t,a_t) + \eta_t \cdot \big(r_{t+1} + \gamma \cdot \max_a Q(s_{t+1},a) - Q(s_t,a_t)\big)$$

where η_t is a learning rate parameter.

The set of comments that are being tracked at time step t is denoted as M_t. All previously tracked comments, as well as the post (root node of the tree), is considered as state s_t ($s_t = \{M_0, M_1, \cdots, M_t\}$), and we initialize $s_0 = M_0$ to be the post. An action is taken when a total of N new comments $\{c_{t,1}, c_{t,2}, \cdots, c_{t,N}\}$ appear as nodes in the subtree of M_t, and the agent picks a set of K comments to be tracked in the next time step $t+1$. Thus we have:

$$a_t = \{c_t^1, c_t^2, \cdots, c_t^K\}, \quad c_t^i \in \{c_{t,1}, c_{t,2}, \cdots, c_{t,N}\} \text{ and } c_t^i \neq c_t^j \text{ if } i \neq j \quad (1)$$

and $M_{t+1} = a_t$. At the same time, by taking action a_t at state s_t, the reward r_{t+1} is the accumulated karma scores, i.e. sum over all comments in M_{t+1}. Note that the reward signal is used in online training, while at model deployment (testing stage), the scores are only used as an evaluation metric.

Following the reinforcement learning tradition, we call tracking of a single discussion tree from start (root node post) to end (no more new comments appear) an *episode*. We also randomly partition all

discussion trees into separate training and testing sets, so that texts seen by the agent in training and testing are from the same domain but different discussions. For each episode, depending on whether training/testing, the simulator randomly picks a discussion tree, and presents the agent with the current state and N new comments.

4.2 Q-function alternatives

With the real-time setting, it is clear that action a_t will affect the next state s_{t+1} and furthermore the future expected reward. The action a_t consists of K comments (sub-actions), making modeling Q-values $Q(s_t, a_t)$ difficult. To handle a large state space, Mnih et al. (2015) proposed a Deep Q-Network (DQN). In case of a large action space, we may use both state and action representations as input to a deep neural network. It is shown that the Deep Reinforcement Relevance Network (DRRN, Figure 2(b)), i.e. two separate deep neural networks for modeling state embedding and action embedding, performs better than per-action DQN (PA-DQN in Figure 2(a)), as well as other DQN variants for dealing with natural language action spaces (He et al., 2016).

Our baseline models include Linear, PA-DQN and DRRN. We concatenate the K sub-actions/comments to form the action representation. The Linear and PA-DQN (Figure 2(a)) take as input a concatenation of state and action representations, and model a single Q-value $Q(s_t, a_t)$ using linear or DNN function approximations. The DRRN consists of a pair of DNNs, one for the state-text embedding and the other for action-text embeddings, which are then used to compute $Q(s_t, a_t)$ via a pairwise interaction function (Figure 2(b)).

One simple alternative approach by utilizing this combinatorial structure is to compute an embedding for each sub-action c_t^i. We can then model the value in picking a particular sub-action, $Q(s_t, c_t^i)$, through a pairwise interaction between the state and this sub-action. $Q(s_t, c_t^i)$ represents the expected accumulated future rewards by including this sub-action. The agent then greedily picks the top-K sub-actions with highest values to achieve the highest $Q(s_t, a_t)$. In this approach, we are assuming the long-term rewards associated with sub-actions are independent of each other. More specifically, greedily picking the top-K sub-actions is equivalent to maximizing the following action-value function:

$$Q(s_t, a_t) = \sum_{i=1}^{K} Q(s_t, c_t^i) \tag{2}$$

while satisfying (1). We call this proposed method DRRN-Sum, and its architecture is shown in Figure 2(c). Similarly as in DRRN, we use two networks to embed state and actions separately. However, for different sub-actions, we keep the network parameters tied. We also use the same top layer dimension and the same pairwise interaction function for all sub-actions.

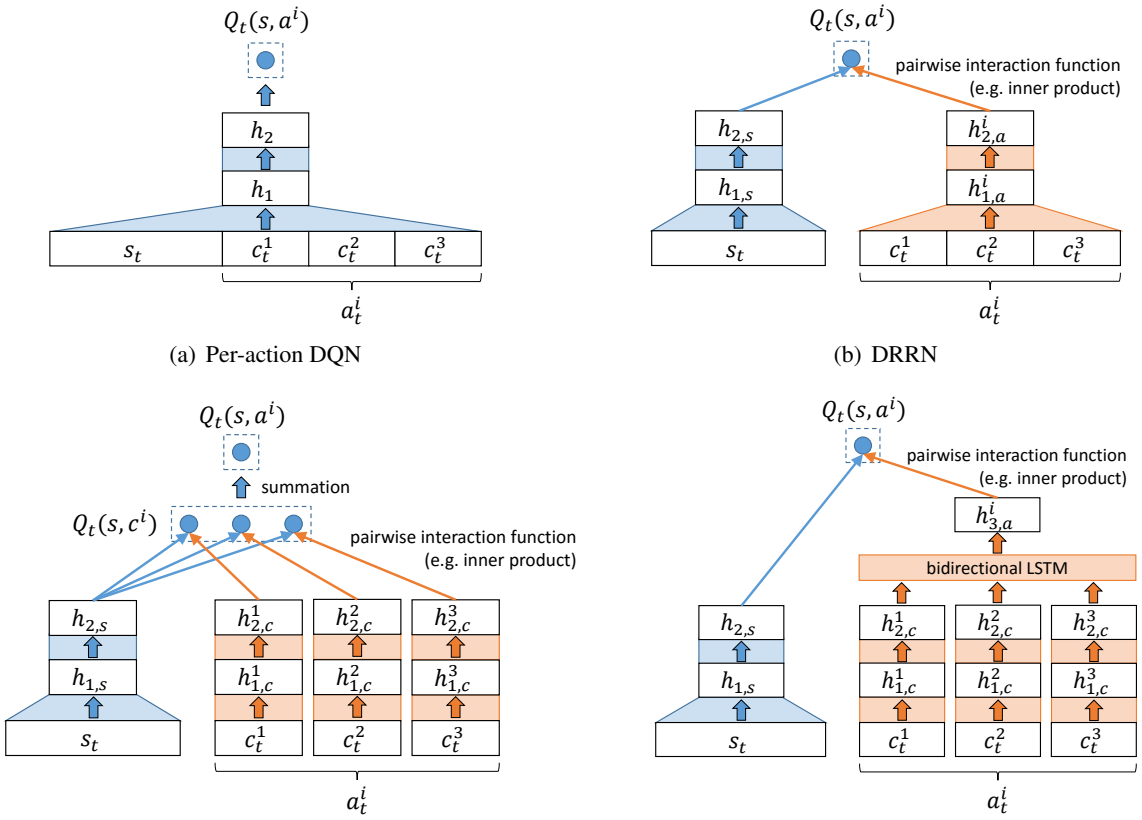
In the case of a linear additive interaction, such as an inner product or bilinear operation, Equation (2) is equivalent to computing the interaction between the state embedding and an action embedding, where the action embedding is obtained linearly by summing over K sub-action embeddings. When sub-actions have strong correlation, this independence assumption is invalid and can result in a poor estimation of $Q(s_t, a_t)$. For example, most people are interested in the total information stored in the combined action a_t. Due to content redundancy in the sub-actions $c_t^1, c_t^2, \cdots, c_t^K$, we expect $Q(s_t, a_t)$ to be smaller than $\sum_i Q(s_t, c_t^i)$.

To come up with a general model for handling a combinatorial action-value function, we further propose the DRRN-BiLSTM (Figure 2(d)). In this architecture, we use a DNN to generate an embedding for each comment. Then a Bidirectional Long Short-Term Memory (Graves and Schmidhuber, 2005) is used to combine a sequence of K comment embeddings. As the Bidirectional LSTM has a larger capacity due to its nonlinear structure, we expect it will capture more details on how the embeddings for the sub-actions combine into an action embedding. Note that both of our proposed methods (DRRN-Sum and DRRN-BiLSTM) can handle a varying value of K, while for the DQN and DRRN baselines, we need to use a fixed K in training and testing.

5 Experiments

5.1 Datasets and Experimental Configurations

Our data consists of 5 subreddits (askscience, askmen, todayilearned, worldnews, nfl) with diverse



(a) Per-action DQN (b) DRRN

(c) DRRN-Sum (d) DRRN-BiLSTM

Figure 2: Different deep Q-learning architectures

topics and genres. In our experiments, in order to have long enough discussion threads, we filter out discussion trees with fewer than 100 comments. For each subreddit, we randomly partition 90% of the data for online training, and 10% of the data for testing (deployment). The basic subreddit statistics are shown in Table 1. We report the random policy performances and heuristic upper bound performances (averaged over 10,000 episodes) in Table 2 and Table 3.[3] The upper bound performances are obtained using stabilized karma scores and offline constructed tree structure. The mean and standard deviation are obtained by 5 independent runs.

In all our experiments we set $N = 10$. Explicitly representing all N-choose-K actions requires a lot of memory and does not scale up. We therefore use a variant of Q-learning: when taking the max over

Subreddit	# Posts (in k)	# Comments (in M)
askscience	0.94	0.32
askmen	4.45	1.06
todayilearned	9.44	5.11
worldnews	9.88	5.99
nfl	11.73	6.12

Table 1: Basic statistics of filtered subreddit data sets

Subreddit	Random	Upper bound
askscience	321.3 (7.0)	2109.0 (16.5)
askmen	132.4 (0.7)	651.4 (2.8)
todayilearned	390.3 (5.7)	2679.6 (30.1)
worldnews	205.8 (4.5)	1853.4 (44.4)
nfl	237.1 (1.4)	1338.2 (13.2)

Table 2: Mean and standard deviation of random and upper-bound performance (with $N = 10, K = 3$) across different subreddits.

[3]Upper bounds are estimated by greedily searching through each discussion tree to find K max karma discussion threads (overlapped comments are counted only once). This upper bound may not be attainable in a real-time setting.

K	Random	Upper bound
2	201.0 (2.1)	1991.3 (2.9)
3	321.3 (7.0)	2109.0 (16.5)
4	447.1 (10.8)	2206.6 (8.2)
5	561.3 (18.8)	2298.0 (29.1)

Table 3: Mean and standard deviation of random and upper-bound performance on askscience, with $N = 10$ and $K = 2, 3, 4, 5$.

possible next-actions, we instead randomly subsample m' actions and take the max over them. We set $m' = 10$ throughout our experiments. This heuristic technique works well in our experiments.

For text preprocessing we remove punctuation and lowercase capital letters. For each state s_t and comment c_t^i, we use a bag-of-words representation with the same vocabulary in all networks. The vocabulary contains the most frequent 5,000 words; the out-of-vocabulary rate is 7.1%.

In terms of the Q-learning agent, fully-connected neural networks are used for text embeddings. The network has $L = 2$ hidden layers, each with 20 nodes, and model parameters are initialized with small random numbers. ϵ-greedy is used for exploration-exploitation, and we keep $\epsilon = 0.1$ throughout online training and testing. We pick the discount factor $\gamma = 0.9$. During online training, we use experience replay (Lin, 1992) and the memory size is set to 10,000 tuples of $(s_t, a_t, r_{t+1}, s_{t+1})$. For each experience replay, 500 episodes are generated and stored in a first-in-first-out fashion, and multiple epochs are trained for each model. Minibatch stochastic gradient descent is implemented with a batch size of 100. The learning rate is kept constant: $\eta_t = 0.000001$.

The proposed methods are compared with three baseline models: Linear, per-action DQN (PA-DQN), and DRRN. For both Linear and PA-DQN, the state and comments are concatenated as an input. For the DRRN, the state and comments are sent through two separate deep neural networks. However, in our baselines, we do not explicitly model how values associated with each comment are combined to form the action value. For the DRRN baseline and proposed methods (DRRN-Sum and DRRN-BiLSTM), we use an inner product as the pairwise interaction function.

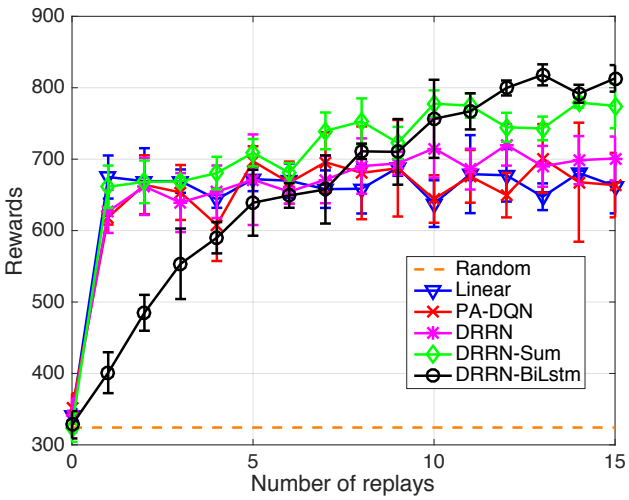


Figure 3: Learning curves of baselines and proposed methods on "askscience"

5.2 Experimental Results

In Figure 3 we provide learning curves of different models on the askscience subreddit during online learning. In this experiment, we set $N = 10, K = 3$. Each curve is obtained by averaging over 3 independent runs, and the error bars are also shown. All models start with random performance, and converge after approximately 15 experience replays. The DRRN-Sum converges as fast as baseline models, with better converged performance. DRRN-BiLSTM converges slower than other methods, but with the best converged performance.

After we train all the models on the training set, we fix the model parameters and apply (deploy) on the test set, where the models predict which action to take but no reward is shown until evaluation. The test performance is averaged over 1000 episodes, and we report mean and standard deviation over 5 independent runs.

On askscience, we try multiple settings with $N = 10$, $K = 2, 3, 4, 5$ and the results are shown in Table 4. Both DRRN-Sum and DRRN-BiLSTM consistently outperform baseline methods. The DRRN-BiLSTM performs better with larger K, probably due to the greater chance of redundancy in combining more sub-actions.

We also perform online training and test across different subreddits. With $N = 10, K = 3$, the test performance gains over the linear baseline are shown in Figure 4. Again, the test performance is

K	Linear	PA-DQN	DRRN	DRRN-Sum	DRRN-BiLSTM
2	553.3 (2.8)	556.8 (14.5)	553.0 (17.5)	569.6 (18.4)	**573.2 (12.9)**
3	656.2 (22.5)	668.3 (19.9)	694.9 (15.5)	704.3 (20.1)	**711.1 (8.7)**
4	812.5 (23.4)	818.0 (29.9)	828.2 (27.5)	829.9 (13.2)	**854.7 (16.0)**
5	861.6 (28.3)	884.3 (11.4)	921.8 (10.7)	942.3 (19.1)	**980.9 (21.1)**

Table 4: On askscience, average karma scores and standard deviation of baselines and proposed methods (with $N = 10$)

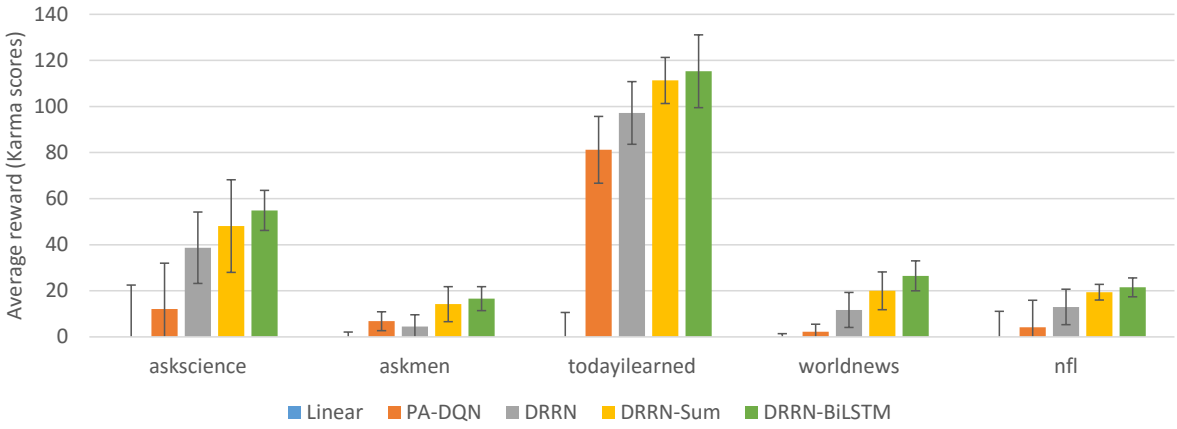

Figure 4: Average karma score gains over the linear baseline and standard deviation across different subreddits (with $N = 10$, $K = 3$).

K	DRRN-Sum	DRRN-BiLSTM
2	538.5 (18.9)	**551.2 (10.5)**
4	819.1 (14.7)	**829.9 (11.1)**
5	921.6 (15.6)	**951.3 (15.7)**

Table 5: On askscience, average karma scores and standard deviation of proposed methods trained with $K = 3$ and test with different K's

averaged over 1000 episodes, and we report mean and standard deviation over 5 independent runs. The findings are consistent with those for askscience. Since different subreddits may have very different karma scores distributions and language style, this suggests the algorithms apply to different text genres.

In actual model deployment, a possible scenario is that users may have different requests. For example, a user may ask the agent to provide $K = 2$ discussion threads on one day, due to limited reading time, and ask the agent to provide $K = 5$ discussion threads on the other day. For the baseline models (Linear, PA-DQN, DRRN), we will need to train separate models for different K's. The proposed methods (DRRN-Sum and DRRN-BiLSTM), on the other hand, can easily handle a varying K. To test whether the performance indeed generalizes well, we train proposed models on askscience with $N = 10, K = 3$ and test them with $N = 10, K \in 2, 4, 5$, as shown in Table 5. Compared to the proposed models that are specifically trained for these K's (Table 4), the generalized test performance indeed degrades, as expected. However, in many cases, our proposed methods still outperform all three baselines (Linear, PA-DQN and DRRN) that are trained specifically for these K's. This shows that the proposed methods can generalize to varying K's even if it is trained on a particular value of K.

In Table 6, we show an anecdotal example with state and sub-actions. The two sub-actions are strongly correlated and have redundant information. By combining the second sub-action compared to choosing just the first sub-action alone, DRRN-Sum and DRRN-BiLSTM predict 86% and 26% relative increase in action-value, respectively. Since these two sub-actions are highly redundant, we hypothesize DRRN-BiLSTM is better than DRRN-Sum at capturing interdependency between sub-actions.

6 Conclusion

In this paper we introduce a new reinforcement learning task associated with predicting and tracking popular threads on Reddit. The states and actions

State text (partially shown)
Are there any cosmological phenomena that we strongly suspect will occur, but the universe just isn't old enough for them to have happened yet?
Comments (sub-actions) (partially shown)
[1] White dwarf stars will eventually stop emitting light and become black dwarfs. [2] Yes, there are quite a few, such as: White dwarfs will cool down to black dwarfs.

Table 6: An example state and its sub-actions

are all described by natural language so the task is useful for language studies. We then develop novel deep Q-learning architectures to better model the state-action value function with a combinatorial action space. The proposed DRRN-BiLSTM method not only performs better across different experimental configurations and domains, but it also generalizes well for scenarios where the user can request changes in the number tracked.

This work represents a first step towards addressing the popularity prediction and tracking problem. While performance of the system beats several baselines, it still falls far short of the oracle result. Prior work has shown that timing is an important factor in predicting popularity (Lampe and Resnick, 2004; Jaech et al., 2015), and all the proposed models would benefit from incorporating this information. Another variant might consider short-term reactions to a comment, if any, in the update window. It would also be of interest to explore implementations of backtracking in the sub-action space (incurring a cost), in order to recommend comments that were not selected earlier but have become highly popular. Lastly, it will be important to study principled solutions for handling the computational complexity of the combinatorial action space.

Abstract

Text reuse refers to citing, copying or alluding text excerpts from a text resource to a new context. While detecting reuse in contemporary languages is well supported—given extensive research, techniques, and corpora—automatically detecting historical text reuse is much more difficult. Corpora of historical languages are less documented and often encompass various genres, linguistic varieties, and topics. In fact, historical text reuse detection is much less understood and empirical studies are necessary to enable and improve its automation. We present a linguistic analysis of text reuse in two ancient data sets. We contribute an automated approach to analyze how an original text was transformed into its reuse, taking linguistic resources into account to understand how they help characterizing the transformation. It is complemented by a manual analysis of a subset of the reuse. Our results show the limitations of approaches focusing on literal reuse detection. Yet, linguistic resources can effectively support understanding the non-literal text reuse transformation process. Our results support practitioners and researchers working on understanding and detecting historical reuse.

1 Introduction

The computational detection of historical text reuse—including citations, quotations or allusions —can be applied in many respects. It can help tracing down historical content (a.k.a., *lines of transmission*), which is essential to the field of textual criticism (Büchler et al., 2012). In the context of massive digitization projects, it can identify relationships between text excerpts referring to the same source. Specifically, detecting copies of the same historical text that have diverged over time (manuscript studies, a.k.a., *Stemma Codicum*) is an important task.

Although much work exists in the field of natural language processing (NLP), many new challenges arise when processing historical text. The most important challenges are the absence of supporting tools and methods, including an agreement on a common orthography, standardization of variants, and a wide range of clean, digitized text (Piotrowski, 2012; Geyken and Gloning, 2014; Zitouni, 2014). Typical statistical approaches from the field of NLP are difficult to apply to historically transferred texts, since these often cover a large timespan and, thus, comprise many different writing styles, text variants or even reuse styles (Büchler, 2013). Our long-term goal is to conceive robust text reuse detection techniques for historical texts. To this end, we need to improve the quantitative empirical understanding of such reuse accompanied by qualitative empirical studies. However, only few such works exist.

We study less- and non-literal text reuse of Bible verses in Ancient Greek and Latin texts. Our focus is on understanding how the reuse instances are transformed from the original verses. We identify operations that characterize how words are changed—e.g., synonymized, capitalized or part-of-speech (PoS) information changed. Since our approach uses external linguistic resources, including Ancient Greek WordNet (AGWN) (Bizzoni et al., 2014; Minozzi, 2009) and various lemma lists, we also show how such resources can help detecting reuse and where the limitations are. We complement the automated approach

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1849–1859,
Austin, Texas, November 1-5, 2016.

with a qualitative manual analysis. We contribute:

- an automated approach to characterize how text is transformed between reuse and original,
- an application of the approach to two text datasets where reuse was manually identified,
- empirical data based on the automated approach, complemented by a manual identification.

Our resulting datasets[1] with rich information about the reuse transformation (e.g., PoS and morphology changes, and words becoming synonyms or hyperonyms, among others) can be used as a benchmark for future reuse detection and classification approaches.

2 Related Work

We first discuss why existing reuse detection approaches are not applicable to historical texts, and then present works trying to address this problem.

Historical Text Reuse and Plagiarism Detection. Büchler (2013) combines state-of-the-art NLP techniques to address reuse detection scenarios for historical texts, ranging from near copies to text excerpts with a minimum overlap. He uses the commonly used method fingerprinting, which selects n-grams from an upfront pre-segmentized corpus. While his approach can discover historical and modern text reuse language-independently, it requires a minimum text similarity—typically at least two common features.

Recognizing modified reuse is difficult in general. Alzahrani et al. (2012) study plagiarism detection techniques: n-gram-, syntax-, and semantics-based approaches. As soon as reused text is slightly modified (e.g., words changed) most systems fail. Barrón-Cedeño et al. (2013) conduct experiments on paraphrasing, observing that complex paraphrasing along with a high paraphrasing density challenges plagiarism detection, and that lexical substitution is the most frequent technique for plagiarizing. The AraPlagDet (Bensalem et al., 2015) initiative focuses on the evaluation of plagiarism detection methods for Arabic texts. Eight methods were submitted and turned out to work with a high accuracy on external plagiarism detection but did not achieve usable results for intrinsic plagiarism detection.

Corpora. Huge parallel corpora of modern languages are used in fields such as paraphrase generation and detection, typically used to train statistical models (Zhao et al., 2009; Madnani and Dorr, 2010). However, such corpora hardly exist for historical languages or are copyrighted, such as the TLG digital library (Pantelia, 2014). Especially in the field of modern reuse investigation, aligned corpora are often used, providing a rich source of paraphrasal sentence pairs in one, sometimes multiple languages. One of such is the Microsoft Research Paraphrase Corpus (MSRP), which contains 5801 manually evaluated, paraphrasal sentence pairs in English (Dolan and Brockett, 2005). Ganitkevitch et al. (2013) present a paraphrase database with over 200 million English paraphrase pairs and 196 million Spanish paraphrases. Each paraphrase pair comes with measures, such as a paraphrase probability score. In ancient literature, efforts are made to collect Biblical reuse. One of such is the collection of Ancinet Greek and Latin quotations based on the the Vetus Latina series and the Novum Testamentum Graecum Editio Critica Maior (Houghton, 2013a; Houghton, 2013b). It contains more than 150,000 Latin citations and about 87,000 Ancient Greek Bible references.

Historical Text Processing in General. Efforts to automatically process ancient texts are made around the Perseus Digital Library project (Crane, 1985), among others. For example, Bamman (2008) presents the discovery of textual allusions in a collection of Classical poetry, using measures such as token similarity, n-grams or syntactic similarity. This allows finding at least the most similar candidates within a closed library. Some works have focused on text reuse in Biblical Greek text. Lee (2007) investigate reuse among the Gospels of the New Testament, aimed at aligning similar sentences. Using source alternation patterns, among others, the approach uses cosine similarity, source verse proximity, and source verse order. Focusing on high recall, the detection of Homeric quotations in Athenaeus' Deipnosophistai' was investigated by Büchler et al. (2012), searching for distinctive words within reuse.

While the approaches above rely on string or feature similarity, Bamman (2011b) attempts to process the semantic space using word-sense disambiguation (Patwardhan et al., 2003; Agirre and Edmonds, 2007). Using a bilingual sense inventory and training set, they classify up to 72 % of word senses correctly.

Utilizing Linguistic Resources. Word nets support

[1] https://bitbucket.org/mariamoritz/emnlp

identifying word relationships. Jing (1998) investigates issues that come with using WordNet (Miller et al., 1990) for language generation. Among others, these comprise issues arising from the adaption of a general lexicon to a specific domain. These were encountered by using a domain corpus and an ontology to prune WordNet to a certain domain.

In our work, we are interested in using linguistic resources (word nets and lemma lists) together with PoS information to model the transformation process of reuse, specifically on an ancient language text to find limitations when applied to non-literal text reuse.

3 Methodology

Our study addresses two main research questions:
RQ1. *What is the extent of non-literal reuse in our datasets?* This analysis provides a baseline for the following characterizations of the non-literal reuse.
RQ2. *How is the non-literally reused text modified in our datasets?* We study kinds and frequencies of semantic, lexical, and morphological changes. We develop an automated approach to identify the reuse transformation, and complement it with a manual, qualitative analysis. We formulate two sub-questions:
RQ2.1. *How can linguistic resources support the discovery of non-literal reuse?* We conjecture that non-literal reuse is difficult to capture automatically (especially due to domain- or author-specific words), but that taking linguistic resources into account helps. We analyze the coverage of words in lemma lists and a synset database, and investigate how useful they are for understanding the reuse transformations.
RQ2.2. *What are the limitations of an automated classification approach relying on linguistic resources?* Our manual analysis investigates the reuse in its full richness, to understand the limitations of the automated approach and identify further characteristics of the reuse in our datasets.

3.1 Study Design

Our study comprises the following main steps. First (**RQ1**), we identify and characterize the literal and non-literal overlap in reuse instances. Second (towards **RQ2**), we define operations reflecting literal reuse, replacements (inspired by semantic relationships, such as synonyms and hyperonyms, supported by AGWN), and morphological changes (e.g., when mapping words contain the same cognate). Our operations are based on a one-word-replacement to better quantify the results. Third (**RQ2.1**), we develop an algorithm that identifies operations by first looking for morphological changes between a word from the reuse and its corresponding candidate from the Bible verse and, in case of no success, by seeking for a semantic relation. We apply it to our two datasets and investigate the relationships of affected words and the literal share. We quantify occurrences of operations and calculate two measures sup_{lem} (lemma support) and sup_{AGWN} (AGWN support) to assess the resources' coverage for our approach. Fourth (**RQ2.2**), we manually analyze a smaller sample of our reuse datasets, using further operations, to understand the full richness of the reuse.

3.2 Datasets

We use the following two text sources, both reusing content from Bible verses. As a ground truth of the reuse, we use manually annotated versions of both, provided to us by Mellerin (2014) and the Biblindex project (Mellerin, 2016; Vinzent et al., 2013).

Our first dataset comes from the primary source text of "Salvation for the Rich" from the Ancient Greek writer Clement of Alexandria (Clément d'Alexandrie, 2011), a well-known author in Biblical literature (Cosaert, 2008). The Biblindex team annotated 128 text passages as Bible reuse instances, adding a footnote with Bible verse pointers to each. We select a total of 95 out of these 128, following four criteria: (i) reuse should not consist of an exact literal copy of a Bible verse (skipping six instances), (ii) reuse should be recognizable by our expert (skipping ten instances), (iii) the reference frame should be within five Bible verses (comparable with sentences) to avoid too much noise in our data to ensure a comparable length to the original Bible verse (skipping nine instances), and (iv) reuse instances should not exceed a length of 40 tokens (1–2 sentences), again to cut the long tail and avoid too much noise (skipping eight instances). Sometimes one reuse instance pointed to different Bible verses or one text passage contained more than one reuse instance, thus, we come up with 199 verse-reuse-pairs. The excerpts point to a total of 15 Bible books.

Our second dataset are extracts from a total of 14 volumes of twelve works and two work collec-

Jer 23 24	si occultabitur vir in absconditis et ego non videbo eum dicit Dominus numquid non caelum **et terram ego impleo** ait Dominus (*Can anyone hide himself in secret places that I will not see him? Said the lord. Do not I fill heaven and earth? Said the Lord*)
literal	**et terram ego impleo** (*and I fill the earth*)
Mk 10 30	Ἤρξατο λέγειν ὁ Πέτρος αὐτῷ, Ἰδοὺ ἡμεῖς ἀφήκαμεν πάντα καὶ ἠκολουθήκαμέν σοι. (*Peter began to say to him: See, we left everything and followed you.*)
literal	ἡμεῖς ἀφήκαμεν πάντα καὶ ἠκολουθήσαμέν σοι (*we left everything and followed you*)
Prv 18 3	**impius cum in profundum venerit** peccatorum **contemnit** sed sequitur eum ignominia et obprobrium (*When the wicked man is come into the depth of sins, also contempt comes but ignominy and reproach follow him)*
more literal	**Impius** , **cum venerit in profundum** malorum , **contemnit** (*When the wicked man is come into the depth of evil*)
1Cor 13 13	νυνὶ δὲ μένει **πίστις** , **ἐλπίς** , **ἀγάπη** , τὰ τρία ταῦτα μείζων δὲ τούτων ἡ **ἀγάπη** (*And now remain faith, hope, love, these three; but the greatest of those is love.*)
less literal	**πίστει** καὶ **ἐλπίδι** καὶ **ἀγάπῃ** (*faith, and hope, and love* - in dative case)
less literal	**ἀγάπην** , **πίστιν** , **ἐλπίδα** (*love, faith, hope* - in accusative case)
less literal	μένει δὲ τὰ τρία ταῦτα , **πίστις** , **ἐλπίς** , **ἀγάπη** · μείζων δὲ ἐν τούτοις ἡ **ἀγάπη** *(and remain these three, faith, hope, love; but the greatest among them is love)*
Mt 12 35	ὁ ἀγαθὸς ἄνθρωπος ἐκ τοῦ ἀγαθοῦ θησαυροῦ ἐκβάλλει ἀγαθά , καὶ ὁ πονηρὸς ἄνθρωπος ἐκ τοῦ πονηροῦ θησαυροῦ ἐκβάλλει πονηρά . (*A good man out of good storage brings out good things , and an evil man out of the evil storage brings evil things .*)
non-literal	Ψυχῆς , τὰ δὲ ἐκτός , κἂν μὲν ἡ ψυχὴ χρῆται καλῶς , καλὰ καὶ ταῦτα δοκεῖ , ἐὰν δὲ πονηρῶς , πονηρά , ὁ κελεύων ἀπαλλοτριοῦν τὰ ὑπάρχοντα (*[are whitin the] soul, and some are out, and if the soul uses them good, those things are also thought of as good, but if [they are used as] bad, [they are thought of as] bad; he who commands the renouncement of possessions*)

Figure 1: Examples of reuse

tions from the Latin writer Bernard of Clairvaux. We again use Biblindex' extracted Bible reuse, which offers over 1,100 reuse instances in alphabetical order. We follow the same selection criteria as for Greek and—starting top-down and dropping only two—we obtain 162 Bible-verse reuse-pairs, which is similar to the number of Greek reuse instances. Specifically, since those reuse instances come from several different primary source works, they point to a total of 31 Bible books. We use the Bible editions from Biblindex, specifically, the data based on *Septuagint* (Rahlfs, 1935b), *Greek New testament* (Aland and Aland, 1966), and *Biblia sacra juxta vulgatam versionem* (Weber R., 1969 1994 2007).

Fig. 1 shows reuse examples, illustrating the wide range of literalness in our data, comprising literal (all tokens overlap), less literal (important tokens overlap), and non-literal (no content word tokens overlap) reuse. For example, Clement's reuse ranges from introducing the overall topic by citing multiple verses, to supporting his argumentation. Specifically, Mk 10 30 is a fully literal reuse from a passage that discusses the problem of rich men in heaven. Clement uses this episode as a main point in his essay. Later he refers to 1Cor 13 13, he again refers to how hard it would be for rich men to enter heaven, explaining that salvation is independent of "external things," but depends on the "virtue of the soul," mentioning faith, hope, and love, the key words in the original verse.

Algorithm 1: Reuse classification algorithm

return OP
```

3.3 PoS Tagging

The automated and the manual approach also take PoS information into account to understand the reuse transformation. Following the Greek morphology tagging system of Perseus (Bamman and Crane, 2011a), which maps PoS and case information to single characters[2], we manually PoS-tag the 199 reuse instances of Ancient Greek and the 162 of Latin, as well as the original Bible verses. Since Latin and Ancinet Greek PoS-taggers lack available implementations, appropriate trained models or simply accu-

Table 1: Coverage of tokens by language resources

racy (Crane, 1991; vor der Brück et al., 2015), we perform this step manually to assure high accuracy. We also assign cases for the classes noun, article, adjective, and pronoun. We introduce *b* to represent the Latin ablative case, which does not exist in Greek.

3.4 Automated Approach

Our approach is to model the transformation process in terms of parameterized operations applied to the words in the reuse instance in order to obtain the original words. These operations use linguistic resources, such as lemma lists of classical Greek and Biblical Koine, and a synset database. For each transformation, we create the set of operations necessary to transform the reuse instance to its original.

Linguistic Resources. We investigate the following lemma lists to look up lemmatized forms of words—a prerequisite for looking up synsets: *Classical Language Tool Kit (CLTK)* (Johnson et al., 2014 2016) provides Ancient Greek and Latin lemma lists for 953,907 Greek and 270,228 Latin words. *Biblindex' Lemma Lists* contain entries for 65,537 Biblical Greek and 315,021 Latin words. *SBLGNT&LXX* refers to the Greek New Testament of the Society of Biblical Literature (SBLGNT)[3] and the Septuaginta (LXX), a translation of the Old Testament (Rahlfs, 1935a)[4] from the Center for Computer Analysis of Texts at UPenn. We acknowledge code-page corrections by M. Munson. SBLGNT&LXX provide 59,510 word-lemma-pairs.

We use *AGWN* (Bizzoni et al., 2014), which also contains Latin WordNet (Minozzi, 2009), to identify synsets (sets of synonyms) as well as hyperonyms, hyponyms, and co-hyponyms. From the wordnets' 98,950 synsets 33,910 synsets contain Ancient Greek and 27,126 synsets contain Latin words.

Coverage. Table 1 shows the coverage of each resource for our datasets. In the lower part of it we merge all lemma resources into one set of word-lemma pairs. The table shows that CLTK covers the Bible data better than the Hellenistic Greek as used in Clement of Alexandria, an author from 2nd century AD, writing in an archaic style with Biblical vocabulary, while also being influenced by Classical Greek. We also check the coverage of lemmata stemming from the same source (Biblindex) as our reuse. To increase the coverage for Greek, we consult SBLGNT&LXX, which in fact increases it. To not miss important information, we integrate all of the resources' data into our approach. For every lemma of a word we check the semantic relations in AGWN. We experimented with different ways of looking up lemmas and found that lower-casing all Latin tokens improved the success. For Greek, it had the opposite effect, which indicates that the Greek text contains more entities that are not available in lowercase in the lemma lists, so we did not change in that case.[5]

Operations and Classification. We define replacement operations using words and PoS as parameters, to transform a reuse instance *back into the Bible verse* it originates from. Table 2 lists the operations for the computational approach. We introduce the operations *NOPmorph*, *repl_pos*, and *repl_case* for words having the same cognate, and *lemma_missing(reuse_word)* when a word is not

repl_syn(reuse_word, orig_word)	Reuse word replaced with a synonym to match original word.	*repl_syn(magnificavit,glorificavit)*
repl_hyper(reuse_word, orig_word)	Word in bible verse is a hyperonym of the reused word.	*hyper(cupit,habens)*
repl_hypo(reuse_word, orig_word)	Word in bible verse is a hyponym of the reused word.	*hypo(dederit,tollet)*
repl_co-hypo(reuse_word, orig_word)	Reused word and original have the same hyperonym.	*repl_co-hypo(magnificavit,fecit)*
NOPmorph(reuse_tags, orig_tags)	Case or PoS did not change between reused and original word.	*NOPmorph(na,na)*
repl_pos(reuse_tag, orig_tag)	Reuse and original contain the same cognate, but PoS changed.	*repl_pos(n,a)*
repl_case(reuse_tag, orig_tag)	Reuse and original have the same cognate, but the case changed	*repl_case(g,d)* - cases genitive, dative
lemma_missing(reuse_word, orig_word)	Lemma unknown for reuse or original word	*lemma_missing(tentari, inlectus)*
no_rel_found(reuse_wword, orig_word)	Relation for reuse or original word not found in AGWN	*no_rel_found(gloria,arguitur)*

Table 2: Operation list for the automated approach

known to any of our lemma resources as well as *no_rel_found(reuse_word, orig_word)* when the relationship between a reuse word and each potential word from the original is not covered by AGWN.

Algorithm 1 shows our approach to classify the reuse transformation by identifying the operations. For each reuse token, we identify the first applicable operation matching the foremost Bible verse word (iterating the verse) in the following order: exact word match (*NOP: no operation*), case changed to *upper* or *lower*. Thereafter, we look up the lemma and return *lem* if the lemma of the reused word matches the lemma of the original. For these four, we also check the morphology, in addition returning whether the original has the same PoS and case (*NOPmorph*) or whether PoS changed (*repl_pos*), case changed (*repl_case*), or both. So up to three operations can be returned per word. Finally, we check for synonyms (*repl_syn*), hyperonyms (*hyper*), hyponyms (*hypo*), and co-hyponyms (*repl_co-hypo*), but do not check morphology. If a Bible verse word is used as a match, it is not used again for any other word from the reuse.

3.5 Qualitative Approach

To obtain a deeper understanding of the limitations of linguistic resources for our purpose, two graduate students (one Latinist, one Classical Archeologist) manually analyze 100 Greek and 60 Latin reuse instances with their expert knowledge, using an extended set of operations. It comprises *ins(word)* (insert a word) and *del(word)* (delete a word)—two operations we ignore in the automated approach where we focuse on the coverage of the resources. It also has a richer set of replacement operations: those from the upper part of Table 2 (without *upper* and *lower*), and instead of only using *repl_case* when a cognate stays the same, we refine it and assign *all* changing morphological categories from Perseus' tag set for *any* "relativeness" between two words (e.g., repl_case_a_g).

4 Results

We now present the results for our research questions in Sec. 4.1–4.3, which are summarized and further interpreted in Sec. 4.4.

4.1 Literal Share of the Reuse (RQ1)

We obtain a first understanding of the reuse by looking at the percentage of overlapping words between reuse instance and original Bible verse. We measure the longest common substring based on word tokens. Fig. 2 shows the distributions, distinguishing between a *lemmatized* and *non-lemmatized* word comparison.

While lemmatizing words before comparison has only a small impact, we observe differences between the datasets. In our Latin dataset, the overlap is significantly higher than in the Greek dataset Sec. 3.2. 25 % (upper quartile) of Bernard's reuse instances have 50 % or more tokens overlap with their original, which is only the case for less than 25 % in Clement's Greek data. Still, large overlaps of up to 75 % (top

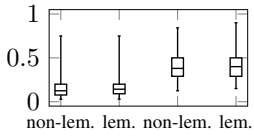

Figure 2: Ratios of literal overlaps between reuse instance and original (left: Greek, right: Latin)

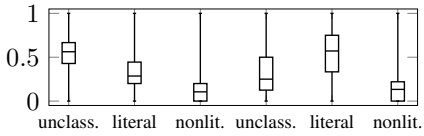

Figure 3: Ratios of unclassified, literal, and non-literal words in reuse instances (left: Greek, right: Latin)

whisker) in our Greek and up to around 90 % in our Latin dataset exist—so a small fraction of the reuse contains literal parts Sec. 3.2.

For a more precise understanding of the literalness, we group operations into literal (NOP, upper, lower, lem), non-literal (repl_syn, repl_hyper, repl_hypo, repl_co-hypo), and unclassified (no_rel_found and lemma_missing). Within each reuse instance, we calculate their relative occurrence using the results of the automated approach (explained shortly). Fig. 3 shows the distribution of these relative occurrences for all reuse instances. It confirms Fig. 2 by showing a higher rate of literalness for Latin compared to Greek. In summary, it also shows that the Latin reuse can be better classified by our approach, which takes the lemma lists and AGWN into account.

4.2 Automated Approach (RQ2.1)

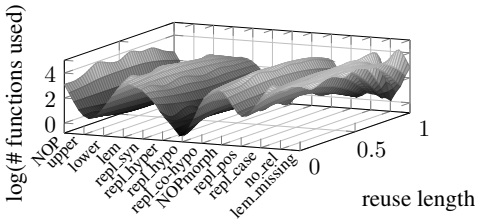
Table 3 shows the total number of operations identified for the transformation from reuse instances to the Greek and Latin originals. For 987 (45 %) out of 2189 words in the Greek instances and for 893 (67 %) out of 1335 words in the Latin instances, we were able to identify at least one operation, which already indicates to what extent the resources are helpful.

Fig. 4 visualizes the distribution of the frequencies (y-axis) of each operation (x-axis) together with the distribution of the operations' positions in the reuse instances (z-axis). The latter is calculated as the relative position $p \in [0..1]$ of an operation with respect to the length of the reuse instance. It indicates that most operation types are distributed over the whole reuse

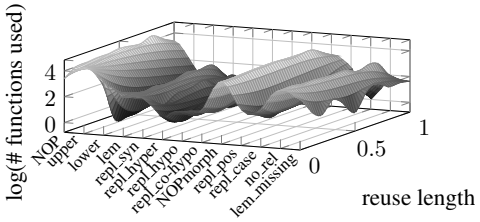
	NOP	upper	lower	lem	syn	hyper	hypo	co-hypo
Occ. Greek	337	6	0	356	153	20	14	101
Occ. Latin	587	0	44	102	60	14	28	68

	NOPmorph	repl_pos	repl_case	no_rel_found	lem_missing
Occ. Greek	420	49	258	563	639
Occ. Latin	617	46	75	347	85

Table 3: Absolute numbers of operations identified automatically



(a) Greek



(b) Latin

Figure 4: Occurrence of operations in reuse instances. X-axis: operations; Y-axis: relative position within reuse instances. Z-axis: natural logarithm of number of operations. Values are smoothed by spline interpolation. The order of operations is arbitrary.

length without a particular trend in both datasets. We only encounter a frequent use of *upper* at the first position in Latin, which means that Bernard often starts his Biblical references with literal Bible words.

After having checked the overall coverage of the linguistic resources for all tokens (cf. Sec. 3.4), we now specifically investigate to what extent the resources support identifying the reuse transformation for the non-literal reuse using our approach. We introduce the measures sup_{lem} and sup_{AGWN} to calculate how often looking up a lemma or subsequently a synset element was successful. This is easy based on our operations. Let $\text{Occ}(o)$ be the number of occurrences of an operation o, obtained from Table 3. The operations that successfully looked up a lemma (before consulting AGWN) are lem_success={lem, syn, repl_hyper, repl_hypo, repl_co-hypo, no_rel_found}. Now recall that lem_missing represents the case when a reuse token was not found in the lemma resources. Then $\text{sup}_{\text{lem}} = \frac{\sum_{\text{Occ}(o)\ o \in \text{lem\_success}}}{\sum_{\text{Occ}(o)\ o \in \text{lem\_success} \cup \{\text{lem\_missing}\}}}$. We obtain a sup_{lem} of 0.65 for the Greek reuse and 0.88 for the Latin reuse. Similarly, the operations that successfully looked up from AGWN are agwn_success={syn,

operation	Greek	Latin	operation	Greek	Latin
repl_syn	78 (40.6%)	91 (40.4%)	repl_gender	6 (3.1%)	1 (0.4%)
repl_ant	1 (0.5%)	0	repl_mood	11 (5.7%)	12 (5.3%)
repl_hyper	3 (1.6%)	0	repl_number	17 (8.9%)	17 (7.6%)
repl_hypo	11 (5.7%)	0	repl_person	5 (2.6%)	14 (6.2%)
lem	1 (0.5%)	2 (0.9%)	repl_pos	18 (9.4%)	33 (14.7%)
repl_co-hypo	0	1 (0.4%)	repl_tense	3 (1.6%)	9 (4.0%)
repl_case	38 (19.8%)	36 (16%)	repl_voice	0	8 (3.6%)

Table 4: Numbers of replacement operations identified for the manual reuse transformation.

operation	Greek	Latin	operation	Greek	Latin
repl_case_a_b	0	6	repl_case_g_a	5	2
repl_case_a_n	9	4	repl_case_g_n	4	2
repl_case_b_a	0	10	repl_case_n_a	7	5
repl_case_d_a	0	2	repl_case_n_d	3	0
repl_case_d_g	3	0	repl_case_v_g	0	2
repl_case_d_n	5	0			

Table 5: Numbers of case replacements

repl_hyper, repl_hypo, repl_co-hypo}, with no_rel_found representing a failed lookup. Then: $\text{sup}_{\text{AGWN}} = \frac{\sum_{\text{Occ}(o)} o \in \text{agwn\_success}}{\sum_{\text{Occ}(o)} o \in \text{agwn\_success} \cup \{\text{no\_rel\_found}\}}$. We obtain sup_{AGWN} of 0.34 for Greek and 0.33 for Latin.

These values can be interpreted as follows. The lemma resources for genre- and time-specific text work well for less-literal reuse, but the resources for semantic relationships (synset databases) show a lack of support and need further development.

4.3 Qualitative Approach (RQ2.2)

We manually identify the transformation operations for 60 reuse instances of the Ancient Greek data and for 100 of the Latin data. Here, NOPs cover 9.3 %, insertions 49.8 %, and deletions cover 30.5 % in the Greek data. NOPs cover 26.1 %, insertions 49.7 %, and deletions 11.9 % in the Latin data.

Table 4 shows the ratios of the various *repl* operations based on the remaining 10.4 % and 12.2 %. Similar to the automated approach, we observe a strong use of synonyms and other semantic-level operations, and also a certain portion of switching morphological categories, which indicates para-phrasal reuse. In the Greek data, PoS changes cover about 9%, out of which a participle became a verb (7 times) and vice-versa (5 times). In our Latin data, PoS changes represent 15% of replacements: often a pronoun changed to a noun (6 times) and a participle became a verb (12 times). Case changes are shown in Table 5. Significantly often, an ablative became an accusative, because often changing prepositions expect different cases, or an accusative was replaced by an ablative or nominative, because para-phrasal expression changed.

We encounter **exceptions** that prevent applying the operations. In the Greek data, one word is replaced with its antonym[6]; once, a synonym also changes its PoS. Four times, more than one morphological category changes, twice an auxiliary is deleted, and five times inserted. We find one writing variance (lem), and three times a synonym is replaced by a multi-word expression. In the Latin data, in 16 cases a synonym is replaced and morphological information changed. Seven times, more than one morphological parameter changes for the same cognate. Eight times, an auxiliary is inserted or deleted, and twice, a writing variance is encountered. A synonym is replaced by more than one word five times. In one case, a reuse is too paraphrasal for any word to match semantic relationships (e.g., *judged calmly*—Bernard vs. *fake friend* - Sal 12 18).

4.4 Summary and Discussion

RQ1. The reuse is significantly non-literal and only lemmatizing words does not help discovering it. Our results show that reuse in two substantial historical texts requires techniques beyond simple preprocessing (e.g., stemming or lemmatizing), which explains why plagiarism-detection systems fail when paraphrases are used (Alzahrani et al., 2012). Bible verses are often used to justify an author's claim, so only relevant parts of the Bible verse are reused. In the reuse the Bible verse is modified to better fit the syntactical and semantic context of an author's new text, as shown in Tables 4 and 5.

RQ2.1. The results from our automated approach are encouraging, showing the feasibility of extending reuse-detection techniques with linguistic resources. Yet, it is not clear which precision and recall could be achieved and how existing techniques need to be adapted and calibrated. This investigation is beyond the scope of this study and subject to our future work.

The linguistic resources support the automated

[6]Translation: "**the** God, the good (**one**)" (Clement) vs. "**none** is good but the God" (Bible).

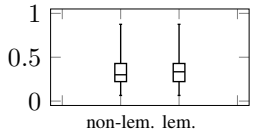


Figure 5: Ratios of literal overlaps in the whole Latin dataset

approach, but only for about one third of the lookups. The manually identified exceptions show that finding a connection between original verse and reuse can be difficult when there is only a vague semantic one.

RQ2.2. Our results show that the automated approach cannot capture the richness of the manual approach. Especially from the exceptions, it is clear that less-literal reuse does not only need information from a word's semantic environment, but also that it needs to be identified by looser relations, such as co-hyponyms, multi-to-multi-word associations or implicit meanings, which can be hidden in structural or more broader expert knowledge.

5 Threats to Validity

External Validity. We enhance the external validity of our work by focusing on Bible verses—one of the oldest, most conveyed, and cited sources of Ancient Greek, offering a vast amount of primary source text and also coming with a long history of scholars studying it. Clement of Alexandria is known for his retelling of biblical excerpts (Clemens, 1905 1909; Freppel, 1865), providing an interesting base for reuse investigation. The french abbot Bernard of Clairvaux (Smith, 2010) is equally known for his influence to the Cistercian order and his work in biblical studies. Furthermore, the chosen lemma resources are the most extensive ones existing for Ancient Greek and Latin. We chose the AGWN, since it is freely available, offering one of the largest synset database for Ancient Greek and Latin.

Internal Validity. A threat is that our ground truth has mistakes, as the PoS tagging was done by one author only and relied on a manual post-correction. The selection criteria in Sec. 3.2 were chosen to ensure quality and comparability. Extreme outliers in the length of the reuse instance or source (multiple Bible verses) are cut-off. For Greek, 33 are cut-off, as opposed to Latin, where our sample is significantly smaller than the whole population that we have. To automatically check whether the sample has similar characteristics with respect to the literal reuse, we create Fig. 5. It shows the overlap of the whole 1128 instances of Bernard's extracted reuse, which when compared to Fig. 2 (right) supports the representativeness of our sample. Last, we can only derive operation replacements when a word token was covered by the lemma sources, contained in AGWN, and when there actually exists a relation between two words. Also, our authors' vocabulary can differ in terms of domain knowledge, personal idiolect, and age of the Biblical vocabulary.

6 Conclusion

We presented a study of historical—and mostly non-literal—text reuse. We automatically and manually characterize the reuse and identify to what extent existing linguistic resources are able to cover non-literal text reuse. Our results show the potential as well as the necessity to develop robust techniques and to extend linguistic resources for analyzing and detecting such reuse. Our results can help to enhance paraphrase generation to model automatic ways on how small text portions can be rephrased. Considering the effects of syntactic rearrangement of reuse can also support such efforts. A smarter automated approach for deriving an original text excerpt would be learning so-called edit scripts (Kehrer, 2014; Chawathe et al., 1996), which more precisely identify operations an author performed on a text to transform it into another version. Whether learning edit scripts on such intricate transformations is possible is an open question and valuable future research. Finally, analyzing further languages and data sets helps to further complete our findings.

Acknowledgments

We thank Laurence Mellerin for providing the datasets we used, and for valuable advice on its content. Our work is funded by the German Federal Ministry of Education and Research (grant 01UG1509).

A Graph Degeneracy-based Approach to Keyword Extraction *

Antoine J.-P. Tixier[1], **Fragkiskos D. Malliaros**[1,2], **Michalis Vazirgiannis**[1]

Abstract

We operate a change of paradigm and hypothesize that keywords are more likely to be found among *influential* nodes of a graph-of-words rather than among its nodes high on *eigenvector*-related centrality measures. To test this hypothesis, we introduce unsupervised techniques that capitalize on *graph degeneracy*. Our methods strongly and significantly outperform all baselines on two datasets (short and medium size documents), and reach best performance on the third one (long documents).

1 Introduction

Keyword extraction is a central task in NLP. It finds applications from information retrieval (notably web search) to text classification, summarization, and visualization. In this study, we focus on the task of *unsupervised single-document keyword extraction*. Following (Mihalcea and Tarau, 2004), we concentrate on *keywords* only, letting the task of *keyphrase* reconstruction as a post-processing step.

More precisely, while we capitalize on a graph representation of text like several previous approaches, we deviate from them by making the assumption that keywords are not found among *prestigious* nodes (or more generally, nodes high on eigenvector-related centrality metrics), but rather among *influential* nodes. Those nodes may not have many important connections (like their prestigious counterparts), but they are ideally placed at the core of the network. In other words, this switches the objective from capturing the *quality* and *quantity* of single node connections, to taking into account the *density* and *cohesiveness* of groups of nodes. To operate this change of paradigm, we propose several algorithms that leverage the concept of *graph degeneracy* (Malliaros et al., 2016a).

Our contributions are threefold: (1) we propose new unsupervised keyword extraction techniques that reach state-of-the art performance, (2) we apply the K-truss algorithm to the task of keyword extraction for the first time, and (3) we report new insights on the interplay between window size, graph-of-words structure, and performance.

2 Graph-of-Words Representation

Many ways of encoding text as a graph have been explored in order to escape the very limiting *term-independence* assumption made by the traditional vector space model. In this study, we adopt the seminal Graph-of-Words representation (GoW) of (Mihalcea and Tarau, 2004), for its simplicity, high historical success, and above all because it was recently used in several approaches that reached very good performance on various tasks such as information retrieval (Rousseau and Vazirgiannis, 2013), document classification (Malliaros and Skianis, 2015; Rousseau et al., 2015), event detection (Meladianos et al., 2015), and keyword extraction (Rousseau and Vazirgiannis, 2015).

While sophisticated variants of the GoW model would be worth exploring (edge weights based on mutual information or word embeddings, adaptive window size, etc.), we aim here at making a bet-

Figure 1: (a) Graph-of-words ($W = 8$) for document #1512 of Huth2003 decomposed with k-core (non-(nouns and adjectives) in *italic*). (b) Keywords extracted by each proposed and baseline method (human assigned keywords in **bold**). (c) Selection criterion of each method except *main* (does not apply).

ter use of an existing representation of text, not at proposing a new one. This is why, to demonstrate the additional skill brought by our proposed methods, we stick to the basic GoW framework.

As shown in Figure 1 (a), the GoW representation of (Mihalcea and Tarau, 2004) encodes a piece of text as an undirected graph where nodes are unique nouns and adjectives in the document, and where there is an edge between two nodes if the terms they represent co-occur within a window of predetermined size W that is slided over the entire document from start to finish, overspanning sentences. Furthermore, edges are assigned integer weights matching co-occurrence counts. This fully statistical approach is based on the *Distributional Hypothesis* (Harris, 1954), that is, on the premise that the relationship between words can be determined by the frequency with which they share local contexts of occurrence.

3 Graph Degeneracy

The concept of graph degeneracy was introduced by (Seidman, 1983) with the k-core decomposition technique and was first applied to the study of cohesion in social networks. Here, we consider it as an umbrella term also encompassing the K-truss algorithm (Cohen, 2008). In what follows, $G(V, E)$ is a graph with $|V|$ nodes and $|E|$ edges. Note that for graphs-of-words, the nodes V are labeled according to the unique terms they represent.

3.1 k-core subgraph

A core of order k (or k-core) of G is a maximal connected subgraph of G in which every vertex v has at least degree k (Seidman, 1983). If the edges are unweighted, the degree of v is simply equal to the count of its neighbors, while in the weighted case, the degree of v is the sum of the weights of its incident edges. Note that with the definition of GoW previously given, node degrees (and thus, k) are integers in both cases since edge weights are integers.

As shown in Figure 2 (a), the **k-core decomposition** of G is the set of all its cores from 0 (G itself) to k_{max} (its main core). It forms a hierarchy of nested subgraphs whose cohesiveness and size respectively increase and decrease with k (Seidman, 1983). The main core of G is a coarse approximation of its densest subgraph (Wang and Cheng, 2012), and should be seen as a *seedbed* within which it is possible to find more cohesive subgraphs (Seidman, 1983). Finally, the **core number** of a node is the highest order of a k-core subgraph that contains this node.

3.2 K-truss subgraph

K-truss is a triangle-based extension of k-core introduced by (Cohen, 2008). More precisely, the K-truss subgraph of G is its largest subgraph where every edge belongs to at least $K-2$ triangles. In other words, every edge in the K-truss joins two vertices that have at least $K-2$ common neighbors. Compared to k-core, K-truss thus does not iteratively prune nodes out based on the number of their *direct links*, but also based on the number of their *shared connections*. This more accurately captures cohesiveness.

As a result, the K-trusses are smaller and denser subgraphs than the k-cores, and the maximal K-truss of G better approximates its densest subgraph. In essence, and as illustrated in Figure 2 (b), the K-trusses can be viewed as the essential parts of the k-cores, i.e., what is left after the less cohesive elements have been filtered out (Wang and Cheng, 2012). By analogy with k-core, the **K-truss decomposition** of G is the set of all its K-trusses from $K=2$ to K_{max}, and the **truss number** of an *edge* is the highest order of a truss the edge belongs to. By extension, we define the truss number of a *node* as the maximum truss number of its incident edges.

3.3 k-shell

Depending on context, we will refer to the k-shell as the part of the k-core (or truss) that is not included in the $(k+1)$-core (or truss).

3.4 Graph degeneracy and spreading influence

In social networks, it has been shown that the best spreaders (i.e., the nodes able to propagate information to a large portion of the network at minimal time and cost) are not necessarily the highly connected individuals (i.e., the hubs), but rather those located at the core of the network (i.e., forming dense and cohesive subgraphs with other central nodes), as indicated by graph degeneracy algorithms (Kitsak et al., 2010). Put differently, the spreading influence of a node is related to its structural position within the graph (*density* and *cohesiveness*) rather than to its *prestige* (random walk-based degree). More recently, (Malliaros et al., 2016b) found that the truss number is an even better indicator of spreading influence than the core number. Motivated by these findings, we posit that taking *cohesiveness* into account with the core and truss decomposition of a graph-of-words could improve keyword extraction performance. That way, by analogy with the notion of influential spreaders in social networks, we hypothesize that *influential words* in graphs-of-words will act as representative keywords.

3.5 Complexity

(Batagelj and Zaveršnik, 2002) proposed $\mathcal{O}(|V| + |E|)$ and $\mathcal{O}(|E| \log |V|)$ time algorithms for k-core decomposition in the unweighted (resp. weighted) case. These algorithms are both $\mathcal{O}(|V|)$ in space. Computing the K-truss decomposition is more expensive, and requires $\mathcal{O}(|E|^{1.5})$ time and $\mathcal{O}(|V| + |E|)$ space (Wang and Cheng, 2012). Finally, building a graph-of-words is linear in time and space: $\mathcal{O}(|V|W)$ and $\mathcal{O}(|V| + |E|)$, respectively.

4 Related Work and Point of Departure

TextRank. One of the most popular approaches to the task of *unsupervised single-document keyword extraction* is TextRank (Mihalcea and Tarau, 2004), or TR in what follows. In TR, the nodes of graphs-of-words are ranked based on a modified version of the PageRank algorithm taking edge weights into account, and the top $p\%$ vertices are kept as keywords.
Limitations. TR has proven successful and has been widely used and adapted. However, PageRank, which is based on the concept of random walks and is also related to *eigenvector centrality*, tends to favor nodes with many important connections regardless of any cohesiveness consideration. For undirected graphs, it was even shown that PageRank values are proportional to node degrees (Grolmusz, 2015). While well suited to the task of

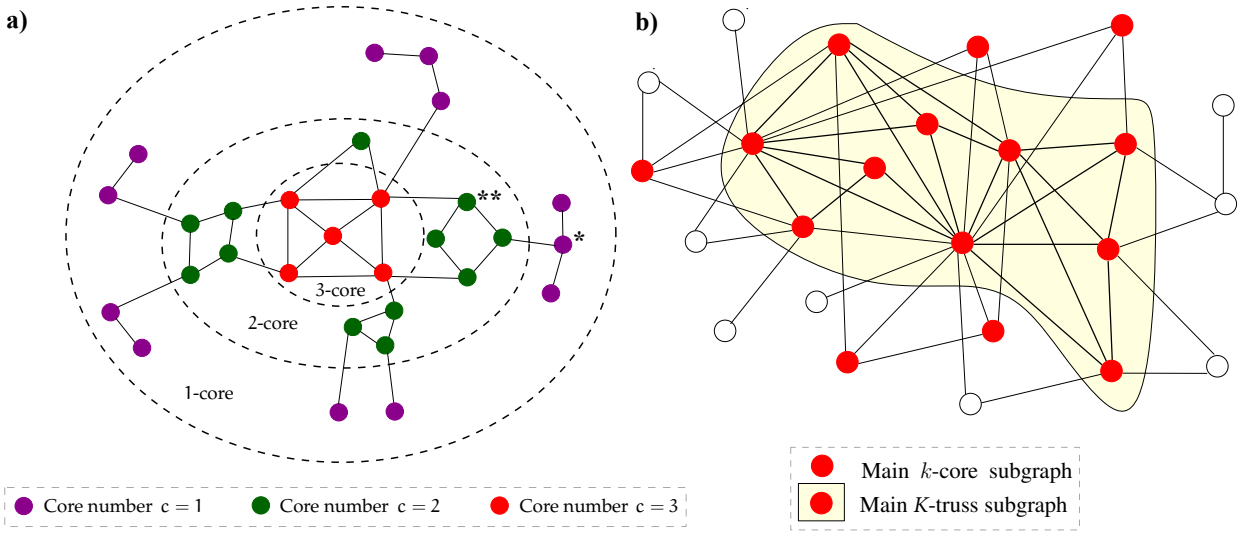

Figure 2: (a) k-core decomposition illustrative example. Note that while nodes * and ** have same degree (3), node ** makes a more influential spreader as it lies in a higher core than node *. (b) k-core versus K-truss. The main K-truss subgraph can be considered as the *core* of the main core.

prestige-based ranking in the Web and social networks (among other things), PageRank may thus not be ideal for keyword extraction. Indeed, a fundamental difference when dealing with text is the paramount importance of cohesiveness: keywords need not only to have many important connections but also to form *dense substructures* with these connections. Actually, most of the time, keywords are n-grams (Rousseau and Vazirgiannis, 2015). Therefore, we hypothesize that keywords are more likely to be found among the *influential spreaders* of a graph-of-words – as extracted by degeneracy-based methods – rather than among the nodes high on *eigenvector*-related centrality measures.

Topical vs. network coherence. Note that, unlike a body of work that tackled the task of keyword extraction and document summarization from a *topical* coherence perspective (Celikyilmaz and Hakkani-Tür, 2011; Chen et al., 2012; Christensen et al., 2013), we deal here with *network* coherence, a purely graph theoretic notion orthogonal to topical coherence.

Graph degeneracy. The aforementioned limitation of TR motivated the use of graph degeneracy to not only extract central nodes, but also nodes forming dense subgraphs. More precisely, (Rousseau and Vazirgiannis, 2015) applied both unweighted and weighted k-core decomposition on graphs-of-words and retained the members of the main cores as keywords. Best results were obtained in the weighted case, with small main cores yielding good precision but low recall, and significantly outperforming TR. As expected, (Rousseau and Vazirgiannis, 2015) observed that cores exhibited the desirable property of containing "long-distance n-grams".

In addition to superior quantitative performance, another advantage of degeneracy-based techniques (compared to TR, which extracts a constant percentage of nodes) is *adaptability*. Indeed, the size of the main core (and more generally, of every level in the hierarchy) depends on the structure of the graph-of-words, which by nature is uniquely tailored to the document at hand. Consequently, the distribution of the number of extracted keywords matches more closely that of the human assigned keywords (Rousseau and Vazirgiannis, 2015).

Limitations. Nevertheless, while (Rousseau and Vazirgiannis, 2015) made great strides, it suffers the following limitations: (1) k-core is *good* but not *best* in capturing cohesiveness; (2) retaining only the main core (or truss) is suboptimal, as one cannot expect all the gold standard keywords to be found within a unique subgraph – actually, many valuable keywords live in lower levels of the hierarchy (see Figure 1); and (3) the coarseness of the k-core

decomposition implies to work at a high granularity level (selecting or discarding a large group of words at a time), which diminishes the flexibility of the extraction process and negatively impacts performance.

Research objectives. To address the aforementioned limitations, we investigate in this study (1) the use of K-truss to get a finer-grained hierarchy of more cohesive subgraphs, in order to filter unwanted words out of the upper levels and improve flexibility; (2) the automated selection of the best level in the core (or truss) hierarchy to increase recall while preserving most of the precision; and (3) the conversion of node core (or truss) numbers into ranks, to decrease granularity from the *subgraph* to the *node* level, while still leveraging the valuable cohesiveness information captured by degeneracy.

5 Proposed Methods

In what follows, we introduce the strategies we devised to implement our research objectives.

5.1 Density

With the underlying assumption that keywords are found in cohesive subgraphs-of-words and are not all contained in the main core (or truss), an intuitive, straightforward stopping criterion when going down the core (or truss) hierarchy is a density-based one. More precisely, it may be advantageous to go down the hierarchy as long as the desirable cohesiveness properties of the main core or truss are maintained, and to stop when these properties are lost. This strategy is more formally detailed in Algorithm 1, where $G(V, E)$ is a graph-of-words, $levels$ corresponds to the vector of the n_{levels} unique k-core (or truss) numbers of V sorted in decreasing order, and the density of G is defined as:

$$density(G) = \frac{|E|}{|V|\,(|V|-1)} \qquad (1)$$

As can be seen in Figure 1 (c) and as detailed in Algorithm 2, the elbow is determined as the most distant point from the line joining the first and last point of the curve. When all points are aligned, the top level is retained (i.e., main core or truss). When there are only two levels, the one giving the highest density is returned.

Algorithm 1: *dens* method

Input : core (or truss) decomposition of G
Output: set of keywords

D $\leftarrow$ empty vector of length n_{levels}
for $n \leftarrow 1$ **to** n_{levels} **do**
  $D[n] \leftarrow density(levels[n]$-core (or truss)$)$
end
$k_{best} \leftarrow levels[elbow(n, D[n])]$
return k_{best}-core (or truss) of G as keywords

Algorithm 2: *elbow*

Input : set of $|S| \geq 2$ points $S = \{(x_0, y_0), ..., (x_{|S|}, y_{|S|})\}$
Output: x_{elbow}

$line \leftarrow \{(x_0, y_0); (x_{|S|}, y_{|S|})\}$
if $|S| > 2$ **then**
  $distance \leftarrow$ empty vector of length $|S|$
  $s \leftarrow 1$
  for (x, y) *in* S **do**
    $distance[s] \leftarrow$ distance from (x, y) to $line$
    $s \leftarrow s + 1$
  end
  if $\exists! s \mid distance[s] = max(distance)$ **then**
    $x_{elbow} \leftarrow x \mid (x, y)$ is most distant from $line$
  else
    $x_{elbow} \leftarrow x_0$
  end
else
  $x_{elbow} \leftarrow x \mid y$ is maximum
end
return x_{elbow}

5.2 Inflexion

The Inflexion method (*inf* in what follows) is an empirically-grounded heuristic that relies on detecting changes in the variation of shell sizes (where size denotes the number of nodes). Recall from subsection 3.3 than the k-shell is the part of the k-core (or truss) that does not survive in the $(k+1)$-core (or truss), that is, the subgraph of G induced by the nodes with core (or truss) number exactly equal to k. In simple terms, the *inf* rule-of-thumb consists in going down the hierarchy as long as the shells in-

crease in size, and stopping otherwise. More precisely, *inf* is implemented as shown in Algorithm 3, by computing the consecutive differences in size across the shells and selecting the first positive point before the drop into the negative half (see Figure 1c). If no point satisfies this requirement, the main core (or truss) is extracted.

Algorithm 3: *inf* method

Input : core (or truss) decomposition of G
Output: set of keywords

CD $\leftarrow$ empty vector of length $n-1$
for $n \leftarrow 1$ **to** $(n_{levels}-1)$ **do**
  $k_l \leftarrow levels[n+1]$; $k_u \leftarrow levels[n]$
  $CD[n] \leftarrow$ size$\big(k_l$-shell$\big)-$size$\big(k_u$-shell$\big)$
end
if $\exists n \mid (CD[n+1] < 0 \wedge CD[n] > 0)$ **then**
  $n_{best} \leftarrow n$
else
  $n_{best} \leftarrow 1$
end
$k_{best} \leftarrow levels[n_{best}]$
return k_{best}-core (or truss) as keywords

Note that both *dens* and *inf* enjoy the same adaptability as the main core retention method of (Rousseau and Vazirgiannis, 2015) explained in Section 4, since the sizes of *all* the subgraphs in the hierarchy suit the structure of the graph-of-words.

5.3 CoreRank

Techniques based on retaining the k_{best}-core (or truss), such as *dens* and *inf* previously described, are better than retaining only the top level but lack flexibility, in that they can only select an entire batch of nodes at a time. This is suboptimal, because of course not all the nodes in a given group are equally good. To address this issue, our proposed CoreRank method (CR in what follows) converts nodes core (or truss) numbers into scores, ranks nodes in decreasing order of their scores, and selects the top $p\%$ nodes (CRP) or the nodes before the elbow in the scores curve (CRE). Note that for simplicity, we still refer to the technique as CR even when dealing with truss numbers.

Flexibility is obviously improved by decreasing granularity from the *subgraph* level to the *node* level. However, to avoid going back to the limitations of TR (absence of cohesiveness considerations), it is crucial to decrease granularity while retaining as much of the desirable information encoded by degeneracy as possible. To accomplish this task, we followed (Bae and Kim, 2014) and assigned to each node the sum of the core (or truss) numbers of its neighbors.

Our CRE method is outlined in Algorithm 4, where $N(v)$ denotes the set of neighbors of vertex v, and $number(v)$ is the core (or truss) number of v. CRP implements the exact same strategy, the only difference being $n_{best} \leftarrow round(|V| * percentage)$ at step 8 (where $percentage$ is a real number between 0 and 1).

Algorithm 4: CRE method

Input : core (or truss) decomposition of G
Output: set of keywords

CR $\leftarrow$ empty vector of length $|V|$
for $n \leftarrow 1$ **to** $|V|$ **do**
  $v \leftarrow V[n]$
  $CR[n] \leftarrow \sum_{u \in N(v)} number(u)$
  $name(CR[n]) \leftarrow label(v)$
end
sort CR in decreasing order
$n_{best} \leftarrow elbow(n, CR[n])$
return $names(CR[1 : n_{best}])$ as keywords

6 Experimental Setup

6.1 Baseline methods

TextRank (TR). We used as our first benchmark the system of (Mihalcea and Tarau, 2004) discussed in Section 4. For the sake of fair comparison with our CRE and CRP methods, we considered two variants of TR that respectively retain nodes based on both the elbow (TRE) and percentage criteria (TRP).

Main. Our second baseline is the main core retention technique of (Rousseau and Vazirgiannis, 2015), also described in Section 4. This method is referred to as *main* in the remainder of this paper.

6.2 Datasets

To evaluate performance, we used three standard, publicly available datasets featuring documents of

various types and sizes. Figure 3 shows the distributions of document size and manually assigned keywords for each dataset.

The **Hulth2003**[1] (Hulth, 2003) dataset contains abstracts drawn from the Inspec database of physics and engineering papers. Following our baselines, we used the 500 documents in the validation set and the "uncontrolled" keywords assigned by human annotators. The mean document size is 120 words and on average, 21 keywords (in terms of unigrams) are available for each document.

We also used the training set of **Marujo2012**[1], containing 450 web news stories of about 440 words on average, covering 10 different topics from art and culture to business, sport, and technology (Marujo et al., 2012). For each story, the keyphrases assigned by at least 9 out of 10 Amazon Mechanical Turkers are provided as gold standard. After splitting the keyphrases into unigrams, this makes for an average of 68 keywords per document, which is much higher than for the two other datasets, even the one comprising long documents (Semeval, see next).

The **Semeval**[2] dataset (Kim et al., 2010) offers parsed scientific papers collected from the ACM Digital Library. More precisely, we used the 100 articles in the test set and the corresponding author-and-reader-assigned keyphrases. Each document is approximately 1,860 words in length and is associated with about 24 keywords.

Notes. In Marujo2012, the keywords were assigned in an extractive manner, but many of them are verbs. In the two other datasets, keywords were freely chosen by human coders in an abstractive way and as such, some of them are not present in the original text. On these datasets, reaching perfect recall is therefore impossible for our methods (and the baselines), which by definition all are extractive.

6.3 Implementation

Before constructing the graphs-of-words and passing them to the keyword extraction methods, we performed the following pre-processing steps:

Stopwords removal. Stopwords from the SMART information retrieval system[3] were discarded.

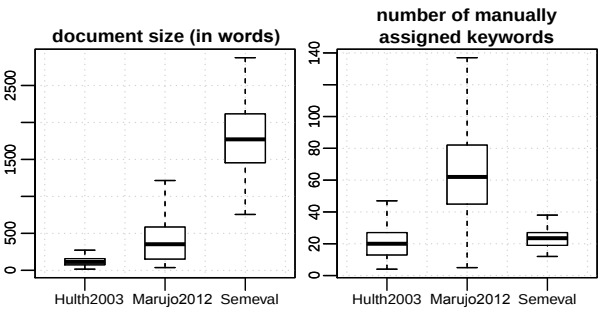

Figure 3: Basic dataset statistics.

Part-of-Speech tagging and screening using the `openNLP` (Hornik, 2015) R (R Core Team, 2015) implementation of the Apache OpenNLP Maxent POS tagger. Then, following (Mihalcea and Tarau, 2004), only nouns and adjectives were kept. For Marujo2012, as many gold standard keywords are verbs, this step was skipped (note that we did experiment with and without POS-based screening but got better results in the second case).

Stemming with the R `SnowballC` package (Bouchet-Valat, 2014) (Porter's stemmer). Gold standard keywords were also stemmed.

After pre-processing, graphs-of-words (as described in Section 2) were constructed for each document and various window sizes (from 3, increasing by 1, until a plateau in scores was reached). We used the R `igraph` package (Csardi and Nepusz, 2006) to write graph building and weighted k-core implementation code. For K-truss, we used the C++ implementation offered by (Wang and Cheng, 2012).

Finally, for TRP and CRP, we retained the top 33% keywords on Hulth2003 and Marujo2012 (short and medium size documents), whereas on Semeval (long documents), we retained the top 15 keywords. This is consistent with our baselines. Indeed, the number of manually assigned keywords increases with document size up to a certain point, and stabilizes afterwards.

The code of the implementation and the datasets can be found here[4].

7 Experimental Results

7.1 Evaluation

We computed the standard precision, recall, and F-1 measures for each document and averaged them at the dataset level (macro-averaging).

7.2 Precision/Recall trade-off

As shown in Figure 5, our methods *dens* and *inf* outperform the baselines by a wide margin on the datasets containing small and medium size documents (Hulth2003 and Marujo2012). As expected, this superiority is gained from a drastic improvement in recall, for a comparatively lower precision loss. TR and *main* exhibit higher precision than recall, which is in accordance with (Rousseau and Vazirgiannis, 2015). The same observation can be made for our CR method. For TR, the unbalance is more severe on the Hulth2003 and Marujo2012 datasets (short/medium documents) when the elbow method is used (TRE), probably because it tends to retain only a few nodes. However, on Semeval (long documents), using the elbow method (TRE) gives the best trade-off between precision and recall. For CR, still on Semeval, using the elbow method (CRE) even gives better recall than precision.

Overall, compared to the baselines, the unbalance between precision and recall for our methods is less extreme or equivalent. On the Marujo2012 dataset for instance, our proposed *inf* method is almost perfectly balanced and ranks second (significantly better than all baselines).

7.3 Impact of window size

The performance of k-core does not dramatically increase with window size, while K-truss exhibits a surprising "cold start" behavior and only begins to kick-in for sizes greater than 4-5. A possible explanation is that the ability of K-truss (which is triangle-based) to extract meaningful information from a graph depends, up to a certain point, on the amount of triangles in the graph. In the case of graph-of-words, the number of triangles is positively correlated with window size (see Figure 4). It also appears that document size (i.e., graph-of-words structure) is responsible for a lot of performance variability. Specifically, on longer documents, performance plateaus at higher window sizes.

7.4 Best models comparison

For each dataset, we retained the degeneracy technique and window size giving the absolute best performance in F1-score, and compared all methods under these settings (see Tables 1–3). We tested for statistical significance in macro-averaged F1 scores using the non-parametric version of the t-test, the Mann-Whitney U test[5].

On Hulth2003 and Marujo2012 (short and medium size documents), our methods *dens* and *inf* strongly and significantly outperform all baselines, with respective absolute improvements of more than 5.5% with respect to the best performing baseline

[5] https://stat.ethz.ch/R-manual/R-devel/library/stats/html/wilcox.test.html

	precision	recall	F1-score
dens	8.44	79.45	15.06
inf	17.70	65.53	26.68
CRP	**49.67**	**32.88**	**38.98***
CRE	25.82	58.80	34.86
main†	25.73	49.61	32.83
TRP†	47.93	31.74	37.64
TRE†	33.87	46.08	37.55

Table 3: Semeval, K-truss, $W = 20$.
*statistical significance at $p < 0.001$ w.r.t. *main*. †baseline systems.

(*main*). On Semeval, which features larger pieces of text, our CRP technique improves on TRP, the best performing baseline, by more than 1 %, altough the difference is not statistically significant. However, CRP is head and shoulders above *main*, with an absolute gain of 6%. This suggests that converting the cohesiveness information captured by degeneracy into ranks may be valuable for large documents.

Finally, the poor performance of the *dens* and *inf* methods on Semeval (Table 3) might be explained by the fact that these methods are only capable of selecting an entire batch of nodes (i.e., subgraph-of-words) at a time. This lack of flexibility seems to become a handicap on long documents for which the graphs-of-words, and thus the subgraphs corresponding to the k-core (or truss) hierarchy levels, are very large. This analysis is consistent with the observation that conversely, approaches that work at a finer granularity level (node level) prove superior on long documents, such as our proposed CRP method which reaches best performance on Semeval.

8 Conclusion and Future Work

Our results provide empirical evidence that *spreading influence* may be a better "keywordness" metric than *eigenvector* (or *random walk*)-based criteria. Our CRP method is currently very basic and leveraging edge weights/direction or combining it with other scores could yield better results. Also, more meaningful edge weights could be obtained by merging local co-occurrence statistics with external semantic knowledge offered by pre-trained word embeddings (Wang et al., 2014). The direct use of density-based objective functions could also prove valuable.

Abstract

The problem of accurately predicting relative reading difficulty across a set of sentences arises in a number of important natural language applications, such as finding and curating effective usage examples for intelligent language tutoring systems. Yet while significant research has explored document- and passage-level reading difficulty, the special challenges involved in assessing aspects of readability for single sentences have received much less attention, particularly when considering the role of surrounding passages. We introduce and evaluate a novel approach for estimating the relative reading difficulty of a set of sentences, with and without surrounding context. Using different sets of lexical and grammatical features, we explore models for predicting pairwise relative difficulty using logistic regression, and examine rankings generated by aggregating pairwise difficulty labels using a Bayesian rating system to form a final ranking. We also compare rankings derived for sentences assessed with and without context, and find that contextual features can help predict differences in relative difficulty judgments across these two conditions.

1 Introduction

The reading difficulty, or *readability*, of a text is an estimate of linguistic complexity and is typically based on lexical and syntactic features, such as text length, word frequency, and grammatical complexity (Collins-Thompson and Callan, 2004; Schwarm and Ostendorf, 2005; Kidwell et al., 2011; Kanungo and Orr, 2009). Such estimates are often expressed as age- or grade-level measures and are useful for a range of educational and research applications. For example, instructors often wish to select stories or books that are appropriately matched to student grade level.

Many measures have been designed to calculate readability at the document level (e.g., for web pages, articles, or books) (Collins-Thompson and Callan, 2004; Schwarm and Ostendorf, 2005), as well as the paragraph or passage level (Kidwell et al., 2011; Kanungo and Orr, 2009). However, much less work has attempted to characterize the readability of single sentences (Pilán et al., 2014). This problem is challenging because single sentences provide less data than is typically required for reliable estimates, particularly for measures that rely on aggregate statistics.

The absence of reliable single-sentence estimates points to a gap in natural language processing (NLP) research. Single sentences are used in a variety of experimental and NLP applications: for example, in studies of reading comprehension. Because readability estimates have been shown to predict a substantial portion of variance in comprehension of different texts, it would be useful to have measures of single-sentence readability. Thus, one aim of the current study was to estimate the *relative readability* of single sentences with a high degree of accuracy. To our knowledge, general-purpose methods for computing such estimates for native language (L1) readers have not been developed, and thus our goal was to develop a method that would characterize sentence-level difficulty for that group.

The second aim is to compare the readability of single sentences in isolation with the readability of

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1871–1881,
Austin, Texas, November 1-5, 2016.

these same sentences embedded in a larger context (e.g., paragraph, passage, or document). When a single sentence is extracted from a text, it is likely to contain linguistic elements, such as anaphora (e.g., "he" or "the man"), that are semantically or syntactically dependent on surrounding context. Not surprisingly, sentences that contain these contextual dependencies take more effort to comprehend: an anaphoric noun phrase, or NP (e.g., "he"), automatically triggers the need to resolve reference, typically by understanding the link between the anaphor and a full NP from a previous sentence (e.g., "John" or "The man that I introduced you to at the party last night" (Perfetti and Frishkoff, 2008). In general, studies have shown a link between reading comprehension and the presence of such cross-sentence relationships in the text (McNamara, 2001; Liederholm et al., 2000; Voss and Silfies, 1996). This implies that the very notion of readability at the sentence level may depend on context as well as word- and sentence-level features. Therefore, it is important to compare readability estimates for single sentences that occur in isolation with those that occur within a larger passage, particularly if the target sentence contains coreferences, implied meanings, or other dependencies with its context.

To address these aims, the present study first conducted two crowdsourcing experiments. In the first, 'sentence-only' experiment, workers were asked to judge which of two "target" sentences they thought was more difficult. In the second, 'sentence-in-passage' experiment, another group of workers was presented with the same target sentences that were used in the first experiment. However, in the second experiment, target sentences were embedded in their original contexts.

Next, we analyzed these judgments of relative readability for each condition (sentence-only versus sentence-in-passage) by developing models for predicting pairwise relative difficulty of sentences. These models used a rich representation of target sentences based on a combination of lexical, syntactic, and discourse features. Significant differences were found in readability judgments for sentences with and without their surrounding context. This demonstrates that discourse-level features (i.e., features related to coherence and cohesion) can affect the readability of single sentences.

2 Related Work

Recent approaches to estimating readability have used a variety of linguistic features and prediction models (Collins-Thompson, 2014). The Lexile Framework (Stenner, 1996) uses word frequency estimates in a large corpus as a proxy for lexical difficulty, and sentence length as a grammatical feature. Methods based on statistical machine learning, such as the reading difficulty measures developed by Collins-Thompson and Callan (Collins-Thompson and Callan, 2004) and (Schwarm and Ostendorf, 2005) used a feature set based on language models. Later work (Heilman et al., 2008) incorporated grammatical features by parsing the sentences in a text, and creating subtrees of one- to three-level depth as separate features. Such features allow more detailed, direct analysis of the sentence structure itself instead of traditional proxies for syntactic complexity likes sentence length. The linguistic features proposed in these works capture specific aspects of language difficulty applied at the document level, whereas our work investigates the effectiveness of these feature types for characterizing aspects of difficulty at the sentence level.

Methods have been proposed to measure the readability of shorter portions of text (e.g. typically less than 100 words), including sentences. The approach most similar to ours is the prediction of relative sentence difficulty (with associated readability ranking) for the deaf introduced by Inui et al. (2001). That work focused on effective morphosyntactic features for that target population with an SVM binary classifier, whereas our approach (1) is intended for a broader population of L1 learners and thus explores the effectiveness of adding a rich, lexically-derived feature set, (2) uses a logistic regression model to estimate class probabilities and interprets the results of that model, compared to applying an SVM without interpretation to obtain a binary label, (3) examines differences in predicting sentence difficulty both in and out of passage context, and (4) creates and uses a new dataset based on a crowdsourced approach, using hundreds of non-experts to gather thousands of pairwise preferences, compared to a questionnaire deployed to a small number of experts. In other domains, a model was proposed to predict the readability of short web summaries in Kanungo and Orr 2009. In Kidwell et al. (2011), , a set of Age of

Acquisition estimates for individual words, representing the lexical component of difficulty, was used to predict the grade levels of passages. Some approaches have explored the classification of specific aspects of sentences, as opposed to reading difficulty classification. For example, (Pilán et al., 2014) classified individual sentences that would be understood by second-language learners. Another work (Kilgarriff et al., 2008) identified sentences that would be good dictionary examples by looking for specific desirable features. Davenport et al. 2014 used a traditional method of readability (Flesch-Kincaid), within the larger context of exploring relationships between the difficulty of tweets in a geographic area and demographics. Research in text simplification has applied sentence-level models of difficulty as part of simplification-based optimization objectives. For example, Woodsend and Lapata (2011) use word and syllable count as proxy features for sentence difficulty when implicitly comparing different simplified variants of a sentence.

Other approaches have considered the relationship of reading difficulty to structures within in the whole text. These relationships can include the number of coreferences present in a text. Coh-Metrix (Graesser et al., 2011) measures text cohesiveness, accounting for both the reading difficulty of the text and other lexical and syntactic measures as well as a measure of prior knowledge needed for comprehension, and the genre of the text. Coh-Metrix uses co-reference detection as a factor in the cohesiveness of a text, typically at the document or passage level. Such cohesiveness factors account for the difficulty of constructing the mental representation of texts with more complex internal structure. TextEvaluator (Sheehan et al., 2013; Sheehan et al., 2014) is designed to help educators select materials for instruction. The tool includes several components in its evaluation of text, including narrativity, style, and cohesion, beyond traditional difficulty and is again at the whole document level. This approach illustrates that the difficulty of a text relies on the relationships within it. This motivates the need to consider context when measuring difficulty.

Generating reading difficulty rankings of longer texts from pairwise preferences has been performed in other contexts. Tanaka-Ishii et al. (2010) explored an approach for sorting texts by readability based on pairwise preferences. Later, Chen et al. (2013) also proposed a model to obtain passage readability ranking by aggregating pairwise comparisons made by crowdworkers. In De Clercq et al.(2014), pairwise judgments of whole passages were obtained from crowdworkers and were found to give comparable results in aggregate to those obtained from experts. A pairwise ranking of text readability was created in Pitler and Nenkova (2008) in which readability was defined by subjective questions asked to the reader after finishing the article, such as "How well-written is this article?". All of the above previous work was focused on ordering longer text passages, not single sentences as we do here.

Finally, research in the Machine Translation field has explored pairwise prediction of the best translation between two sentence options. For example, in Song and Cohn (2011), a pairwise prediction model was built using n-gram precision and recall, as well as function, content, and word counts. However, unlike pairwise prediction of difficulty, the prediction is done with respect to a reference sentence, or set of reference sentences.

3 Data Collection and Processing

We now describe methods used to create our dataset of sentences, to collect pairwise assessments of difficulty, and to aggregate these pairwise preferences into a complete ranking.

3.1 Data Set

The study sentences were drawn from a corpus combining the American National Corpus (Reppen et al., 2005), the New York Times Corpus (Sandhaus, 2008), and the North American News Text Corpus (McClosky et al., 2008). The domain of these corpora is largely news text, but also includes other topics, such as travel guides and other non-fiction. In total, this database contains 60,663,803 sentences that served as initial candidates. Sentences were filtered out that didn't include one of the 70 target words that the third author selected for a study on teaching vocabulary to 8-14 year-old students. Other sentences were removed based on length, keeping only sentences of between 6 and 20 words. Some sentences were removed due to the presence of one or more rare words. Finally, sentences were annotated with the surrounding document reading level, us-

ing a lexical readability model (Collins-Thompson and Callan, 2004).The data set gathered by (Collins-Thompson and Callan, 2004) was used in order to add to the amount of lower-level reading material in the collected corpora.

With these sentences, two crowdsourced tasks were prepared to gather pairwise assessments of sentence reading difficulty. In one task, the sentences were presented alone, outside of their original passage context. In the other task, the same sentences were presented within their original passage context. The objective was to generate two sets of pairwise comparisons of the readability of a sentence. In total, 120 sentence pairs were used for the first task and 120 passage pairs were used for the second. Each sentence was compared to five others, which created 300 comparisons in each task. The five sentences matched to each sentence were selected to ensure that pairs with a range of document level differences would be created. Within each type of pair, a random pair was selected.

There were several constraints when generating pairs for comparison. To allow for sentences to be taken from documents with a range of reading levels, sentences were selected evenly from documents at each reading level. From the twelve standard U.S. grade levels used in readability, each document was considered to be part of a bin consisting of two adjacent grade levels, such as grades 1 and 2, for example. Sentences were selected evenly from those bins.

Each sentence needed sufficient context to ensure there would be equivalent context for each item that would be compared, so only passages of sufficient size were included. To ensure passages were of similar length, only passages that had between 136 and 160 words were included. Contexts having at least two sentences before and after the sentence in question were strongly preferred. Each selected sentence was paired with one sentence from each of the other grade level bins. For example, a sentence from grade 1 would be paired with one sentence each from grade 3-4, 5-6, 7-8, 9-10, and 11-12. Finally, each pair of sentences was presented in AB and BA order. For each pair, there were seven worker decisions. There were 296 unique workers for the sentence-only task, and 355 for the sentence-in-passage task.

3.2 Crowdsourcing

Both of these tasks were carried out on the Crowdflower platform. The workers were first given instructions for each task, which included a description of the general purpose of the task. In the sentence-only task, workers were asked to select which of the two sentences was more difficult. In the sentence-within-passage task, workers were similarly asked to decide which underlined sentence was more difficult. The instructions for the latter requested that the workers make their judgment only on the sentence, not on the whole context. In both tasks, there was an option for "I don't know or can't decide". The workers were asked to make their decision based on the vocabulary and grammatical structure of the sentences. Finally, examples for each task were provided with explanations for each answer.

For each task, at least 40 gold standard questions were created from pairs of sentences that were judged to be sufficiently distinct from one another so that they could easily be answered correctly. For the sentence-in-passage task, several gold standard questions were written to verify that the instructions were being followed, since it was possible that a worker might judge the sentences based on the quality of the passage alone. These gold examples consisted of an easier sentence in a difficult passage compared with a difficult sentence within an easy passage. For each task, the worker saw three questions, including one gold standard question. A worker needed to maintain an 85% accuracy rating on gold standard questions to continue, and needed to spend at least 25 seconds per page, which contained 3 questions each.

A weighted disagreement rate was calculated for each worker. If a worker's response to a question differed from the most frequent answer to that question, the percentage of agreement was counted against the worker. If a worker, for the sentence-only task, had a disagreement rate (the weighted disagreement penalty divided by the total questions they answered) of 15% or higher, their contribution was removed from the data set (or 17% or higher for the sentence in passage task). The agreement for the sentence-in-passage task is lower than the sentence-only task (88.93% and 90.33% respectively), so the permitted disagreement level is higher for that task. This resulted in the removal of 5.7% and 4.5% of

pairwise judgments, respectively. For each question, there was an optional text form to allow workers to submit feedback. The sentence-only task paid 11 cents per page, and the sentence-in-passage task paid 22 cents per page.

3.3 Ranking Generation

Each task resulted in 4,200 pairwise preference judgments, excluding gold-standard answers. To aggregate these pairwise preferences into an overall ranking of sentences, we use a simple, publicly available approach evaluated by Chen et al. as being competitive with their own Crowd-BT aggregation method: the Microsoft Trueskill algorithm (Herbrich et al., 2007). Trueskill is a Bayesian skill rating system that generalized the well-known Elo rating system, in that it generates a ranking from pairwise decisions. As Trueskill's ranking algorithm depends on the order in which the samples are processed, we report the ranking as an average of 50 runs.

The judgments were not aggregated for each comparison. Instead, each of the judgments was treated individually. This allows Trueskill to consider the degree of agreement between workers, since a sentence judgment that has high agreement reflects a larger difference in ranking than one that has lower agreement. Each sentence was considered a player, and the winner between two, A or B, was the sentence considered most difficult. If a worker chose "I don't know or can't tell", it was considered a draw. The prediction resulting in "I don't know or can't tell" is rare; 2.2% of decisions in the sentence only task resulted in a draw, and 2.0% for sentences within passages. After processing each of the judgments, a rating can be built of sentences, ranked from least difficult to most difficult. We can compare the resulting rankings for the sentence-only task and the sentence-in-passage task to see the effect of context on relative sentence difficulty.

4 Modeling Pairwise Relative Difficulty

Our first step in exploring relative difficulty ordering for a set of sentences was to develop a model that could accurately predict relative difficulty for a single pair of sentences, corresponding to the pairwise judgements of relative difficulty we gathered from the crowd. We did this for both the sentence-only and the sentence-in-passage tasks. In predicting a pairwise judgment for the sentence-only task, the model uses only the sentence texts. In the model for the sentence-in-passage task, the Stanford Deterministic Coreference Resolution System (Raghunathan et al., 2010) is used to find coreference chains within the passage. From these coreference chains, sentences with references to and from the target sentence can be identified. If any additional sentences are found, these are used in a separate feature set that is included in the model; for all possible features, they are calculated for the target sentence, and separately for the additional sentence set.

Prior to training the final model, feature selection was done on random splits of the training data. Training data was used to fit a Random Forest Classifier, and based on the resulting classifier, the most important variables were selected using sklearn's feature importance method. The top 2% of the features (or 1% for the sentence-in-passage with coreference, since the feature set size is doubled) were selected automatically. This resulted in a feature size of 40-50 features. We implemented our models using scikit-learn (Pedregosa et al., 2011) in Python.

The resulting features were used to train a Logistic Regression model. While other prediction models such as Support Vector Machines have been applied to relative readability prediction (Inui and Yamamoto, 2001), we chose Logistic Regression due to its ability to provide estimates of class probabilities (which may be important for reliability when deploying a system that recommends high-quality items for learners), its connection to the Rasch psychometric model used with reading assessments (Ehara et al., 2012), and the interpretable nature of the resulting parameter weights. Since a given feature has a value for sentence A and B, if a feature was selected for only Sentence A or B, the feature for the other sentence was also added. We used the NLTK library (Bird et al., 2009) to tokenize the sentence for feature processing.

At the sentence level, the familiarity of the words is a significant factor to consider in any judgment of difficulty. The grammatical structure of a sentence is also important to consider: if the sentence uses a more familiar structure, it is likely to be considered less difficult than a sentence with more unusual structure. We thus identified two groups of potential

features: lexical and grammatical, described below.

4.1 Lexical Features

For lexical features, based partly on the work of (Song and Cohn 2011) we included the percentage of non-stop words (using NLTK list), the total number of words and the total number of characters as features. We included the percentage of words in the text found in the Revised Dale-Chall word list (Dale and Chall, 2000) to capture the presence of more difficult words in the sentence.

Because sentences that contain rarer sequences of words are likely to be more difficult, and the likelihood of the sentence based on a large corpus should reflect this, we included the n-gram likelihood of each sentence, over each of 1-5 n-grams, as a feature. The Microsoft WebLM service (Wang et al., 2010) was used to calculate the n-gram likelihood.

In the field of psycholinguistics, Age of Acquisition (AoA) refers to the age at which a word is first learned by a child. A database of 51,715 words collected by (Kuperman et al., 2012) provides a rich resource for use in reading difficulty measures. With this dataset, we computed several additional features: the average, maximum, and standard deviation of the aggregated AoA for all words in a sentence that were present in the database. Since the data set also includes the number of syllables in each word, and as (Kincaid et al., 1975) proposes that words with more syllables are more difficult, we also included the average and maximum syllable count as potential features.

4.2 Syntactic Features

We parsed each sentence in the data set using the BLLIP Parser (Charniak and Johnson, 2005), which includes a pre-trained model built on the Wall Street Journal Corpus. This provided both a syntactic tree and part of speech tags for the sentence. As Part of Speech tagging is often used as a high-level linguistic feature, we computed percentages for each PoS tag present, since the percentages might vary between difficult sentences and easier sentences. The percentage for each Part of Speech tag is defined as the number of times a certain tag occurred, divided by the total tags. The diversity of part of speech tags was used since this might vary between difficult and easier sentences.

Using the syntactic tree provided by the parser, we obtained the likelihood of the parse, and the likelihood produced by the re-ranker, as syntactic features. If a sentence parse has a comparatively high likelihood, it is likely to be a more common structure and thus more likely to be easier to read. The length and height of the parse were also included as features, since each of these could reflect the difficulty of the parse. Including the entire parse of the sentence would create too much sparsity since syntactic parses vary highly from sentence to sentence. Therefore, as was done in (Heilman et al., 2008), subtrees of depth one to three were created from the syntactic parse, and were added as features. This creates a smaller feature set, and one that can potentially model specific grammatical structures that are associated with a specific level of difficulty.

5 Pairwise Difficulty Prediction Results

The performance of the logistic regression models trained with different feature sets, for each task, is shown in Table 1. We reported the mean and standard deviation of the accuracy of each model over 200 randomly selected training and testing splits. Each test set consisted of 20% of the data, and contained 60 aggregate pairs, all of which are sentences (24 in total) that were not present in the training data. The test sets for the sentence-in-passage and sentence-only task contain the same sentence pairs, but the individual judgements are different.

For comparison, an oracle is included that represents the accuracy a model would achieve if it made the optimal prediction for each aggregate pair. Due to disagreement within the crowd, the oracle cannot reach 100% accuracy. For example, for some pair A and B, if 10 workers selected A as the more difficult sentence, and 4 workers selected B, the oracle's prediction for that pair would be that that A is more difficult. The judgments of the four workers that selected B would be counted as inaccurate, since the feature set is the same for the judgments with A and the judgments with B. Therefore, the oracle represents the highest accuracy a model can achieve, consistent with the provided labels, using the features provided.

Examining the results in Table 1, we find the best performing configuration, Model B, used all features as candidates. The exact number of features selected

Model	Sentence Only			In Passage, With Coref			In Passage, No Coref		
	Acc.	S.D.	p-value	Acc.	S.D.	p-value	Acc.	S.D.	p-value
Oracle (A)	90.13%	2.71%	—	87.81%	1.84%	—	87.81%	1.84%	—
All Features (B)	**84.69%**	3.46%	0.01 ↓	**81.66%**	3.17%	0.005 ↓	**81.91%**	3.27%	← 0.04
AoA + Parse L. (C)	**84.33%**	3.13%	0.001 ↓	**81.27%**	3.93%	0.001 ↓	**80.84%**	3.61%	← 0.001
AoA (D)	**79.62%**	2.71%	0.001 ↓	**79.72%**	2.86%	0.001 ↓	**78.99%**	2.58%	← 0.001
Strat. Random	50.28%	1.68%	—	50.31%	2.01%	—	50.31%	2.01%	—

Table 1: Mean and standard deviation of accuracy on 200 randomized samples of 20% held out data. 'With coref' indicates coreference features were used. The arrow indicates which immediately adjacent accuracy result is used for p-value comparison, e.g. Model B sentence-only is compared to model C sentence-only, and model B passage, no coref is compared to model B passage, with coref.

varied depending on the task. However, the simplest model, the Age of Acquisition model (D) consisting of the average, standard deviation, and maximum AoA features (sentence-only: 6 features, sentence-in-passage: 12 features) performed well, achieving over 78% accuracy on all tasks, showing that most of the relative difficulty signal at the sentence level can be captured with a few lexical difficulty features. The Age of Acquisition + Parse Likelihood model (C) consists of all Age of Acquisition features, plus the likelihood of the parse (sentence-only: 10 features, sentence-in-passage: 20 features)[1].

To assess the contribution of different features to the model prediction, feature group importances are reported in Table 2. As features for a given group are often highly correlated with each other, such as in Age of Acquisition, the importance is calculated for feature groups. Based on the method described for Model B, each feature group is removed from consideration in the model, and the resulting error rate from Model B is used to calculate an importance measure. The most important feature is normalized to have a value of 1.0, with the rest being relative to the difference in error rate from the original model, averaged across splits.

These prediction results show that relative reading difficulty can be predicted for sentence pairs with high accuracy, even with fairly simple feature sets. In particular, the results for AoA model D, which uses a small number of targeted features, are competitive with the best model B that relies on a much larger feature set. The addition of coreference features did result in small but significant changes in the accuracy of the sentence-in-passage task, although in one case the accuracy was reduced with coreference features.

[1]The p-value for each accuracy measurement compares its significance, using a paired t-test, to the neighboring model in the direction of the arrow. For example, the sentence-only Model B is compared to sentence-only Model A.

Sentence Only		Sentence in Passage (with Coref)	
Feature	Imp.	Feature	Imp.
Age of Acq.	1.00	Age of Acq.	1.00
Part of Speech	0.28	Syllables	0.27
Syn. Score	0.22	Part of Speech	0.23

dering of sentences changes across these conditions, we can identify differences in how workers judged the relative difficulty of sentences with and without context.

6.1 Rank Differences

We report differences in ranking in terms of mean and standard deviation of the absolute difference in rank index of each sentence across the two rankings, along with Pearson's coefficient and Spearman's rank order coefficients. Comparisons between the rankings for each task are shown in Table 3.

In comparing crowd-generated rankings for the sentence-only and sentence-in-passage task, the results show a statistically significant aggregate difference in how the crowd ranks sentence difficulty with and without the surrounding passage. While the correlation between the two rankings is high, and the average normalized change in rank position is 7.7%, multiple sentences exhibited a large change in ranking. For example, the sentence '*As a result, the police had little incentive to make concessions.*' was ranked significantly easier when presented out of context than when presented in context (rank change: -30 positions). For that example, the surrounding passage explained the complex political environment referred to indirectly in that sentence.

6.2 Feature Correlation with Rank Differences

To examine why sentences may be ranked as more or less difficult, depending on the context, we examined the correlation between a sentence's change in rank (Sentence-Only Ranking minus the Sentence-in-Passage ranking) and the normalized difference in feature values between the sentence representation and the remaining context representation. We found that percentage change in parser and reranker likelihoods had the most significant correlation (-0.33) with ranking change, as shown in Table 4.

To interpret this result, note that the parser and reranker likelihood represent the probability the parser and reranker models assign to the syntactic parse produced by the sentence. In other words, they are a measure of how likely it is that the sentence structure occurs, based on the model's training data. If the difficulty of the sentence-in-passage is ranked higher than the sentence alone, this correlates with the target sentence having a syntactic structure with higher likelihood than the average of the surrounding sentence structures. This means that if a sentence that has a frequently-seen syntactic structure is in a passage with sentences that have less common structures, the sentence within the passage is more likely to be judged as more difficult. The reverse is also true: if a sentence that has a more unusual syntactic structure is in a passage with sentences with more familiar structures, the sentence without the surrounding passage is more likely to be ranked as more difficult.

We also examined the rank correlation of crowd-generated rankings with rankings produced by sorting sentences based on the value of individual features. In addition to the full rankings, we constructed a ranking produced only by the gold standard examples, denoted *Gold Only* and included this in the comparison. The gold standard questions consist of examples constructed by the authors to have a clear relative difficulty result. The rank correlations are shown in Table 5 for both tasks.

The reasons for discrepancies in relative difficulty assessment between the sentence-only and sentence-in-passage conditions require further exploration. While the correlation between the percentage change in probability of the parse and the difference in ranking is significant, it is not large. It does indicate that despite judges being explicitly

told to only consider the sentence, the properties of the surrounding passage may indeed influence the perceived relative difficulty of the sentence.

6.3 Review of Data

The pairwise prediction results indicate that a large proportion of the crowdsourced pair orderings can be decided using vocabulary features, due to the strong performance of the Age of Acquisition features. To identify the relative importance of vocabulary and syntax in our data, we reviewed each pair and judged whether the sentence's syntax or vocabulary, or the combination of both, were needed to correctly predict the more difficult sentence. For many pairs, either syntax or vocabulary could be used to correctly predict the more difficult sentence since each factor indicated the same sentence was more difficult. We found that 19% of pairs had only a vocabulary distinction, and 65% of pairs could be judged correctly either by vocabulary or syntax. Therefore, 84% of pairs could be judged using vocabulary, which explains the high performance of the Age of Acquisition features.

The level of a sentence's source document was used as a proxy for the sentence's grade level when building the pairs. To build a sentence-level gold standard for this dataset, we asked a teacher with a Master of Education with a Reading Specialist focus and 30 years of experience in elementary and high school reading instruction, to identify the grade level of each sentence. This expert was asked to assign either a single grade level or a range of levels to each of the 120 sentences. From this, an expert ranking was created, using the midpoint of each expert-assigned range. The correlation between the expert sentence ranking and the crowd ranking can be seen in Table 6, reinforcing the finding that crowdsourced judgments can provide an accurate ranking of difficulty (De Clercq et al., 2014).

7 Conclusion

Using a rich sentence representation based on lexical and syntactic features leveraged from previous work on document-level readability, we introduced and evaluated several models for predicting the relative reading difficulty of single sentences, with and without surrounding context. We found that while the best prediction performance was obtained by using all feature classes, simpler representations based on lexical features such as Age of Acquisition norms were effective. The accuracy achieved by the best prediction model came within 6% of the oracle accuracy for both tasks.

Many of the features identified had a high correlation with the rankings produced by the crowd. This indicates that these features can be used to build a model of sentence difficulty. With the rankings built from crowdsourced judgments on sentence difficulty, small but significant differences were found in how sentences are ranked with and without the surrounding passages. This result suggests that properties of the surrounding passage of a sentence can change the perceived difficulty of a sentence.

In future work, we plan to increase the number of sentences in our data set, so that additional more fine-grained features might be considered. For example, weights for lexical features could be more accurately estimated with more data. Our use of the crowd-based labels was intended to reduce noise in the ranking analysis, but we also intend to use the pairwise predictions produced by the logistic model as the input to the aggregation model, so that rankings can be obtained for previously unseen sentences in operational settings. Another goal is to obtain absolute difficulty labels for sentences by calibrating ordinal ranges based on the relative ranking. Finally, we are interested in the contribution of context in understanding the meaning of an unknown word.

Acknowledgments

We thank the anonymous reviewers for their suggestions, and Ann Schumacher for serving as grade level annotator. Abstract

Traditional automated essay scoring systems rely on carefully designed features to evaluate and score essays. The performance of such systems is tightly bound to the quality of the underlying features. However, it is laborious to manually design the most informative features for such a system. In this paper, we develop an approach based on recurrent neural networks to learn the relation between an essay and its assigned score, without any feature engineering. We explore several neural network models for the task of automated essay scoring and perform some analysis to get some insights of the models. The results show that our best system, which is based on long short-term memory networks, outperforms a strong baseline by 5.6% in terms of quadratic weighted Kappa, without requiring any feature engineering.

1 Introduction

There is a recent surge of interest in neural networks, which are based on continuous-space representation of the input and non-linear functions. Hence, neural networks are capable of modeling complex patterns in data. Moreover, since these methods do not depend on manual engineering of features, they can be applied to solve problems in an end-to-end fashion. SENNA (Collobert et al., 2011) and neural machine translation (Bahdanau et al., 2015) are two notable examples in natural language processing that operate without any external task-specific knowledge. In this paper, we report a system based on neural networks to take advantage of their modeling capacity and generalization power for the automated essay scoring (AES) task.

Essay writing is usually a part of the student assessment process. Several organizations, such as Educational Testing Service (ETS)[1], evaluate the writing skills of students in their examinations. Because of the large number of students participating in these exams, grading all essays is very time-consuming. Thus, some organizations have been using AES systems to reduce the time and cost of scoring essays.

Automated essay scoring refers to the process of grading student essays without human interference. An AES system takes as input an essay written for a given prompt, and then assigns a numeric score to the essay reflecting its quality, based on its content, grammar, and organization. Such AES systems are usually based on regression methods applied to a set of carefully designed features. The process of feature engineering is the most difficult part of building AES systems. Moreover, it is challenging for humans to consider all the factors that are involved in assigning a score to an essay.

Our AES system, on the other hand, *learns* the features and relation between an essay and its score automatically. Since the system is based on recurrent neural networks, it can effectively encode the information required for essay evaluation and learn the complex patterns in the data through non-linear neural layers. Our system is among the first AES systems based on neural networks designed without any hand-crafted features. Our results show that our system outperforms a strong baseline and

[1] https://www.ets.org

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1882–1891,
Austin, Texas, November 1-5, 2016.

achieves state-of-the-art performance in automated essay scoring. In order to make it easier for other researchers to replicate our results, we have made the source code of our system publicly available[2].

The rest of this paper is organized as follows. Section 2 gives an overview of related work in the literature. Section 3 describes the automated essay scoring task and the evaluation metric used in this paper. We provide the details of our approach in Section 4, and present and discuss the results of our experimental evaluation in Section 5. Finally, we conclude the paper in Section 6.

2 Related Work

There exist many automated essay scoring systems (Shermis and Burstein, 2013) and some of them are being used in high-stakes assessments. e-rater (Attali and Burstein, 2004) and Intelligent Essay Assessor (Foltz et al., 1999) are two notable examples of AES systems. In 2012, a competition on automated essay scoring called 'Automated Student Assessment Prize' (ASAP)[3] was organized by Kaggle and sponsored by the Hewlett Foundation. A comprehensive comparison of AES systems was made in the ASAP competition. Although many AES systems have been developed to date, they have been built with hand-crafted features and supervised machine learning algorithms.

Researchers have devoted a substantial amount of effort to design effective features for automated essay scoring. These features can be as simple as essay length (Chen and He, 2013) or more complicated such as lexical complexity, grammaticality of a text (Attali and Burstein, 2004), or syntactic features (Chen and He, 2013). Readability features (Zesch et al., 2015) have also been proposed in the literature as another source of information. Moreover, text coherence has also been exploited to assess the flow of information and argumentation of an essay (Chen and He, 2013). A detailed overview of the features used in AES systems can be found in (Zesch et al., 2015). Moreover, some attempts have been made to address different aspects of essay writing independently. For example, argument strength and organization of essays have been tackled by some researchers through designing task-specific features for each aspect (Persing et al., 2010; Persing and Ng, 2015).

Our system, however, accepts an essay text as input directly and learns the features automatically from the data. To do so, we have developed a method based on recurrent neural networks to score the essays in an end-to-end manner. We have explored a variety of neural network models in this paper to identify the most suitable model. Our best model is a long short-term memory neural network (Hochreiter and Schmidhuber, 1997) and is trained as a regression method. Similar recurrent neural network approaches have recently been used successfully in a number of other NLP tasks. For example, Bahdanau et al. (2015) have proposed an attentive neural approach to machine translation based on gated recurrent units (Cho et al., 2014). Neural approaches have also been used for syntactic parsing. In (Vinyals et al., 2015), long short-term memory networks have been used to obtain parse trees by using a sequence-to-sequence model and formulating the parsing task as a sequence generation problem. Apart from these examples, recurrent neural networks have also been used for opinion mining (Irsoy and Cardie, 2014), sequence labeling (Ma and Hovy, 2016), language modeling (Kim et al., 2016; Sundermeyer et al., 2015), etc.

3 Automated Essay Scoring

In this section, we define the automated essay scoring task and the evaluation metric used for assessing the quality of AES systems.

3.1 Task Description

Automated essay scoring systems are used in evaluating and scoring student essays written based on a given prompt. The performance of these systems is assessed by comparing their scores assigned to a set of essays to human-assigned gold-standard scores. Since the output of AES systems is usually a real-valued number, the task is often addressed as a supervised machine learning task (mostly by regression or preference ranking). Machine learning algorithms are used to learn the relationship between the essays and reference scores.

[2]https://github.com/nusnlp/nea

[3]https://www.kaggle.com/c/asap-aes

3.2 Evaluation Metric

The output of an AES system can be compared to the ratings assigned by human annotators using various measures of correlation or agreement (Yannakoudakis and Cummins, 2015). These measures include Pearson's correlation, Spearman's correlation, Kendall's Tau, and quadratic weighted Kappa (QWK). The ASAP competition adopted QWK as the official evaluation metric. Since we use the ASAP data set for evaluation in this paper, we also use QWK as the evaluation metric in our experiments.

Quadratic weighted Kappa is calculated as follows. First, a weight matrix $\mathbf{W}$ is constructed according to Equation 1:

$$\mathbf{W}_{i,j} = \frac{(i-j)^2}{(N-1)^2} \tag{1}$$

where i and j are the reference rating (assigned by a human annotator) and the hypothesis rating (assigned by an AES system), respectively, and N is the number of possible ratings. A matrix $\mathbf{O}$ is calculated such that $\mathbf{O}_{i,j}$ denotes the number of essays that receive a rating i by the human annotator and a rating j by the AES system. An expected count matrix $\mathbf{E}$ is calculated as the outer product of histogram vectors of the two (reference and hypothesis) ratings. The matrix $\mathbf{E}$ is then normalized such that the sum of elements in $\mathbf{E}$ and the sum of elements in $\mathbf{O}$ are the same. Finally, given the matrices $\mathbf{O}$ and $\mathbf{E}$, the QWK score is calculated according to Equation 2:

$$\kappa = 1 - \frac{\sum_{i,j} \mathbf{W}_{i,j}\mathbf{O}_{i,j}}{\sum_{i,j} \mathbf{W}_{i,j}\mathbf{E}_{i,j}} \tag{2}$$

In our experiments, we compare the QWK score of our system to well-established baselines. We also perform a one-tailed paired t-test to determine whether the obtained improvement is statistically significant.

4 A Recurrent Neural Network Approach

Recurrent neural networks are one of the most successful machine learning models and have attracted the attention of researchers from various fields. Compared to feed-forward neural networks, recurrent neural networks are theoretically more powerful and are capable of learning more complex patterns from data. Therefore, we have mainly focused on recurrent networks in this paper. This section gives a description of the recurrent neural network architecture that we have used for the essay scoring task and the training process.

4.1 Model Architecture

The neural network architecture that we have used in this paper is illustrated in Figure 1. We now describe each layer in our neural network in detail.

Lookup Table Layer: The first layer of our neural network projects each word into a d_{LT} dimensional space. Given a sequence of words $\mathcal{W}$ represented by their *one-hot* representations $(\mathbf{w}_1, \mathbf{w}_2, \cdots, \mathbf{w}_M)$, the output of the lookup table layer is calculated by Equation 3:

$$LT(\mathcal{W}) = (\mathbf{E}.\mathbf{w}_1, \mathbf{E}.\mathbf{w}_2, \cdots, \mathbf{E}.\mathbf{w}_M) \tag{3}$$

where $\mathbf{E}$ is the word embeddings matrix and will be learnt during training.

Convolution Layer: Once the dense representation of the input sequence $\mathcal{W}$ is calculated, it is fed into the recurrent layer of the network. However, it might be beneficial for the network to extract *local features* from the sequence before applying the recurrent operation. This *optional* characteristic can be achieved by applying a convolution layer on the output of the lookup table layer. In order to extract local features from the sequence, the convolution layer applies a linear transformation to all M windows in the given sequence of vectors[4]. Given a window of dense word representations $\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_l$, the convolution layer first concatenates these vectors to form a vector $\bar{\mathbf{x}}$ of length $l.d_{LT}$ and then uses Equation 4 to calculate the output vector of length d_c:

$$Conv(\bar{\mathbf{x}}) = \mathbf{W}.\bar{\mathbf{x}} + \mathbf{b} \tag{4}$$

In Equation 4, $\mathbf{W}$ and $\mathbf{b}$ are the parameters of the network and are *shared* across all windows in the sequence.

[4]The number of input vectors and the number of output vectors of the convolution layer are the same because we pad the sequence to avoid losing border windows.

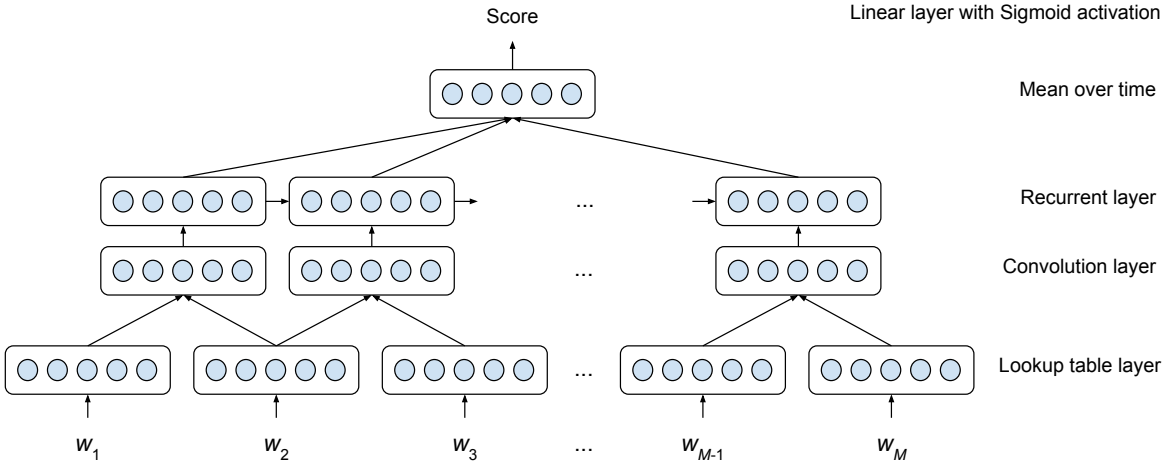

Figure 1: The convolutional recurrent neural network architecture.

The convolution layer can be seen as a function that extracts feature vectors from n-grams. Since this layer provides n-gram level information to the subsequent layers of the neural network, it can potentially capture local contextual dependencies in the essay and consequently improve the performance of the system.

Recurrent Layer: After generating embeddings (whether from the convolution layer or directly from the lookup table layer), the recurrent layer starts processing the input to generate a representation for the given essay. This representation should ideally encode all the information required for grading the essay. However, since the essays are usually long, consisting of hundreds of words, the learnt vector representation might not be sufficient for accurate scoring. For this reason, we preserve all the intermediate states of the recurrent layer to keep track of the important bits of information from processing the essay. We experimented with basic recurrent units (RNN) (Elman, 1990), gated recurrent units (GRU) (Cho et al., 2014), and long short-term memory units (LSTM) (Hochreiter and Schmidhuber, 1997) to identify the best choice for our task. Since LSTM outperforms the other two units, we only describe LSTM in this section.

Long short-term memory units are modified recurrent units that can cope with the problem of vanishing gradients more effectively (Pascanu et al., 2013). LSTMs can learn to preserve or forget the information required for the final representation. In order to control the flow of information during processing of the input sequence, LSTM units make use of three gates to discard (forget) or pass the information through time. The following equations formally describe the LSTM function:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_i.\mathbf{x}_t + \mathbf{U}_i.\mathbf{h}_{t-1} + \mathbf{b}_i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}_f.\mathbf{x}_t + \mathbf{U}_f.\mathbf{h}_{t-1} + \mathbf{b}_f) \\
\tilde{\mathbf{c}}_t &= \tanh(\mathbf{W}_c.\mathbf{x}_t + \mathbf{U}_c.\mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{c}_t &= \mathbf{i}_t \circ \tilde{\mathbf{c}}_t + \mathbf{f}_t \circ \mathbf{c}_{t-1} \\
\mathbf{o}_t &= \sigma(\mathbf{W}_o.\mathbf{x}_t + \mathbf{U}_o.\mathbf{h}_{t-1} + \mathbf{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \circ \tanh(\mathbf{c}_t)
\end{aligned} \tag{5}$$

$\mathbf{x}_t$ and $\mathbf{h}_t$ are the input and output vectors at time t, respectively. $\mathbf{W}_i$, $\mathbf{W}_f$, $\mathbf{W}_c$, $\mathbf{W}_o$, $\mathbf{U}_i$, $\mathbf{U}_f$, $\mathbf{U}_c$, and $\mathbf{U}_o$ are weight matrices and $\mathbf{b}_i$, $\mathbf{b}_f$, $\mathbf{b}_c$, and $\mathbf{b}_o$ are bias vectors. The symbol $\circ$ denotes element-wise multiplication and σ represents the sigmoid function.

Mean over Time: The outputs of the recurrent layer, $\mathcal{H} = (\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_M)$, are fed into the mean-over-time layer. This layer receives M vectors of length d_r as input and calculates an average vector of the same length. This layer's function is defined in Equation 6:

$$MoT(\mathcal{H}) = \frac{1}{M}\sum_{t=1}^{M}\mathbf{h}_t \tag{6}$$

The mean-over-time layer is responsible for aggregating the variable number of inputs into a fixed length vector. Once this vector is calculated, it is fed into the linear layer to be mapped into a score.

Instead of taking the mean of the intermediate recurrent layer states $\mathbf{h}_t$, we could use the last state vector $\mathbf{h}_M$ to compute the score and remove the mean-over-time layer. However, as we will show in Section 5.2, it is much more effective to use the mean-over-time layer and take all recurrent states into account.

Linear Layer with Sigmoid Activation: The linear layer maps its input vector generated by the mean-over-time layer to a scalar value. This mapping is simply a linear transformation of the input vector and therefore, the computed value is not bounded. Since we need a bounded value in the range of valid scores for each prompt, we apply a sigmoid function to limit the possible scores to the range of $(0, 1)$. The mapping of the linear layer after applying the sigmoid activation function is given by Equation 7:

$$s(\mathbf{x}) = \text{sigmoid}(\mathbf{w}.\mathbf{x} + b) \tag{7}$$

where $\mathbf{x}$ is the input vector ($MoT(\mathcal{H})$), $\mathbf{w}$ is the weight vector, and b is the bias value.

We normalize all gold-standard scores to $[0, 1]$ and use them to train the network. However, during testing, we rescale the output of the network to the original score range and use the rescaled scores to evaluate the system.

4.2 Training

We use the RMSProp optimization algorithm (Dauphin et al., 2015) to minimize the mean squared error (MSE) loss function over the training data. Given N training essays and their corresponding normalized gold-standard scores s_i^*, the model computes the predicted scores s_i for all training essays and then updates the network parameters such that the mean squared error is minimized. The loss function is shown in Equation 8:

$$MSE(\mathbf{s}, \mathbf{s}^*) = \frac{1}{N}\sum_{i=1}^{N}(s_i - s_i^*)^2 \tag{8}$$

Additionally, we make use of dropout regularization to avoid overfitting. We also clip the gradient if the norm of the gradient is larger than a threshold.

We do not use any early stopping methods. Instead, we train the neural network model for a fixed number of epochs and monitor the performance of the model on the development set after each epoch. Once training is finished, we select the model with the best QWK score on the development set.

5 Experiments

In this section, we describe our experimental setup and present the results. Moreover, an analysis of the results and some discussion are provided in this section.

5.1 Setup

The dataset that we have used in our experiments is the same dataset used in the ASAP competition run by Kaggle (see Table 1 for some statistics). We use quadratic weighted Kappa as the evaluation metric, following the ASAP competition. Since the test set used in the competition is not publicly available, we use 5-fold cross validation to evaluate our systems. In each fold, 60% of the data is used as our training set, 20% as the development set, and 20% as the test set. We train the model for a fixed number of epochs and then choose the best model based on the development set. We tokenize the essays using the NLTK[5] tokenizer, lowercase the text, and normalize the gold-standard scores to the range of $[0, 1]$. During testing, we rescale the system-generated normalized scores to the original range of scores and measure the performance.

Prompt	#Essays	Avg length	Scores
1	1,783	350	2–12
2	1,800	350	1–6
3	1,726	150	0–3
4	1,772	150	0–3
5	1,805	150	0–4
6	1,800	150	0–4
7	1,569	250	0–30
8	723	650	0–60

Table 1: Statistics of the ASAP dataset.

In order to evaluate the performance of our system, we compare it to a publicly available open-source[6] AES system called 'Enhanced AI Scor-

[5]http://www.nltk.org

[6]https://github.com/edx/ease

ing Engine' (EASE). This system is the best open-source system that participated in the ASAP competition, and was ranked third among all 154 participating teams. EASE is based on hand-crafted features and regression methods. The features that are extracted by EASE can be categorized into four classes:

- Length-based features
- Parts-of-Speech (POS)
- Word overlap with the prompt
- Bag of n-grams

After extracting the features, a regression algorithm is used to build a model based on the training data. The details of the features and the results of using support vector regression (SVR) and Bayesian linear ridge regression (BLRR) are reported in (Phandi et al., 2015). We use these two regression methods as our baseline systems.

Our system has several hyper-parameters that need to be set. We use the RMSProp optimizer with decay rate (ρ) set to 0.9 to train the network and we set the base learning rate to 0.001. The mini-batch size is 32 in our experiments[7] and we train the network for 50 epochs. The vocabulary is the 4,000 most frequent words in the training data and all other words are mapped to a special token that represents unknown words. We regularize the network by using dropout (Srivastava et al., 2014) and we set the dropout probability to 0.5. During training, the norm of the gradient is clipped to a maximum value of 10. We set the word embedding dimension (d_{LT}) to 50 and the output dimension of the recurrent layer (d_r) to 300. If a convolution layer is used, the window size (l) is set to 3 and the output dimension of this layer (d_c) is set to 50. Finally, we initialize the lookup table layer using pre-trained word embeddings[8] released by Zou et al. (2013). Moreover, the bias value of the linear layer is initialized such that the network's output before training is almost equal to the average score in the training data.

[7]To create mini-batches for training, we pad all essays in a mini-batch using a dummy token to make them have the same length. To eliminate the effect of padding tokens during training, we mask them to prevent the network from miscalculating the gradients.

[8]http://ai.stanford.edu/∼wzou/mt

We have performed several experiments to identify the best model architecture for our task. These architectural choices are summarized below:

- Convolutional vs. recurrent neural network
- RNN unit type (basic RNN, GRU, or LSTM)
- Using mean-over-time over all recurrent states vs. using only the last recurrent state
- Using mean-over-time vs. an attention mechanism
- Using a recurrent layer vs. a convolutional recurrent layer
- Unidirectional vs. bidirectional LSTM

We have used 8 Tesla K80 GPUs to perform our experiments in parallel.

5.2 Results and Discussion

In this section, we present the results of our evaluation by comparing our system to the above-mentioned baselines (SVR and BLRR). Table 2 (rows 1 to 4) shows the QWK scores of our systems on the eight prompts from the ASAP dataset[9]. This table also contains the results of our statistical significance tests. The baseline score that we have used for hypothesis testing is underlined and the statistically significant improvements ($p < 0.05$) over the baseline are marked with '*'. It should be noted that all neural network models in Table 2 are unidirectional and include the mean-over-time layer. Except for the CNN model, convolution layer is *not* included in the networks.

According to Table 2, all model variations are able to learn the task properly and perform competitively compared to the baselines. However, LSTM performs significantly better than all other systems and outperforms the baseline by a large margin (4.1%). However, basic RNN falls behind other models and does not perform as accurately as GRU or LSTM.

[9]To aggregate the QWK scores of all prompts, Fisher transformation was used in the ASAP competition before averaging QWK scores. However, we found that applying Fisher transformation only slightly changes the scores. (If we apply this method to aggregate QWK scores, our best ensemble system (row 7, Table 2) would obtain a QWK score of 0.768.) Therefore we simply take the average of QWK scores across prompts.

ID	Systems	Prompts								
		1	2	3	4	5	6	7	8	Avg QWK
1	CNN	0.797	0.634	0.646	0.767	0.746	0.757	0.746	**0.687**	0.722
2	RNN	0.687	0.633	0.552	0.744	0.732	0.757	0.743	0.553	0.675
3	GRU	0.616	0.591	0.668	0.787	0.795	0.800	0.752	0.573	0.698
4	LSTM	0.775	0.687	0.683	0.795	**0.818**	0.813	0.805	0.594	0.746*
5	CNN (10 runs)	0.804	0.656	0.637	0.762	0.752	0.765	0.750	0.680	0.726*
6	LSTM (10 runs)	0.808	**0.697**	0.689	**0.805**	**0.818**	**0.827**	**0.811**	0.598	0.756*
7	(5) + (6)	**0.821**	0.688	**0.694**	**0.805**	0.807	0.819	0.808	0.644	**0.761***
8	EASE (SVR)	0.781	0.621	0.630	0.749	0.782	0.771	0.727	0.534	0.699
9	EASE (BLRR)	0.761	0.606	0.621	0.742	0.784	0.775	0.730	0.617	0.705

Table 2: The QWK scores of the various neural network models and the baselines. The baseline for the statistical significance tests is underlined and statistically significant improvements ($p < 0.05$) are marked with '*'.

This behaviour is probably because of the relatively long sequences of words in essays. GRU and LSTM have been shown to 'remember' sequences and long-term dependencies much more effectively and therefore, we believe this is the reason behind RNN's relatively poor performance.

Additionally, we perform some experiments to evaluate ensembles of our systems. We create variants of our network by training with different random initializations of the parameters. To combine these models, we simply take the average of the scores predicted by these networks. This approach is shown to improve performance by reducing the variance of the model and therefore make the predictions more accurate. Table 2 (rows 5 and 6) shows the results of CNN and LSTM ensembles over 10 runs. Moreover, we combine CNN ensembles and LSTM ensembles together to make the predictions (row 7).

As shown in Table 2, ensembles of models always lead to improvements. We obtain 0.4% and 1.0% improvement from CNN and LSTM ensembles, respectively. However, our best model (row 7 in Table 2) is the ensemble of 10 instances of CNN models and 10 instances of LSTM models and outperforms the baseline BLRR system by 5.6%.

It is possible to use the last state of the recurrent layer to predict the score instead of taking the mean over all intermediate states. In order to observe the effects of this architectural choice, we test the network with and without the mean-over-time layer. The results of this experiment are presented in Table 3, clearly showing that the neural network fails to learn the task properly in the absence of the mean-over-time layer. When the mean-over-time layer is not used in the model, the network needs to efficiently encode the whole essay into a single state vector and then use it to predict the score. However, when the mean-over-time layer is included, the model has *direct* access to all intermediate states and can recall the required intermediate information much more effectively and therefore is able to predict the score more accurately.

Systems	Avg QWK
LSTM	**0.746***
LSTM w/o MoT	0.540
LSTM+attention	0.731*
CNN+LSTM	0.708
BLSTM	0.699
EASE (SVR)	0.699
EASE (BLRR)	0.705

Table 3: The QWK scores of LSTM neural network variants. The baseline for the statistical significance tests is underlined and statistically significant improvements ($p < 0.05$) are marked with '*'.

Additionally, we experiment with three other neural network architectures. Instead of using mean-over-time to average intermediate states, we use an attention mechanism (Bahdanau et al., 2015) to compute a weighted sum of the states. In this case, we calculate the dot product of the intermediate states and a vector trained by the neural network, and then apply a softmax operation to obtain the normalized weights. Another alternative is to add a convolution layer before feeding the embeddings to the recurrent LSTM layer (CNN+LSTM) and evaluate the model. We also use a bidirectional LSTM model (BLSTM), in which the sequence of words

is processed in both directions and the intermediate states generated by both LSTM layers are merged and then fed into the mean-over-time layer. The results of testing these architectures are summarized in Table 3.

The attention mechanism significantly improves the results compared to LSTM without mean-over-time, but it does not perform as well as LSTM with mean-over-time. The other two architectural choices do not lead to further improvements over the LSTM neural network. This observation is in line with the findings of some other researchers (Kadlec et al., 2015) and is probably because of the relatively small number of training examples compared to the capacity of the models.

We have also compared the accuracy of our best system (shown as 'AES') with human performance, presented in Table 4. To do so, we calculate the agreement (QWK scores) between our system and each of the two human annotators separately ('AES - H1' and 'AES - H2'), as well as the agreement between the two human annotators ('H1 - H2'). According to Table 4, the performance of our system on average is very close to human annotators. In fact, for some of the prompts, the agreement between our system and the human annotators is even higher than the agreement between human annotators. In general, we can conclude that our method is just below the upper limit and approaching human-level performance.

We also compare our system to a recently published automated essay scoring method based on neural networks (Alikaniotis et al., 2016). Instead of performing cross validation, Alikaniotis et al. (2016) partition the ASAP dataset into two parts by using 80% of the data for training and the remaining 20% for testing. For comparison, we also carry out an experiment on the same training and test data used in (Alikaniotis et al., 2016). Following how QWK scores are computed in Alikaniotis et al. (2016), instead of calculating QWK for each prompt separately and averaging them, we calculate the QWK score for the whole test set, by setting the minimum score to 0 and the maximum score to 60. Using this evaluation setup, our LSTM system achieves a QWK score of 0.987, higher than the QWK score of 0.96 of the best system in (Alikaniotis et al., 2016). In this way of calculating QWK scores, since

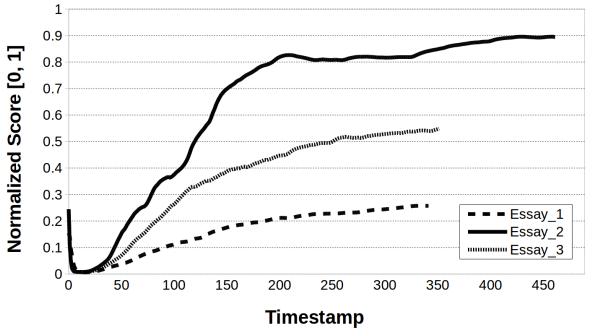

Figure 2: Score variations per timestamp. All scores are normalized to the range of $[0, 1]$.

the majority of the test essays have a much smaller score range (see Table 1) compared to $[0, 60]$, the differences between the system-predicted scores and the gold-standard scores will be small most of the time. For example, more than 55% of the essays in the test set have a score range of $[0, 3]$ or $[0, 4]$ and therefore, for these prompts, the differences between human-assigned gold-standard scores and the scores predicted by an AES system will be small in the range of $[0, 60]$. For this reason, in contrast to prompt-specific QWK calculation, the QWK scores are much higher in this evaluation setting and far exceed the QWK score for human agreement when computed in a prompt-specific way (see Table 4).

Interpreting neural network models and the interactions between nodes is not an easy task. However, it is possible to gain an insight of a network by analyzing the behavior of particular nodes. In order to understand how our neural network assigns the scores, we monitor the score variations while testing the model. Figure 2 displays the score variations for three essays after processing each word (at each timestamp) by the neural network. We have selected a poorly written essay, a well written essay, and an average essay with *normalized* gold-standard scores of 0.2, 0.8, and 0.6, respectively.

According to Figure 2, the network learns to take *essay length* into account and assigns a very low score to all short essays with fewer than 50 words, regardless of the content. This pattern recurs for all essays and is not specific to the three selected essays in Figure 2. However, if an essay is long enough, the content becomes more important and the AES system starts discriminating well written

Description	Prompts								
	1	2	3	4	5	6	7	8	Avg QWK
AES - H1	0.750	0.684	0.662	0.759	0.751	0.791	0.731	0.607	0.717
AES - H2	0.767	0.690	0.632	0.762	0.769	0.775	0.752	0.530	0.710
H1 - H2	0.721	0.812	0.769	0.851	0.753	0.776	0.720	0.627	0.754

Table 4: Comparison with human performance. H1 and H2 denote human rater 1 and human rater 2, respectively, and AES refers to our best system (ensemble of CNN and LSTM models).

essays from poorly written ones. As shown in Figure 2, the model properly assigns a higher score to the well written essay 2, while giving lower scores to the other essays. This observation confirms that the model successfully learns the required features for automated essay scoring. While it is difficult to associate different parts of the neural network model with specific features, it is clear that appropriate indicators of essay quality are being learnt, including essay length and essay content.

6 Conclusion

In this paper, we have proposed an approach based on recurrent neural networks to tackle the task of automated essay scoring. Our method does not rely on any feature engineering and automatically learns the representations required for the task. We have explored a variety of neural network model architectures for automated essay scoring and have achieved significant improvements over a strong open-source baseline. Our best system outperforms the baseline by 5.6% in terms of quadratic weighted Kappa. Furthermore, an analysis of the network has been performed to get an insight of the recurrent neural network model and we show that the method effectively utilizes essay content to extract the required information for scoring essays.

Abstract

Technical writing in professional environments, such as user manual authoring, requires the use of uniform language. Non-uniform language detection is a novel task, which aims to guarantee the consistency for technical writing by detecting sentences in a document that are intended to have the same meaning within a similar context but use different words or writing style. This paper proposes an approach that utilizes text similarity algorithms at lexical, syntactic, semantic and pragmatic levels. Different features are extracted and integrated by applying a machine learning classification method. We tested our method using smart phone user manuals, and compared its performance against the state-of-the-art methods in a related area. The experiments demonstrate that our approach achieves the upper bound performance for this task.

1 Introduction

Technical writing, such as creating device operation manuals and user guide handbooks, is a special writing task that requires accurate text to describe a certain product or operation. To avoid ambiguity and bring accurate and straightforward understanding to readers, technical writing requires consistency in the use of terminology and uniform language (Farkas, 1985). There are always demands from modern industries to improve the quality of technical documents in cost-efficient ways.

Non-uniform Language Detection (NLD) aims to avoid inner-inconsistency and ambiguity of technical content by identifying non-uniform sentences. Such sentences are intended to have the same meaning or usage within a similar context but use different words or writing style. However, even though non-uniform sentences tend to have similar wording, similar sentence pairs do not necessarily indicate a non-uniform language instance. For example, here are four similar sentence pairs cited from the iPhone user manual (Apple Inc., 2015), where only two pairs are true non-uniform language instances:

(1) tap the screen to **show** the controls.
tap the screen to **display** the controls.

(2) tap the screen to **show** the controls.
tap the screen to **display** the controls.

(3) if the **photo** hasn't been downloaded yet, tap the download notice first.
if the **video** hasn't been downloaded yet, tap the download notice first.

(4) you can also turn blue tooth on or off in control center.
you can also turn **wi-fi and** blue tooth on or off in control center.

As we can see above, the pattern of difference within each sentence pair could be between one word and one word, or one word and multiple words, or one sentence having extra words or phrases that the other sentence does not have. Each pattern could be a true or false non-uniform language instance depending on the content and context. The word '**show**' and '**display**' are synonyms in Example (1). Both sentences convey the same meaning, so they are an instance of non-uniform language. In Example (2), even though '**enter**' and '**write**' are not synonyms, since the two sentences describe the same

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1892–1900,
Austin, Texas, November 1-5, 2016.

operation, they should be considered as non-uniform language as well. In Example (3), even though the only different words between the sentences, '**photo**' and '**video**', are both media contents, because they are different objects, they should not be regarded as non-uniform language. In Example (4), it is a false candidate because each sentence mentions different functions. However, the two sentences are unequal in length, thus it is hard to know what the extra phrase '**wi-fi and**' should be compared against. Therefore, it is challenging to distinguish true and false occurrences of non-uniform cases based on text similarity algorithms only, and finer grained analyses need to be applied. To address the problem of NLD, this paper proposes a methodology for detecting non-uniform language within a technical document at the sentence level. A schematic diagram of our approach is shown in Figure 1.

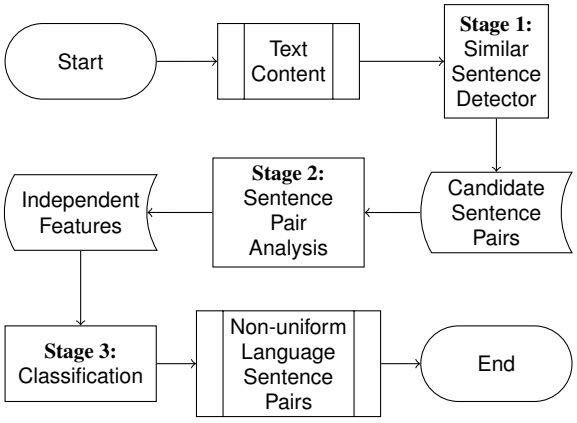

Figure 1: Schematic diagram of our approach

It is worth to mention that NLD is similar to Plagiarism Detection and Paraphrase Detection (PD) as all these tasks aim to capture similar sentences with the same meaning (Das and Smith, 2009). However, the goal of authors in plagiarism and paraphrasing is to change as many words as possible to increase the differences between texts, whereas in technical writing, the authors try to avoid such differences, but they do not always succeed and thus NLD solutions are needed. Cases of plagiarism and paraphrasing with high lexical differences will be typically classified as NLD negative, and cases with low lexical differences will be typically classified as NLD positive. While true positive cases for both NLD and PD can exist, there are not likely to happen in practice since textual differences in PD tend to be much higher than in NLD.

To address the NLD task, Natural Language Processing (NLP) techniques at lexical, syntactic, semantic, and pragmatic levels are utilized. Our approach also integrates resources such as Part-of-Speech (POS) tagger (Bird et al., 2009), WordNet (Miller et al., 1990), Google Tri-gram Method (GTM) (Islam et al., 2012; Mei et al., 2015), and Flickr[1]. Analyses from different perspectives are applied, and the results are regarded as independent features that are finally integrated by applying a classification method based on Support Vector Machine (SVM). A ground truth dataset created from three smart phone user manuals is used for evaluation, and it is made publicly available[2]. The experiments on this dataset demonstrate that the proposed solution to the NLD task is the most efficient method to date, and the final result is close to the upper bound performance.

2 Related Work

NLD is closely related to PD, which aims to detect sentences that have essentially the same meaning. However, paraphrase is a restatement using different words to make it appear different from the original text. PD techniques cannot perform well on the NLD task as they focus on variations at a coarser granularity. We reviewed studies in the PD area, and found the Recursive Auto-Encoder (RAE) (Socher et al., 2011), and the Semantic Text Similarity (STS) (Islam and Inkpen, 2008) to be the state-of-the-art methods using supervised and unsupervised-based PD, respectively. However, all the four examples provided in the introduction section would be recognized as paraphrases by these analyzers, even though only two of the pairs are real non-uniform language cases. Thus, state-of-the-art PD techniques are unable to make accurate judgments on these instances since PD do not address the necessary level of detail for the NLD task.

Another related area to NLD is near-duplicate text detection. It focuses on short text such as mobile phone short messages, or tweets, which are intended to have the same meaning but differ in terms of in-

[1]Flickr: https://www.flickr.com/

[2]The resource is available at: https://goo.gl/6wRchr

formal abbreviations, transliterations, and network languages (Gong et al., 2008). The detection and elimination of near-duplicate text is of great importance for other text language processing such as clustering, opinion mining, and topic detection (Sun et al., 2013). However, the studies in this area focus on reducing the comparison time in large scale text databases and creating informal abbreviation corpus, rather than exploring the text similarity methods. Basic similarity methods, such as Longest Common Substring (LCS) are utilized, but they are not sufficient to address the NLD task as LCS captures the matching words and their order between texts and using LCS alone will give high recall and low precision for the NLD task. For the following NLD negative example, LCS returns a high similarity score:

(5) If the **photo** hasn't been downloaded yet, tap the download notice first.
If the **music** hasn't been downloaded yet, tap the download notice first.

Examples of this type are common in technical writing, so other features are needed besides LCS to recognize NLD positives.

There is a research domain named near-duplicate document detection, which seems literally related to NLD, but also represents a different task. It focuses on documents that are identical in terms of written content but differ in a small portion of the document such as advertisements, counters and timestamps (Manku et al., 2007). Such documents are important to be identified for web crawling and the automatic collection of digital libraries. Since this area focuses on the variations between two documents, especially the variations on metadata, rather than the written content within one document, their proposed solutions are not a good fit for the NLD tasks.

3 Non-uniform Language Detection

As we have shown in Figure 1, a framework consisting of three stages is proposed to address the NLD task. The first stage extracts candidate sentence pairs that have high text similarity within a document. The second stage performs comprehensive analyses on each candidate sentence pair. The analyses are performed at lexical, syntactical, semantic, and pragmatic levels, where multiple NLP resources such as POS tagger, WordNet, GTM, and Flickr are utilized. The final stage integrates all the analysis results by applying a classification method based on SVM to classify the candidate sentence pairs as true or false cases of non-uniform language.

3.1 Stage 1: Similar Sentences Detection

To extract the candidate sentence pairs, three text similarity algorithms are combined and applied at the sentence level. GTM is an unsupervised corpus-based approach for measuring semantic relatedness between texts. LCS focuses on the word order of sentences. Cosine Similarity provides bag-of-word similarity. GTM, LCS, and Cosine Similarity are used to filter out the pairs based on semantics, sentence structure, and word frequency, respectively.

The filtering thresholds were set by running experiments at the sentence level on the iPhone user manual (Apple Inc., 2015). Algorithm 1 is used to set the filtering threshold for each average sentence length[3].

We utilize a sentence detector and a tokenizer[4] to divide the text of the manual into a sentence set of n sentence pairs (Line 2). We separately run Algorithm 1 three times to set the threshold sets for GTM, LCS, and Cosine. The thresholds are set based on the lengths of both sentences of a sentence pair. The average length starts from 2 and is increased by one once the threshold for the current length is set. We discovered that once the sentence length goes above 10, the thresholds vary little. Therefore, we stop the algorithm when the threshold for pairs of average length equal to 10 is found (Line 6).

For each different average length, the algorithm starts by asking the user to input an initial similarity threshold and an increasing step value (Line 4-5). An initial threshold range is generated based on the user setting. The lower bound of the range is T and the upper bound of the range is T+*Step* (Line 9-10). Then the algorithm would loop over all the sentence pairs (Line 11-20) and add the pairs within the current threshold range into set C (Line 14-16).

[3]See the Example (4) in Section 1, where two sentences within one sentence pair could be unequal in length, thus we compute the average length to represent the length of each candidate pair.

22 **while** *(Check(C)=True)* /*Checked by human, True when all the sentence pairs are not instances of non-uniform language.*/;
24 *Threshold-Length_List* $\overset{add}{\longleftarrow} (T_{low}, L)$
25 $L++;$
26 **end**
27 **end**

Algorithm 1: Setting similarity thresholds

The similarity of sentence pairs above the previous threshold and below the current threshold are captured and analyzed (Line 15-16). If they consist of all false non-uniform language candidates, we repeat the loop with a higher threshold to filter more false candidates. Once we discover that a true candidate is filtered by the current thresholds, we stop increasing and set the prior value as the threshold to maximize the recall ratio. The whole experiment is repeated for different sentence pair lengths. The final thresholds for different similarity methods are shown in Figure 2.

To filter the sentence pairs, we applied the thresholds of the three text similarity algorithms. For example, assume there are two sentences of nine-word length on average. The similarity scores of this pair have to be above all the GTM, LCS and Cosine thresholds (which are 0.943, 0.836, and 0.932, according to Figure 2) to make it a candidate instance.

By applying the thresholds shown in Figure 2, candidate pairs could be detected in reasonable scale in terms of the size of the corpus, and achieve good

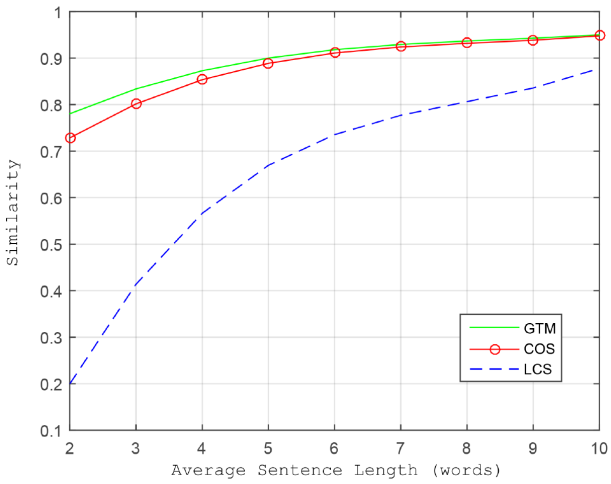

Figure 2: Candidate filtering thresholds

recall ratio as well. As for precision, around 40% of the candidates are true non-uniform language cases, where the remaining candidates are supposed to be filtered in the second stage.

3.2 Stage 2: Sentence Pair Analysis

In this stage, we aim to determine for the two sentences of a candidate pair whether they describe the same object or operation using different words or writing style (i.e., true non-uniform language) or they just appear similar but actually have different intended meanings, by using the following features.

3.2.1 Part-of-Speech Tagging Analysis

POS tags are added for each candidate pair using NLTK (Bird et al., 2009) tagger to gain a grammatical view over the sentences.

As Table 1 shows, some differences in sentence content can be captured using POS tags, but some cannot. Thus, it is necessary to make further syntactic and semantic analysis to distinguish true candidates from false ones.

We categorized the different POS tags into the following groups shown in Table 2. The different POS tags are mapped to different categories, which are then used as one more feature of the sentence pair representation.

3.2.2 Character N-gram Analysis

In the character N-gram analysis, the relatedness between the different words of each candidate pair is calculated in terms of character unigram, bigram

Candidate Sentence Pair with POS Tag	Ground Truth
Link/NNP your/PRP device/NN to/TO iTunes/NNS **stores/NNS** Link/NNP your/PRP device/NN to/TO iTunes/NNS **store/NN**	True Candidate
go/VB to/TO settings/NNS >/SYS general/JJ >/SYS accessibility/NN >/SYS **audio/NN** go/VB to/TO settings/NNS >/SYS general/JJ >/SYS accessibility/NN >/SYS **video/NN**	False Candidate
Hold/VB the/DT power/NN button/NN for/IN two/NN seconds/NNS to/TO **shutdown/NN** the/DT device/NN Hold/VB the/DT power/NN button/NN for/IN two/NN seconds/NNS to/TO **shut/VBN down/RB** the/DT device/NN	True Candidate
Hold/VB the/DT power/NN button/NN for/IN two/NN seconds/NNS to/TO **turn/VBN off/IN** the/DT device/NN Hold/VB the/DT power/NN button/NN for/IN two/NN seconds/NNS to/TO **shut/VBN down/RB** the/DT device/NN	True Candidate

Table 1: POS analysis on candidate sentence pairs

Label	Description	Example
1	Equal length, same POS tag	**/NN** vs. **/NN**, **/VB** vs. **/VB**
2	Equal length, plural noun with singular noun	**/NN** vs. **/NNS**
3	Equal length, different POS	**/NN** vs. **/VB**
4	Unequal length, extra article	**/NN** vs. **/DT/NN**
5	Unequal length, extra conjunction	**/NN** vs. **/CC/NN**
6	Unequal length, extra adjective	**/NN** vs. **/JJ/NN**
7	Other POS tag types.	**/NN** vs. **N/A**

Table 2: POS tag categorizing

and trigram similarity. The character N-gram frequencies with a window size from 1 to 3 is firstly calculated. Then, the N-gram distance based on the frequencies is calculated using the Common N-gram distance (CNG) (Kešelj and Cercone, 2004):

$$d(f_1, f_2) = \sum_{n \in dom(f_1) \cup dom(f_2)} \left(\frac{f_1(n) - f_2(n)}{\frac{f_1(n)+f_2(n)}{2}}\right)^2 \quad (1)$$

where $dom(f_i)$ is the domain of function f_i. In the equation above, n represents a certain N-gram unit. $f_i(n)$ represents the frequency of n in sentence i *(i=1,2)*. If n does not appear in sentence i, $f_i(n)$=0. The lower bound of the N-gram distance is 0 (when the two units to be compared are exactly the same). The higher the value of N-gram distance, the larger the difference, thus there is no upper bound. CNG was demonstrated to be a robust measure of dissimilarity for character N-grams in different domains (Wołkowicz and Kešelj, 2013).

3.2.3 WordNet Lexical Relation Analysis

For a given candidate sentence pair, if the different wordingF are synonymous to each other, there is a high likelihood that the two sentences try to convey the same meaning but using different expressions. On the other hand, if the different parts of a candidate pair are not related at the lexical level, then it is reasonable to assume that this pair is describing different objects/actions and thus they might not be instances of non-uniform language.

WordNet is utilized here to analyze the lexical relationship within each candidate pair to determine whether they are synonyms to each other. To perform this analysis, we only used synset information from WordNet, and we only considered words as synonyms if they belong to a same synset. The rationale is that a similar sentence pair tends to be an instance of non-uniform language if the different words are synonyms, rather than having other

relationships such as hypernymy, hyponymy, and antonymy. Therefore, we do not deem necessary to include these relationships into our analysis. For example, given a similar sentence pair:

(6) if the **photo** hasn't been downloaded yet, tap the download notice first.
if the **video** hasn't been downloaded yet, tap the download notice first.

The sentence pair above is not a non-uniform language instance. However, the relatedness score between '**photo**' and '**video**' given by Wu-Palmer metric (Wu and Palmer, 1994) using WordNet is 0.6, which is fairly high compared to a random word pair. Yet we do not know how these words are related, e.g., "photo is a kind of video", "photo is a part of video", or "photo and video are examples of media content". Thus, we might make wrong judgments based on such a similarity score. However, using synset information, we know that these words are not synonyms and thus probably not suggesting a non-uniform language instance. Therefore, we considered as one more feature of our classifier whether mismatching words belong to the same synset.

3.2.4 GTM Word Relatedness Analysis

Besides text similarity, GTM also measures semantic relatedness between words. To find the relatedness between a pair of words, GTM takes into account all the trigrams that start and end with the given pair of words and then normalizes their mean frequency using unigram frequency of each of the words as well as the most frequent unigram in the Google Web 1T N-gram corpus (Brants and Franz, 2006), and extends the word relatedness method to measure document relatedness.

3.2.5 Flickr Related Concept Analysis

In some cases, word to word relatedness exists that goes beyond dictionary definitions, such as metonymy, in which a thing or concept is called not by its own name but rather by the name of something associated in meaning with that thing or concept (Kövecses and Radden, 1998). Metonymy detection is actually a task at the pragmatic level of NLP area, which can be appied for NLD in technical writing.

Flickr is a popular photo sharing website that supports time and location metadata and user tagging for each photo. Since the tags are added by humans and aim to describe or comment on a certain photo, the tags are somehow related from a human perspective. As a result, Flickr becomes a large online resource with the potential to find metonymy relationships in text.

Flickr made available statistical information about their dataset that can be used to query related concepts of a certain word or phrase online. We utilized this resource to detect whether the different parts within a candidate sentence pair are related at the pragmatic level. A boolean value that indicates metonymy relationship is obtained and regarded as another feature of our sentence pair representation for our NLD analysis. Table 3 gives some examples of relatedness that could be discovered in this stage.

Different Content	Is Metonymy
aeroplane, A380	True
film, hollywood	True
apple, iPhone	True
audio, grayscale	False

Table 3: Example of analysis using Flickr

3.3 Stage 3: SVM Classification

All the metrics described above are regarded as features of our candidate sentence pairs. To make a comprehensive judgment based on these different signals, a classification method based on SVM (Vladimir and Vapnik, 1995) is applied. We implemented the SVM classification using "e1071" package[5] in R.

Using our labeled corpus, we trained an SVM model on 61.5% of the data and used the remaining for testing.

4 Experiments and Evaluation

In this section, we present the dataset, experimental work and results, including results using other baseline methods for comparative purposes.

4.1 Experiment Data

We downloaded smart phone user manuals of iPhone (Apple Inc., 2015), LG (LG, 2009) and Samsung (Samsung, 2011), which are available online

[5]https://cran.r-project.org/web/packages/e1071/

as three raw datasets. Then, we performed Stage 1 three times on the three different datasets, and identified 325 candidate sentence pairs (650 sentences) as part of Stage 1, which is considered as our candidate dataset. Before applying the sentence analysis and classification stages, each candidate sentence pair in the dataset was labeled by three different annotators as true or false. Then the ground truth for each instance is generated by annotators' voting. The annotators worked separately to label the sentence pairs. Cases of disagreement were sent again to the annotators to double-check their judgement. Some statistics from the manuals are shown in Table 4.

Data Source	Data Volume (Pages)	Candidate Pairs (True, False)
iPhone	196	208 (102, 106)
LG	274	54 (16, 38)
Samsung	190	63 (32, 31)

Table 4: Experiment data distribution

To prepare for the SVM based classification stage, we split the dataset into a training set DS_{train}, and a testing set DS_{test}. Considering that the data distribution is nearly balanced in terms of true and false instances, DS_{train} was formed by randomly selecting 200 instances from the dataset and the remaining 125 instances were used for DS_{test}.

4.2 Evaluation Methods and Results

The performance of each annotator against the majority voting is evaluated in terms of Precision, Recall, Accuracy, and F-measure. These results along with the number of true/ false, positive/ negative cases for each annotator are presented in Table 5.

Parameters	Expert 1	Expert 2	Expert 3
True-positive	130	99	125
True-negative	161	164	166
False-positive	20	51	25
False-negative	14	11	9
Precision	**86.67**	66.00	83.33
Recall	90.27	90.00	**93.28**
Accuracy	**89.54**	80.92	**89.54**
F-Measure	**88.43**	76.15	88.03

Table 5: Evaluation of annotators performance

To measure the agreement among annotators, the Fleiss' Kappa test (Fleiss and Cohen, 1973) is used. Fleiss' Kappa is an extension of Cohen's Kappa (Cohen, 1968). Unlike Cohen's Kappa, which only measures the agreement between two annotators, Fleiss' Kappa measures the agreement among three or more annotators. In our case, we have 3 annotators (the annotator number n is 3), each annotator labeled 325 candidate pairs (the subject volume N is 325), each candidate pair is labeled either 0 or 1 (the value of category k is 2). The final Fleiss' Kappa Value is 0.545, which indicates a moderate agreement level (0.41-0.60) based on the Kappa Interpretation Model (Fleiss and Cohen, 1973). In other words, the performance of the annotators reveal that the NLD task is not simple, since there are many cases that are ambiguous and hard to make accurate judgments on, even for humans.

As Table 5 shows, the best performance of annotators is highlighted and regarded as the upper bound performance (UB) of the NLD task on our dataset. The state-of-the-art unsupervised PD system named STS (Islam and Inkpen, 2008), as well as the state-of-the-art supervised PD system named RAE (Socher et al., 2011), are utilized to generate the baselines of the NLD task. STS uses the similarity score of 0.5 as the threshold to evaluate their method in the PD task. RAE applies supervised learning to classify a pair as a true or false instance of paraphrasing. These approaches are utilized on our evaluation as baselines for the NLD task.

After defining the upper bound and baseline performances, we evaluated our proposed method, which we name as Non-uniform Language Detecting System (NLDS), by training the SVM classifier on DS_{train}, and then performing classification using the SVM classifier on DS_{test}. The result is shown in Table 6 as the NLDS method. The first row presents the upper bound performance and the following two rows present the baseline performances.

To assess the importance of each feature utilized in the proposed framework, we performed a feature ablation study (Cohen and Howe, 1988) on N-gram, POS analysis, lexical analysis (GTM and WordNet), and Flickr, separately on the DS_{test} dataset. The results are listed in Table 6.

A series of cross-validation and Student's t-tests are applied after running NLDS, STS, RAE, and UB

Method	R(%)	P (%)	A(%)	F1(%)
UB	92.38	86.67	**89.54**	**88.43**
STS	**100**	46.15	46.15	63.16
RAE	**100**	46.40	46.40	63.39
Uni-gram	11.11	35.29	52.80	16.90
Bi-gram	44.44	61.54	64.00	51.61
Tri-gram	50.00	62.79	65.60	55.67
POS	77.78	72.77	78.40	76.52
Lexical	85.18	59.74	68.80	70.23
Flickr	48.96	94.00	74.00	64.38
NLDS	80.95	**96.22**	88.80	87.93

Table 6: Evaluation of NLDS

methods on the F-measure metric. The tests reveal that the performance of NLDS is significantly better than STS and RAE, no significant differences could be found between UB and NLDS. These results demonstrate that NLDS would represent an effective approach for NLD that is on pair with annotator judgement and overcomes state-of-the-art approaches for related tasks.

4.3 Discussion

As Table 6 shows, the PD systems STS and RAE regard all the test cases as true non-uniform language cases, so the recall ratio is 1 but the precision is low.

It is worth noting that by using character N-gram analysis alone, it is not possible to obtain good results. This is because the character N-gram analysis using a probabilistic method is unable to capture any difference or relatedness in the meaning, while the NLD task relies heavily on discovering such relatedness. The reason we applied the N-gram analysis is to use it as a supplementary method to catch differences such as between '**shut down**' (two words) and '**shutdown**' (one word), or some spelling errors.

POS analysis provides a syntactic perspective for the text instances. For instances, '**then(/RB)**' versus '**and(/CC)**', and '**store(/NN)**' versus '**stores(/NNS)**', the differences can be reflected in POS tags. Yet, POS analysis alone could not capture the difference between words such as '**writing(/VBG)**' versus '**entering(/VBG)**' since they share the same POS tag. These features make POS analysis outperform the character N-gram analysis, but not semantic-based approaches.

Lexical analysis (GTM and WordNet) achieves the best recall ratio since it can provide semantic relatedness, which is the most important aspect for the NLD task. Flickr is utilized as a supplementary resource to provide pragmatic relatedness.

By combining the different types of analyses above, the differences of each sentence pair are analyzed at different NLP levels and thus, the relatedness and difference from structural, grammatical, syntactic, semantic and pragmatic perspectives can be captured and integrated by the classification method.

5 Conclusions

This paper proposes NLDS to detect non-uniform language for technical writings at sentence level. Text, stream-based, and word similarity algorithms at the lexical, syntactic, semantic, and pragmatic levels are integrated through an SVM-based classification method. To evaluate the proposed method, three annotators manually labeled all the candidate instances identified in Stage 1. Then we assigned the ground truth for each instance pair by annotators' voting. Fleiss' Kappa test is applied to reflect the difference of human judgments and thus to reveal the difficulty of this task.

We also evaluated each annotator against the ground truth, and defined the best performance of human as the upper bound performance for this task. With the generated ground truth, a series of experiments using our implemented system were carried out with different smart phone user manuals data. We evaluated the results by comparing the outcome of the classifier with the results using each single feature, as well as the state-of-the-art PD methods.

Considering the different annotators' judgments as reflected by Fleiss' Kappa Value, the NLD task is fairly difficult. Yet, the performance of our system is close to human performance. The experiments reveal that our solution is the most effective method to date and the performance is close to the upper bound that we defined. As for future work, we would apply deeper analysis on true non-uniform language pairs to indicate which sentence of the pair fits better with the style and language of the rest of the document. We would then provide a semi-automatic correction function to facilitate authors with the task of removing non-uniform language occurrences.

Acknowledgments

This research work was supported by Innovatia Inc. and NSERC. We are thankful to our colleagues Andrew Albert, David Crowley, and Erika Allen who proposed and defined this NLD task, and provided expertise that contributed on the preparation of this paper.

Abstract

An important aspect for the task of grammatical error correction (GEC) that has not yet been adequately explored is adaptation based on the native language (L1) of writers, despite the marked influences of L1 on second language (L2) writing. In this paper, we adapt a neural network joint model (NNJM) using L1-specific learner text and integrate it into a statistical machine translation (SMT) based GEC system. Specifically, we train an NNJM on general learner text (not L1-specific) and subsequently train on L1-specific data using a Kullback-Leibler divergence regularized objective function in order to preserve generalization of the model. We incorporate this adapted NNJM as a feature in an SMT-based English GEC system and show that adaptation achieves significant $F_{0.5}$ score gains on English texts written by L1 Chinese, Russian, and Spanish writers.

1 Introduction

Grammatical error correction (GEC) deals with the automatic correction of errors (spelling, grammar, and collocation errors), particularly in non-native written text. The native language (L1) background of the writer has a noticeable influence on the errors made in second language (L2) writing, and considering this factor can potentially improve the performance of GEC systems. For example, consider the following sentence written by a Finnish writer (Jarvis and Odlin, 2000): *"When they had escaped **in** the police car they sat under the tree.*" The preposition *in* appears to be grammatically correct. However, in the given context, the preposition '*from*' is the correct choice in place of the preposition '*in*'. Finnish learners of English tend to overgeneralize the use of the preposition '*in*'. Knowledge of L1 makes the correction more probable whenever the preposition *in* appears in texts written by Finnish writers. Similarly, Chinese learners of English tend to make frequent verb tense and verb form errors, since Chinese lacks verb inflection (Shaughnessy, 1977). The cross-linguistic influence of L1 on L2 writing is a highly complex phenomenon, and the errors made by learners cannot be directly attributed to the similarities or differences between the two languages. As Ortega (2009) points out, learners seem to operate on two complementary principles: "what works in L1 may work in L2 because human languages are fundamentally alike; but if it sounds too L1-like, it will probably not work in L2". In this paper, we follow a data-driven approach to model these influences and adapt GEC systems using L2 texts written by writers of the same L1 background.

The two most popular approaches for grammatical error correction are the classification approach (Dahlmeier et al., 2012; Rozovskaya et al., 2014) and the statistical machine translation (SMT) approach (Chollampatt et al., 2016; Junczys-Dowmunt and Grundkiewicz, 2014). The SMT approach has emerged as a popular paradigm for GEC because of its ability to learn text transformations from ill-formed to well-formed text enabling it to correct a wide variety of errors including complex errors that are difficult to handle for the classification approach (Rozovskaya and Roth, 2016). The phrase-based SMT approach has been used in state-of-the-art GEC systems (Rozovskaya and Roth, 2016;

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1901–1911,
Austin, Texas, November 1-5, 2016.

Chollampatt et al., 2016; Hoang et al., 2016). The SMT approach does not model error types specifically, nor does it require linguistic analysis like parsing and part-of-speech (POS) tagging. We adopt a phrase-based SMT approach to GEC in this paper. Additionally, we implement and incorporate a neural network joint model (NNJM) (Devlin et al., 2014) as a feature in our SMT-based GEC system. It is easy to integrate an NNJM into the SMT decoding framework as it uses a fixed-window context and it has shown to improve SMT-based GEC (Chollampatt et al., 2016). We adapt the NNJM to L1-specific data (i.e., English text written by writers of a particular L1) and obtain significant improvements over the baseline which uses an unadapted NNJM. Adaptation is done by using the unadapted NNJM trained on general domain data (i.e., not L1-specific) using a log likelihood objective function with self-normalization (Devlin et al., 2014) as the starting point, and training for subsequent iterations using the smaller L1-specific in-domain data with a modified objective function which includes a Kullback-Leibler (KL) divergence regularization term. This modified objective function prevents overfitting on the smaller in-domain data and preserves the generalization capability of the NNJM. We show that this method of adaptation works on very small and high-quality L1-specific data as well (50–100 essays).

In summary, the two major contributions of this paper are as follows. (1) This is the first work that performs L1-based adaptation for GEC using the SMT approach and covering all error types. (2) We introduce a *novel* method of NNJM adaptation and demonstrate that this method can work with in-domain data that are much smaller than the general domain data.

2 Related Work

In the past decade, there has been increasing attention on GEC in English, mainly due to the growing number of English as second language (ESL) learners around the world. The popularity of this problem grew further through Helping Our Own (HOO) (Dale and Kilgarriff, 2011; Dale et al., 2012) and CoNLL shared tasks (Ng et al., 2013; Ng et al., 2014). The majority of the published work on GEC aimed at building classifiers or rule-based systems for specific error types and combined them to build hybrid systems (Dahlmeier et al., 2012; Rozovskaya et al., 2014).

The cross-linguistic influences between L1 and L2 have been mainly used for the task of native language identification (Massung and Zhai, 2016). It has also been used in typology prediction (Berzak et al., 2014) and predicting error distributions in ESL data (Berzak et al., 2015). L1-based adaptation has previously shown to improve GEC for specific error types using the classification approach. Rozovskaya and Roth (2010) used an approach to correct preposition errors by restricting the candidate corrections to those observed in L1-specific data. They further added artificial training data that mimic the error frequency in L1-specific text to improve accuracy. In their later work, Rozovskaya and Roth (2011) focused on L1-based adaptation for preposition and article correction, by modifying the prior probabilities in the naïve Bayes classifier during decision time based on L1-specific ESL learner text. Both approaches use native data for training, but rely on non-native L1-specific text to introduce artificial errors or to modify the prior probabilities. Dahlmeier and Ng (2011) implemented a system to correct collocation errors, by adding paraphrases derived from L1 into the confusion set. Specifically, they use a bilingual L1-L2 corpus, to obtain L2 paraphrases, which are likely to be translated to the same phrase in L1. There is no prior work on L1-based adaptation for GEC using the machine translation approach, which is a one of the most popular approaches for GEC.

With the availability of large-scale error corrected data (Mizumoto et al., 2011), the statistical machine translation (SMT) approach to GEC became popular and was employed in state-of-the-art GEC systems. Comparison of the classification approach and the machine translation approach can be found in (Rozovskaya and Roth, 2016) and (Susanto et al., 2014). Recently, an end-to-end neural machine translation framework was proposed for GEC (Yuan and Briscoe, 2016), which was shown to achieve competitive results. Neural network joint models have shown to be improve SMT-based GEC systems (Chollampatt et al., 2016) due to their ability to model words and phrases in a continuous space, access to larger contexts from source side, and abil-

ity to learn non-linear mappings from input to output. In this paper, we exploit the advantages of the SMT approach and neural network joint models (NNJMs) by adapting an NNJM based on the L1 background of the writers and integrating it into the SMT framework. We perform KL divergence regularized adaptation to prevent overfitting on the smaller in-domain data. KL divergence regularization was previously used by Yu et al. (2013) for speaker adaptation. Joty et al. (2015) proposed another NNJM adaptation method, which uses a regularized objective function that encourages a network trained on general-domain data to be closer to an in-domain NNJM. Other adaptation techniques used in SMT include mixture modeling (Foster and Kuhn, 2007; Moore and Lewis, 2010; Sennrich, 2012) and alternative decoding paths (Koehn and Schroeder, 2007).

3 A Machine Translation Framework for Grammatical Error Correction

We formulate GEC as a translation task from a possibly erroneous input sentence to a corrected sentence. We use the popular phrase-based SMT system, Moses (Koehn et al., 2007), which employs a log linear model to find the best correction hypothesis T^* given an input sentence S:

$$T^* = \underset{T}{\operatorname{argmax}}\, P(T|S) = \underset{T}{\operatorname{argmax}} \sum_{i=1}^{N} \mu_i f_i(T, S)$$

where μ_i and $f_i(T, S)$ are the i^{th} feature weight and feature function, respectively. We use the standard features in Moses, without any re-ordering models. The two main components of an SMT system are the translation model (TM) and the language model (LM). The TM (typically, a phrase table), responsible for generating hypotheses, is trained using parallel data, i.e., learner-written sentences (source data) and their corresponding corrected sentences (target data). It also scores the hypotheses using features like forward and inverse phrase translation probabilities and lexical weights. The LM is trained on well-formed text and ensures the fluency of the corrected output. The feature weights μ_i are computed by minimum error rate training (MERT), optimizing the $F_{0.5}$ measure (Junczys-Dowmunt and Grundkiewicz, 2014) using a development set. The $F_{0.5}$ measure computed using the MaxMatch scorer (Dahlmeier and Ng, 2012) is the standard evaluation metric for GEC used in the CoNLL-2014 shared task (Ng et al., 2014), weighting precision twice as much as recall.

Apart from the TM and the n-gram LM, we add a neural network joint model (NNJM) (Devlin et al., 2014) as a feature, following Chollampatt et al. (2016), who reported that NNJM improves the performance of a state-of-the-art SMT-based GEC system. Unlike Recurrent Neural Networks (RNNs) and Long Short Term Memory networks (LSTMs), NNJMs have a feed-forward architecture which relies on a fixed context. This makes it easy to integrate NNJMs into a machine translation decoder as a feature. The feature value is given by $\log P(T|S)$, which is the sum of the log probabilities of individual target words in the hypothesis T given the context:

$$\log P(T|S) \approx \sum_{i=1}^{|T|} \log P(t_i|h_i) \tag{1}$$

where $|T|$ is the number of words in the target hypothesis (corrected sentence), t_i is the i^{th} target word, and h_i is the context of t_i. The context h_i consists of $n-1$ previous target words and m source words surrounding the source word that is aligned to the target word t_i.

Each dimension in the output layer of the neural network (Chollampatt et al., 2016) gives the probability of a word t in the output vocabulary given its context h:

$$P(y = t|h) = \frac{\exp(U_t(h))}{Z(h)} = \frac{\exp(U_t(h))}{\sum_{t' \in V_o} \exp(U_{t'}(h))}$$

where $U_t(h)$ is the unnormalized output score before the softmax, and V_o is the output vocabulary.

The neural network parameters which include the weights, biases, and embedding matrices are trained using back propagation with stochastic gradient descent (LeCun et al., 1998). Instead of using the noise contrastive estimation (NCE) loss as done in (Chollampatt et al., 2016), we use the log likelihood objective function with a self-normalization term similar to Devlin et al. (2014):

$$L = \frac{1}{N} \sum_{i=1}^{N} \left[\log p(y = t_i|h_i) - \alpha \log^2(Z(h_i))\right] \tag{2}$$

where N is the number of training instances, and t_i is the target word in the i^{th} training instance. Each training instance consists of a target word t and its context h. α is the self-normalization coefficient which we set to 0.1, following Devlin et al. (2014). The training can be done efficiently on GPUs. We adapt this NNJM using L1-specific learner text using a Kullback-Leibler divergence regularized objective function as described in Section 4.

4 KL Divergence Regularized Adaptation

We first train an NNJM with the general-domain data (the erroneous and corrected texts, not considering the L1 of the writers) as described in the previous section. Let $p^{GD}(y|h)$ be the probability distribution estimated by the general-domain NNJM. Starting from this NNJM, subsequent iterations of training are done using the L1-specific in-domain data alone. The in-domain data consists of the erroneous texts written by writers of a specific L1 and their corresponding corrected texts. This adaptive training is done using a modified objective function having a regularization term K, which is used to minimize the KL divergence between $p^{GD}(y|h)$ and the network's output probability distribution $p(y|h)$ (Yu et al., 2013):

$$K = \frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{V_o} p^{GD}(y = t_j|h_i)\log p(y = t_j|h_i)$$

The term K will prevent the estimated probability distribution from deviating too much from that of the general domain NNJM during training. Our final objective function for the adaptation step is a linear combination of the terms in L and K, with a regularization weight λ and a self-normalization coefficient α:

$$\begin{aligned} L' =& \lambda K + (1-\lambda)\frac{1}{N}\sum_{i=1}^{N}\log p(y = t_i|h_i) \\ & - \alpha\frac{1}{N}\sum_{i=1}^{N}\log^2(Z(h_i)) \end{aligned}$$

We integrate the unadapted NNJM and adapted NNJM independently into our SMT-based GEC system in order to compare the effect of adaptation.

5 Other Adaptation Methods

We compare our method against two other adaptation methods previously used in SMT.

Translation Model Interpolation: Following Sennrich (2012), we linearly interpolate the features in two phrase tables, one trained on in-domain data (L1-specific learner text) and the other on out-of-domain data. The interpolation weights are set by minimization of perplexity using phrase pairs extracted from our in-domain development set. The lexical weights are re-computed from the lexical counts and the interpolation weights are re-normalized if a phrase pair exists only in one of the phrase tables.

Neural Domain Adaptation Model: Joty et al. (2015) proposed an adaptation of NNJM for SMT. They first train an NNJM using in-domain data, and then perform regularized adaptation on the general domain data (concatenation of in-domain and out-of-domain data) which restricts the model from drifting away from the in-domain NNJM. Specifically, they add a regularization term J to the objective function in their adaptive training step:

$$J = \frac{1}{N}\sum_{i=1}^{N} p^{ID}(y = t_i|h_i)\log p(y = t_i|h_i)$$

where $p^{ID}(y|h)$ id probability distribution estimated by the in-domain NNJM.

NDAM has the following drawbacks compared to our method: (1) Regularization is done using probabilities of the target words alone and not on the entire probability distribution over all words, leading to a weak regularization. (2) If the in-domain data is too small, the probability distribution learnt by the in-domain NNJM will be overfitted. Therefore, encouraging adaptation to be closer to this probability distribution may not yield a good model. Our method, on the other hand, can utilize in-domain data of very small sizes to fine tune a general NNJM. (3) Their method requires retraining of the model on complete training data in order to adapt to each domain. On the contrary, our method can adapt a single general model to different domains using small in-domain data, leading to a considerable reduction in training time.

We re-implement their method by incorporating this regularization term into the log likelihood objec-

tive function with self-normalization, L (Equation 2), during adaptive training.

6 Data and Evaluation

The training data consist of two corpora: the NUS Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013) and the Lang-8 Learner Corpora v2 (Mizumoto et al., 2011). We extract texts written by learners who learn only English from Lang-8. A language identification tool `langid.py`[1] (Lui and Baldwin, 2011) is then used to obtain purely English sentences. In addition, we remove noisy source-target sentence pairs in Lang8 where the ratio of the lengths of the source and target sentences is outside $[0.5, 2.0]$, or their word overlap ratio is less than 0.2. A sentence pair where the source or target sentence has more than 80 words is also removed from both NUCLE and Lang-8. The statistics of the data after pre-processing are shown in Table 1.

Corpus	#sents	#src tokens	#tgt tokens
NUCLE	57,063	1,156,460	1,151,278
LANG-8	2,048,654	24,649,768	25,912,707
CONCAT	2,105,717	25,806,228	27,063,985

Table 1: Statistics of training data

We obtain L1-specific in-domain data for adaptation based on the L1 information provided in Lang-8. Adaptation is performed on English texts written by learners of three different L1 backgrounds: Chinese, Russian, and Spanish. The statistics of the in-domain data from Lang-8 for each L1 are given in Table 2. For each L1, its out-of-domain data are obtained by excluding the L1-specific in-domain data (from Table 2) from the combined training data (CONCAT).

L1	#sents	#src tokens	#tgt tokens
Chinese	260,872	3,521,336	3,688,098
Russian	43,488	566,517	596,692
Spanish	19,357	292,257	309,236

Table 2: Statistics of L1-specific data in Lang-8

We use the publicly available CLC-FCE (Yannakoudakis et al., 2011) corpus to obtain the development and test data. The FCE corpus contains 1,244 scripts written by 1,244 distinct candidates sitting the Cambridge ESOL First Certificate in English (FCE) examination in 2000 and 2001. The corpus identifies the L1 of each writer. We extract the scripts written by Chinese, Russian, and Spanish native writers. We split the data for each L1 into two roughly equal parts based on the number of scripts, of which one part is used as the development data and other part is used as the test data. Splitting based on the number of scripts ensures that there is no overlap between the writers of the development and test data, as each script is written by a unique learner. The details of the FCE dataset corresponding to each L1 are given in Table 3.

	#scripts	#sents	#src tokens	#tgt tokens	#errors
L1: *Chinese*					
DEV	33	1,041	15,424	15,601	1,751
TEST	33	1,078	15,640	15,816	1,487
L1: *Russian*					
DEV	41	1,125	17,021	17,267	1,782
TEST	42	1,263	18,738	18,920	1,934
L1: *Spanish*					
DEV	100	2,281	41,375	41,681	4,133
TEST	100	2,431	41,557	42,035	4,237

Table 3: Statistics of the FCE dataset for each L1

For evaluation, we use the $F_{0.5}$ measure, computed by the M^2scorer v3.2 (Dahlmeier and Ng, 2012), as our evaluation metric. The error annotations in FCE are converted to the format required by the M^2scorer. The statistics of error annotations after converting to this format are given in Table 3. To deal with the instability of parameter tuning in SMT, we perform five runs of tuning and calculate the statistical significance by stratified approximate randomization test, as recommended by (Clark et al., 2011).

7 Experiments and Results

7.1 Baseline SMT-based GEC system

We use Moses (Version 3) to build all our SMT-based GEC systems. The phrase table of the baseline system (S_{CONCAT}) is trained using the complete

Table 4: Precision (P), recall (R), and $F_{0.5}$ of L1-based adaptation of GEC systems. All results are averaged over 5 runs of tuning and evaluation.

training data. We use two 5-gram language models (LMs) trained using KenLM (Heafield et al., 2013). One LM is trained on the English Wikipedia (about 1.78 billion tokens) and another on the target side of the complete training data. The system is tuned using MERT, optimizing the $F_{0.5}$ measure on the L1-specific development data in Table 2.

For comparison, we show two other baselines S_{IN} and S_{OUT}, where the phrase tables for each L1 are trained on the in-domain data only (Table 2) and the out-of-domain data only, respectively. The results of the above baseline GEC systems on L1 Chinese, Russian, and Spanish FCE test data are summarized in Table 4. We enhance the baseline S_{CONCAT} with an NNJM feature, as described in following subsection.

7.2 NNJM Adaptation

We implement NNJM in Python using the deep learning library Theano[2] (Bergstra et al., 2010) in order to use the massively parallel processing power of GPUs for training. We first train an NNJM ($NNJM_{BASELINE}$) with complete training data for 10 epochs. The source context window size is set to 5 and the target context window size is set to 4, making it a (5+5)-gram joint model. Training is done using stochastic gradient descent with a mini-batch size of 128 and learning rate of 0.1. To speed up training and decoding, a single hidden layer neural network is used with an input embedding dimension of 192 and 512 hidden units. We use a self-normalization coefficient of 0.1. We pick 16,000 and 32,000 most frequent words on the source and target sides as our source context vocabulary and target context vocabulary, respectively. The output vocabulary is set to be the same as the target vocabulary. The vocabulary is selected from the complete training data, and not based on the L1-specific in-domain data. We add the self-normalized NNJM as a feature to our baseline GEC system, S_{CONCAT} to build a stronger baseline. This is referred to as S_{CONCAT} + $NNJM_{BASELINE}$ in Table 4.

We perform adaptation on $NNJM_{BASELINE}$ by training for 10 additional epochs using the in-domain training data alone. We use the same hyper-parameters, network structure, and vocabulary, but with the KL-divergence regularized objective function (regularization weight $\lambda = 0.5$). We train the adapted NNJM ($NNJM_{ADAPTED}$) specific to each L1. We integrate these to our baseline GEC system, and the adapted systems are referred to as S_{CONCAT} + $NNJM_{ADAPTED}$ in Table 4. The results are averaged over five runs of tuning and evaluation. Our evaluation shows that each adapted system S_{CONCAT}

[2]http://deeplearning.net/software/theano

+ $\text{NNJM}_{\text{ADAPTED}}$ outperforms every baseline system (S_{IN}, S_{OUT}, S_{CONCAT}, and S_{CONCAT} + $\text{NNJM}_{\text{BASELINE}}$) significantly on all three L1s ($p < 0.01$).

7.3 Comparison to Other Adaptation Techniques

We compare our method to two different adaptation techniques described in Section 5: Translation Model Interpolation (TM_{INT}) (Sennrich, 2012) and Neural Domain Adaptation Model (NDAM) (Joty et al., 2015)[3]. The optimization of interpolation weights for TM_{INT} is done using the L1-specific FCE development data. NDAM is trained on the complete training data (CONCAT) for 10 epochs by regularizing using an in-domain NNJM also trained for 10 epochs on L1-specific in-domain data from Lang-8. For NDAM, we use the same vocabulary and hyperparameters as our NNJMs.

The results are shown in the rows TM_{INT} + $\text{NNJM}_{\text{BASELINE}}$ and S_{CONCAT} + NDAM in Table 4. Our evaluation shows that for L1 Russian and L1 Spanish, our adapted system S_{CONCAT} + $\text{NNJM}_{\text{ADAPTED}}$ significantly outperforms both TM_{INT} + $\text{NNJM}_{\text{BASELINE}}$ and S_{CONCAT} + NDAM ($p < 0.01$), but the improvement is not statistically significant for L1 Chinese.

Our evaluation also shows that the combination of TM_{INT} and adapted NNJM is similar (for L1 Chinese and Russian) or worse (for Spanish) in performance compared to S_{CONCAT} + $\text{NNJM}_{\text{ADAPTED}}$. This is because $\text{NNJM}_{\text{ADAPTED}}$ by itself is a translation model adaptation (because it considers source and target side contexts) and hence using TM_{INT} along with it does not bring in any newer information and may even hurt the performance when the in-domain data is very small (in the case of Spanish).

7.4 Effect of Adaptation Data

We also perform adaptation on the L1-specific FCE development set in Table 3 (which is also our development data for the GEC systems), instead of the in-domain data from Lang-8 in Table 2. Our neural network overfits easily on the FCE development set due to its much smaller size. Hence, we perform adaptive training for only 2 epochs on top of $\text{NNJM}_{\text{BASELINE}}$. The results are shown in the row S_{CONCAT} + $\text{NNJM}_{\text{ADAPTED (FCE)}}$ in Table 4. Although the FCE development data is much smaller in size than the L1-specific in-domain data from Lang-8, we observe similar improvements on all three L1s. This is likely due to the similarity of the development and test sets, which are obtained from the same FCE corpus. These experiments show that smaller high-quality L1-specific error annotated data (1,000–2,000 sentences) similar to the target data can be used for adaptation to give competitive results compared to using much larger in-domain data (20,000–250,000 sentences) from other sources.

We perform experiments with smaller general domain data. In order to do this, we select a subset of CONCAT composed of the in-domain data of the three L1s along with 300,000 sentences randomly selected from the rest of CONCAT. This corpus is referred to as SMALL-CONCAT (623,717 sentences and 7,990,659 source tokens). We perform both KL-divergence regularized NNJM adaptation ($\text{NNJM}_{\text{SMALL-ADAPTED}}$) as well as Neural Domain Adaptation Model (Joty et al., 2015) ($\text{NDAM}_{\text{SMALL}}$) and compare them to NNJM trained with SMALL-CONCAT ($\text{NNJM}_{\text{SMALL-BASELINE}}$). We use these NNJMs with our S_{CONCAT} baseline. The results are summarized in Table 4. When the ratio between in-domain data and general domain data is high, both adaptation methods do not significantly improve over an unadapted NNJM. In the case of L1 Spanish, KL-divergence regularized adaptation significantly outperforms the unadapted NNJM and NDAM as the size of in-domain data is smaller.

7.5 Effect of Regularization

To analyze the effect of regularization when smaller data are used, we vary the regularization weight λ in our objective function (Section 4). The results are shown in Figure 1. $\lambda = 0$ corresponds to no regularization and training completely depends on the in-domain data apart from using the general NNJM as a starting point. On the other hand, setting $\lambda = 1$ forces the distribution learnt by the network to be similar to that of the unadapted model. We see that having no regularization ($\lambda = 0$) fails on all three L1s, due to overfitting on the smaller in-domain data. However, the effect of varying regularization is more significant on L1 Russian and Spanish, as the general NNJM has seen much smaller in-domain

[3] We use the NDAM_{vl} (Joty et al., 2015) trained using the log likelihood objective function with self-normalization.

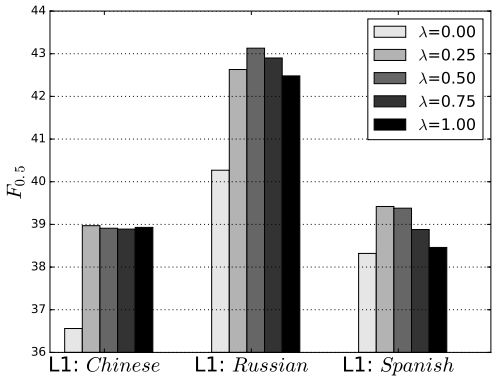

Figure 1: Effect of regularization for S_{CONCAT} + $NNJM_{ADAPTED\ (FCE)}$

data compared to L1 Chinese.

7.6 Evaluation on Benchmark Dataset

We also evaluate our system on the benchmark CoNLL-2014 shared task (Ng et al., 2014) test set for GEC in English. The CoNLL-2014 shared task consists of 1,312 sentences with two annotators. We also perform evaluation on the extension of CoNLL-2014 test set (Bryant and Ng, 2015), which contains eight additional sets of annotations over the two sets of annotations provided in the original test set. Following the settings of the CoNLL-2014 shared task, we tune our unadapted baseline system and the L1-adapted systems on the CoNLL-2013 shared task test set consisting of 1,381 test sentences. The results are summarized in Table 5.

We find that only the systems adapted based on L1 Chinese improves over the unadapted baseline system (S_{CONCAT} + $NNJM_{BASELINE}$). When the smaller-sized, high-quality FCE data is used for adaptation the margin of improvement is higher. This could be due to large proportion of Chinese learner written text in CoNLL-2014 test set, as the essays are written by the students of National University of Singapore comprising mostly of native Chinese speakers. Adaptation to L1 Russian and Spanish, does not help the system on CoNLL-2014 test set. We also compare our baseline SMT-based system with other state-of-the-art GEC systems. Our baseline system which is SMT-based, achieves the best $F_{0.5}$ score compared to other systems using the SMT approach alone, making it a competitive SMT-based GEC baseline. Overall, (Rozovskaya and Roth, 2016)

achieves the best $F_{0.5}$ score (47.40) after adding classifier components, spelling checker, punctuation and capitalization correction components in a pipeline with their SMT-based system. However, their SMT-based system alone achieves an $F_{0.5}$ score of 39.48 only.

8 Discussion and Error Analysis

Our results show that L1-based adaptation of the NNJM using L1-specific in-domain data from Lang-8 significantly improves the $F_{0.5}$ score of the GEC system on the three L1s by 1.27 (Chinese), 0.88 (Russian), and 0.64 (Spanish). We observe similar gains when smaller in-domain development data from FCE is used for adaptation. These results show that adaptation based on L1 is beneficial for targeted error correction based on the native language of the writers. Our results also show that the proposed method of NNJM adaptation is scalable to different sizes of in-domain and general domain data and outperforms other methods of adaptation like phrase table interpolation (Sennrich, 2012) and Neural Domain Adaptation Model (NDAM) (Joty et al., 2015).

We perform error analysis on four error types

Error type	Δ $F_{0.5}$		
	Chinese	*Russian*	*Spanish*
verb form/tense	+0.394	+0.298	-0.124
determiner	**+2.892**	**+2.440**	+1.648
preposition	+0.084	+2.010	**+1.806**
noun number	+0.130	-0.706	+0.822
all	+0.400	+1.068	+0.586

Table 6: Differences between per error type $F_{0.5}$ scores of *system* and *baseline* for the three L1s

which are difficult for non-native learners of English.

We compare the outputs produced by our adapted *system*: S_{CONCAT} + $NNJM_{ADAPTED}$ and the *baseline*: S_{CONCAT} + $NNJM_{BASELINE}$. We perform per error type quantitative analysis of our results by observing the difference in the per error type $F_{0.5}$ scores averaged over five runs of tuning and evaluation of *baseline* and *system*. Computing per error type $F_{0.5}$ scores is difficult for SMT-based GEC systems, as the error types for corrections proposed by the SMT-based GEC system cannot be determined trivially. To overcome this difficulty, we attempt to determine the error type of the proposed corrections by matching them to the available human annotations (the source/target phrase without the surrounding context) in the complete FCE dataset (1,244 scripts). We select those sentences from the test data where the error type of every correction proposed by the *baseline* and the *system* can be determined. This process selects 928, 1102, and 2179 sentences for L1 Chinese, Russian, and Spanish, respectively. The differences in per error type $F_{0.5}$ scores between *system* and *baseline* are shown in Table 6. For Chinese, the largest gain in $F_{0.5}$ is observed for determiner errors. Determiner errors are frequent in our L1 Chinese FCE test set (10.02%) . Moreover, we see that adaptation improves verb form errors by approximately 0.4% $F_{0.5}$. Verb form errors are the most frequent error type in our L1 Chinese test set (14.46%). Also, the highest gain for L1 Russian comes from determiner errors which is the most frequent error type in our FCE test data for L1 Russian (13.55%). Similarly, the highest gain for L1 Spanish comes from preposition errors which is the most frequent error type for L1 Spanish (12.51%).

From a practical standpoint, the adapted system can be used as an educational aid in English classes of local students in non-English-speaking countries, where all the students share the same L1 and their L1 is known in advance. The adapted system can give focused feedback to learners by correcting mistakes frequently made by learners having the same L1. Also, NNJM adaptation proposed in this paper can be done using a small number of essays (50–100 essays) in a relatively short time (20–30 minutes), making it easy to adapt GEC systems in practice.

9 Conclusion

In this paper, we perform NNJM adaptation using L1-specific learner text with a KL divergence regularized objective function. We integrate adaptation into an SMT-based GEC system. The systems with adapted NNJMs outperform unadapted baselines significantly. We also demonstrate the necessity for regularization when adapting on smaller in-domain data. Our method of adaptation performs better compared to other adaptation methods, especially when smaller in-domain data is used. Our results show that adapting GEC systems for learners of similar L1 background gives significant improvement and can be adopted in practice to improve GEC systems.

Orthographic Syllable as basic unit for SMT between Related Languages

Anoop Kunchukuttan, Pushpak Bhattacharyya
Center For Indian Language Technology,
Department of Computer Science & Engineering
Indian Institute of Technology Bombay
{anoopk,pb}@cse.iitb.ac.in

Abstract

We explore the use of the *orthographic syllable*, a variable-length consonant-vowel sequence, as a basic unit of translation between *related* languages which use abugida or alphabetic scripts. We show that orthographic syllable level translation significantly outperforms models trained over other basic units (word, morpheme and character) when training over small parallel corpora.

1 Introduction

Related languages exhibit lexical and structural similarities on account of sharing a **common ancestry** (Indo-Aryan, Slavic languages) or being in **prolonged contact** for a long period of time (Indian subcontinent, Standard Average European linguistic areas) (Bhattacharyya et al., 2016). Translation between *related* languages is an important requirement due to substantial government, business and social communication among people speaking these languages. However, most of these languages have few parallel corpora resources, an important requirement for building good quality SMT systems.

Modelling the lexical similarity among related languages is the key to building good-quality SMT systems with limited parallel corpora. *Lexical similarity* implies that the languages share many words with the similar form (spelling/pronunciation) and meaning *e.g.* `blindness` is `andhapana` in Hindi, `aandhaLepaNaa` in Marathi. These words could be cognates, lateral borrowings or loan words from other languages. Translation for such words can be achieved by sub-word level transformations. For instance, lexical similarity can be modelled in the standard SMT pipeline by transliteration of words while decoding (Durrani et al., 2010) or post-processing (Nakov and Tiedemann, 2012; Kunchukuttan et al., 2014).

A different paradigm is to drop the notion of word boundary and consider the character n-gram as the basic unit of translation (Vilar et al., 2007; Tiedemann, 2009a). Such character-level SMT bas been explored for closely related languages like *Bulgarian-Macedonian, Indonesian-Malay* with modest success, with the short context of unigrams being a limiting factor (Tiedemann, 2012). The use of character n-gram units to address this limitation leads to data sparsity for higher order n-grams and provides little benefit (Tiedemann and Nakov, 2013).

In this work, we present a linguistically motivated, variable length unit of translation — **orthographic syllable (OS)** — which provides more context for translation while limiting the number of basic units. The OS consists of one or more consonants followed by a vowel and is inspired from the *akshara*, a consonant-vowel unit, which is the fundamental organizing principle of Indic scripts (Sproat, 2003; Singh, 2006). It can be thought of as an *approximate syllable* with the onset and nucleus, but no coda. While true syllabification is hard, orthographic syllabification can be easily done. Atreya et al. (2016) and Ekbal et al. (2006) have shown that the OS is a useful unit for transliteration involving Indian languages.

We show that orthographic syllable-level trans-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1912–1917,
Austin, Texas, November 1-5, 2016.

lation significantly outperforms character-level and strong word-level and morpheme-level baselines over multiple related language pairs (Indian as well as others). Character-level approaches have been previously shown to work well for language pairs with high lexical similarity. Our major finding is that OS-level translation outperforms other approaches even when the language pairs have relatively less lexical similarity or belong to different language families (but have sufficient contact relation).

2 Orthographic Syllabification

The *orthographic syllable* is a sequence of one or more consonants followed by a vowel, *i.e* a C^+V unit. We describe briefly procedures for orthographic syllabification of Indian scripts and non-Indic alphabetic scripts. Orthographic syllabification cannot be done for languages using *logographic* and *abjad* scripts as these scripts do not have vowels.

Indic Scripts: Indic scripts are *abugida* scripts, consisting of consonant-vowel sequences, with a consonant core (C^+) and a dependent vowel (*matra*). If no vowel follows a consonant, an implicit *schwa* vowel [IPA: ə] is assumed. Suppression of *schwa* is indicated by the *halanta* character following a consonant. This script design makes for a straightforward syllabification process as shown in the following example. *e.g.* लक्षमी $\left(\frac{lakShamI}{CVCCCVCV}\right)$ is segmented as ल क्ष मी $\left(\frac{la\ \ kSha\ \ mI}{CV\ \ CCV\ \ CV}\right)$. There are two exceptions to this scheme: (i) Indic scripts distinguish between dependent vowels (vowel diacritics) and independent vowels, and the latter will constitute an OS on its own. *e.g.* मुम्बई $(mumbaI) \rightarrow$ मु म्ब ई $(mu\ \ mba\ \ I)$ (ii) The characters *anusvaara* and *chandrabindu* are part of the OS to the left if they represents nasalization of the vowel/consonant or start a new OS if they represent a nasal consonant. Their exact role is determined by the character following the *anusvaara*.

Non-Indic Alphabetic Scripts: We use a simpler method for the alphabetic scripts used in our experiments (Latin and Cyrillic). The OS is identified by a C^+V^+ sequence. *e.g. lakshami→la ksha mi*, *mumbai→mu mbai*. The OS could contains multiple terminal vowel characters representing long vowels (*oo* in *cool*) or diphthongs (*ai* in *mumbai*). A vowel starting a word is considered to be an OS.

Basic Unit	Example	Transliteration
Word	घरासमोरचा	gharAsamoracA
Morph Segment	घरा समोर चा	gharA samora cA
Orthographic Syllable	घ रा स मो र चा	gha rA sa mo racA
Character unigram	घ र ा स म ो र च ा	gha r A sa m o ra c A
Character 3-gram	घरा समो रचा	gharA samo rcA

something that is in front of home: ghara=home, samora=front, cA=of

Table 1: Various translation units for a Marathi word

3 Translation Models

We compared the orthographic syllable level model (O) with models based on other translation units that have been reported in previous work: word (W), morpheme (M), unigram (C) and trigram characters. Table 1 shows examples of these representations.

The first step to build these translation systems is to transform sentences to the correct representation. Each word is segmented as the per the unit of representation, punctuations are retained and a special *word boundary marker* character (_) is introduced to indicate word boundaries as shown here:

W: राजू , घराबाहेर जाऊ नको .
O: रा जू _ , _ घ रा बा हे र _ जा ऊ _ न को _ .

For all units of representation, we trained phrase-based SMT (PBSMT) systems. Since related languages have similar word order, we used distance based distortion model and monotonic decoding. For character and orthographic syllable level models, we use higher order (10-gram) languages models since data sparsity is a lesser concern due to small vocabulary size (Vilar et al., 2007). As suggested by Nakov and Tiedemann (2012), we used word-level tuning for character and orthographic syllable level models by post-processing n-best lists in each tuning step to calculate the usual word-based BLEU score.

While decoding, the word and morpheme level systems will not be able to translate OOV words. Since the languages involved share vocabulary, we transliterate the untranslated words resulting in the post-edited systems W_X and M_X corresponding to the systems W and M respectively. Following decoding, we used a simple method to regenerate words from sub-word level units: Since we represent word boundaries using a word boundary marker, we

IA→IA		DR→DR		IA→DR	
ben-hin	52.30	mal-tam	39.04	hin-mal	33.24

IA: Indo-Aryan, DR: Dravidian

Table 2: Language pairs used in experiments along with Lexical Similarity between them, in terms of LCSR between training corpus sentences

simply concat the output units between consecutive occurrences of the marker character.

4 Experimental Setup

Languages: Our experiments primarily concentrated on multiple language pairs from the two major language families of the Indian sub-continent (Indo-Aryan branch of Indo-European and Dravidian). These languages have been in contact for a long time, hence there are many lexical and grammatical similarities among them, leading to the subcontinent being considered a *linguistic area* (Emeneau, 1956). Specifically, there is overlap between the vocabulary of these languages to varying degrees due to cognates, language contact and loanwords from Sanskrit (throughout history) and English (in recent times). Table 2 lists the languages involved in the experiments and provides an indication of the lexical similarity between them in terms of the Longest Common Subsequence Ratio (LCSR) (Melamed, 1995) between the parallel training sentences at character level. All these language have a rich inflectional morphology with Dravidian languages, and Marathi and Konkani to some degree, being agglutinative. *kok-mar* and *pan-hin* have a high degree of lexical similarity.

Dataset: We used the multilingual ILCI corpus for our experiments (Jha, 2012), consisting of a modest number of sentences from tourism and health domains. The data split is as follows – *training: 44,777, tuning 1K, test: 2K* sentences. Language models for word-level systems were trained on the target side of training corpora plus monolingual corpora from various sources [hin: 10M (Bojar et al., 2014), tam: 1M (Ramasamy et al., 2012), mar: 1.8M (news websites), mal: 200K (Quasthoff et al., 2006) sentences]. We used the target language side of the parallel corpora for character, morpheme and OS level LMs.

System details: PBSMT systems were trained using the *Moses* system (Koehn et al., 2007), with the *grow-diag-final-and* heuristic for extracting phrases, and Batch MIRA (Cherry and Foster, 2012) for tuning (default parameters). We trained 5-gram LMs with Kneser-Ney smoothing for word and morpheme level models and 10-gram LMs for character and OS level models. We used the *BrahmiNet* transliteration system (Kunchukuttan et al., 2015) for post-editing, which is based on the transliteration Module in Moses (Durrani et al., 2014). We used unsupervised morphological segmenters trained with *Morfessor* (Virpioja et al., 2013) for obtaining morpheme representations. The unsupervised morphological segmenters were trained on the ILCI corpus and the Leipzig corpus (Quasthoff et al., 2006).The morph-segmenters and our implementation of orthographic syllabification are made available as part of the *Indic NLP Library*[1].

Evaluation: We use BLEU (Papineni et al., 2002) and Le-BLEU (Virpioja and Grönroos, 2015) for evaluation. Le-BLEU does fuzzy matches of words and hence is suitable for evaluating SMT systems that perform transformation at the sub-word level.

5 Results and Discussion

This section discusses the results on Indian and non-Indian languages and cross-domain translation.

Comparison of Translation Units: Table 3 compares the BLEU scores for various translation systems. The orthographic syllable level system is clearly better than all other systems. It significantly outperforms the character-level system (by 46% on an average). The character-based system is competitive only for highly lexically similar language pairs like *pan-hin* and *kok-mar*. The system also outperforms two strong baselines which address data sparsity: (a) a word-level system with transliteration of OOV words (10% improvement), (b) a morph-level system with transliteration of OOV words (5% improvement). The OS-level representation is more beneficial when morphologically rich

languages are involved in translation. Significantly, OS-level translation is also the best system for translation between languages of different language families. The Le-BLEU scores also show the same trend as BLEU scores, but we have not reported it due to space limits. There are a very small number of untranslated OSes, which we handled by simple mapping of untranslated characters from source to target script. This barely increased translation accuracy (0.02% increase in BLEU score).

Why is OS better than other units?: The improved performance of OS level representation can be attributed to the following factors:

One, the number of basic translation units is limited and small compared to word-level and morpheme-level representations. For word-level representation, the number of translation units can increase with corpus size, especially for morphologically rich languages which leads to many OOVs. Thus, OS-level units **address data sparsity**.

	W_X	M_X	C	O
ben-hin	*Corpus not available*			
pan-hin	61.56	**59.75**	58.07	58.48
kok-mar	19.32	18.32	17.97	**19.65**
mal-tam	**5.88**	6.02	4.12	**5.88**
tel-mal	3.19	**4.07**	3.11	3.77
hin-mal	5.20	6.00	3.85	**6.26**
mal-hin	9.68	11.44	8.42	**13.32**

Table 5: Results: Agricuture Domain (% BLEU)

Two, while character level representation too does not suffer from data sparsity, we observe that the translation accuracy is highly correlated to lexical similarity (Table 4). The high correlation of character-level system and lexical similarity explains why character-level translation performs nearly as well other methods for language pairs which have high lexical similarity, but performs badly otherwise. On the other hand, the OS-level representation has lesser correlation with lexical similarity and sits somewhere between character-level and word/morpheme level systems. Hence it is able to make **generalizations beyond simple character level mappings**. We observed that OS-level representation was able to correctly generate words whose translations are not cognate with the source language. This is an important property since function words and suffixes tend to be less similar lexically across languages.

Can improved translation performance be explained by longer basic translation units? To verify this, we trained translation systems with character trigrams as basic units. We chose trigrams since the average length of the OS was 3-5 characters for the languages we tested with. The translation accuracies were far less than even unigram representation. The number of unique basic units was about 8-10 times larger than orthographic syllables, thus making data sparsity an issue again. So, improved translation performance **cannot be attributed to longer n-gram units alone**.

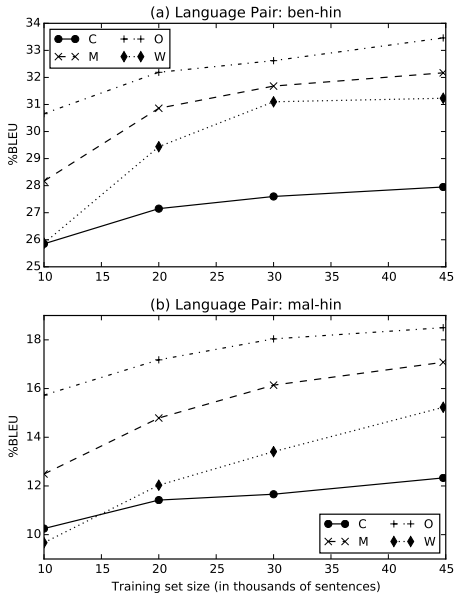

Figure 1: Effect of training data size on translation accuracy for different basic units

	Corpus Stats	Lex-Sim	W	C	O
bul-mac	(150k,1k,2k)	62.85	21.20	20.61	**21.38**
dan-swe	(150k,1k,2k)	63.39	35.13	35.36	**35.46**
may-ind	(137k,1k,2k)	73.54	61.33	60.50	**61.24**

Table 6: Translation among non-Indic languages (%BLEU). Corpus Stats show (train,tune,test) split

Robustness to Domain Change: We also tested the translation models trained on tourism & health domains on an agriculture domain test set of 1000 sentences. In this cross-domain translation scenario too, the OS level model outperforms most units of representation. The only exceptions are the *pan-hin* and *tel-mal* language pairs for the system $\mathbf{M}_X$ (accuracies of the OS-level system are within 10% of the $\mathbf{M}_X$ system). Since the word level model depends on coverage of the lexicon, it is highly domain dependent, whereas the sub-word units are not. So, even unigram-level models outperform word-level models in a cross-domain setting.

Experiments with non-Indian languages: Table 6 shows the corpus statistics and our results for translation between some related non-Indic language pairs (Bulgarian-Macedonian, Danish-Swedish, Malay-Indonesian). OS level representation outperforms character and word level representation, though the gains are not as significant as Indic language pairs. This could be due to short length of sentences in training corpus [OPUS movie subtitles (Tiedemann, 2009b)] and high lexical similarity between the language pairs. Further experiments between less lexically related languages on general parallel corpora will be useful.

Effect of training data size: For different training set sizes, we trained SMT systems with various representation units (Figure 1 shows the learning curves for two language pairs). BPE level models are consistently better than word as well as morph-level models, and are competitive or better than OS level models. Note that *bn-hi* is a relatively morphologically simpler language where BPE is just competitive with OS over the complete dataset too as discussed earlier.

6 Conclusion & Future Work

We focus on the task of translation between *related languages*. This aspect of MT research is important to make available translation technologies to language pairs with limited parallel corpus, but huge potential translation requirements. We propose the use of the *orthographic syllable*, a variable-length, linguistically motivated, approximate syllable, as a basic unit for translation between related languages. We show that it significantly outperforms other units of representation, over multiple language pairs, spanning different language families, with varying degrees of lexical similarity and is robust to domain changes too. This opens up the possibility of further exploration of sub-word level translation units *e.g.* segments learnt using byte pair encoding (Sennrich et al., 2016).

Abstract

This paper explores the task of translating natural language queries into regular expressions which embody their meaning. In contrast to prior work, the proposed neural model does not utilize domain-specific crafting, learning to translate directly from a parallel corpus. To fully explore the potential of neural models, we propose a methodology for collecting a large corpus[1] of regular expression, natural language pairs. Our resulting model achieves a performance gain of 19.6% over previous state-of-the-art models.

1 Introduction

This paper explores the task of translating natural language text queries into regular expressions which embody their meaning. Regular expressions are built into many application interfaces, yet most users of these applications have difficulty writing them (Friedl, 2002). Thus a system for automatically generating regular expressions from natural language would be useful in many contexts. Furthermore, such technologies can ultimately scale to translate into other formal representations, such as program scripts (Raza et al., 2015).

Prior work has demonstrated the feasibility of this task. Kushman and Barzilay (2013) proposed a model that learns to perform the task from a parallel corpus of regular expressions and the text descriptions. To account for the given representational disparity between formal regular expressions and natural language, their model utilizes a domain specific component which computes the semantic equivalence between two regular expressions. Since their model relies heavily on this component, it cannot be readily applied to other formal representations where such semantic equivalence calculations are not possible.

In this paper, we reexamine the need for such specialized domain knowledge for this task. Given the same parallel corpus used in Kushman and Barzilay (2013), we use an LSTM-based sequence to sequence neural network to perform the mapping. Our model does not utilize semantic equivalence in any form, or make any other special assumptions about the formalism. Despite this and the relatively small size of the original dataset (824 examples), our neural model exhibits a small 0.1% boost in accuracy.

To further explore the power of neural networks, we created a much larger public dataset, **NL-RX**. Since creation of regular expressions requires specialized knowledge, standard crowd-sourcing methods are not applicable here. Instead, we employ a two-step generate-and-paraphrase procedure that circumvents this problem. During the generate step, we use a small but expansive manually-crafted grammar that translates regular expression into natural language. In the paraphrase step, we rely on crowd-sourcing to paraphrase these rigid descriptions into more natural and fluid descriptions. Using this methodology, we have constructed a corpus of 10,000 regular expressions, with corresponding verbalizations.

Our results demonstrate that our sequence to sequence model significantly outperforms the domain specific technique on the larger dataset, reaching a

gain of 19.6% over of the state-of-the-art technique.

2 Related Work

Regular Expressions from Natural Language There have been several attempts at generating regular expressions from textual descriptions. Early research into this task used rule-based techniques to create a natural language interface to regular expression writing (Ranta, 1998). Our work, however, is closest to Kushman and Barzilay (2013). They learned a semantic parsing translation model from a parallel dataset of natural language and regular expressions. Their model used a regular expression-specific semantic unification technique to disambiguate the meaning of the natural language descriptions. Our method is similar in that we require only description and regex pairs to learn.r However, we treat the problem as a direct translation task without applying any domain-specific knowledge.

Neural Machine Translation Recent advances in neural machine translation (NMT) (Bahdanau et al., 2014; Devlin et al., 2014) using the framework of sequence to sequence learning (Sutskever et al., 2014) have demonstrated the effectiveness of deep learning models at capturing and translating language semantics. In particular, recurrent neural networks augmented with attention mechanisms (Luong et al., 2015) have proved to be successful at handling very long sequences. In light of these successes, we chose to model regular expression generation as a neural translation problem.

3 Regex Generation as Translation

We use a Recurrent Neural Network (RNN) with attention (Mnih et al., 2014) for both encoding and decoding (Figure 1).

Let $W = w_1, w_2 ... w_m$ be the input text description where each w_i is a word in the vocabulary. We wish to generate the regex $R = r_1, r_2, ... r_n$ where each r_i is a character in the regex.

We use Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) cells in our model, the transition equations for which can be summarized as:

$$\begin{aligned} i_t &= \sigma(U^{(i)} x_t + V^{(i)} h_{t-1} + b^{(i)}), \\ f_t &= \sigma(U^{(f)} x_t + V^{(f)} h_{t-1} + b^{(f)}), \\ o_t &= \sigma(U^{(o)} x_t + V^{(o)} h_{t-1} + b^{(o)}) \\ z_t &= \tanh(U^{(z)} x_t + V^{(z)} h_{t-1} + b^{(z)}) \\ c_t &= i_t \odot z_t + f_t \odot c_{t-1} \\ h_t &= o_t \odot \tanh(c_t) \end{aligned} \tag{1}$$

where σ represents the sigmoid function and $\odot$ is elementwise multiplication. i_t refers to the input gate, f_t is the forget gate, and o_t is the output gate at each time step. The U and V variables are weight matrices for each gate while the b variables are the bias parameters. The input x_t is a word (w_t) for the encoder and the previously generated character r_{t-1} for the decoder.

The attention mechanism is essentially a 'soft' weighting over the encoder's hidden states during decoding:

$$\alpha_t(e) = \frac{\exp(\text{score}(h_t, h_e))}{\sum_{e'} \exp(\text{score}(h_t, h_{e'}))}$$

where h_e is a hidden state in the encoder and *score* is the scoring function. We use the general attention matrix weight (as described in (Luong et al., 2015)) for our scoring function. The outputs of the decoder r_t are generated using a final softmax layer.

Our model is six layers deep, with one word embedding layer, two encoder layers, two decoder layers, and one dense output layer. Our encoder and decoder layers use a stacked LSTM architecture with a width of 512 nodes. We use a global attention mechanism (Bahdanau et al., 2014), which considers all hidden states of the encoder when computing the model's context vector. We perform standard dropout during training (Srivastava et al., 2014) after every LSTM layer with dropout probability equal to 0.25. We train for 20 epochs, utilizing a minibatch size of 32, and a learning-rate of 1.0. The learning rate is decayed by a factor 0.5 if evaluation perplexity does not increase.

4 Creating a Large Corpus of Natural Language / Regular Expression Pairs

Previous work in regular expression generation has used fairly small datasets for training and evaluation.

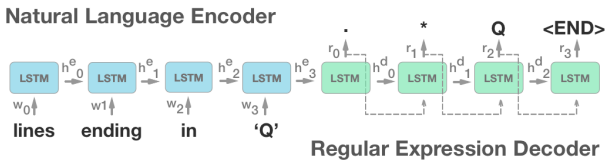

Figure 1: Deep-Regex Encoder-Decoder setup. Blue cells represent the encoder and the green ones represent the decoder.

Non-Terminals		
x & y → x and y	x | y → x or y	∼(x) → not x
.*x.*y → x followed by y	.*x.* → contains x	x{N,} → x, N or more times
x& y& z → x and y and z	x | y | z → x or y or z	x{1,N} → x, at most N times
x.* → starts with x	.*x → ends with x	\b x\b → words with x
(x)+ → x, at least once	(x)* → x, zero or more times	x → only x

Terminals		
[AEIOUaeiou] → a vowel	[0-9] → a number	word → the string 'word'
[A-Z] → an uppercase letter	[a-z] → a lowercase letter	. → a character

Table 1: Regex → Synthetic Grammar for Data Generation

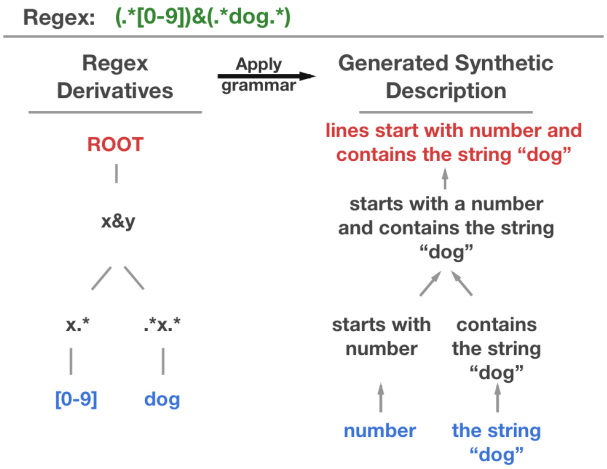

Figure 2: Process for generating Synthetic Descriptions from Regular Expressions. Grammar rules from Table 1 are applied to a node's children and the resulting string is passed to the node's parent.

Synthetic:	lines not words with starting with a capital letter
Paraphrased:	lines that do not contain words that begin with a capital letter
Regex:	∼ (\b([A-Z])(.*)\b)

Table 2: NL-RX Text Descriptions and Regular Expression

In order to fully utilize the power of neural translation models, we create a new large corpus of regular expression, natural language pairs titled **NL-RX**.

The challenge in collecting such corpora is that typical crowdsourcing workers do not possess the specialized knowledge to write regular expressions. To solve this, we employ a two-step generate-and-paraphrase procedure to gather our data. This technique is similar to the methods used by Wang et al. (2015) to create a semantic parsing corpus.

In the generate step, we generate regular expression representations from a small manually-crafted grammar (Table 1). Our grammar includes 15 non-terminal derivations and 6 terminals and of both basic and high-level operations. We identify these via frequency analysis of smaller datasets from previous work (Kushman and Barzilay, 2013). Every grammar rule has associated verbalizations for both regular expressions and language descriptions. We use this grammar to stochastically generate regular expressions and their corresponding synthetic language descriptions. This generation process is shown in Figure 2.

While the automatically generated descriptions are semantically correct, they do not exhibit richness and variability of human-generated descriptions. To obtain natural language (non-synthetic) descriptions, we perform the paraphrase step. In this step, Mechanical Turk (Amazon, 2003) human workers paraphrase the generated synthetic descriptions into the fluent verbalizations.

NL-RX Using the procedure described above, we create a new public dataset (NL-RX) comprising of 10,000 regular expressions and their corresponding natural language descriptions. Table 2 shows an example from our dataset.

Our data collection procedure enables us to create a substantially larger and more varied dataset than previously possible. Employing standard crowdsource workers to paraphrase is more cost-efficient and scalable than employing professional regex programmers, enabling us to create a much larger dataset. Furthermore, our stochastic generation of regular expressions from a grammar results in a more varied dataset because it is not subject to the bias of human workers who, in previous work, wrote many duplicate examples (see Results).

Corpora Statistics Our seed regular expression grammar (Table 1), covers approximately 85% of the original KB13 regular expressions. Additionally, NL-RX contains exact matches with 30.1% of the original KB13 dataset regular expressions. This means that 248 of the 824 regular expressions in the

Verbalization	Frequency
'the word x'	12.6%
'x before y'	9.1%
'x or y'	7.7%
'x, at least once'	6.2%
'a vowel'	5.3%

Table 3: Top Frequent Verbalizations from NL-RX

KB13 dataset were also in our dataset. The average length of regular expressions in NL-RX is 25.9 characters, the average in the KB13 dataset is 19.7 characters. We also computed the grammar breakdown of our NL-RX. The top 5 occurring terminals in our generated regular expressions are those corresponding with the verbalizations shown in Table 3.

Crowdsourcing details We utilize Mechanical Turk for our crowdsource workers. A total of 243 workers completed the 10,000 tasks, with an average task completion time of 101 seconds. The workers proved capable of handling complex and awkward phrasings, such as the example in Table 2, which is one of the most difficult in the set.

We applied several quality assurance measures on the crowdsourced data. Firstly, we ensured that our workers performing the task were of high quality, requiring a record of 97% accuracy over at least 1000 other previous tasks completed on Mechanical Turk. In addition, we ran automatic scripts that filtered out bad submissions (e.g. submissions shorter than 5 characters). In all, we rejected 1.1% of submissions, which were resubmitted for another worker to complete. The combination of these measures ensured a high quality dataset, and we confirmed this by performing a manual check of 100 random examples. This manual check determined that approximately 89% of submissions were a correct interpretation, and 97% were written in fluent English.

5 Experiments

Datasets We split the 10,000 regexp and description pairs in NL-RX into 65% train, 10% dev, and 25% test sets.

In addition, we also evaluate our model on the dataset used by Kushman and Barzilay (2013) (KB13), although it contains far fewer data points (824). We use the 75/25 train/test split used in their work in order directly compare our performance to theirs.

Training We perform a hyper-parameter grid-search (on the dev set), to determine our model hyper-parameters: learning-rate = 1.0, encoder-depth = 2, decoder-depth = 2, batch size = 32, dropout = 0.25. We use a Torch (Collobert et al., 2002) implementation of attention sequence to sequence networks from (Kim, 2016). We train our models on the train set for 20 epochs, and choose the model with the best average loss on the dev set.

Evaluation Metric To accurately evaluate our model, we perform a *functional* equality check called DFA-Equal. We employ functional equality because there are many ways to write equivalent regular expressions. For example, (a|b) is functionally equivalent to (b|a), despite their string representations differing. We report DFA-Equal accuracy as our model's evaluation metric, using Kushman and Barzilay (2013)'s implementation to directly compare our results.

Baselines We compare our model against two baselines:

BoW-NN: BoW-NN is a simple baseline that is a Nearest Neighbor classifier using Bag Of Words representation for each natural language description. For a given test example, it finds the closest cosine-similar neighbor from the training set and uses the regexp from that example for its prediction.

Semantic-Unify: Our second baseline, Semantic-Unify, is the previous state-of-the-art model from (Kushman and Barzilay, 2013), explained above. [2]

6 Results

Our model significantly outperforms the baselines on the NL-RX dataset and achieves comparable performance to *Semantic Unify* on the KB13 dataset (Table 4). Despite the small size of KB13, our model achieves state-of-the-art results on this very resource-constrained dataset (824 examples). Using NL-RX, we investigate the impact of training data size on our model's accuracy. Figure 3 shows how

[2]We trained and evaluated Semantic-Unify in consultation with the original authors.

Models	NL-RX-Synth		NL-RX-Turk		KB13
	Dev	Test	Dev	Test	Test
BoW NN	31.7%	30.6%	18.2%	16.4%	48.5%
Semantic-Unify	41.2%	46.3%	39.5%	38.6%	65.5%
Deep-RegEx	**85.75%**	**88.7%**	**61.2%**	**58.2%**	**65.6%**

Table 4: DFA-Equal accuracy on different datasets. **KB13**: Dataset from Kushman and Barzilay(2013), **NL-RX-Synth**: NL Dataset with original synthetic descriptions, **NL-RX-Turk**: NL Dataset with Mechanical Turk paraphrased descriptions. Best scores are in bold.

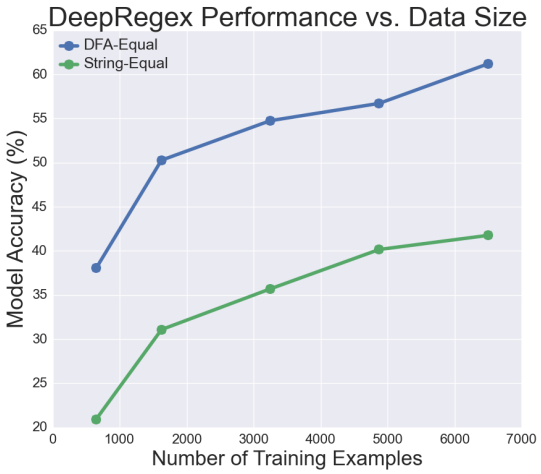

Figure 3: Our model's performance, like many deep learning models, increases significantly with larger datasets. **String-Equal**:Accuracy on direct string match, **DFA-Equal**:Accuracy using the DFA-Equal evaluation.

our model's performance improves as the number of training examples grows.

Differences in Datasets Keeping the previous section in mind, a seemingly unusual finding is that the model's accuracy is higher for the smaller dataset, KB13, than for the larger dataset, NL-RX-Turk. On further analysis, we learned that the KB13 dataset is a much less varied and complex dataset than NL-RX-Turk. KB13 contains many duplicates, with only 45% of its regular expressions being unique. This makes the translation task easier because over half of the correct test predictions will be exact repetitions from the training set. In contrast, NL-RX-Turk does not suffer from this variance problem and contains 97% unique regular expressions. The relative easiness of the KB13 dataset is further illustrated by the high performance of the Nearest-Neighbor baselines on the KB13 dataset.

7 Conclusions

In this paper we demonstrate that generic neural architectures for generating regular expressions outperform customized, heavily engineered models. The results suggest that this technique can be employed to tackle more challenging problems in broader families of formal languages, such as mapping between language description and program scripts. We also have created a large parallel corpus of regular expressions and natural language queries using typical crowd-sourcing workers, which we make available publicly.

Abstract

The problem of noisy and unbalanced training data for supervised keyphrase extraction results from the subjectivity of keyphrase assignment, which we quantify by crowdsourcing keyphrases for news and fashion magazine articles with many annotators per document. We show that annotators exhibit substantial disagreement, meaning that single annotator data could lead to very different training sets for supervised keyphrase extractors. Thus, annotations from single authors or readers lead to noisy training data and poor extraction performance of the resulting supervised extractor. We provide a simple but effective solution to still work with such data by reweighting the importance of unlabeled candidate phrases in a two stage Positive Unlabeled Learning setting. We show that performance of trained keyphrase extractors approximates a classifier trained on articles labeled by multiple annotators, leading to higher average F_1scores and better rankings of keyphrases. We apply this strategy to a variety of test collections from different backgrounds and show improvements over strong baseline models.

1 Introduction

Keyphrase extraction is the task of extracting a selection of phrases from a text document to concisely summarize its contents. Applications of keyphrases range from summarization (D'Avanzo et al., 2004) to contextual advertisement (Yih et al., 2006) or simply as aid for navigation through large text corpora.

Existing work on automatic keyphrase extraction can be divided in supervised and unsupervised approaches. While unsupervised approaches are domain independent and do not require labeled training data, supervised keyphrase extraction allows for more expressive feature design and is reported to outperform unsupervised methods on many occasions (Kim et al., 2012; Caragea et al., 2014). A requirement for supervised keyphrase extractors is the availability of labeled training data. In literature, training collections for supervised keyphrase extraction are generated in different settings. In these collections, keyphrases for text documents are either supplied by the authors or their readers. In the first case, authors of academic papers or news articles assign keyphrases to their content to enable fast indexing or to allow for the discovery of their work in electronic libraries (Frank et al., 1999; Hulth, 2003; Bulgarov and Caragea, 2015). Other collections are created by crowdsourcing (Marujo et al., 2012) or based on explicit deliberation by a small group of readers (Wan and Xiao, 2008). A minority of test collections provide multiple opinions per document, but even then the amount of opinions per document is kept minimal (Nguyen and Kan, 2007).

The traditional procedure for supervised keyphrase extraction is reformulating the task as a binary classification of keyphrase candidates. Supervision for keyphrase extraction faces several shortcomings. Candidate phrases (generated in a separate candidate generation procedure), which are not annotated as keyphrases, are seen as non-keyphrase and are used as negative training data for the supervised classifiers. First, on many occasions these negative phrases outnumber true keyphrases many times, creating an unbalanced

training set (Frank et al., 1999; Kim et al., 2012). Second, as Frank et al. (1999) noted: authors do not always choose keyphrases that best describe the content of their paper, but they may choose phrases to slant their work a certain way, or to maximize its chance of being noticed by searchers. Another problem is that keyphrases are inherently subjective, i.e., keyphrases assigned by one annotator are not the only correct ones (Nguyen and Kan, 2007). These assumptions have consequences for training, developing and evaluating supervised models. Unfortunately, a large collection of annotated documents by reliable annotators with high overlap per document is missing, making it difficult to study disagreement between annotators or the resulting influence on trained extractors, as well as to provide a reliable evaluation setting. In this paper, we address these problems by creating a large test collection of articles with many different opinions per article, evaluate the effect on extraction performance, and present a procedure for supervised keyphrase extraction with noisy labels.

2 Noisy Training Data for Supervised Keyphrase Extraction

A collection of online news articles and lifestyle magazine articles was presented to a panel of 357 annotators of various ages and backgrounds, (selected and managed by iMinds - Living Labs[1]) who were trained to select a *limited number* of *short* phrases that concisely reflect the documents' contents. No prior limits or constraints were set on the amount, length, or form of the keyphrases. Each document was presented multiple times to different users. Each user was assigned with 140 articles, but was not required to finish the full assignment. The constructed training collections have on average six and up to ten different opinions per article.

We visualize the agreement on single keyphrases in Figure 1, which shows the fraction of annotated keyphrases versus agreement by the complete set of readers. Agreement on keyphrases appears low, as a large fraction of all keyphrases assigned to documents (>50%) are only assigned by single annotators. We note that different sets of keyphrases by different annotators are the result of the subjectiveness of the task, of different interpretations by the annotators of the document, but also because of semantically equivalent keyphrases being annotated in different forms, e.g., "Louis Michel" vs. "Prime Minister Louis Michel" or "Traffic Collision" vs. "Car Accident".

The observation in Figure 1 has important consequences for training models on keyphrases annotated by a single annotator, since other annotators may have chosen some among the ones that the sin-

[1] https://www.iminds.be/en/succeed-with-digital-research/proeftuinonderzoek/

gle selected annotator did not indicate (and hence these should not be used as negative training data).

A single annotator assigning keyphrases to 100 documents results on average in a training set with 369 positive training instances and 4,981 negative training instances generated by the candidate extractor. When assigning these 100 documents to 9 other annotators, the amount of positive instances increases to 1,258 keyphrases, which means that labels for 889 keyphrase candidates, or 17% of the original negative candidates when training on annotations by a single annotator, can be considered noise and relabeled. As a result, ratios of positive to negative data also change drastically. We visualize the effect of using training data from multiple annotators per document in Figure 2. Classifiers trained on the aggregated training collection with multiple opinions (using all assigned keyphrases at least once as positive training data) perform better on held-out test collections containing only keyphrases of high agreement (assigned by > 2 annotators).

When using keyphrases from many different annotators per document, the amount of positive candidates increases and as a result, the Macro Average F_1 (MAF_1) of the corresponding classifier. We detail our experimental setup and supervised classifier in Section 4.

3 Reweighting Keyphrase Candidates

Observations described in Section 2 indicate that unlabeled keyphrase candidates are not reliable as negative examples by default. A more suitable assumption is to treat supervised keyphrase extraction as Positive Unlabeled Learning, i.e., an incomplete set of positive examples is available as well as a set of unlabeled examples, of which some are positive and others negative. This topic has received much attention as it knows many applications (Ren et al., 2014; du Plessis et al., 2014), but has not been linked to supervised keyphrase extraction. We base our approach on work by Elkan and Noto (2008) and modify the supervised extractor by assigning individual weights to training examples. Instead of assuming the noise to be random, we assign weights depending on the document and the candidate.

By reweighting importance of training samples, we seek to mimic the case of multiple annotators, to model the uncertainty of negative keyphrase candidates, based only on annotations by a single annotator. In a first stage, we train a classifier on the single annotator data and use predictions on the negative or unlabeled candidates, to reweigh training instances. The reweighted training collection is then used to train a second classifier to predict a final ranking or the binary labels of the keyphrase candidates.

Feature	**Definition**
Head match	$head_{keyphrase} == head_{candidate}$
Extent match	$extent_{keyphrase} == extent_{candidate}$
Substring	$head_{keyphrase}$ substring of $head_{candidate}$
Alias	$acronym(head_{keyphrase}) == head_{candidate}$

Table 1: String relation features for coreference resolution

Positive examples are given unit weight and unlabeled examples are duplicated; one copy of each unlabeled keyphrase candidate x is made positive with weight $w(x) = P(keyphrase|x, s = 0)$ and the other copy is made negative with weight $1 - w(x)$ with s indicating whether x is labeled or not.

Instead of assigning this weight as a constant factor of the predictions by the initial classifier as in Elkan and Noto (2008), we found that two modifications allow improving the weight estimate, $w(x) \leq 1$. We normalize probabilities $P(keyphrase, x, s = 0)$ to candidates not included in the initial set of keyphrases per document. Next to this self-predicted probability, we include a simple measure indicating pairwise coreference between unlabeled candidates and known keyphrases in a function $\text{Coref}(candidate, keyphrase) \in \{0, 1\}$, returning 1 if one of the binary indicator features, presented in (Bengtson and Roth, 2008) and shown in Table 1, is present. In this description, the term *head* means the head noun phrase of a candidate or keyphrase and the *extent* is the largest noun phrase headed by the head noun phrase. The self-predicted probability is summed with the output of the coreference resolver and the final weight becomes:

$$w(x) = min\left(1, \frac{P(keyphrase|x)}{\max_{(x',s=0)\in d} P(keyphrase|x')} \cdot + \max_{\forall keyphrase \in d} \text{Coref}(x, keyphrase)\right) \quad (1)$$

with d being a document from the training collection.

4 Experiments and Results

Hasan and Ng (2010) have shown that techniques for keyphrase extraction are inconsistent and need to be tested across different test collections. Next to our collections with multiple opinions (*Online News* and *Lifestyle Magazines*), we apply the reweighting strategy on test collections with sets of author-assigned keyphrases: two sets from CiteSeer abstracts from the World Wide Web Conference (*WWW*) and Knowledge Discovery and Data Mining (*KDD*), similar to the ones used in (Bulgarov and Caragea, 2015). The *Inspec* dataset is a collection of 2,000 abstracts commonly used in keyphrase extraction literature, where we use the ground truth phrases from controlled vocabulary (Hulth, 2003). Descriptive statistics of these test collections are given in Table 2.

We use a rich feature set consisting of statistical, structural, and semantic properties for each candidate phrase, that have been reported as effective in previous studies on supervised extractors (Frank et al., 1999; Hulth, 2003; Kim and Kan, 2009): (i) term frequency, (ii) number of tokens in the phrase, (iii) length of the longest term in the phrase, (iv) number of capital letters in the phrase, (v) the phrase's POS-tags, (vi) relative position of first occurrence, (vii) span (relative last occurrence minus relative first occurrence), (viii) TF*IDF (IDF's trained on large background collections from the same source) and (ix) Topical Word Importance, a feature measuring the similarity between the word-topic topic-document distributions presented in (Sterckx et al., 2015), with topic models trained on background collections from a corresponding source of content.

As classifier we use gradient boosted decision trees implemented in the XGBoost package (Chen and Guestrin, 2016). During development, this classifier consistently outperformed Naive Bayes and linear classifiers like logistic regression or support vector machines.

We compare the reweighting strategy with uniform reweighting and strategies to counter the imbalance or noise of the training collections, such as subsampling, weighting unlabeled training data as in (Elkan and Noto, 2008), and self-training in which only confident initial predictions are used as positive and negative data. For every method, global thresholds are chosen to optimize the macro averaged F_1 per document (MAF_1). Next to the threshold sensitive F_1, we report on ranking quality using the Precision@5 metric.

Results are shown in Table 3 with five-fold cross-validation. To study the effect of reweighting, we limit training collections during folds to 100 documents for each test collection. Our approach consistently improves on single annotator trained classifiers, on one occasion even outperforming a training collection with multiple opinions. Compensating for

imbalance and noise tends to have less effect when the ratio of keyphrases versus candidates is high (as for *Inspec*) or training collection is very large. When the amount of training documents increases, the ratio of noisy versus true negative labels drops.

5 Conclusion

It has been suggested that keyphrase annotation is highly subjective. We present two data sets where we purposely gathered multiple annotations of the same document, as to quantify the limited overlap between keyphrases selected by different annotators. We suggest to treat non-selected phrases as *unlabeled* rather than *negative* training data. We further show that using multiple annotations leads to more robust automatic keyphrase extractors, and propose reweighting of single annotator labels based on probabilities from a first-stage classifier. This reweighting approach outperforms other single-annotator state-of-the-art automatic keyphrase extractors on different test collections, when we normalize probabilities per document and include co-reference indicators.

Abstract

A natural language interface to answers on the Web can help us access information more efficiently. We start with an interesting source of information—infoboxes in Wikipedia that summarize factoid knowledge—and develop a comprehensive approach to answering questions with high precision. We first build a system to access data in infoboxes in a structured manner. We use our system to construct a crowdsourced dataset of over 15,000 high-quality, diverse questions. With these questions, we train a convolutional neural network model that outperforms models that achieve top results in similar answer selection tasks.

1 Introduction

The goal of open-domain question answering is to provide high-precision access to information. With many sources of knowledge on the Web, selecting the right answer to a user's question remains challenging. Wikipedia contains over five million articles in its English version. Providing a natural language interface to answers in Wikipedia is an important step towards more effective information access.

Many Wikipedia articles have an *infobox*, a table that summarizes key information in the article in the form of attribute–value pairs like "Narrated by: Fred Astaire". This data source is appealing for question answering because it covers a broad range of facts that are inherently relevant: a human editor manually highlighted this information in the infobox.

Although many infoboxes appear to be similar, they are only semi-structured—few attributes have consistent value types across articles, infobox templates do not mandate which attributes must be included, and editors are allowed to add article-specific attributes. Infobox-like tables are very common on the Web. Since it is infeasible to incorporate every such source into structured knowledge bases like Freebase (Bollacker et al., 2008), we need techniques that do not rely on ontology or value type information.

Table 1: Example questions and answers with little lexical overlap from the INFOBOXQA dataset.

We focus on the answer selection problem, where the goal is to select the best answer out of a given candidate set of attribute–value pairs from infoboxes corresponding to a named entity in the question. Table 1 illustrates how questions from users may have little lexical overlap with the correct attribute–value pair. Answer selection is an important subtask in building an end-to-end question answering system.

Our work has two main contributions: (1) We compiled the INFOBOXQA dataset, a crowdsourced corpus of over 15,000 questions with answers from

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1930–1935,
Austin, Texas, November 1-5, 2016.

infoboxes in 150 articles in Wikipedia. Unlike existing answer selection datasets with answers from knowledge bases or long-form text, INFOBOXQA targets tabular data that is not augmented with value types or linked to an ontology. (2) We built a multichannel convolutional neural network (CNN) model that achieves the best results on INFOBOXQA compared to other neural network models in the answer selection task.

2 The INFOBOXQA dataset

Infoboxes are designed to be human-readable, not machine-interpretable. This allowed us to devise a crowdsourced assignment where we ask participants to generate questions from infoboxes. With little to no training, humans can form coherent questions out of terse, potentially ambiguous attribute–value pairs.

Wikipedia does not provide a way to access specific information segments; its API returns the entire article. We first worked on the data access problem and developed a system called WikipediaBase to robustly extract attribute–value pairs from infoboxes. Inspired by Omnibase (Katz et al., 2002), we organize infoboxes in an *object–attribute–value* data model, where an object (Lake Titicaca) has an attribute ("Surface area") with a value (8,372 km^2). Attributes are grouped by infobox class (for instance, the `film` class contains attributes like "Directed by" and "Cinematography"). The data model allowed us to extend WikipediaBase to information outside of infoboxes. We implemented methods for accessing images, categories, and article sections.

We then created a question-writing assignment where participants see infoboxes constructed using data from WikipediaBase. These infoboxes visually resembled the original ones in Wikipedia but were designed to control for variables. To prevent participants from only generating questions for attributes at the top of the table, the order of attributes was randomly shuffled. To ensure that the task could be completed in a reasonable amount of time, infoboxes were partitioned into assignments with up to ten attributes. A major goal of this data collection was to gather question paraphrases. For each attribute, we asked participants to write two questions. It is likely that at least one of the questions will use words from the attribute, but requiring an additional question encouraged them to think of alternative phrasings.

Total questions	15266
Total attributes	762
Average questions per attribute	20.0
Average answers per question	17.8

Table 2: Statistics of the INFOBOXQA dataset.

Every infobox in the experiment included a picture to help disambiguate the article. For instance, the cover image for "Grand Theft Auto III" (in concert with the values in the infobox) makes it reasonably clear that the assignment is about a video game and not a type of crime. We asked participants to include an explicit referent to the article title in each question (e.g., "Where was Albert Einstein born?" instead of "Where was he born?").

We analyzed the occurrences of infobox attributes in Wikipedia and found that they fit a rapidly-decaying exponential distribution with a long tail of attributes that occur in few articles. This distribution means that with a carefully chosen subset of articles we can achieve a large coverage of frequently appearing attributes. We developed a greedy approximation algorithm that selects a subset of infobox classes, picks a random sample of articles in the class, and chooses three representative articles that contain the largest quantity of attributes. 150 articles from 50 classes were selected, covering roughly half of common attributes found in Wikipedia.

The dataset contains example questions q_i, with an attribute–value pair (a_i, v_i) that answers the question. To generate negative examples for the answer selection task, we picked every other tuple $(a_j, v_j); \forall j \neq i$ from the infobox that contains the correct answer. If we know that a question asks about a specific entity, we must consider every attribute in the entity's infobox as a possible answer. In INFOBOXQA, candidate answers are just attribute–value pairs with no type information. Because of this, every attribute in the infobox is indistinguishable a priori, and is thus in the candidate set. Not having type information makes the task harder but also more realistic. Table 2 shows statistics of INFOBOXQA. The dataset is available online.[1]

3 Model description

Deep learning models for answer selection assume that there is a high similarity between question and answer representations (Yu et al., 2014). Instead of comparing them directly, the main intuition in our model is to use the *attribute* as an explicit bridge to facilitate the match between question and answer. Consider the question "Who replaced Dwight D. Eisenhower?", with answer "Succeeded by: John F. Kennedy". Clearly, the attribute "Succeeded by" plays a crucial role in indicating the match between the question and the answer. If the question and attribute have certain semantic similarities, and those similarities match the similarities of the answer and the attribute, then the answer must be a good match for the question.

We propose an architecture with three weight-sharing CNNs, each one processing either the question, the attribute, or the answer. We then use an element-wise product merge layer to compute similarities between the question and attribute, and between the attribute and answer. We refer to this model as Tri-CNN. Tri-CNN has five types of layers: an input layer, a convolution layer, a max-pooling layer, a merge layer, and a final multi-layer perceptron (MLP) scoring layer that solves the answer selection task. We now describe each layer.

Input layer. Let s_q be a matrix $\in \mathbb{R}^{|s_q| \times d}$, where row i is a d-dimensional word embedding of the i-th word in the question. Similarly, let s_{attr} and s_{ans} be word embedding matrices for the attribute and answer, respectively. s_q, s_{attr}, and s_{ans} are zero-padded to have the same length. We use pre-trained GloVe[2] embeddings with $d = 300$ (Pennington et al., 2014), which we keep adaptable during training.

Convolution layer. We use the multi-channel CNN architecture of (Kim, 2014) with three weight-sharing CNNs, one each for s_q, s_{attr}, and s_{ans}. Different lengths of token substrings (e.g., unigrams or bigrams) are used as channels. The CNNs share weights among the three inputs in a Siamese architecture (Bromley et al., 1993). Weight-sharing allows the model to compute the representation of one input influenced by the other inputs; i.e., the representation of the question is influenced by the representations of the attribute and answer.

[2]http://nlp.stanford.edu/projects/glove/

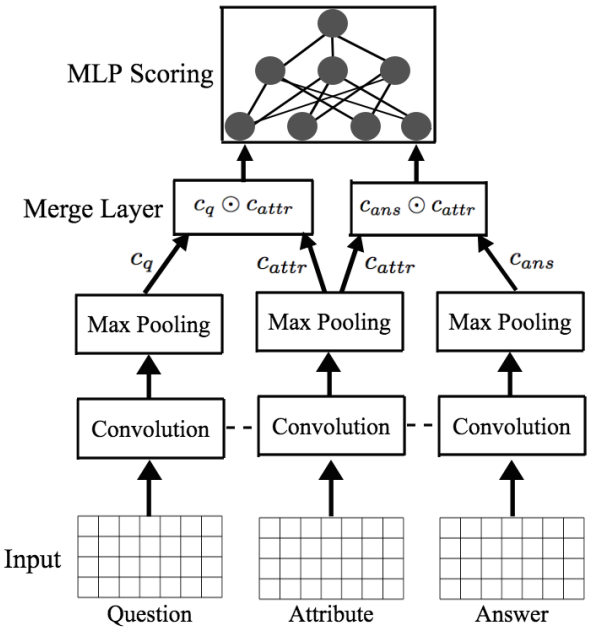

Figure 1: A schematic of the Tri-CNN model.

We describe the convolution layer with respect to the input s, which can stand for s_q, s_{attr}, or s_{ans}. For each channel $h \in [1...M]$, a filter $w \in \mathbb{R}^{h \times d}$ is applied to a sliding window of h rows of s to produce a feature map C. Formally, C is a matrix where:

$$C[i,:] = \tanh(w \cdot s[i...i+h-1,:] + b) \quad (1)$$

and $b \in \mathbb{R}^d$ is the bias. We use *wide convolution* to ensure that terminal and non-terminal words are considered equally when applying the filter w (Blunsom et al., 2014).

Max-pooling layer. Pooling is used to extract meaningful features from the output of convolution (Yin et al., 2015). We apply a max-pooling layer to the output of each channel h. The result is a vector $c_h \in \mathbb{R}^d$ where

$$c_h[i] = \max\{C[:,i]\} \quad (2)$$

Max-pooling is applied to all M channels. The resulting vectors c_h for $h \in [1...M]$ are concatenated into a single vector c.

Merge layer. Our goal is to model the semantic similarities between the question and the attribute, and between the answer and the attribute. We compute the element-wise product of the feature vectors

generated by convolution and max-pooling as follows:

$$d_{q,attr} = c_q \odot c_{attr} \quad (3)$$

$$d_{ans,attr} = c_{ans} \odot c_{attr} \quad (4)$$

where $\odot$ is the element-wise product operator, such that d_{ij} is a vector. Each element in d_{ij} encodes a similarity in a single semantic aspect between two feature representations.

MLP scoring layer. We wish to compute a real-valued similarity between the distance vectors from the merge layer. Instead of directly computing this using, e.g., cosine similarity, we follow (Baudiš and Šedivỳ, 2016) and first project the two distance vectors into a shared embedding space. We compute element-wise sums and products of the embeddings, which are then input to a two-layer perceptron.

4 Experiments

We implemented Tri-CNN in the `dataset-sts`[3] framework for semantic text similarity, built on top of the Keras deep learning library (Chollet, 2015). The framework aims to unify various sentence matching tasks, including answer selection, and provides implementations for variants of sentence-matching models that achieve state-of-the-art results on the TREC answer selection dataset (Wang et al., 2007). We evaluated the performance of various models in `dataset-sts` against INFOBOXQA for the task of answer selection. We report the average and the standard deviation for mean average precision (MAP) and mean reciprocal rank (MRR) from five-fold cross validation. We used 10% of the training set for validation.

In answer selection, a model learns a function to score candidate answers; the set of candidate answers is already given. Entity linking is needed to generate candidate answers and is often treated as a separate module. For INFOBOXQA, we asked humans to generate questions from pre-specified infoboxes. Given this setup, we already know which entity the question refers to; we also know that the question is answerable by the infobox. Entity linking was therefore out of scope in our experiments. By effectively asking humans to identify the named entity, our evaluation results are not affected by noise caused by a faulty entity linking strategy.

Table 3: Results of five-fold cross validation. Our Tri-CNN model achieves the best results in MAP and MRR.

4.1 Benchmarks

We compare against TF-IDF and BM25 (Robertson et al., 1995), two models from the information retrieval literature that calculate weighted measures of word co-occurrence between the question and answer. We also experiment with various neural network sentence matching models. AVG is a baseline model that computes averages of unigram word embeddings. CNN is the model most similar to Tri-CNN, with two CNNs in a Siamese architecture, one for the question and one for the answer. Max-pooling is computed on the output of convolution, and then fed to the output layer directly. RNN computes summary embeddings of the question and answer using bidirectional GRUs (Cho et al., 2014). ATTN1511 feeds the outputs of the bi-GRU into the convolution layer. It implements an asymmetric attention mechanism as in (Tan et al., 2015), where the output of convolution and max-pooling of the question is used to re-weight the input to convolution of the answer. The convolution weights are not shared. For these neural architectures, we use the same MLP scoring layer used in Tri-CNN as the output layer and train using bipartite RankNet loss (Burges et al., 2005).

4.2 Results

Table 3 summarizes the results of experiments on INFOBOXQA. The performance of the baselines indicates that unigram bag-of-words models are not sufficiently expressive for matching; Tri-CNN makes use of larger semantic units through its multiple channels. The attention mechanism and the combination of an RNN and CNN in ATTN1511 achieves better results than RNN, but still performs

slightly worse than the CNN model with weight-sharing. The Siamese architecture allows an input's representation to be influenced by the other inputs. The convolution feature maps are thus encoded in a comparable scheme that is more amenable to a matching task. Our Tri-CNN model built on top of this weight-sharing architecture achieves the best performance. Tri-CNN computes the match by comparing the similarities between question–attribute and answer–attribute, which leads to improved results over models that compare the question and answer directly.

5 Related work

Deep learning approaches to answer selection have been successful on the standard TREC dataset and the more recent WIKIQA corpus (Yang et al., 2015). Models like (Feng et al., 2015) and (Wang and Nyberg, 2015) generate feature representations of questions and answers using neural networks, computing the similarity of these representations to select an answer. Recently, attention mechanisms to influence the calculation of the representation (Tan et al., 2015) or to re-weight feature maps before matching (Santos et al., 2016) have achieved good results. Our work differs from past approaches in that we use the attribute as an additional input to the matching task. Other approaches to question answering over structured knowledge bases focus on mapping questions into executable database queries (Berant et al., 2013) or traversing embedded sub-graphs in vector space (Bordes et al., 2014).

6 Conclusion

We presented an approach to answering questions from infoboxes in Wikipedia. We first compiled the INFOBOXQA dataset, a large and varied corpus of interesting questions from infoboxes. We then trained a convolutional neural network model on this dataset that uses the infobox attribute as a bridge in matching the question to the answer. Our Tri-CNN model achieved the best results when compared to recent CNN and RNN-based architectures. We plan to test our model's ability to generalize to other types of infobox-like tables on the Web. We expect our methods to achieve good results for sources such as product descriptions on shopping websites.

Abstract

In timeline extraction the goal is to order all the events in which a target entity is involved in a timeline. Due to the lack of explicitly annotated data, previous work is primarily rule-based and uses pre-trained temporal linking systems. In this work, we propose a distantly supervised approach by heuristically aligning timelines with documents. The noisy training data created allows us to learn models that anchor events to temporal expressions and entities; during testing, the predictions of these models are combined to produce the timeline. Furthermore, we show how to improve performance using joint inference. In experiments in the SemEval-2015 TimeLine task we show that our distantly supervised approach matches the state-of-the-art performance while joint inference further improves on it by 3.2 F-score points.

1 Introduction

Temporal information extraction focuses on extracting relations and events along with the time when they were true or happened. In this work we focus on timeline extraction, following the recent SemEval TimeLine shared task (Minard et al., 2015). The aim of the task is to extract timelines from multiple documents consisting of events in which a given target entity is the main participant. An example timeline for the entity *Steve Jobs* extracted from 4 documents is given in Fig.1.

The development data provided by the TimeLine shared task does not contain annotations for the various intermediate processing stages needed, only a set of documents with annotated event mentions (input) and the timelines extracted for a few target entities (output). No training data was provided, thus participating systems used rules combined with temporal linking systems trained on related tasks in order to anchor events to temporal expressions and entities to construct the timelines.

We propose a new approach to timeline extraction that uses the development data provided as distant supervision to generate noisy training data (Craven and Kumlien, 1999; Mintz et al., 2009). More specifically, we heuristically align the target entity and the timestamps from the timelines with automatically recognized entities and temporal expressions in the documents. This noisy labeled data set allows us to learn models for the subtasks of anchoring events to temporal expressions and to entities, without requiring training models on additional data. Also, we improve the performance using joint inference for both anchoring subtasks. In our experiments, we show that our distantly supervised approach matches the state-of-the-art performance while joint inference further improves on it by 3.2 F-score points. Our code is publicly available at `http://github.com/savac/timeline`.

2 Timeline extraction

The task of timeline extraction given a target entity and a set of documents can be decomposed as follows. The initial stages are event mention extraction, target entity recognition, and temporal expression identification and resolution. The next stages are anchoring event mentions to target entities and temporal expressions. The final stages are event corefer-

Figure 1: Example timeline for target entity *Steve Jobs*. The input to the system is the documents annotated with event mentions annotations and their Document Creation Time (DCT). The event mentions appearing in the timeline are identified by their document id-sentence index. The annotations for the target entities and temporal expression mentions need to be done by the system.

ence resolution and ordering of the events in a timeline, which rely largely on their anchoring to temporal expressions. The TimeLine shared task had two tracks, A and B, the only difference being that in Track B the event mentions are provided in the input. We consider this track in this paper and focus on learning the anchoring of events to temporal expressions and entities.

The development data provided in the context of the shared task consisted of documents related to *Apple* and gold timelines for six target entities. Evaluation was performed by extracting timelines from three document sets, each related to *Airbus*, *GM* and *Stock market* respectively. We used the official evaluation which is based on the metric introduced by UzZaman and Allen (2011) which assesses a predicted timeline versus the gold standard one using precision, recall and F-score over binary temporal relations between the events.

3 Distant supervision

In order to generate training data for anchoring event mentions to target entities and temporal expressions via distant supervision, we first need to identify them. For entity recognition we use approximate string matching combined with the Stanford Coreference Resolution System (Lee et al., 2013). For temporal expression identification and resolution to absolute timestamps we use the UWTime temporal parser (Lee et al., 2014).

Next we generate labeled instances as follows. For anchoring events to entities, we consider for each event mention the correct entity mention to be the nearest mention of the target entity in the same sentence, and all others to be incorrect. Similarly, for anchoring events to timestamps, we consider for each event mention the correct temporal expression to be the nearest temporal expression that exactly matches the timestamp according to the timeline (but not necessarily in the same sentence), and all others to be incorrect. The datasets generated will be noisy since correct anchors may be entity mentions and temporal expressions that are not the nearest ones. Further noise is expected due to errors in the entity recognition and temporal expression identification and resolution stages.

Features	type
Measure distance in tokens between event and target entity mentions	local

4 Event anchoring

After generating training data for anchoring event mentions to target entities and to temporal expressions with distant supervision, we now proceed to developing linear models for each of these tasks.

4.1 Classification

Using distant supervision we obtained examples of correct and incorrect anchoring of event mentions to entities and temporal expressions. Thus we learn for each of the two tasks a binary linear classifier of the form:

$$score(x, y, \mathbf{w}) = \mathbf{w} \cdot \phi(x, y) \quad (1)$$

where x is an event mention, y is the anchor (either the target entity or the temporal expression) and $\mathbf{w}$ are the parameters to be learned. The features extracted by ϕ represent various distance measures and syntactic dependencies between the event mention and the anchor obtained using Stanford CoreNLP (Manning et al., 2014). The temporal expression anchoring model also uses a few feature templates that depend on the timestamp of the temporal expression. The full list of features extracted by ϕ are denoted as local in Tables 1 and 2.

4.2 Alignment

The classification approach described is limited to anchoring each event mention to an entity or a temporal expression in isolation. However it would be preferable to infer the decisions for each task jointly at the document level and take into account the dependencies in anchoring different events, e.g. that consecutive events in text are likely to be anchored to the same entity, as shown in Figure 2, or to the same temporal expression. Capturing such dependencies can be crucial when the correct anchor is not explicitly signalled in the text but can be inferred considering other relations and/or their ordering in text (Derczynski, 2013).

Defining our joint model formally, let $\mathbf{x}$ be a vector containing all event mentions in a document and $\mathbf{y}$ be the vector of all anchors (target entity mentions or temporal expressions) in the same document. The order of the events in $\mathbf{x}$ is as they appear in the document. Let $\mathbf{z}$ be a vector of the same length as $\mathbf{x}$ that defines the alignment between $\mathbf{x}$ and $\mathbf{y}$ by containing pointers to elements in $\mathbf{y}$, thus allowing for multiple events to share the same anchor. The scoring function is defined as

$$score(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}) = \mathbf{w} \cdot \Phi(\mathbf{x}, \mathbf{y}, \mathbf{z}) \quad (2)$$

where the global feature function Φ, in addition to the features returned by the local scoring function (Eq. 1), also returns features taking into account anchoring predictions across the document. Apart from features encoding subsequences of anchoring

Documents:

DocId: 17036, DCT: 2010-07-17, Sentence: 9,10,11:

Jobs[Steve Jobs] *also said that those who had already purchased a bumper will receive a full refund for the accessory. For consumers still dissatisfied with iPhone 4*[iPhone 4]*, Jobs*[Steve Jobs] *said that the phones can be returned for a refund as well. Jobs*[Steve Jobs] *acknowledged that "a very small percentage of users" were experiencing antenna issues, but dismissed the existence of an "Antennagate," saying that similar problems plague all cellular phones and that the iPhone*[iPhone 4] *issue "has been blown so out of proportion that it is incredible."*

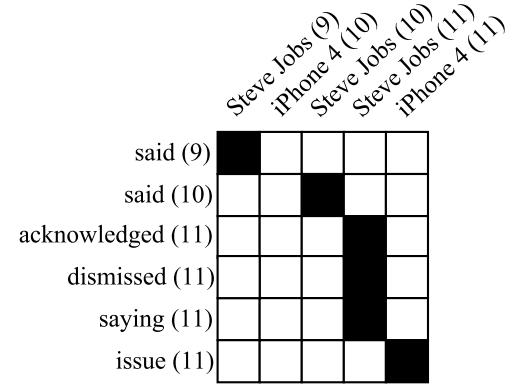

Figure 2: The correct alignment of events and target entity mentions is shown with the numbers in brackets denoting the index of the sentence in which the mention is found. The consecutive events acknowledged, dismissed and saying are anchored to entity Steve Jobs that was only mentioned once in the beginning of the sentence.

predictions, it also makes possible to make them dependent on the events, e.g. a binary indicator encoding whether two consecutive events with the same stem share the same anchor or not. The full list of local and global features extracted by Φ are presented in Tables 1 and 2. Predicting with the scoring function in Eq.2 amounts to finding the anchoring sequence vector $\mathbf{z}$ that maximizes it. To be able to perform exact inference efficiently, we impose a first order Markov assumption and use the Viterbi algorithm (Viterbi, 1967). Similar approaches have been successful in word alignment for machine translation (Blunsom and Cohn, 2006).

4.3 Post-processing

During testing, we need to construct the timeline for each target entity using the events that were predicted to be anchored to it and the timestamps of the temporal expressions each event was anchored to. Thus, we need to perform two additional tasks, event coreference and ordering. For the former we define a simple heuristic by which if two mentions have the same stems and timestamps then they refer to the same event. The only exception is that if two mentions represent communication events (*said*, *announced* etc.), then they are resolved to different events when in the same document. We finally order the events according to their timestamp.

5 Results

We evaluate our system using the setup provided by the TimeLine task ensuring that the training and validation are performed only using the development data i.e. the *Apple* collection. All linear models were trained with the perceptron update rule (Pedregosa et al., 2011). We tuned the number of perceptron iterations by performing cross-validation using the development data by holding out the timeline for one target entity and training on the timelines for the remaining ones.

In Table 3 we compare the binary classification model (Our_System_Binary) against the alignment model (Our_System_Alignment) and show that the latter outperforms the former by a margin of 3.2 points in F-score, achieving a micro F_1-score of 28.58 across the three test corpora, thus confirming the benefits of joint inference. The only corpus in which joint inference did not help was *Stock* which has on average shorter event chains per document (Minard et al., 2015) and thus renders joint anchoring less likely to be useful.

We now compare our approach to the two participants in the TimeLine shared task with two runs each. The best-performing GPLSIUA team (Navarro and Saquete, 2015) used the TIPSem tool developed by Llorens et al. (2010) for temporal relation processing which extracts events and temporal expressions and uses a Conditional Random Field model to anchor them against each other. However, TIPSem only considers anchoring of events to temporal expressions that are in the same sentence. GPLSIUA also used the semantic role labeler from SENNA (Collobert et al., 2011) and OpenNER and anchored entities to events using a rule-based approach. The HeidelToul team (Moulahi et al., 2015) used HeidelTime (Strötgen et al., 2013) to identify and resolve temporal expressions and de-

System	Airbus F_1	GM F_1	Stock F_1	Total P	Total R	Total F_1

Table 3: Results for our system and other participants in the SemEval 2015 Task 4: TimeLine.

veloped a target entity mention identification tool similar to ours using Stanford CoreNLP (Manning et al., 2014). However, they rely on a rule-based approach for event anchoring. Our binary model matches the performance of the best system, and our alignment model exceeds it by 3.2 F_1-score points across, even though we do not use any off-the-shelf components developed for temporal relation extraction. Instead we rely on training data generated with distant supervision, and UWTime for temporal expression identification and resolution, for which the participants also used similar components.

6 Related work

In recent work, Laparra et al. (2015) also considered anchoring at the document-level in the context of the Track A of the TimeLine shared task, however they developed a rule-based approach. The structure features used in our joint inference approach encode similar intuitions, but we are learning model weights using distant supervision so that we can combine them more flexibly. And even though the noise in the trainng data generated with distant supervision is a concern, manual annotation of temporal relations is known to have low inter-annotator agreement rates[1] and thus also likely to be noisy.

Prior to the TimeLine shared task, TempEval (Verhagen et al., 2007) was the original task that focused on categorising the relations between events, temporal expressions and Document Creation Time using the the TimeML annotation language. The task classified only the relations between mentions in the same or consecutive sentences. The two following tasks, TempEval-2 (Verhagen et al., 2010) and TempEval-3 (UzZaman et al., 2013), added tasks for event and temporal expression identification as well as an end-to-end temporal relation processing task that was performed on raw text.

Beyond TempEval, McClosky and Manning (2012) used distant supervision in order to learn how to extract the temporal bounds for events in the context of the TAC temporal knowledge base population task (Ji et al., 2011). However they focus on learning real-world event ordering constraints (e.g. people go to school before university) instead of how events are reported in text.

7 Conclusions

In this paper we proposed a timeline extraction approach in which we generate noisy training data for anchoring events to entities and temporal expressions using distant supervision. By learning a binary classifier we match the state-of-the-art F_1-score for the Track B of the TimeLine shared task. We further improve this result by 3.2 F_1-score points using joint inference.

Abstract

We propose an algorithm that combines supervised and unsupervised methods to ensemble multiple systems for two popular Knowledge Base Population (KBP) tasks, Cold Start Slot Filling (CSSF) and Tri-lingual Entity Discovery and Linking (TEDL). We demonstrate that it outperforms the best system for both tasks in the 2015 competition, several ensembling baselines, as well as a state-of-the-art stacking approach. The success of our technique on two different and challenging problems demonstrates the power and generality of our combined approach to ensembling.

1 Introduction

Ensembling multiple systems is a well known standard approach to improving accuracy in several machine learning applications (Dietterich, 2000). Ensembles have been applied to parsing (Henderson and Brill, 1999), word sense disambiguation (Pedersen, 2000), sentiment analysis (Whitehead and Yaeger, 2010) and information extraction (IE) (Florian et al., 2003; McClosky et al., 2012). Recently, using *stacking* (Wolpert, 1992) to ensemble systems was shown to give state-of-the-art results on slot-filling and entity linking for *Knowledge Base Population* (KBP) (Viswanathan et al., 2015; Rajani and Mooney, 2016). Stacking uses supervised learning to train a meta-classifier to combine multiple system outputs; therefore, it requires historical data on the performance of each system. Rajani and Mooney (2016) use data from the 2014 iteration of the KBP competition for training and then test on the data from the 2015 competition, therefore they can only ensemble the *shared systems* that participated in both years.

However, we would sometimes like to ensemble systems for which we have no historical performance data. For example, due to privacy, some companies may be unwilling to share their performance on arbitrary training sets. Simple methods such as voting permit "unsupervised" ensembling, and several more sophisticated methods have also been developed for this scenario (Wang et al., 2013). However, such methods fail to exploit supervision for those systems for which we *do* have training data. Therefore, we present an approach that utilizes supervised *and* unsupervised ensembling to exploit the advantages of both. We first use unsupervised ensembling to combine systems without training data, and then use stacking to combine this ensembled system with other systems with available training data.

Using this new approach, we demonstrate new state-of-the-art results on two NIST KBP challenge tasks: *Cold Start Slot-Filling* (CSSF)[1] and the *Trilingual Entity Discovery and Linking* (TEDL) (Ji et al., 2015). Our approach outperforms the best system as well as other state-of-the-art ensembling methods on both tasks in the most recent 2015 competition. There is one previous work on ensembling supervised and unsupervised models using graph-based consensus maximization (Gao et al., 2009), however we show that it does not do as well as our stacking method.

Austin, Texas, November 1-5, 2016.

2 Overview of KBP Tasks

2.1 Cold Start Slot Filling (CSSF)

The goal of CSSF is to collect information (fills) about specific attributes (slots) for a set of entities (queries) from a given corpus. The query entities can be a person, organization, or geo-political entity (PER/ORG/GPE). The input is a set of queries along with a text corpus in which to look for information. The output is a set of slot fills for each query. Systems must also provide *provenance* in the form of *docid:startoffset-endoffset*, where *docid* specifies a source document and the offsets demarcate the text in this document supporting the filler. Systems may also provide a confidence score to indicate their certainty in the extracted information.

2.2 Tri-lingual Entity Discovery and Linking (TEDL)

The first step in the TEDL task is to discover all entity mentions in a corpus with English, Spanish and Chinese documents. The entities can be a person, organization or geo-political entity (PER/ORG/GPE) and in 2015 two more entity types were introduced – facility and location (FAC/LOC). The extracted mentions are then linked to an existing English KB (a version of FreeBase) entity via its ID. If there is no KB entry for an entity, systems are expected to cluster all the mentions for that entity using a NIL ID. The output for the task is a set of extracted mentions, each with a string, its provenance in the corpus, and a corresponding KB ID if the system could successfully link the mention, or else a mention cluster with a NIL ID. Systems can also provide a confidence score for each mention.

3 Ensembling Algorithm

Figure 1 illustrates our system which trains a final meta-classifier for combining multiple systems using confidence scores and other auxiliary features depending on the task.

3.1 Supervised Ensembling Approach

For the KBP systems that are common between years, we use the stacking method of Viswanathan et al. (2015) for these shared systems.

The meta-classifier makes a binary decision for each distinct output represented as a *key-value* pair.

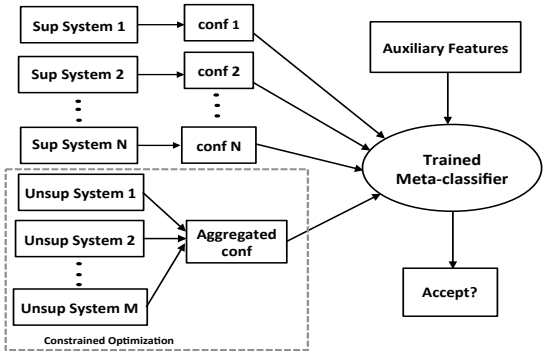

Figure 1: Illustration of our approach to combine supervised and unsupervised ensembles.

The function of the *key* is to provide a handle for aggregating outputs that are common across systems. For the CSSF task, the *key* for ensembling multiple systems is a query along with a slot type, for example, per:age of "Barack Obama" and the *value* is a computed *slot fill*. For TEDL, the key is the *KB (or NIL) ID* and the value is a *mention*, that is a specific reference to an entity in the text. The top half of Figure 1 illustrates ensembling multiple systems with historical training data using a supervised approach.

3.2 Unsupervised Ensembling Approach

Only 38 of the 70 systems that participated in CSSF 2015 also participated in 2014, and only 24 of the 34 systems that participated in TEDL 2015 also participated in 2014 EDL. Therefore, many KBP systems in 2015 were new and did not have past training data. In fact, some of the new systems performed better than the shared systems, for example the *hltcoe* system did not participate in 2014 but was ranked 4^{th} in the 2015 TEDL task (Ji et al., 2015). Thus, for improving *recall* and performance in general, it is crucial to use systems without historical training data, which we call unsupervised systems. To achieve this end, we first ensemble such systems using an unsupervised technique. Frequently, the confidence scores provided by systems are not well-calibrated probabilities. So in order to calibrate the confidence scores across unsupervised systems, we use the constrained optimization approach proposed by Wang et al. (2013). The idea is to aggregate the raw confidence values produced by individual KBP systems,

to arrive at a single aggregated confidence value for each *key-value* pair. The constraints ensure that the aggregated confidence score is close to the raw score as well as proportional to the agreement among systems on a value for a given key. Thus for a given key, if a system's value is also produced by multiple other systems, it would have a higher score than if it were not produced by any other system. The authors use the inverse ranking of the average precision previously achieved by individual systems as the weights in their algorithm. However since we use this approach for systems with no historical performance data, we use uniform weights across all unsupervised systems for both the tasks.

We use the slot type for the CSSF task and entity type for the TEDL task to define the constraints on the values. The output from the constrained optimization approach for both tasks is a set of key-values with aggregated confidence scores across all unsupervised systems which go directly into the stacker as shown in the lower half of Figure 1. Using the aggregation approach as opposed to directly using the raw confidence scores allows the classifier to meaningfully compare confidence scores across multiple systems although they are produced by very diverse systems.

Another unsupervised ensembling method we tried in place of the constrained optimization approach is the Bipartite Graph based Consensus Maximization (BGCM) approach of Gao et al. (2009). BGCM is presented as a way of combining supervised and unsupervised models, so we compare it to our stacking approach to combining supervised and unsupervised systems, as well as an alternative approach to ensembling *just* the unsupervised systems before passing their output to the stacker. BGCM performs an optimization over a bipartite graph of systems and outputs, where the objective function favors the smoothness of the label assignments over the graph, as well as penalizing deviations from the initial labeling provided by supervised models.

3.3 Combining Supervised and Unsupervised

We propose a novel approach to combine the aforementioned supervised and unsupervised methods using a stacked meta-classifier as the final arbiter for accepting a given key-value. The outputs from the supervised and unsupervised systems are fed into the stacker in a consistent format such that there is a unique input *key-value* pair. Most KBP teams submit multiple variations of their system. Before ensembling, we first combine multiple runs of the same team into one. Of the 38 CSSF systems from 10 teams for which we have 2014 data for training and the 32 systems from 13 teams that do not have training data, we combine the runs of each team into one to ensure diversity of the final ensemble. For the slot fills that were common between the runs of a given team, we compute an average confidence value, and then add any additional fills that are not common between runs. Thus, we obtained 10 systems (one for each team) for which we have supervised data for training stacking. Similarly, we combine the 24 TEDL systems from 6 teams that have 2014 training data and 10 systems from 4 teams that did not have training data into one per team. Thus using the notation in Figure 1, for TEDL, $N = 6$ and $M = 4$ while for CSSF, $N = 10$ and $M = 13$.

The unsupervised method produces aggregated, calibrated confidence scores which go directly into our final meta-classifier. We treat this combination as a single system called the *unsupervised ensemble*. We add the unsupervised ensemble as an additional system to the stacker, thus giving us a total of $N+1$, that is 11 CSSF and 7 TEDL systems. Once we have extracted the auxiliary features for each of the N supervised systems and the unsupervised ensemble for both years, we train the stacker on 2014 systems, and test on the 2015 systems. The unsupervised ensemble for each year is composed of different systems, but hopefully the stacker learns to combine a generic unsupervised ensemble with the supervised systems that are shared across years. This allows the stacker to arbitrate the final correctness of a key-value pair, combining systems for which we have no historical data with systems for which training data *is* available. To learn the meta-classifier, we use an L1-regularized SVM with a linear kernel (Fan et al., 2008) (other classifiers gave similar results).

3.4 Post-processing

Once we obtain the decisions on each key-value pair from the stacker, we perform some final post-processing. For CSSF, each list-valued slot fill that is classified as correct is included in the final output. For single-valued slot fills, if they are multiple fills

Table 2: Results on 2015 Tri-lingual Entity Discovery and Linking (TEDL) using official NIST scorer and CEAF metric

that were classified as correct for the same query and slot type, we include the fill with the highest meta-classifier confidence.

For TEDL, for each entity mention link that is classified as correct, if the link is a KB cluster ID then we include it in the final output, but if the link is a NIL cluster ID then we keep it aside until all mention links are processed. Thereafter, we resolve the NIL IDs across systems since NIL ID's for each system are unique. We merge NIL clusters across systems into one if there is at least one common entity mention among them.

4 Experimental Results

All results were obtained using the official NIST scorers after the competitions ended.[2] We compare to the purely supervised approach of Viswanathan et al. (2015) using shared systems between 2014 and 2015, and the constrained optimization approach of Wang et al. (2013) using all 2015 systems. We also compare to BGCM (Gao et al., 2009) in two ways. First, we use BGCM in place of the constrained optimization approach to ensemble unsupervised systems while keeping the rest of our pipeline the same. Secondly, we also compare to combining both supervised and unsupervised systems using BGCM instead of stacking. We also include an *"oracle"* voting ensembling baseline, which varies the threshold on the number of systems that must agree to identify an "oracle" threshold that results in the highest F1 score for 2015. We find that for CSSF a threshold of 3, and for TEDL a threshold of 4, gives us the best F1 score.

Tables 1 and 2 show CSSF and TEDL results. Our full system, which combines supervised and unsupervised ensembling performed the best on both tasks. TAC-KBP also includes the Slot Filler Validation (SFV) task[3] where the goal is to ensemble/filter outputs from multiple slot filling systems. The top ranked system in 2015 (Rodriguez et al., 2015) does substantially better than many of the other ensembling approaches, but it does not do as well as our best performing system. The purely

[3] http://www.nist.gov/tac/2015/KBP/SFValidation/index.html

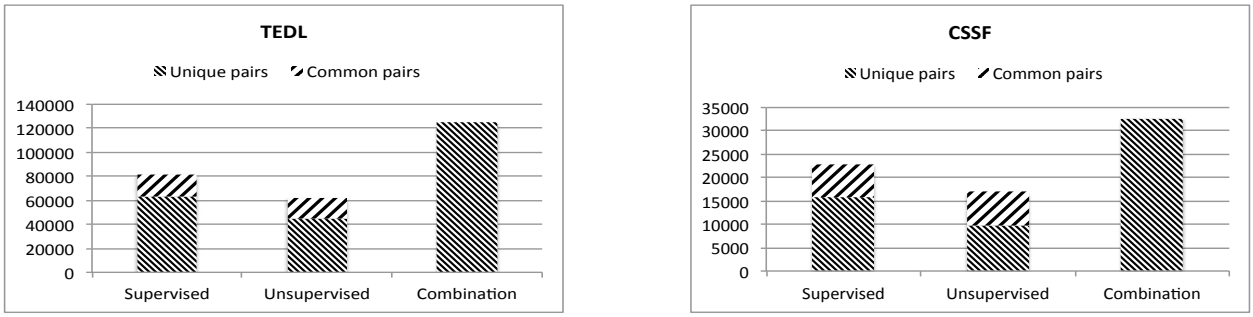

Figure 2: Total number of unique and common input pairs contributed by the supervised and unsupervised systems to the combination for the TEDL and CSSF tasks respectively.

supervised approach of Viswanathan et al. (2015) and the auxiliary features approach of Rajani and Mooney (2016) performs substantially worse, although still outperforming the top-ranked individual system in the 2015 competition. These approaches only use the common systems from 2014, thus ignoring approximately half of the systems. The approach of Wang et al. (2013) performs very poorly by itself; but when combined with stacking gives a boost to recall and thus the overall $F1$. Note that all our combined methods have a substantially higher recall. The oracle voting baseline also performs very poorly indicating that naive ensembling is not advantageous.

TEDL provides three different approaches to measuring accuracy: entity discovery, entity linking, and mention CEAF (Ji et al., 2015). CEAF finds the optimal alignment between system and gold standard clusters, then evaluates precision and recall micro-averaged. We obtained similar results on all three metrics and only include CEAF. The purely supervised stacking approach over shared systems does not do as well as any of our combined approaches even though it beats the best performing system (i.e. IBM) in the 2015 competition (Sil et al., 2015). The relative ranking of the approaches is similar to those obtained for CSSF, proving that our approach is very general and improves performance on two quite different and challenging problems.

Even though it is obvious that the boost in our recall was because of adding the unsupervised systems, it isn't clear how many new *key-value* pairs were generated by these systems. We thus evaluated the contribution of the systems ensembled using the supervised approach and those ensembled using the unsupervised approach, to the final combination for both the tasks. Figure 2 shows the number of unique as well as common *key-value* pairs that were contributed by each of the approaches. The unique pairs are those that were produced by one approach but not the other and the common pairs are those that were produced by both approaches. The number of unique pairs in the combination is the union of unique pairs in the supervised and unsupervised approaches. We found that approximately one third of the input pairs in the combination came from the unique pairs produced just by the unsupervised systems for both the TEDL and CSSF tasks. Only about 15% and 22% of the total input pairs were common between the two approaches for the TEDL and CSSF tasks respectively. Our findings highlight the importance of utilizing systems that do not have historical training data.

5 Conclusion

We presented results on two diverse KBP tasks, showing that a novel stacking-based approach to ensembling both supervised and unsupervised systems is very promising. The approach outperforms the top ranked systems from both 2015 competitions as well as several other ensembling methods, achieving a new state-of-the-art for both of these important, challenging tasks. We found that adding the unsupervised ensemble along with the shared systems specifically increased recall substantially.

Abstract

We present a neural network architecture to predict a point in color space from the sequence of characters in the color's name. Using large scale color–name pairs obtained from an online color design forum, we evaluate our model on a "color Turing test" and find that, given a name, the colors predicted by our model are preferred by annotators to color names created by humans. Our datasets and demo system are available online at http://colorlab.us.

1 Introduction

Color is a valuable vehicle for studying the association between words and their nonlinguistic referents. Perception of color has long been studied in psychology, and quantitative models linking physical stimuli and psychological perception have been in place since the 1920s (Broadbent, 2004). Although perceptually faithful color representations require only a few dimensions (§2), linguistic expressions of color often rely on association and figurative language. There are, for example, 34,000 examples of "blue" in our data. The varieties of blue range can be emotional, descriptive, metaphoric, literal, and whimsical. Consider these examples (best viewed in color): murkey blue, blueberry muffin, greeny blue, and jazzy blue.

This rich variety of descriptive names of colors provides an ideal way to study linguistic creativity, its variation, and an important aspect of visual understanding. This paper uses predictive modeling to explore the relationship between colors (represented in three dimensions) and casual, voluntary linguistic descriptions of them by users of a crafting and design website (§3).[1]

In this dataset's creative vocabulary, word-level representations are so sparse as to be useless, so we turn to models that build name representations out of *characters* (§4). We evaluate our model on a "color Turing test" and find that, given a name, it tends to generate a color that humans find matches the name better than the color that actually inspired the name. We also investigate the reverse mapping, from colors to names (§5). We compare a conditional LSTM language model used in caption generation (Karpathy and Fei-Fei, 2014) to a new latent-variable model, achieving a 10% perplexity reduction.

We expect such modeling to find purchase in computational creativity applications (Veale and Al-Najjar, 2015), design and marketing aids (Deng et al., 2010), and new methods for studying the interface between the human visual and linguistic systems (Marcus, 1991).

2 Color Spaces

In electronic displays and other products, colors are commonly represented in RGB space where each color is embedded in $\{0, \ldots, 255\}^3$, with coordinates corresponding to red, green, and blue levels. While convenient for digital processing, distances in this space are perceptually non-uniform. We instead use a different three-dimensional representation, *Lab*, which was originally designed so that Euclidean distances correlate with human-perceived differences (Hunter, 1958). *Lab* is also continu-

ous, making it more suitable for the gradient-based learning used in this paper. The transformation from RGB to *Lab* is nonlinear.

3 Task and Dataset

We consider the task of predicting a color in *Lab* space given its name. Our dataset is a collection of user-named colors downloaded from COLOURlovers,[1] a creative community where people create and share colors, palettes, and patterns. Our dataset contains 776,364 pairs with 581,483 unique names. Examples of the color/name pairs from COLOURlovers are the following: Sugar Hearts You, Vitamin C, Haunted milk.

We considered two held-out datasets from other sources; these do not overlap with the training data.
ggplot2: the 141 officially-named colors used in ggplot2, a common plotting package for the R programming language (e.g., MidnightBlue. MediumSeaGreen),[2]
Paint: The paint manufacturer Sherwin Williams has 7,750 named colors (e.g., Pompeii Red, Butter Up).[3]

4 Names to Colors

Our word-to-color model is used to predict a color in *Lab* space given the sequence of characters in a color's name, $\boldsymbol{c} = \langle c_1, c_2, \ldots, c_{|\boldsymbol{c}|} \rangle$, where each c_i is a character in a finite alphabet. Each character c_i is represented by learned vector embedding in $\mathbb{R}^{300}$. To build a color out of the sequence, we use an LSTM (Hochreiter and Schmidhuber, 1997) with 300 hidden units. The final hidden state is used as a vector representation $\mathbf{h} \in \mathbb{R}^{300}$ of the sequence. The associated color value in *Lab* space is then defined to be $\hat{\mathbf{y}} = \sigma(\mathbf{W}\mathbf{h} + \mathbf{b})$, where $\mathbf{W} \in \mathbb{R}^{3\times 300}$ and $\mathbf{b} \in \mathbb{R}^3$ transform $\mathbf{h}$.

This model instantiates the one proposed by Ling et al. (2015) for learning word embeddings built from representations of characters.

To learn the parameters of the model (i.e., the parameters of the LSTMs, the character embeddings, and $\mathbf{W}$ and $\mathbf{b}$), we use reference color labels $\mathbf{y}$ from our training set and minimize squared error, $||\mathbf{y} - \hat{\mathbf{y}}||^2$, averaged across the training set. Learning is accomplished using backpropagation and the Adam update rule (Kingma and Ba, 2014).

4.1 Evaluation

We evaluated our model in two ways. First, we computed mean-squared error on held-out data using several variants of our model. The baseline models are linear regression models, which predict a color from a bag of character unigrams and bigrams. We compare an RNN and LSTMs with one and two layers. Table 2 shows that the two-layer LSTM achieves lower error than the unigram and bigram baselines and an RNN. We see the same pattern of results on the out-of-domain test sets.

The Color Turing Test. Our second evaluation attempts to assess whether our model's associations are human-like. For this evaluation, we asked human judges to choose the color better described by a name from one of our test sets: our model's predicted color or the color in the data. For each dataset, we randomly selected 20 examples. 111 judges considered each instance.[4] Judges were presented instances in random order and forced to make a choice between the two and explicitly directed to

[2] http://sape.inf.usi.ch/quick-reference/ggplot2/colour

[3] http://bit.ly/PaintColorNames

[4] We excluded results from an additional 19 annotators who made more than one mistake in a color blindness test (Oliver, 1888).

Preference	Test	ggplot2	Paint
Actual color	43.2%	32.6%	31.0%
Predicted color	56.7%	67.3%	69.0%

Table 3: Summary of color Turing test results.

make an arbitrary choice if neither was better.[5] The test is shown at `http://colorlab.us/turk`.

Results are shown in Table 3; on the ggplot2 and Paint datasets, our prediction is preferred to the actual names in a majority of cases. The Test dataset from COLOURlovers is a little bit challenging, with more noisy and creative names; still, in the majority of cases, our prediction is preferred.

4.2 Visualization and Exploration

To better understand our model, we provide illustrations of its predictions on several kinds of inputs.

Character by character prediction. We consider how our model reads color names character by character. Fig. 1 shows some examples, such as *blue*, variously modified. The word *deep* starts dark brown, but eventually modifies *blue* to a dark blue. Our model also performs sensibly on colors named after things (*mint*, *cream*, *sand*).

D	A	M	G	R
De	Aq	Mi	Go	Ro
Dee	Aqu	Min	Gol	Ros
Deep	Aqua	Mint	Gold	Rosy
Deep	Aqua	MintC	Gold	Rosy
Deep B	Aqua B	MintCr	Gold S	Rosy P
Deep Bl	Aqua Bl	MintCre	Gold Sa	Rosy Pi
Deep Blu	Aqua Blu	MintCrea	Gold San	Rosy Pin
Deep Blue	Aqua Blue	MintCream	Gold Sand	Rosy Pink

Figure 1: Visualization of character-by-character prediction.

Genre and color. We can use our model to investigate how colors are evoked in text by predicting the colors of each word in a text. Fig. 3 shows a colored recipe. Noting that many words are rendered in neutral grays and tans, we investigated how our model colors words in three corpora: 3,300 English poems (1800–present), 256 recipes from the CURD dataset (Tasse and Smith, 2008),[6] and 6,000 beer reviews.[7] For each corpus, we examine the distribution of Euclidean distances of $\hat{\mathbf{y}}$ from the *Lab* representation of the "middle" color RGB (128, 128, 128). The Euclidean distances from the mean are measuring the variance of the color of words in a document. Fig. 2 shows these distributions; recipes and beer reviews are more "colorful" than poems, under our model's learned definition of color.

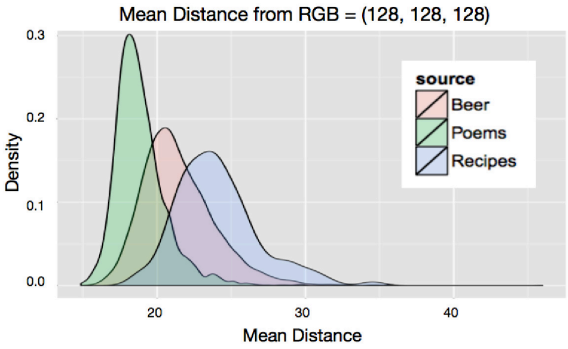

Figure 2: Distribution of Euclidean distances in *Lab* from estimated colors of words in each corpus to RGB (128, 128, 128).

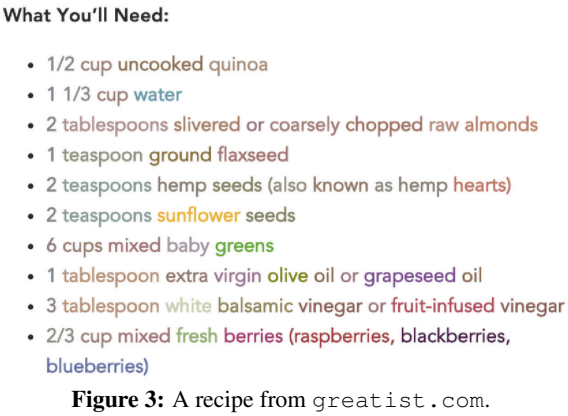

What You'll Need:

- 1/2 cup uncooked quinoa
- 1 1/3 cup water
- 2 tablespoons slivered or coarsely chopped raw almonds
- 1 teaspoon ground flaxseed
- 2 teaspoons hemp seeds (also known as hemp hearts)
- 2 teaspoons sunflower seeds
- 6 cups mixed baby greens
- 1 tablespoon extra virgin olive oil or grapeseed oil
- 3 tablespoon white balsamic vinegar or fruit-infused vinegar
- 2/3 cup mixed fresh berries (raspberries, blackberries, blueberries)

Figure 3: A recipe from `greatist.com`.

5 Generating Names from Colors

The first of our two color naming models generates character sequences conditioned on *Lab* color representations, following other sequence-to-sequence approaches (Sutskever et al., 2014; Karpathy and Fei-Fei, 2014). The transformation is as follows: First, a linear transformation maps the color vector into 300 dimensions, together comprising the initial

[5] A preliminary study that allowed a judge to say that there was no difference led to a similar result.

[6] `http://www.cs.cmu.edu/~ark/CURD/`

[7] `http://beeradvocate.com`

hidden and memory vectors. Next a character LSTM is iteratively applied to the hidden, memory, and next-character vectors, and the next character produced by applying affine and then softmax functions to the hidden vector. The model is trained to maximize conditional likelihood of each character given its history. We used 300 dimensions for character embeddings and recurrence weights. The output vocabulary size was 98 without lowercasing.

We also propose a model to capture variations in color description with latent variables by extending the variational autoencoder (Kingma and Welling, 2013) to a conditional model. We want to model the conditional probability of word $\mathbf{y}$ and latent variables $\mathbf{z}$ given color $\mathbf{x}$. The latent variable gives the model capacity to account for the complexity of the color–word mapping. Since $p(\mathbf{y}, \mathbf{z} \mid \mathbf{x}) = p(\mathbf{z})p(\mathbf{y} \mid \mathbf{x}, \mathbf{z})$, the variational objective is:

$$\begin{aligned}
&\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[-\log q_\phi(\mathbf{z} \mid \mathbf{x}) + \log p_\theta(\mathbf{y}, \mathbf{z} \mid \mathbf{x})] \\
&= \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[-\log q_\phi(\mathbf{z} \mid \mathbf{x}) + \log p_\theta(\mathbf{y} \mid \mathbf{x}, \mathbf{z})p(\mathbf{z})] \\
&\simeq -D_{KL}(q_\phi(\mathbf{z} \mid \mathbf{x}) \mid\mid p(\mathbf{z})) + \frac{1}{L}\sum_{l=1}^{L} \log p_\theta(\mathbf{y} \mid \mathbf{x}, \mathbf{z}^l)
\end{aligned}$$

The first term regularizes the shape of posterior, $q(\mathbf{z} \mid \mathbf{x})$, to be close to prior $p(\mathbf{z})$ where it is a Gaussian distribution, $p(\mathbf{z}) = \mathcal{N}(\mathbf{0}, \mathbf{I})$. The second term is the log likelihood of the character sequence conditioned on color values. To optimize θ and ϕ, we reparameterize the model, we write $\mathbf{z}$ in terms of a mean and variance and samples from a standard normal distribution, i.e., $\mathbf{z} = \mu + \sigma\epsilon$ with $\epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. We predict mean and log variance of the model with a multi-layer perceptron and initialize the decoder-LSTM with $\mathbf{h}_0 = \tanh(\mathbf{W}\mathbf{z} + \mathbf{b})$. We trained the model with mini-batch size 128 and Adam optimizer. The sample size L was set to 1.

Evaluation. We evaluated our models by estimating perplexity on the Test set (Table 1). Our baseline is a character-level unconditional LSTM language model. Conditioning on color improved per-character perplexity by 7% and the latent variable gave a further 3%; see Table 4.

A second dataset we evaluate on is the Munroe Color Corpus[8] which contains 2,176,417 color description for 829 words (i.e., single words have multiple color descriptions). Monroe et al. (2016) have developed word-based (rather character-based) recurrent neural network model.

[8] https://blog.xkcd.com/2010/05/03/color-survey-results/

Model	Perplexity
LSTM-LM	5.9
VAE	5.9
color-conditioned LSTM-LM	5.5
color-conditioned VAE	**5.3**

Table 4: Comparison of language models.

Our character-based model with 1024 hidden units achieved 12.48 per-description perplexity, marginally better than 12.58 obtained with a word-based neural network model reported in that work. Thus, we see that modeling color names as sequences of characters is wholly feasible. However, since the corpus only contains color description for 829 words, the model trained on the Munroe Color Corpus does not provide suitable supervision for evaluation on our more lexically diverse dataset.

6 Related Work and Discussion

Color is one of the lowest-level visual signals playing an important role in cognition (Wurm et al., 1993) and behavior (Maier et al., 2008; Lichtenfeld et al., 2009). It plays a role in human object recognition: to name an object, we first need to encode visual information such as shape and surface information including color and texture. Given a visual encoding, we search our memory for a structural, semantic and phonological description (Humphreys et al., 1999). Adding color information to shape significantly improves naming accuracy and speeds correct response times (Rossion et al., 2004).

Colors and their names have some association in our cognition. The Stroop (1935) effect is a well-known example showing interference of colors and color terms: when we see a color term printed in a different color—blue—it takes us longer to name the word, and we are more prone to naming errors than when the ink matches—blue (De Houwer, 2003).

Recent evidence suggests that colors and words are associated in the brain. The brain uses different regions to perceive various modalities, but processing a color word activates the same brain region as the color it denotes (del Prado Martín et al., 2006; Simmons et al., 2007).

Closer to NLP, the relationship between visual

stimuli and their linguistic descriptions by humans has been explored extensively through automatic text generation from images (Kiros et al., 2014; Karpathy and Fei-Fei, 2014; Xu et al., 2015). Color association with word semantics has also been investigated in several previous papers (Mohammad, 2011; Heer and Stone, 2012; Andreas and Klein, 2014; McMahan and Stone, 2015).

7 Conclusion

In this paper, we introduced a computational model to predict a point in color space from the sequence of characters in the color's name. Using a large set of color–name pairs obtained from a color design forum, we evaluate our model on a "color Turing test" and find that, given a name, the colors predicted by our model are preferred by annotators to color names created by humans. We also investigate the reverse mapping, from colors to names. We compare a conditional LSTM language model to a new latent-variable model, achieving a 10% perplexity reduction.

Acknowledgments

We thank Lucas Beyer for very helpful comments and discussions, and we also appreciate all the participants of our color Turing test.

Analyzing the Behavior of Visual Question Answering Models

Aishwarya Agrawal[*], **Dhruv Batra**[†,*], **Devi Parikh**[†,*]
[*]Virginia Tech [†]Georgia Institute of Technology
{aish, dbatra, parikh}@vt.edu

Abstract

Recently, a number of deep-learning based models have been proposed for the task of Visual Question Answering (VQA). The performance of most models is clustered around 60-70%. In this paper we propose systematic methods to analyze the behavior of these models as a first step towards recognizing their strengths and weaknesses, and identifying the most fruitful directions for progress. We analyze two models, one each from two major classes of VQA models – with-attention and without-attention and show the similarities and differences in the behavior of these models. We also analyze the winning entry of the VQA Challenge 2016.

Our behavior analysis reveals that despite recent progress, today's VQA models are "myopic" (tend to fail on sufficiently novel instances), often "jump to conclusions" (converge on a predicted answer after 'listening' to just half the question), and are "stubborn" (do not change their answers across images).

1 Introduction

Visual Question Answering (VQA) is a recently-introduced (Antol et al., 2015; Geman et al., 2014; Malinowski and Fritz, 2014) problem where given an image and a natural language question (e.g., "What kind of store is this?", "How many people are waiting in the queue?"), the task is to automatically produce an accurate natural language answer ("bakery", "5"). A flurry of recent deep-learning based models have been proposed for VQA (Antol et al., 2015; Chen et al., 2015; Yang et al., 2016; Xu and Saenko, 2016; Jiang et al., 2015; Andreas et al., 2016a; Wang et al., 2015; Kafle and Kanan, 2016; Lu et al., 2016; Andreas et al., 2016b; Shih et al., 2016; Kim et al., 2016; Fukui et al., 2016; Noh and Han, 2016; Ilievski et al., 2016; Wu et al., 2016; Xiong et al., 2016; Zhou et al., 2015; Saito et al., 2016). Curiously, the performance of most methods is clustered around 60-70% (compared to human performance of 83% on open-ended task and 91% on multiple-choice task) with a mere 5% gap between the top-9 entries on the VQA Challenge 2016.[1] It seems clear that as a first step to understand these models, to meaningfully compare strengths and weaknesses of different models, to develop insights into their failure modes, and to identify the most fruitful directions for progress, it is crucial to develop techniques to understand the behavior of VQA models.

In this paper, we develop novel techniques to characterize the behavior of VQA models. As concrete instantiations, we analyze two VQA models (Lu et al., 2015; Lu et al., 2016), one each from two major classes of VQA models – with-attention and without-attention. We also analyze the winning entry (Fukui et al., 2016) of the VQA Challenge 2016.

2 Related Work

Our work is inspired by previous works that diagnose the failure modes of models for different tasks. (Karpathy et al., 2016) constructed a series of oracles to measure the performance of a character level

[1] http://www.visualqa.org/challenge.html

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1955–1960,
Austin, Texas, November 1-5, 2016.

language model. (Hoiem et al., 2012) provided analysis tools to facilitate detailed and meaningful investigation of object detector performance. This paper aims to perform behavior analyses as a first step towards diagnosing errors for VQA.

(Yang et al., 2016) categorize the errors made by their VQA model into four categories – model focuses attention on incorrect regions, model focuses attention on appropriate regions but predicts incorrect answers, predicted answers are different from labels but might be acceptable, labels are wrong. While these are coarse but useful failure modes, we are interested in understanding the behavior of VQA models along specific dimensions – whether they generalize to novel instances, whether they listen to the entire question, whether they look at the image.

3 Behavior Analyses

We analyze the behavior of VQA models along the following three dimensions –

Generalization to novel instances: We investigate whether the test instances that are incorrectly answered are the ones that are "novel" i.e., not similar to training instances. The novelty of the test instances may be in two ways – 1) the test question-image (QI) pair is "novel", i.e., too different from training QI pairs; and 2) the test QI pair is "familiar", but the answer required at test time is "novel", i.e., answers seen during training are different from what needs to be produced for the test QI pairs.

Complete question understanding: To investigate whether a VQA model is understanding the input question or not, we analyze if the model 'listens' to only first few words of the question or the entire question, if it 'listens' to only question (wh) words and nouns or all the words in the question.

Complete image understanding: The absence of a large gap between performance of language-alone and language + vision VQA models (Antol et al., 2015) provides evidence that current VQA models seem to be heavily reliant on the language model, perhaps not really understanding the image. In order to analyze this behavior, we investigate whether the predictions of the model change across images for a given question.

We present our behavioral analyses on the VQA dataset (Antol et al., 2015). VQA is a large-scale free-form natural-language dataset containing $\sim$0.25M images, $\sim$0.76M questions, and $\sim$10M answers, with open-ended and multiple-choice modalities for answering the visual questions. All the experimental results are reported on the VQA validation set using the following models trained on the VQA training set for the open-ended task –

CNN + LSTM based model without-attention (CNN+LSTM): We use the best performing model of (Antol et al., 2015) (code provided by (Lu et al., 2015)), which achieves an accuracy of 54.13% on the VQA validation set. It is a two channel model – one channel processes the image (using Convolutional Neural Network (CNN) to extract image features) and the other channel processes the question (using Long Short-Term Memory (LSTM) recurrent neural network to obtain question embedding). The image and question features obtained from the two channels are combined and passed through a fully connected (FC) layer to obtain a softmax distribution over the space of answers.

CNN + LSTM based model with-attention (ATT): We use the top-entry on the VQA challenge leaderboard (as of June 03, 2016) (Lu et al., 2016), which achieves an accuracy of 57.02% on the VQA validation set.[2] This model jointly reasons about image and question attention, in a hierarchical fashion. The attended image and question features obtained from different levels of the hierarchy are combined and passed through a FC layer to obtain a softmax distribution over the space of answers.

VQA Challenge 2016 winning entry (MCB): This is the multimodal compact bilinear (mcb) pooling model from (Fukui et al., 2016) which won the real image track of the VQA Challenge 2016. This model achieves an accuracy of 60.36% on the VQA validation set.[3] In this model, multimodal compact bilinear pooling is used to predict attention over image features and also to combine the attended image features with the question features. These combined features are passed through a FC layer to obtain a softmax distribution over the space of answers.

3.1 Generalization to novel instances

Do VQA models make mistakes because test instances are too different from training ones? To analyze the first type of novelty (the test QI pair is novel), we measure the correlation between test accuracy and distance of test QI pairs from its k nearest neighbor (k-NN) training QI pairs. For each test QI pair we find its k-NNs in the training set and compute the average distance between the test QI pair and its k-NNs. The k-NNs are computed in the space of combined image + question embedding (just before passing through FC layer) for all the three models (using euclidean distance metric for the CNN+LSTM model and cosine distance metric for the ATT and MCB models).

The correlation between accuracy and average distance is significant (-0.41 at k=50[4] for the CNN+LSTM model and -0.42 at k=15[5] for the ATT model). A high negative correlation value tells that the model is less likely to predict correct answers for test QI pairs which are not very similar to training QI pairs, suggesting that the model is not very good at generalizing to novel test QI pairs. The correlation between accuracy and average distance is not significant for the MCB model (-0.14 at k=1[6]) suggesting that MCB is better at generalizing to novel test QI pairs.

We also found that 67.5% of mistakes made by the CNN+LSTM model *can be successfully predicted* by checking distance of test QI pair from its k-NN training QI pairs (66.7% for the ATT model, 55.08% for the MCB model). Thus, this analysis not only exposes a reason for mistakes made by VQA models, but also allows us to build human-like models that can predict their own oncoming failures, and potentially refuse to answer questions that are 'too different' from ones seen in past.

To analyze the second type of novelty (the answer required at test time is not familiar), we compute the correlation between test accuracy and the average distance of the test ground truth (GT) answer with GT answers of its k-NN training QI pairs. The distance between answers is computed in the space of average Word2Vec (Mikolov et al., 2013) vectors of answers. This correlation turns out to be quite high (-0.62) for both CNN+LSTM and ATT models and significant (-0.47) for the MCB model. A high negative correlation value tells that the model tends to regurgitate answers seen during training.

Figure 1: Examples from test set where the CNN+LSTM model makes mistakes and their corresponding nearest neighbor training instances. See supplementary for more examples.

These distance features are also good at predicting failures – 74.19% of failures can be predicted by checking distance of test GT answer with GT answers of its k-NN training QI pairs for CNN+LSTM model (75.41% for the ATT model, 70.17% for the MCB model). Note that unlike the previous analysis, this analysis only explains failures but cannot be used to predict failures (since it uses GT labels). See Fig. 1 for qualitative examples.

From Fig. 1 (row1) we can see that the test QI pair is semantically quite different from its k-NN training QI pairs ({1st, 2nd, 3rd}-NN distances are {15.05, 15.13, 15.17}, which are higher than the corresponding distances averaged across all success cases: {8.74, 9.23, 9.50.}), explaining the mistake. Row2 shows an example where the model has seen the same question in the training set (test QI pair is semantically similar to training QI pairs) but, since it has not seen "green cone" for training instances (answers seen during training are different from what needs to be produced for the test QI pair), it is unable to answer the test QI pair correctly. This shows that current models lack compositionality: the ability to combine the concepts of "cone" and "green" (both of which have been seen in training set) to answer "green cone" for the test QI pair. This compositionality is desirable and central to intelligence.

[4] k=50 leads to highest correlation
[5] k=15 leads to highest correlation
[6] k=1 leads to highest correlation

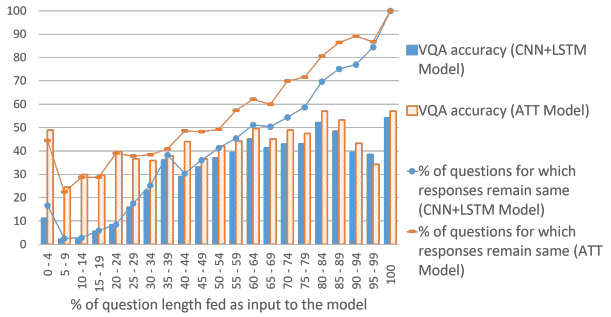

Figure 2: X-axis shows length of partial question (in %) fed as input. Y-axis shows percentage of questions for which responses of these partial questions are the same as full questions and VQA accuracy of partial questions.

3.2 Complete question understanding

We feed partial questions of increasing lengths (from 0-100% of question from left to right). We then compute what percentage of responses do not change when more and more words are fed.

Fig. 2 shows the test accuracy and percentage of questions for which responses remain same (compared to entire question) as a function of partial question length. We can see that for 40% of the questions, the CNN+LSTM model seems to have converged on a predicted answer after 'listening' to just half the question. This shows that the model is listening to first few words of the question more than the words towards the end. Also, the model has 68% of the final accuracy (54%) when making predictions based on half the original question. When making predictions just based on the image, the accuracy of the model is 24%. The ATT model seems to have converged on a predicted answer after listening to just half the question more often (49% of the time), achieving 74% of the final accuracy (57%). The MCB model converges on a predicted answer after listening to just half the question 45% of the time, achieving 67% of the final accuracy (60%). See Fig. 3 for qualitative examples.

We also analyze the change in responses of the model's predictions (see Fig. 4), when words of a particular part-of-the-speech (POS) tag are dropped from the question. The experimental results indicate that wh-words effect the model's decisions the most (most of the responses get changed on dropping these words from the question), and that pronouns effect the model's decisions the least.

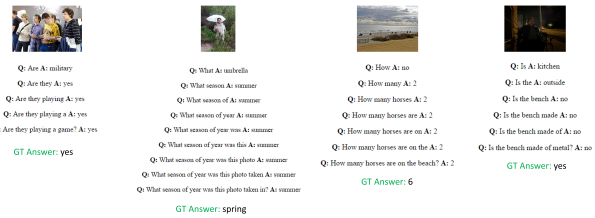

Figure 3: Examples where the CNN+LSTM model does not change its answer after first few question words. On doing so, it is correct for some cases (the extreme left example) and incorrect for other cases (the remaining three examples). See supplementary for more examples.

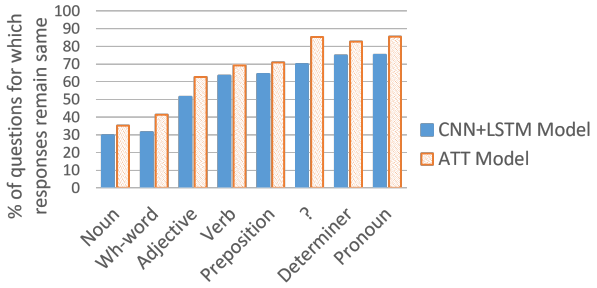

Figure 4: Percentage of questions for which responses remain same (compared to entire question) as a function of POS tags dropped from the question.

3.3 Complete image understanding

Does a VQA model really 'look' at the image? To analyze this, we compute the percentage of the time (say X) the response does not change across images (e.g.,, answer for all images is "2") for a given question (e.g., "How many zebras?") and plot histogram of X across questions (see Fig. 5). We do this analysis for questions occurring for atleast 25 images in the VQA validation set, resulting in total 263 questions. The cumulative plot indicates that for 56% questions, the CNN+LSTM model outputs the same answer for at least half the images. This is fairly high, suggesting that the model is picking the same answer no matter what the image is. Promisingly, the ATT and MCB models (that do not work with a holistic entire-image representation and purportedly pay attention to specific spatial regions in an image) produce the same response for at least half the images for fewer questions (42% for the ATT model, 40% for the MCB model).

Interestingly, the average accuracy (see the VQA accuracy plots in Fig. 5) for questions for which the models produce same response for $>$50% and $<$55% of the images is 56% for the CNN+LSTM

Figure 5: Histogram of percentage of images for which model produces same answer for a given question and its comparison with test accuracy. The cumulative plot shows the % of questions for which model produces same answer for *atleast* x % of images.

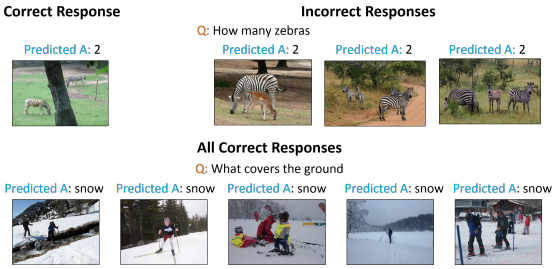

Figure 6: Examples where the predicted answers do not change across images for a given question. See supplementary for more examples.

model (60% for the ATT model, 73% for the MCB model) which is more than the respective average accuracy on the entire VQA validation set (54.13% for the CNN+LSTM model, 57.02% for the ATT model, 60.36% for the MCB model). Thus, producing the same response across images seems to be statistically favorable. Fig. 6 shows examples where the CNN+LSTM model predicts the same response across images for a given question. The first row shows examples where the model makes errors on several images by predicting the same answer for all images. The second row shows examples where the model is always correct even if it predicts the same answer across images. This is so because questions such as *"What covers the ground?"* are asked for an image in the VQA dataset only when ground is covered with snow (because subjects were looking at the image while asking questions about it). Thus, this analysis exposes label biases in the dataset. Label biases (in particular, for "yes/no" questions) have also been reported in (Zhang et al., 2016).

4 Conclusion

We develop novel techniques to characterize the behavior of VQA models, as a first step towards understanding these models, meaningfully comparing the strengths and weaknesses of different models, developing insights into their failure modes, and identifying the most fruitful directions for progress. Our behavior analysis reveals that despite recent progress, today's VQA models are "myopic" (tend to fail on sufficiently novel instances), often "jump to conclusions" (converge on a predicted answer after 'listening' to just half the question), and are "stubborn" (do not change their answers across images), with attention based models being less "stubborn" than non-attention based models.

As a final thought, we note that the somewhat pathological behaviors exposed in the paper are in some sense "correct" given the model architectures and the dataset being trained on. Ignoring optimization error, the maximum-likelihood training objective is clearly intended to capture statistics of the dataset. Our motive is simply to better understand current generation models via their behaviors, and use these observations to guide future choices – do we need novel model classes? or dataset with different biases? etc. Finally, it should be clear that our use of anthropomorphic adjectives such as "stubborn", "myopic" etc. is purely for pedagogical reasons – to easily communicate our observations to our readers. No claims are being made about today's VQA models being human-like.

Abstract

This paper investigates how linguistic knowledge mined from large text corpora can aid the generation of natural language descriptions of videos. Specifically, we integrate both a neural language model and distributional semantics trained on large text corpora into a recent LSTM-based architecture for video description. We evaluate our approach on a collection of Youtube videos as well as two large movie description datasets showing significant improvements in grammaticality while modestly improving descriptive quality.

1 Introduction

The ability to automatically describe videos in natural language (NL) enables many important applications including content-based video retrieval and video description for the visually impaired. The most effective recent methods (Venugopalan et al., 2015a; Yao et al., 2015) use recurrent neural networks (RNN) and treat the problem as machine translation (MT) from video to natural language. Deep learning methods such as RNNs need large training corpora; however, there is a lack of high-quality paired video-sentence data. In contrast, raw text corpora are widely available and exhibit rich linguistic structure that can aid video description. Most work in statistical MT utilizes both a language model trained on a large corpus of monolingual target language data as well as a translation model trained on more limited parallel bilingual data. This paper explores methods to incorporate knowledge from language corpora to capture general linguistic regularities to aid video description.

This paper integrates linguistic information into a video-captioning model based on Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) RNNs which have shown state-of-the-art performance on the task. Further, LSTMs are also effective as language models (LMs) (Sundermeyer et al., 2010). Our first approach (early fusion) is to pre-train the network on plain text before training on parallel video-text corpora. Our next two approaches, inspired by recent MT work (Gulcehre et al., 2015), integrate an LSTM LM with the existing video-to-text model. Furthermore, we also explore replacing the standard one-hot word encoding with distributional vectors trained on external corpora.

We present detailed comparisons between the approaches, evaluating them on a standard Youtube corpus and two recent large movie description datasets. The results demonstrate significant improvements in grammaticality of the descriptions (as determined by crowdsourced human evaluations) and more modest improvements in descriptive quality (as determined by both crowdsourced human judgements and standard automated comparison to human-generated descriptions). Our main contributions are 1) multiple ways to incorporate knowledge from external text into an existing captioning model, 2) extensive experiments comparing the methods on three large video-caption datasets, and 3) human judgements to show that external linguistic knowledge has a significant impact on grammar.

2 LSTM-based Video Description

We use the successful S2VT video description framework from Venugopalan et al. (2015a) as our

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1961–1966,
Austin, Texas, November 1-5, 2016.

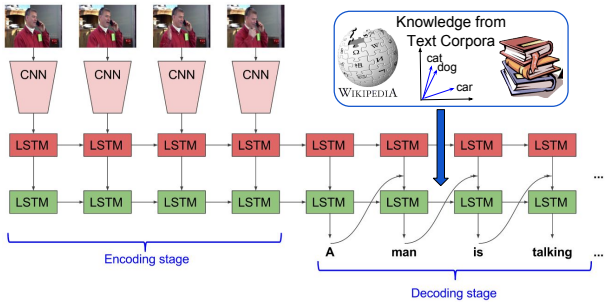

Figure 1: The S2VT architecture encodes a sequence of frames and decodes them to a sentence. We propose to add knowledge from text corpora to enhance the quality of video description.

underlying model and describe it briefly here. S2VT uses a sequence to sequence approach (Sutskever et al., 2014; Cho et al., 2014) that maps an input $\vec{x} = (x_1, ..., x_T)$ video frame feature sequence to a fixed dimensional vector and then decodes this into a sequence of output words $\vec{y} = (y_1, ..., y_N)$.

As shown in Fig. 1, it employs a stack of two LSTM layers. The input $\vec{x}$ to the first LSTM layer is a sequence of frame features obtained from the penultimate layer (fc_7) of a Convolutional Neural Network (CNN) after the ReLu operation. This LSTM layer encodes the video sequence. At each time step, the hidden control state h_t is provided as input to a second LSTM layer. After viewing all the frames, the second LSTM layer learns to decode this state into a sequence of words. This can be viewed as using one LSTM layer to model the visual features, and a second LSTM layer to model language conditioned on the visual representation. We modify this architecture to incorporate linguistic knowledge at different stages of the training and generation process. Although our methods use S2VT, they are sufficiently general and could be incorporated into other CNN-RNN based captioning models.

3 Approach

Existing visual captioning models (Vinyals et al., 2015; Donahue et al., 2015) are trained solely on text from the caption datasets and tend to exhibit some linguistic irregularities associated with a restricted language model and a small vocabulary. Here, we investigate several techniques to integrate prior linguistic knowledge into a CNN/LSTM-based network for video to text (S2VT) and evaluate their effectiveness at improving the overall description.

Early Fusion. Our first approach (*early fusion*), is to pre-train portions of the network modeling language on large corpora of raw NL text and then continue "fine-tuning" the parameters on the paired video-text corpus. An LSTM model learns to estimate the probability of an output sequence given an input sequence. To learn a language model, we train the LSTM layer to predict the next word given the previous words. Following the S2VT architecture, we embed one-hot encoded words in lower dimensional vectors. The network is trained on web-scale text corpora and the parameters are learned through backpropagation using stochastic gradient descent.[1] The weights from this network are then used to *initialize* the embedding and weights of the LSTM layers of S2VT, which is then trained on video-text data. This trained LM is also used as the LSTM LM in the late and deep fusion models.

Late Fusion. Our late fusion approach is similar to how neural machine translation models incorporate a trained language model during decoding. At each step of sentence generation, the video caption model proposes a distribution over the vocabulary. We then use the language model to re-score the final output by considering the weighted average of the sum of scores proposed by the LM as well as the S2VT video-description model (VM). More specifically, if y_t denotes the output at time step t, and if p_{VM} and p_{LM} denote the proposal distributions of the video captioning model, and the language models respectively, then for all words $y' \in V$ in the vocabulary we can recompute the score of each new word, $p(y_t = y')$ as:

$$\alpha \cdot p_{VM}(y_t = y') + (1 - \alpha) \cdot p_{LM}(y_t = y') \quad (1)$$

Hyper-parameter α is tuned on the validation set.

Deep Fusion. In the deep fusion approach (Fig. 2), we integrate the LM a step deeper in the generation process by concatenating the hidden state of the language model LSTM (h_t^{LM}) with the hidden state of the S2VT video description model (h_t^{VM}) and use the combined latent vector to predict the output word. This is similar to the technique proposed by Gulcehre et al. (2015) for incorporating language models trained on monolingual corpora for machine translation. However, our approach differs in two

[1] The LM was trained to achieve a perplexity of 120

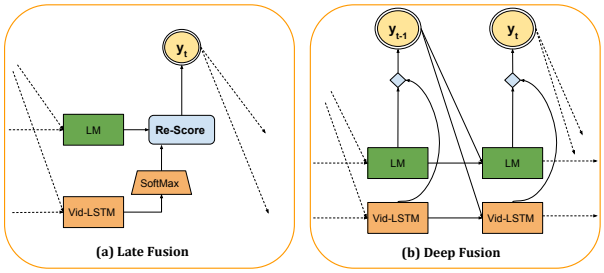

Figure 2: Illustration of our late and deep fusion approaches to integrate an independently trained LM to aid video captioning. The deep fusion model learns jointly from the hidden representations of the LM and S2VT video-to-text model (Vid-LSTM), whereas the late fusion re-scores the softmax output of the video-to-text model.

key ways: (1) we only concatenate the hidden states of the S2VT LSTM and language LSTM and do not use any additional context information, (2) we fix the weights of the LSTM language model but train the full video captioning network. In this case, the probability of the predicted word at time step t is:

$$p(y_t|\vec{y}_{<t}, \vec{x}) \propto \exp(\mathrm{Wf}(h_t^{VM}, h_t^{LM}) + b) \quad (2)$$

where $\vec{x}$ is the visual feature input, W is the weight matrix, and b the biases. We avoid tuning the LSTM LM to prevent overwriting already learned weights of a strong language model. But we train the full video caption model to incorporate the LM outputs while training on the caption domain.

Distributional Word Representations. The S2VT network, like most image and video captioning models, represents words using a 1-of-N (one hot) encoding. During training, the model learns to embed "one-hot" words into a lower 500d space by applying a linear transformation. However, the embedding is learned only from the limited and possibly noisy text in the caption data. There are many approaches (Mikolov et al., 2013; Pennington et al., 2014) that use large text corpora to learn vector-space representations of words that capture fine-grained semantic and syntactic regularities. We propose to take advantage of these to aid video description. Specifically, we replace the embedding matrix from one-hot vectors and instead use 300-dimensional GloVe vectors (Pennington et al., 2014) pre-trained on 6B tokens from Gigaword and Wikipedia 2014. In addition to using the distributional vectors for the input, we also explore variations where the model predicts both the one-hot word (trained on the $\mathrm{softmax}$ loss), as well as predicting the distributional vector from the LSTM hidden state using Euclidean loss as the objective. Here the output vector (y_t) is computed as $y_t = (W_g h_t + b_g)$, and the loss is given by:

$$\mathbb{L}(y_t, w_{glove}) = \|(W_g h_t + b_g) - w_{glove}\|^2 \quad (3)$$

where h_t is the LSTM output, w_{glove} is the word's GloVe embedding and W, b are weights and biases. The network then essentially becomes a multi-task model with two loss functions. However, we use this loss only to influence the weights learned by the network, the predicted word embedding is not used.

Ensembling. The overall loss function of the video-caption network is non-convex, and difficult to optimize. In practice, using an ensemble of networks trained slightly differently can improve performance (Hansen and Salamon, 1990). In our work we also present results of an ensemble by averaging the predictions of the best performing models.

4 Experiments

Datasets. Our language model was trained on sentences from Gigaword, BNC, UkWaC, and Wikipedia. The vocabulary consisted of 72,700 most frequent tokens also containing GloVe embeddings. Following the evaluation in Venugopalan et al. (2015a), we compare our models on the Youtube dataset (Chen and Dolan, 2011), as well as two large movie description corpora: MPII-MD (Rohrbach et al., 2015) and M-VAD (Torabi et al., 2015).

Evaluation Metrics. We evaluate performance using machine translation (MT) metrics METEOR (Denkowski and Lavie, 2014) and BLEU (Papineni et al., 2002) to compare the machine-generated descriptions to human ones. For the movie corpora which have just a single description we use only METEOR which is more robust.

Human Evaluation. We also obtain human judgements using Amazon Turk on a random subset of 200 video clips for each dataset. Each sentence was rated by 3 workers on a Likert scale of 1 to 5 (higher is better) for relevance and grammar. No video was provided during grammar evaluation. For movies, due to copyright, we only evaluate on grammar.

Model	METEOR	B-4	Relevance	Grammar
S2VT	29.2	37.0	2.06	3.76
Early Fusion	29.6	37.6	-	-
Late Fusion	29.4	37.2	-	-
Deep Fusion	29.6	39.3	-	-
Glove	30.0	37.0	-	-
Glove+Deep				
- Web Corpus	30.3	38.1	2.12	4.05*
- In-Domain	30.3	38.8	2.21*	4.17*
Ensemble	**31.4**	**42.1**	**2.24***	**4.20***

Table 1: Youtube dataset: METEOR and BLEU@4 in %, and human ratings (1-5) on relevance and grammar. Best results in bold, * indicates significant over S2VT.

4.1 Youtube Video Dataset Results

Comparison of the proposed techniques in Table 1 shows that Deep Fusion performs well on both METEOR and BLEU; incorporating Glove embeddings substantially increases METEOR, and combining them both does best. Our final model is an ensemble (weighted average) of the Glove, and the two Glove+Deep Fusion models trained on the external and in-domain COCO (Lin et al., 2014) sentences. We note here that the state-of-the-art on this dataset is achieved by HRNE (Pan et al., 2015) (METEOR 33.1) which proposes a superior visual processing pipeline using attention to encode the video.

Human ratings also correlate well with the METEOR scores, confirming that our methods give a modest improvement in descriptive quality. However, incorporating linguistic knowledge significantly[2] improves the grammaticality of the results, making them more comprehensible to human users.

Embedding Influence. We experimented multiple ways to incorporate word embeddings: *(1) GloVe input:* Replacing one-hot vectors with GloVe on the LSTM input performed best. *(2) Fine-tuning:* Initializing with GloVe and subsequently fine-tuning the embedding matrix reduced validation results by 0.4 METEOR. *(3) Input and Predict.* Training the LSTM to accept and predict GloVe vectors, as described in Section 3, performed similar to (1). All scores reported in Tables 1 and 2 correspond to the setting in (1) with GloVe embeddings only as input.

[2]Using the Wilcoxon Signed-Rank test, results were significant with $p < 0.02$ on relevance and $p < 0.001$ on grammar.

Model	MPII-MD		M-VAD	
	METEOR	Grammar	METEOR	Grammar
S2VT†	6.5	2.6	6.6	2.2
Early Fusion	6.7	-	6.8	-
Late Fusion	6.5	-	6.7	-
Deep Fusion	6.8	-	6.8	-
Glove	6.7	3.9*	6.7	3.1*
Glove+Deep	6.8	**4.1***	6.7	**3.3***

Table 2: Movie Corpora: METEOR (%) and human grammar ratings (1-5, higher is better). Best results in bold, * indicates significant over S2VT.

S2VT: Someone sits in the bed.
Glove: Someone sits on the couch and watches her phone.
Glove+Deep: Someone sits on the couch, watching her, her feet on her lap.
GT: Someone drops the flowers and kisses someone.

Figure 3: Two frames from a clip. Models generate visually relevant sentences but differ from groundtruth (GT).

4.2 Movie Description Results

Results on the movie corpora are presented in Table 2. Both MPII-MD and M-VAD have only a single ground truth description for each video, which makes both learning and evaluation very challenging (E.g. Fig.3). METEOR scores are fairly low on both datasets since generated sentences are compared to a single reference translation. S2VT† is a re-implementation of the base S2VT model with the new vocabulary and architecture (embedding dimension). We observe that the ability of external linguistic knowledge to improve METEOR scores on these challenging datasets is small but consistent. Again, human evaluations show significant (with $p < 0.0001$) improvement in grammatical quality.

5 Related Work

Following the success of LSTM-based models on Machine Translation (Sutskever et al., 2014; Bahdanau et al., 2015), and image captioning (Vinyals et al., 2015; Donahue et al., 2015), recent video description works (Venugopalan et al., 2015b; Venugopalan et al., 2015a; Yao et al., 2015) propose CNN-RNN based models that generate a vector representation for the video and "decode" it using an LSTM sequence model to generate a description. Venugopalan et al. (2015b) also incorporate external data such as images with captions to improve

video description, however in this work, our focus is on integrating external linguistic knowledge for video captioning. We specifically investigate the use of distributional semantic embeddings and LSTM-based language models trained on external text corpora to aid existing CNN-RNN based video description models.

LSTMs have proven to be very effective language models (Sundermeyer et al., 2010). Gulcehre et al. (2015) developed an LSTM model for machine translation that incorporates a monolingual language model for the target language showing improved results. We utilize similar approaches (late fusion, deep fusion) to train an LSTM for translating video to text that exploits large monolingual-English corpora (Wikipedia, BNC, UkWac) to improve RNN based video description networks. However, unlike Gulcehre et al. (2015) where the monolingual LM is used only to tune specific parameters of the translation network, the key advantage of our approach is that the output of the monolingual language model is used (as an input) when training the full underlying video description network.

Contemporaneous to us, Yu et al. (2015), Pan et al. (2015) and Ballas et al. (2016) propose video description models focusing primarily on improving the video representation itself using a hierarchical visual pipeline, and attention. Without the attention mechanism their models achieve METEOR scores of 31.1, 32.1 and 31.6 respectively on the Youtube dataset. The interesting aspect, as demonstrated in our experiments (Table 1), is that the contribution of language alone is considerable and only slightly less than the visual contribution on this dataset. Hence, it is important to focus on both aspects to generate better descriptions.

6 Conclusion

This paper investigates multiple techniques to incorporate linguistic knowledge from text corpora to aid video captioning. We empirically evaluate our approaches on Youtube clips as well as two movie description corpora. Our results show significant improvements on human evaluations of grammar while modestly improving the overall descriptive quality of sentences on all datasets. While the proposed techniques are evaluated on a specific video-caption network, they are generic and can be applied to many captioning models. The code and models are shared on `http://vsubhashini.github.io/language_fusion.html`.

Abstract

Several studies on sentence processing suggest that the mental lexicon keeps track of the mutual expectations between words. Current DSMs, however, represent context words as separate features, thereby loosing important information for word expectations, such as word interrelations. In this paper, we present a DSM that addresses this issue by defining verb contexts as joint syntactic dependencies. We test our representation in a verb similarity task on two datasets, showing that joint contexts achieve performances comparable to single dependencies or even better. Moreover, they are able to overcome the data sparsity problem of joint feature spaces, in spite of the limited size of our training corpus.

1 Introduction

Distributional Semantic Models (DSMs) rely on the Distributional Hypothesis (Harris, 1954; Sahlgren, 2008), stating that words occurring in similar contexts have similar meanings. On such theoretical grounds, word co-occurrences extracted from corpora are used to build semantic representations in the form of vectors, which have become very popular in the NLP community. Proximity between word vectors is taken as an index of meaning similarity, and vector cosine is generally adopted to measure such proximity, even though other measures have been proposed (Weeds et al., 2004; Santus et al., 2016).

Most of DSMs adopt a bag-of-words approach, that is they turn a text span (i.e., a word window or a parsed sentence) into a set of words and they register separately the co-occurrence of each word with a given target. The problem with this approach is that valuable information concerning word interrelations in a context gets lost, because words co-occurring with a target are treated as independent features. This is why works like Ruiz-Casado et al. (2005), Agirre et al. (2009) and Melamud et al. (2014) proposed to introduce richer contexts in distributional spaces, by using entire word windows as features. These richer contexts proved to be helpful to semantically represent verbs, which are characterized by highly context-sensitive meanings, and complex argument structures. In fact, two verbs may share independent words as features despite being very dissimilar from the semantic point of view. For instance *kill* and *heal* share the same object nouns in *The doctor healed the patient* and the *The poison killed the patient*, but are highly different if we consider their joint dependencies as a single context. Nonetheless, richer contexts like these suffer from data sparsity, therefore requiring either larger corpora or complex smoothing processes.

In this paper, we propose a syntactically savvy notion of **joint contexts**. To test our representation, we implement several DSMs and we evaluate them in a verb similarity task on two datasets. The results show that, even using a relatively small corpus, our syntactic joint contexts are robust with respect to

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1967–1972,
Austin, Texas, November 1-5, 2016.

data sparseness and perform similarly or better than single dependencies in a wider range of parameter settings.

The paper is organized as follows. In Section 2, we provide psycholinguistic and computational background for this research, describing recent models based on word windows. In Section 3, we describe our reinterpretation of joint contexts with syntactic dependencies. Evaluation settings and results are presented in Section 4.

2 Related Work

A number of studies in sentence processing suggests that verbs activate expectations on their typical argument nouns and vice versa (McRae et al., 1998; McRae et al., 2005) and nouns do the same with other nouns occurring as co-arguments in the same events (Hare et al., 2009; Bicknell et al., 2010). Experimental subjects seem to exploit a rich event knowledge to activate or inhibit dynamically the representations of the potential arguments. This phenomenon, generally referred to as *thematic fit* (McRae et al., 1998), supports the idea of a mental lexicon arranged as a web of mutual expectations.

Some past works in computational linguistics (Baroni and Lenci, 2010; Lenci, 2011; Sayeed and Demberg, 2014; Greenberg et al., 2015) modeled thematic fit estimations by means of dependency-based or of thematic roles-based DSMs. However, these semantic spaces are built similarly to traditional DSMs as they split verb arguments into separate vector dimensions. By using syntactic-semantic links, they encode the relation between an event and each of its participants, but they do not encode directly the relation between participants co-occurring in the same event.

Another trend of studies in the NLP community aimed at the introduction of richer contextual features in DSMs, mostly based on word windows. The first example was the composite-feature model by Ruiz-Casado et al. (2005), who extracted word windows through a Web Search engine. A composite feature for the target word *watches* is *Alicia always ____ romantic movies*, extracted from the sentence *I heard that Alicia always watches romantic movies with Antony* (the placeholder represents the target position). Thanks to this approach, Ruiz-Casado and colleagues achieved 82.50 in the TOEFL synonym detection test, outperforming Latent Semantic Analysis (LSA; see Landauer et al. (1998)) and several other methods.

Agirre et al. (2009) adopted an analogous approach, relying on a huge learning corpus (1.6 Teraword) to build composite-feature vectors. Their model outperformed a traditional DSM on the similarity subset of the WordSim-353 test set (Finkelstein et al., 2001).

Melamud et al. (2014) introduced a probabilistic similarity scheme for modeling the so-called joint context. By making use of the Kneser-Ney language model (Kneser and Ney, 1995) and of a probabilistic distributional measure, they were able to overcome data sparsity, outperforming a wide variety of DSMs on two similarity tasks, evaluated on VerbSim (Yang and Powers, 2006) and on a set of 1,000 verbs extracted from WordNet (Fellbaum, 1998). On the basis of their results, the authors claimed that composite-feature models are particularly advantageous for measuring verb similarity.

3 Syntactic joint contexts

A joint context, as defined in Melamud et al. (2014), is a word window of order n around a target word. The target is replaced by a placeholder, and the value of the feature for a word w is the probability of w to fill the placeholder position. Assuming n=3, a word like *love* would be represented by a collection of contexts such as *the new students ____ the school campus*. Such representation introduces data sparseness, which has been addressed by previous studies either by adopting huge corpora or by relying on n-gram language models to approximate the probabilities of long sequences of words.

However, features based on word windows do not guarantee to include all the most salient event participants. Moreover, they could include unrelated words, also differentiating contexts describing the same event (e.g. consider *Luis ____ the red ball* and *Luis ____ the blue ball*).

For these reasons, we introduce the notion of *syntactic joint contexts*, further abstracting from linear word windows by using dependencies. Each feature of the word vector, in our view, should correspond to a typical verb-argument combination, as an approx-

imation to our knowledge about typical event participants. In the present study, we are focusing on verbs because verb meaning is highly context sensitive and include information about complex argument configurations. Therefore, verb representation should benefit more from the introduction of joint features (Melamud et al., 2014).

The procedure for defining of our representations is the following:

- we extract a list of verb-argument dependencies from a parsed corpus, and for each target verb we extract all the direct dependencies from the sentence of occurrence. For instance, in *Finally, the dictator acknowledged his failure*, we will have: target = 'acknowledge-v'; subject = 'dictator-n'; and object = 'failure-n'.

- for each sentence, we generate a joint context feature by joining all the dependencies for the grammatical relations of interest. From the example above, we would generate the feature *dictator-n.subj+____+failure-n.obj*.

For our experiments, the grammatical relations that we used are *subject*, *object* and *complement*, where *complement* is a generic relation grouping together all dependencies introduced by a preposition. Our distributional representation for a target word is a vector of syntatic joint contexts. For instance, the word vector for the verb *to begin* would include features like {*jury-n.subj+____+deliberation-n.obj*, *operation-n.subj+____+on-i_thursday-n.comp*, *recruit-n.subj+____+training-n.obj+on-i_street-n.comp* ...}. The value of each joint feature will be the frequency of occurrence of the target verb with the corresponding argument combination, possibly weighted by some statistical association measure.

4 Evaluation

4.1 Corpus and DSMs

We trained our DSMs on the RCV1 corpus, which contains approximately 150 million words (Lewis et al., 2004). The corpus was tagged with the tagger described in Dell'Orletta (2009) and dependency-parsed with DeSR (Attardi et al., 2009). RCV1 was chosen for two reasons: i) to show that our joint context-based representation can deal with data sparseness even with a training corpus of limited size; ii) to allow a comparison with the results reported by Melamud et al. (2014).

All DSMs adopt Positive Pointwise Mutual Information (PPMI; Church and Hanks (1990)) as a context weighting scheme and vary according to three main parameters: i) type of contexts; ii) number of dimensions; iii) application of Singular Value Decomposition (SVD; see Landauer et al. (1998)).

For what concerns the first parameter, we developed three types of DSMs: a) traditional bag-of-words DSMs, where the features are content words co-occurring with the target in a window of width 2; b) dependency-based DSMs, where the features are words in a direct dependency relation with the target; c) joint context-based DSMs, using the joint features described in the previous section. The second parameter refers instead to the number of contexts that have been used as vector dimensions. Several values were explored (i.e. 10K, 50K and 100K), selecting the contexts according to their frequency. Finally, the third parameter concerns the application of SVD to reduce the matrix. We report only the results for a number k of latent dimensions ranging from 200 to 400, since the performance drops significantly out of this interval.

4.2 Similarity Measures

As a similarity measure, we used vector cosine, which is by far the most popular in the existing literature (Turney et al., 2010). Melamud et al. (2014) have proposed the Probabilistic Distributional Similarity (PDS), based on the intuition that two words, w_1 and w_2, are similar if they are likely to occur in each other's contexts. PDS assigns a high similarity score when both $p(w_1|$ contexts of $w_2)$ and $p(w_2|$ contexts of $w_1)$ are high. We tried to test variations of this measure with our representation, but we were not able to achieve satisfying results. Therefore, we report here only the scores with the cosine.

4.3 Datasets

The DSMs are evaluated on two test sets: VerbSim (Yang and Powers, 2006) and the verb subset of SimLex-999 (Hill et al., 2015). The former includes 130 verb pairs, while the latter includes 222 verb pairs.

Both datasets are annotated with similarity judgements, so we measured the Spearman correlation between them and the scores assigned by the model. The VerbSim dataset allows for comparison with Melamud et al. (2014), since they also evaluated their model on this test set, achieving a Spearman correlation score of 0.616 and outperforming all the baseline methods.

The verb subset of SimLex-999, at the best of our knowledge, has never been used as a benchmark dataset for verb similarity. The SimLex dataset is known for being quite challenging: as reported by Hill et al. (2015), the average performances of similarity models on this dataset are much lower than on alternative benchmarks like WordSim (Finkelstein et al., 2001) and MEN (Bruni et al., 2014).

We exclude from the evaluation datasets all the target words occurring less than 100 times in our corpus. Consequently, we cover 107 pairs in the VerbSim dataset (82.3, the same of Melamud et al. (2014)) and 214 pairs in the SimLex verbs dataset (96.3).

4.4 Results

Table 1 reports the Spearman correlation scores for the vector cosine on our DSMs. At a glance, we can notice the discrepancy between the results obtained in the two datasets, as SimLex verbs confirms to be very difficult to model. We can also recognize a trend related to the number of contexts, as the performance tends to improve when more contexts are taken into account (with some exceptions). Single dependencies and joint contexts perform very similarly, and no one has a clear edge on the other. Both of them outperform the bag-of-words model on the VerbSim dataset by a nice margin, whereas the scores of all the model types are pretty much the same on SimLex verbs. Finally, it is noteworthy that the score obtained on VerbSim by the joint context model with 100K dimensions goes very close to the result reported by Melamud et al. (2014) (0.616).

Table 2 and Table 3 report the results of the models with SVD reduction. Independently of the number of dimensions k, the joint contexts almost always outperform the other model types. Overall, the performance of the joint contexts seems to be more stable across several parameter configurations, whereas bag-of-words and single dependencies are subject to bigger drops. Exceptions can be noticed only for the VerbSim dataset, and only with a low number of dimensions. Finally, the correlation coefficients for the two datasets seem to follow different trends, as the models with a higher number of contexts perform better on SimLex verbs, while the opposite is true for the VerbSim dataset.

On the VerbSim dataset, both single dependencies and joint contexts have again a clear advantage over bag-of-words representations Although they achieve a similar performance with 10K contexts, the correlation scores of the former decrease more quickly as the number of contexts increases, while the latter are more stable. Moreover, joint contexts are able to outperform single dependencies.
On SimLex verbs, all the models are very close and – differently from the previous dataset – the higher-dimensional DSMs are the better performing ones. Though differences are not statistically significant, joint context are able to achieve top scores over the other models.[1]

More in general, the best results are obtained with SVD reduction and k=200. The joint context-based DSM with 10K dimensions and k = 200 achieves 0.65, which is above the result of Melamud et al. (2014), although the difference between the two correlation scores is not significant. As for SimLex verbs, the best result (0.283) is obtained by the joint context DSM with 100K dimensions and k = 200.

Model	VerbSim	SimLex verbs
Bag-of-Words-10K	0.385	0.085
Single - 10k	0.561	0.090

4.5 Conclusions

In this paper, we have presented our proposal for a new type of vector representation based on joint features, which should emulate more closely the general knowledge about event participants that seems to be the organizing principle of our mental lexicon. A core issue of previous studies was the data sparseness challenge, and we coped with it by means of a more abstract, syntactic notion of joint context.

The models using joint dependencies were able at least to perform comparably to traditional, dependency-based DSMs. In our experiments, they even achieved the best correlation scores across several parameter settings, especially after the application of SVD. We want to emphasize that previous works such as Agirre et al. (2009) already showed that large word windows can have a higher discriminative power than indipendent features, but they did it by using a huge training corpus. In our study, joint context-based representations derived from a small corpus such as RCV1 are already showing competitive performances. This result strengthens our belief that dependencies are a possible solution for the data sparsity problem of joint feature spaces.

We also believe that verb similarity might not be the best task to show the usefulness of joint contexts for semantic representation. The main goal of the present paper was to show that joint contexts are a viable option to exploit the full potential of distributional information. Our successful tests on verb similarity prove that syntactic joint contexts do not suffer of data sparsity and are also able to beat other types of representations based on independent word features. Moreover, syntactic joint contexts are much simpler and more competitive with respect to window-based ones.

The good performance in the verb similarity task motivates us to further test syntactic joint contexts on a larger range of tasks, such as word sense disambiguation, textual entailment and classification of semantic relations, so that they can unleash their full potential. Moreover, our proposal opens interesting perspectives for computational psycholinguistics, especially for modeling those semantic phenomena that are inherently related to the activation of event knowledge (e.g. thematic fit).

Speed-Accuracy Tradeoffs in Tagging with Variable-Order CRFs and Structured Sparsity

Tim Vieira* and **Ryan Cotterell*** and **Jason Eisner**
Department of Computer Science
Johns Hopkins University
{timv,ryan.cotterell,jason}@cs.jhu.edu

Abstract

We propose a method for learning the structure of variable-order CRFs, a more flexible variant of higher-order linear-chain CRFs. Variable-order CRFs achieve faster inference by including features for only some of the tag n-grams. Our learning method discovers the useful higher-order features at the same time as it trains their weights, by maximizing an objective that combines log-likelihood with a structured-sparsity regularizer. An active-set outer loop allows the feature set to grow as far as needed. On part-of-speech tagging in 5 randomly chosen languages from the Universal Dependencies dataset, our method of shrinking the model achieved a 2–6x speedup over a baseline, with no significant drop in accuracy.

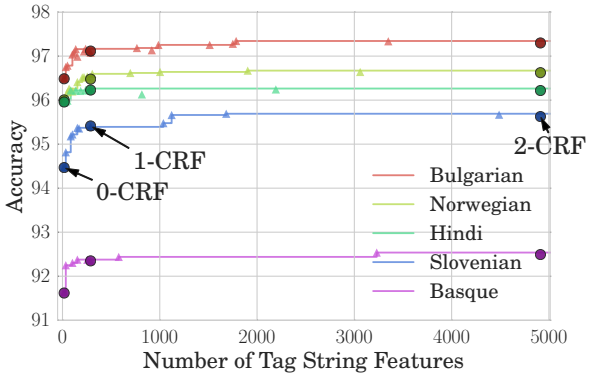

Figure 1: Speed-accuracy tradeoff curves on test data for the 5 languages. Large dark circles represent the k-CRFs of ascending orders along x-axis (marked on for Slovenian). Smaller triangles each represent a VoCRF discovered by sweeping the speed parameters γ. We find faster models at similar accuracy to the best k-CRFs (§5).

1 Introduction

Conditional Random Fields (CRFs) (Lafferty et al., 2001) are a convenient formalism for sequence labeling tasks common in NLP. A CRF defines a feature-rich conditional distribution over tag sequences (output) given an observed word sequence (input).

The key advantage of the CRF framework is the flexibility to consider arbitrary features of the input, as well as enough features over the output structure to encourage it to be well-formed and consistent. However, inference in CRFs is fast only if the features over the output structure are limited. For example, an order-k CRF (or "k-CRF" for short, with $k > 1$ being "higher-order") allows expressive features over a window of $k+1$ adjacent tags (as well as the input), and then inference takes time $\mathcal{O}(n \cdot |Y|^{k+1})$, where Y is the set of tags and n is the length of the input.

How large does k need to be? Typically $k = 2$ works well, with big gains from $0 \rightarrow 1$ and modest gains from $1 \rightarrow 2$ (Fig. 1). Small k may be sufficient when there is enough training data to allow the model to attend to many fine-grained features of the input (Toutanova et al., 2003; Liang et al., 2008). For example, when predicting POS tags in morphologically-rich languages, certain words are easily tagged based on their spelling without considering the context ($k = 0$). In fact, such languages tend to have a more free word order, making tag context less useful.

We investigate a hybrid approach that gives the accuracy of higher-order models while reducing runtime. We build on variable-order CRFs (Ye et al., 2009) (VoCRF), which support features on tag subsequences of mixed orders. Since only modest gains are obtained from moving to higher-order models, we posit that only a small fraction of the higher-order features are necessary. We introduce a hyperparameter γ that *discourages* the model from using many higher-order features (= faster inference) and a hyperparameter λ that *encourages* generalization. Thus, sweeping a range of values for γ and λ gives rise to a

*Equal contribution

Austin, Texas, November 1-5, 2016.

number of operating points along the speed-accuracy curve (triangle points in Fig. 1).

We present three contributions: (1) A simplified exposition of VoCRFs, including an algorithm for computing gradients that is asymptotically more efficient than prior art (Cuong et al., 2014). (2) We develop a structure learning algorithm for *discovering* the essential set of higher-order dependencies so that inference is fast *and* accurate. (3) We investigate the effectiveness of our approach on POS tagging in five diverse languages. We find that the amount of required context for accurate prediction is highly language-dependent. In all languages, however, our approach meets the accuracy of fixed-order models at a fraction of the runtime.

2 Variable-Order CRFs

An order-k CRF (k-CRF, for short) is a conditional probability distribution of the form

$$p_{\boldsymbol{\theta}}(\boldsymbol{y} \mid \boldsymbol{x}) = \frac{1}{Z_{\boldsymbol{\theta}}(\boldsymbol{x})} \exp\Big(\sum_{t=1}^{n+1} \boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}, t, y_{t-k} \dots y_t)\Big)$$

where n is the length of the input $\boldsymbol{x}$, $\boldsymbol{\theta} \in \mathbb{R}^d$ is the model parameter, and $\boldsymbol{f}$ is an arbitrary user-defined function that computes a vector in $\mathbb{R}^d$ of features of the tag substring $\boldsymbol{s} = y_{t-k} \dots y_t$ when it appears at position t of input $\boldsymbol{x}$. We define y_i to be a distinguished boundary tag # when $i \notin [1, n]$.

A variable-order CRF or VoCRF is a refinement of the k-CRF, in which $\boldsymbol{f}$ may not always depend on all $k+1$ of the tags that it has access to. The features of a particular tag substring $\boldsymbol{s}$ may sometimes be determined by a shorter suffix of $\boldsymbol{s}$.

To be precise, a VoCRF specifies a finite set $\mathcal{W} \subset Y^*$ that is sufficient for feature computation (where Y^* denotes the set of all tag sequences).[1] The VoCRF's featurization function $\boldsymbol{f}(\boldsymbol{x}, t, \boldsymbol{s})$ is then defined as $\boldsymbol{f}'(\boldsymbol{x}, t, \boldsymbol{w}(\boldsymbol{s}))$ where $\boldsymbol{f}'$ can be any function and $\boldsymbol{w}(\boldsymbol{s}) \in Y^*$ is the longest suffix of $\boldsymbol{s}$ that appears in $\mathcal{W}$ (or ε if none exists). The full power of a k-CRF can be obtained by specifying $\mathcal{W} = Y^{k+1}$, but smaller $\mathcal{W}$ will in general allow speedups.

To support our algorithms, we define $\overline{\mathcal{W}}$ to be the closure of $\mathcal{W}$ under prefixes and last-character substitution. Formally, $\overline{\mathcal{W}}$ is the smallest nonempty superset of $\mathcal{W}$ such that if $\boldsymbol{h}y \in \overline{\mathcal{W}}$ for some $\boldsymbol{h} \in Y^*$ and $y \in Y$, then $\boldsymbol{h} \in \overline{\mathcal{W}}$ and also $\boldsymbol{h}y' \in \overline{\mathcal{W}}$ for all $y' \in Y$. This implies that we can factor $\overline{\mathcal{W}}$ as $\mathcal{H} \times Y$, where $\mathcal{H} \subset Y^*$ is called the set of *histories*.

We now define $\textsc{Next}(h, y)$ to return the longest suffix of hy that is in $\mathcal{H}$ (which may be hy itself, or even ε). We may regard NEXT as the transition function of a deterministic finite-state automaton (DFA) with state set $\mathcal{H}$ and alphabet Y. If this DFA is used to read any tag sequence $\boldsymbol{y} \in Y^*$, then the arc that reads y_t comes from a state $\boldsymbol{h}$ such that $\boldsymbol{h}y_t$ is the longest suffix of $\boldsymbol{s} = y_{t-k} \dots y_t$ that appears in $\overline{\mathcal{W}}$—and thus $\boldsymbol{w}(\boldsymbol{h}y_t) = \boldsymbol{w}(\boldsymbol{s}) \in \mathcal{W}$ and provides sufficient information to compute $\boldsymbol{f}(\boldsymbol{x}, t, \boldsymbol{s})$.[2]

For a given $\boldsymbol{x}$ of length n and given parameters $\boldsymbol{\theta}$, the log-normalizer $\log Z_{\boldsymbol{\theta}}(\boldsymbol{x})$—which will be needed to compute the log-probability in eq. (1) below—can be found in time $\mathcal{O}(|\overline{\mathcal{W}}|\, n)$ by dynamic programming. Concise pseudocode is in Alg. 1. In effect, this

Algorithm 1 FORWARD: Compute $\log Z_{\boldsymbol{\theta}}(\boldsymbol{x})$.

$\alpha(\cdot, \cdot) = 0$; $\alpha(0, \#) = 1$ ▷ *initialization*
for $t = 1$ **to** $n+1$:
  if $t = n+1$ **then** $Y_t = \{\#\}$ **else** $y_t = Y \backslash \{\#\}$
  for $\boldsymbol{h} \in \mathcal{H}, y_t \in Y_t$:
    $\boldsymbol{h}' = \textsc{Next}(\boldsymbol{h}, y_t)$
    $z = \exp\big(\boldsymbol{\theta}^\top \boldsymbol{f}'(\boldsymbol{x}, t, \boldsymbol{w}(\boldsymbol{h}y_t))\big)$
    $\alpha(t, \boldsymbol{h}')$ += $\alpha(t-1, \boldsymbol{h}) \cdot z$
$Z = \sum_{\boldsymbol{h} \in \mathcal{H}} \alpha(n+1, \boldsymbol{h})$ ▷ *sum over final states*
return $\log Z$

Algorithm 2 GRADIENT: Compute $\nabla_{\boldsymbol{\theta}} \log Z_{\boldsymbol{\theta}}(\boldsymbol{x})$.

$\beta(\cdot, \cdot) = 0$; $\boldsymbol{\Delta} = \mathbf{0}$
$\beta(n+1, \boldsymbol{h}) = 1$ for all $\boldsymbol{h} \in \mathcal{H}$ ▷ *initialization*
for $t = n+1$ **downto** 1 :
  for $\boldsymbol{h} \in \mathcal{H}, y_t \in Y_t$:
    $\boldsymbol{h}' = \textsc{Next}(\boldsymbol{h}, y_t)$
    $z = \exp\big(\boldsymbol{\theta}^\top \boldsymbol{f}'(\boldsymbol{x}, t, \boldsymbol{w}(\boldsymbol{h}y_t))\big)$
    $\boldsymbol{\Delta}$ += $\boldsymbol{f}'(\boldsymbol{x}, t, \boldsymbol{w}(\boldsymbol{h}y_t)) \cdot \alpha(t-1, \boldsymbol{h}) \cdot z \cdot \beta(t, \boldsymbol{h}')$
    $\beta(t-1, \boldsymbol{h})$ += $z \cdot \beta(t, \boldsymbol{h}')$
return $\boldsymbol{\Delta}/Z$

[1] The constructions given in this section assume that $\mathcal{W}$ does not contain ε nor any sequence having ## as a proper prefix.

[2] Our DFA construction is essentially that of Cotterell and Eisner (2015, Appendix B.5). However, Appendix B of that paper also gives a construction that obtains an even smaller DFA by using failure arcs (Allauzen et al., 2003), which remove the requirement that $\overline{\mathcal{W}}$ be closed under last-character substitution. This would yield a further speedup to our Alg. 1 (replacing it with the efficient backward algorithm in footnote 16 of that paper) and similarly to our Alg. 2 (by differentiating the new Alg. 1).

runs the forward algorithm on the lattice of taggings given by length-n paths through the DFA.

For finding the parameters $\boldsymbol{\theta}$ that minimize eq. (1) below, we want the gradient $\nabla_{\boldsymbol{\theta}} \log Z_{\boldsymbol{\theta}}(\boldsymbol{x})$. By applying algorithmic differentiation to Alg. 1, we obtain Alg. 2, which uses back-propagation to compute the gradient (asymptotically) as fast as Alg. 1 and $|\mathcal{H}|$ times faster than Cuong et al. (2014)'s algorithm—a significant speedup since $|\mathcal{H}|$ is often quite large (up to 300 in our experiments). Algs. 1–2 together effectively run the forward-backward algorithm on the lattice of taggings.[3]

It is straightforward to modify Alg. 1 to obtain a Viterbi decoder that finds the most-likely tag sequence under $p_{\boldsymbol{\theta}}(\cdot \mid \boldsymbol{x})$. It is also straightforward to modify Alg. 2 to compute the marginal probabilities of tag substrings occurring at particular positions.

3 Structured Sparsity and Active Sets

We begin with a k-CRF model whose feature vector $\boldsymbol{f}(\boldsymbol{x}, t, y_{t-k} \dots y_t)$ is partitioned into non-stationary local features $\boldsymbol{f}^{(1)}(\boldsymbol{x}, t, y_t)$ and stationary higher-order features $\boldsymbol{f}^{(2)}(y_{t-k} \dots y_t)$. Specifically, $\boldsymbol{f}^{(2)}$ includes an indicator feature for each tag string $\boldsymbol{w} \in Y^*$ with $1 \leq |\boldsymbol{w}| \leq k+1$, where $f^{(2)}_{\boldsymbol{w}}(y_{t-k} \dots y_t)$ is 1 if $\boldsymbol{w}$ is a suffix of $y_{t-k} \dots y_t$ and is 0 otherwise.[4]

To obtain the advantages of a VoCRF, we merely have to choose a *sparse* weight vector $\boldsymbol{\theta}$. The set $\mathcal{W}$ can then be defined to be the set of strings in Y^* whose features have nonzero weight. Prior work (Cuong et al., 2014) has left the construction of $\mathcal{W}$ to domain experts or "one size fits all" strategies (e.g., k-CRF). Our goal is to choose $\boldsymbol{\theta}$—and thus $\mathcal{W}$—so that inference is accurate *and* fast.

Our approach is to modify the usual L_2-regularized log-likelihood training criterion with a carefully defined runtime penalty scaled by a parameter γ to balance competing objectives: likelihood on the data $\{(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})\}_{i=1}^m$ vs. efficiency (small $\mathcal{W}$).

$$-\sum_{i=1}^{m} \underbrace{\log p_{\boldsymbol{\theta}}(\boldsymbol{y}^{(i)} \mid \boldsymbol{x}^{(i)})}_{\text{loss}} + \underbrace{\lambda ||\boldsymbol{\theta}||_2^2}_{\text{generalization}} + \underbrace{\gamma \mathcal{R}(\boldsymbol{\theta})}_{\text{runtime}} \quad (1)$$

Recall that the runtime of inference on a given sentence is proportional to the size of $\overline{\mathcal{W}}$, the *closure* of $\mathcal{W}$ under prefixes and last-character replacement. (Any tag strings in $\overline{\mathcal{W}} \backslash \mathcal{W}$ can get nonzero weight without increasing runtime.) Thus, $\mathcal{R}(\boldsymbol{\theta})$ would ideally measure $|\overline{\mathcal{W}}|$, or proportionately, $|\mathcal{H}|$. Experimentally, we find that $|\overline{\mathcal{W}}|$ has $> 99\%$ Pearson correlation with wallclock time, making it an excellent proxy for wallclock time while being more replicable.

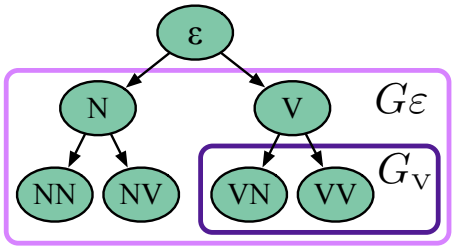

Figure 2: A visual depiction of the tree-structured group lasso penalty. Each node represents a tag string feature. The group indexed by a node's tag string is defined as the *set* of features that are *proper descendants* of the node. For example, the lavender box indicates the largest group G_ε and the aubergine box indicates a smaller group G_{V}. To avoid clutter, not all groups are marked.

We relax this regularizer to a convex function—a tree-structured *group lasso* objective (Yuan and Lin, 2006; Nelakanti et al., 2013). For each string $\boldsymbol{h} \in Y^*$, we have a group $G_{\boldsymbol{h}}$ consisting of the indicator features (in $\boldsymbol{f}^{(2)}$) for all strings $w \in \overline{\mathcal{W}}$ that have $\boldsymbol{h}$ as a proper prefix. Fig. 2 gives a visual depiction. We now define $\mathcal{R}(\boldsymbol{\theta}) = \sum_{\boldsymbol{h} \in Y^*} ||\boldsymbol{\theta}_{G_{\boldsymbol{h}}}||_2$. This penalty encourages each group of weights to remain all at zero (thereby conserving runtime, in our setting, because it means that $\boldsymbol{h}$ does not need to be added to $\mathcal{H}$). Once a single weight in a group becomes nonzero, the "initial inertia" induced by the group lasso penalty is overcome, and other features in the group can be more cheaply adjusted away from zero.

Although eq. (1) is now convex, directly optimizing it would be expensive for large k, since $\boldsymbol{\theta}$ then contains very many parameters. We thus use a heuristic optimization algorithm, the *active set* method (Schmidt, 2010), which starts with a low-dimensional $\boldsymbol{\theta}$ and *incrementally* adds features to the model. This also frees us from needing to specify a limit k. Rather, $\mathcal{W}$ grows until further extensions are unhelpful, and then implicitly $k = \max_{\boldsymbol{w} \in \mathcal{W}} |\boldsymbol{w}| - 1$.

The method defines $\boldsymbol{f}^{(2)}$ to include indicator features for all tag sequences $\boldsymbol{w}$ in an *active set* $\mathcal{W}_{\text{active}}$. Thus, $\boldsymbol{\theta}^{(2)}$ is always a vector of $|\mathcal{W}_{\text{active}}|$ real numbers. Initially, we take $\mathcal{W}_{\text{active}} = Y$ and $\boldsymbol{\theta} = \mathbf{0}$. At each

[3] Eisner (2016) explains the connection between algorithmic differentiation and the forward-backward algorithm.

[4] Extensions to richer sets of higher-order features are possible, such as conjunctions with properties of the words at position t.

active set iteration, we fully optimize eq. (1) to obtain a sparse $\boldsymbol{\theta}$ and a set $\mathcal{W} = \{\boldsymbol{w} \in \mathcal{W}_{\text{active}} \mid \boldsymbol{\theta}^{(2)}_{\boldsymbol{w}} \neq 0\}$ of features that are known to be "useful."[5] We then update $\mathcal{W}_{\text{active}}$ to $\{\boldsymbol{w}y \mid \boldsymbol{w} \in \mathcal{W}, y \in Y\}$, so that it includes single-tag extensions of these useful features; this expands $\boldsymbol{\theta}$ to consider additional features that plausibly might prove useful. Finally, we complete the iteration by updating $\mathcal{W}_{\text{active}}$ to its closure $\overline{\mathcal{W}_{\text{active}}}$, simply because this further expansion of the feature set will not slow down our algorithms. When eq. (1) is re-optimized at the next iteration, some of these newly added features in $\mathcal{W}_{\text{active}}$ may acquire nonzero weights and thus enter $\mathcal{W}$, allowing further extensions. We can halt once $\mathcal{W}$ no longer changes.

As a final step, we follow common practice by running "debiasing" (Martins et al., 2011a), where we fix our $\boldsymbol{f}^{(2)}$ feature set to be given by the final $\overline{\mathcal{W}}$, and retrain $\boldsymbol{\theta}$ without the group lasso penalty term.

In practice, we optimized eq. (1) using the online proximal gradient algorithm SPOM (Martins et al., 2011b) and Adagrad (Duchi et al., 2011) with $\eta = 0.01$ and 15 inner epochs. We limited to 3 active set iterations, and as a result, our final $\overline{\mathcal{W}}$ contained at most tag trigrams.

4 Related Work

Our paper can be seen as transferring methods of Cotterell and Eisner (2015) to the CRF setting. They too used tree-structured group lasso and active set to select variable-order n-gram features $\mathcal{W}$ for globally-normalized sequence models (in their case, to rapidly and accurately approximate beliefs during message-passing inference). Similarly, Nelakanti et al. (2013) used tree-structured group lasso to regularize a variable-order language model (though their focus was *training* speed). Here we apply these techniques to *conditional* models for tagging.

Our work directly builds on the variable-order CRF of Cuong et al. (2014), with a speedup in Alg. 2, but our approach also learns the VoCRF structure. Our method is also related to the *generative* variable-order tagger of Schütze and Singer (1994).

Our static feature selection chooses a single model that permits fast exact marginal inference, similar to learning a low-treewidth graphical model (Bach and Jordan, 2001; Elidan and Gould, 2008). This contrasts with recent papers that learn to do approximate 1-best inference using a sequence of models, whether by dynamic feature selection within a greedy inference algorithm (Strubell et al., 2015), or by gradually increasing the feature set of a 1-best global inference algorithm and pruning its hypothesis space after each increase (Weiss and Taskar, 2010; He et al., 2013).

Schmidt (2010) explores the use of group lasso penalties and the active set method for learning the structure of a graphical model, but does not consider learning repeated structures (in our setting, $\overline{\mathcal{W}}$ defines a structure that is reused at each position). Steinhardt and Liang (2015) jointly modeled the amount of context to use in a variable-order model that dynamically determines how much context to use in a beam search decoder.

5 Experiments[6]

Data: We conduct experiments on multilingual POS tagging. The task is to label each word in a sentence with one of $|Y| = 17$ labels. We train on five typologically-diverse languages from the Universal Dependencies (UD) corpora (Petrov et al., 2012): Basque, Bulgarian, Hindi, Norwegian and Slovenian. For each language, we start with the original train / dev / test split in the UD dataset, then move random sentences from train into dev until the dev set has 3000 sentences. This ensures more stable hyperparameter tuning. We use these new splits below.

Eval: We train models with $(\lambda, \gamma) \in \{10^{-4} \cdot m, 10^{-3} \cdot m, 10^{-2} \cdot m\} \times \{0, 0.1 \cdot m, 0.2 \cdot m, \ldots, m\}$, where m is the number of training sentences. To tag a dev or test sentence, we choose its most probable tag sequence. For each of several model sizes, Table 1 selects the model of that size that achieved the highest per-token tagging accuracy on the dev set, and reports that model's accuracy on the test set.

Features: Recall from §3 that our features include non-stationary zeroth-order features $\boldsymbol{f}^{(1)}$ as well as the stationary features based on $\mathcal{W}$. For $\boldsymbol{f}^{(1)}(\boldsymbol{x}, t, y_t)$ we consider the following language-agnostic properties of $(\boldsymbol{x}, t)$:

- The identities of the tokens $x_{t-3}, ..., x_{t+3}$, and the token bigrams (x_{t+1}, x_t), (x_t, x_{t-1}),

[5] Each gradient computation in this inner optimization takes time $\mathcal{O}(|\overline{\mathcal{W}_{\text{active}}}|\, n)$, which is especially fast at early iterations.
