Preface by the General Chair

October 17, 2016

Welcome to the 2016 Conference on Empirical Methods in Natural Language Processing (EMNLP 2016) in Austin, Texas, USA!

EMNLP is annually organized by SIGDAT, the Association for Computational Linguistics' special interest group on linguistic data and corpus-based approaches to NLP. At EMNLP 2016, one of the top tier conferences in Natural Language Processing (NLP), we have witnessed how our field thrives. This is not only reflected in the number of paper submissions but also in the number of sponsors. The number of long paper submissions has increased 14.5% over that of 2015. This year, we also have seen a record high number of sponsors in EMNLP history. We're honored and grateful to have Amazon, Baidu, Google and Grammarly as the Platinum Sponsors, Bloomberg, Citadel, eBay, Facebook, IBM Research, Maluuba and Microsoft as the Gold Sponsors, AI@ISI as the Silver Sponsor, Nuance, VoiceBox and Yandex as the Bronze Sponsors. We also have Oracle as the Student Volunteer Sponsor.

A large number of people worked hard to bring this annual meeting to fruition, to whom I'm very grateful. Program Chairs, **Kevin Duh** and **Xavier Carreras**, the Area Chairs, reviewers, best paper committee members put in an immense amount of work to develop the technical program. Tutorial Chairs, **Bishan Yang** and **Rebecca Hwa**, Workshop Chairs, **Annie Louis** and **Greg Kondrak** conducted a competitive selection process in collaboration with NAACL and ACL to select 6 tutorials and 8 workshops. Sponsorship Chairs, **Michel Galley**, **Hang Li** (ACL International Sponsorship Committee Representative for EMNLP) did an excellent job to attract the record number of sponsors. Publication Chairs, **Siddharth Patwardhan**, **Daniele Pighin** (advisor), Handbook Chair, **Swapna Somasundaran** worked with a very tight schedule to assemble the proceedings, C4Me Mobile app, and handbooks. Publicity Chair, **Saif M. Mohammad** disseminated the call for papers, call for participation and other announcements in a timely manner. Webmaster, **Jackie C.K. Cheung** kept the website updated all the time, providing a professional outlook of the conference. Student Scholarship Chair and Student Volunteer Coordinator, **Vincent Ng**, played two critical roles, managing the NSF and SIGDAT scholarship, and the review of applications, coordinating the student volunteers to support the conference. SIGDAT Secretary, **Chris Callison-Burch** acted as the liaison between SIGDAT and the conference organizers. He is always available to provide great suggestions.

As usual, the conference cannot be done without Local Arrangements Chair, **Priscilla Rasmussen**, who single-handedly took care of all conference logistics. I would like to mention that I benefited greatly from last year's General Chair, **Lluís Màrquez**, for the monthly progress reports and other valuable experience. We are also grateful to the invited speakers, **Christopher Potts**, **Andreas Stolcke** and **Stefanie Tellex** who will share with us their exciting research.

I really appreciate the trust from SIGDAT officers, including previous secretary, **Noah Smith**, to coordinate the conference as the General Chair.

Finally, I'd like to thank all the authors and attendees. Your participation made a difference to the conference. I hope that you have an enjoyable and productive time at Austin. My best wishes for a successful conference!

Jian Su
EMNLP 2016 General Chair

Preface by the Program Committee Co-Chairs

October 17, 2016

Welcome to the 2016 Conference on Empirical Methods in Natural Language Processing! This year we received 1,087 valid submissions, of which 687 were long papers and 400 were short papers. We accepted 177 long papers (25.8% acceptance rate) and 87 short papers (21.8% acceptance rate), for a total of 264 papers and an overall acceptance rate of 24.3%.

The technical program at EMNLP 2016 consists of a total of 273 papers, including 9 journal papers accepted by the Transactions of ACL. We have structured the conference into three parallel oral sessions in the day and two poster sessions in the evening. Borrowing from recent NAACL conference innovations, we also run poster spotlight sessions (also called *HMM: Half-Minute Madness*[1]), where poster presenters of long papers have 30 seconds and one slide to advertise their work. Poster sessions are becoming larger due to the rapid growth in our field, and we believe it is important to ensure that all papers receive the exposure they deserve.

We are excited and grateful to have three distinguished speakers for our invited keynote talks. Christopher Potts (Stanford University) will present recent advances in rational speech acts and pragmatics. Andreas Stolcke (Microsoft Research) will talk about the challenges and opportunities in human-human-machine dialog. Stefanie Tellex (Brown University) will discuss novel methods and frameworks for enabling human-robot collaboration. We think that these are exciting research areas that can potentially impact—and be impacted by—the EMNLP community in the near future. We look forward to their keynotes and the conversations afterwards.

The program committee includes 823 primary reviewers and 99 secondary reviewers. The committee was structured into 12 thematic areas, handled by 41 area chairs. We are grateful to all program committee members for their effort and dedication during our tight reviewing schedule; without them we cannot create a strong high-quality program. We are also thankful for all authors who submitted papers, which overall cover a diverse range of topics.

Best paper awards were organized around three categories: best paper, best short paper, and best resource paper. The latter category was introduced at EMNLP 2015. Since resources have become central for scientific progress in our field, we would like this category of award to become a standard. The selection process was bottom-up: reviewers and area chairs suggested candidates, which were short-listed by us program chairs. Then, for each category we created a committee of experts to discuss the papers in depth, and we chaired the committees.

For **best paper**, the committee members were Stephen Clark, Hal Daumé III, Chris Dyer, and Julia

[1] Neologism coined by Joel Tetreault, our HMM chair.

	Long	Short	Total
Initial submissions	747	438	1,185
Withdrawn or rejected without review	60	38	98
Submissions reviewed	687	400	1,087
Submissions accepted	177	87	264
Acceptance rate	25.76%	21.75%	24.29%
TACL papers	9	0	9
Papers at EMNLP 2016	186	87	273
Oral talks	87	22	109
Poster presentations	99	65	164

Table 1: Submission statistics of EMNLP 2016

Hockenmaier. The committee selected two best long papers:

- Best Paper: *Improving Information Extraction by Acquiring External Evidence with Reinforcement Learning*, by Karthik Narasimhan, Adam Yala and Regina Barzilay.
- Best Paper: *Global Neural CCG Parsing with Optimality Guarantees*, by Kenton Lee, Mike Lewis and Luke Zettlemoyer.

In addition, two papers were given an honorable mention for best paper:

- Honorable Mention for Best Paper: *Span-Based Constituency Parsing with a Structure-Label System and Provably Optimal Dynamic Oracles*, by James Cross and Liang Huang.
- Honorable Mention for Best Paper: *Sequence-to-Sequence Learning as Beam-Search Optimization*, by Sam Wiseman and Alexander M. Rush.

For **best short paper**, the committee had Stefan Riezler, Anoop Sarkar, and Noah Smith, and the award went to:

- Best Short Paper: *Learning a Lexicon and Translation Model from Phoneme Lattices*, by Oliver Adams, Graham Neubig, Trevor Cohn, Steven Bird, Quoc Truong Do and Satoshi Nakamura.

For **best resource paper**, the committee consisted of Eneko Agirre, Mirella Lapata, and Sebastian Riedel, and the award went to:

- Best Resource Paper: *SQuAD: 100,000+ Questions for Machine Comprehension of Text*, by Pranav Rajpurkar, Jian Zhang, Konstantin Lopyrev and Percy Liang.

We are grateful to the many people who helped us at various stages of the program preparation. In particular, we would like to thank:

- Jian Su and Chris Callison-Burch, who gave us advice and support throughout the whole process, not only in their capacity as program chairs of EMNLP 2015, but also as general chair of EMNLP 2016 (Jian) and SIGDAT secretary-treasurer (Chris).
- The 41 area chairs, whose expertise and dedication we relied on heavily. They selected reviewers, coordinated the review process, led discussions, and made recommendations. We owe you a favor: Yoav Artzi, Tim Baldwin, Guillaume Bouchard, Nate Chambers, Kyunghyun Cho, Michael Collins, John DeNero, Georgiana Dinu, Sanja Fidler, Alex Fraser, Kuzman Ganchev, Ed Grefenstette, Julia Hockenmaier, Dirk Hovy, Liang Huang, Ruihong Huang, Min-Yen Kan, Daisuke Kawahara, Yang Liu, Bing Liu, André F.T. Martins, Saif Mohammad, Ray Mooney, Smaranda Muresan, Preslav Nakov, Vivi Nastase, Ariadna Quattoni, Laura Rimell, Eric Ringger, Alan Ritter, Brian Roark, David Smith, Manfred Stede, Suzanne Stevenson, Michael Strube, Joel Tetreault, Lucy Vanderwende, Dekai Wu, Wei Xu, Scott Wen-Tau Yih, and Geoff Zweig.
- Priscilla Rasmussen, our local organizer who performed amazing feats to make everything work.
- Siddharth Patwardhan and Daniele Pighin, the publication chairs.
- Swapna Somasundaran, handbook chair.
- Joel Tetreault, Brendan O'Connor, and Courtney Napoles for organizing and chairing *the HMM sessions*.
- The session chairs: Regina Barzilay, Alexandra Birch, Phil Blunsom, Yejin Choi, Ido Dagan, Marie-Catherine de Marneffe, Katrin Erk, Pascale Fung, Alona Fyshe, Rebecca Hwa, Heng Ji, Diane Litman, Yang Liu, Lluís Màrquez, André F.T. Martins, Kathy McKeown, Raymond Mooney, Preslav Nakov, Hinrich Schütze, Thamar Solorio, Hiroya Takamura, Kristina Toutanova, Bonnie Webber, and Wei Xu.
- Jackie C.K. Cheung, who maintained the EMNLP 2016 website with up-to-date information.
- Yejin Choi, who kept us connected with the ACL Exec.
- Kristina Toutanova and Lillian Lee, who helped us regarding TACL papers.
- Janyce Wiebe, Michael Strube, and Anoop Sarkar, who provided detailed advice about chairing a program committee of a large conference at the initial planning stages of the process.
- Ani Nenkova, Owen Rambow, Katrin Erk and Noah Smith (program co-chairs of NAACL and ACL this year), with which we coordinated several aspects of the major conferences this year.
- The Softconf support team, Rich Gerber and Paolo Gai, who assisted us in using the Start Conference Manager.

On behalf of all attendees at the conference, we would also like to acknowledge the generosity of our sponsors: Amazon, Baidu, Google, Grammarly, Bloomberg, Citadel, eBay, Facebook, IBM Research, Maluuba, Microsoft, AI@ISI, Nuance, VoiceBox, Yandex, and Oracle.

Chairing the program committee of EMNLP has been a great honor and a rich scientific experience. We are grateful to SIGDAT for giving us this opportunity. And we hope that you will find the program as exciting and enjoyable as we do!

Xavier Carreras and Kevin Duh
EMNLP 2016 Program Committee Co-Chairs

Organizing Committee

General Chair

Jian Su, Institute for Infocomm Research (I2R)

Program Co-chairs

Kevin Duh, Johns Hopkins University
Xavier Carreras, Xerox Research Centre Europe

Workshop Co-chairs

Annie Louis, University of Essex
Greg Kondrak, University of Alberta

Tutorial Co-chairs

Bishan Yang, Carnegie Mellon University
Rebecca Hwa, University of Pittsburgh

Publication Co-chairs

Siddharth Patwardhan, Apple
Daniele Pighin (advisor), Google

Publicity Chairs

Saif Mohammad, National Research Council Canada

Handbook Chair

Swapna Somasundaran, Educational Testing Services

Website Chair

Jackie C.K. Cheung, McGill University

Sponsorship Team

Michel Galley, Microsoft Research
Hang Li (ISC Representative for EMNLP), Huawei Technologies

Student Scholarship Chair and Student Volunteer Co-ordinator

Vincent Ng, University of Texas at Dallas

SIGDAT Liason

Chris Callison-Burch, University of Pennsylvania

Local Arrangements Chair

Priscilla Rasmussen, ACL Business Manager

Program Committee

Program Co-chairs

Xavier Carreras, Xerox Research Centre Europe
Kevin Duh, Johns Hopkins University

Area chairs

Information Extraction, Information Retrieval, and Question Answering
Nathanael Chambers, US Naval Academy
Ruihong Huang, Texas A&M University
Min-Yen Kan, National University of Singapore
Alan Ritter, The Ohio State University
Scott Wen-tau Yih, Microsoft Research

Language and Vision
Sanja Fidler, University of Toronto
Julia Hockenmaier, University of Illinois Urbana-Champaign

Linguistic Theories and Psycholinguistics
Suzanne Stevenson, University of Toronto

Machine Learning
Guillaume Bouchard, University College London
Kyunghyun Cho, New York University
Kuzman Ganchev, Google
Ariadna Quattoni, Xerox Research Centre Europe
Eric Ringger, Facebook and Brigham Young University

Machine Translation and Multilinguality
John DeNero, UC Berkeley
Alexander Fraser, Ludwig-Maximilians-Universität München
Yang Liu, Tsinghua University
Dekai Wu, HKUST

Segmentation, Tagging, and Parsing
Michael Collins, Columbia University and Google
Liang Huang, Oregon State University
Daisuke Kawahara, Kyoto University
André F.T. Martins, Unbabel and Instituto de Telecomunicações

Semantics

Yoav Artzi, Cornell University
Georgiana Dinu, IBM Watson
Edward Grefenstette, Google DeepMind
Raymond Mooney, University of Texas at Austin
Laura Rimell, University of Cambridge

Sentiment Analysis and Opinion Mining

Dirk Hovy, University of Copenhagen
Bing Liu, University of Illinois at Chicago
Saif Mohammad, National Research Council Canada

Social Media and Computational Social Science

Timothy Baldwin, The University of Melbourne
Smaranda Muresan, Columbia University

Spoken Language Processing

Brian Roark, Google Inc.
Geoffrey Zweig, Microsoft Research

Summarization, Generation, Discourse, Dialogue

Manfred Stede, University of Potsdam
Michael Strube, Heidelberg Institute for Theoretical Studies
Lucy Vanderwende, Microsoft Research
Wei Xu, The Ohio State University

Text Mining and NLP Applications

Preslav Nakov, Qatar Computing Research Institute
Vivi Nastase, University of Heidelberg
David Smith, Northeastern University
Joel Tetreault, Grammarly

Invited Speaker: Christopher Potts

Learning in Extended and Approximate Rational Speech Acts Models

Abstract: The Rational Speech Acts (RSA) model treats language use as a recursive process in which probabilistic speaker and listener agents reason about each other's intentions to enrich, and negotiate, the semantics of their language along broadly Gricean lines. RSA builds on early work by the philosopher David Lewis and others on signaling systems as well as more recent developments in Bayesian cognitive modeling. Over the last five years, RSA has been shown to provide a unified account of numerous core phenomena in pragmatics, including metaphor, hyperbole, sarcasm, politeness, and a wide range of conversational implicatures. Its precise, quantitative nature has also facilitated an outpouring of new experimental work on these phenomena. However, applications of RSA to large-scale problems in NLP and AI have so far been limited, because the exact version of the model is intractable along several dimensions. In this talk, I'll report on recent progress in approximating RSA in ways that retains its core properties while enabling application to large datasets and complex environments in which language and action are brought together.

Bio: Christopher Potts is Professor of Linguistics and, by courtesy, of Computer Science, at Stanford, and Director of the Center for the Study of Language and Information (CSLI) at Stanford. He earned his BA in Linguistics from NYU in 1999 and his PhD from UC Santa Cruz in 2003. He was on the faculty in Linguistics at UMass Amherst from 2003 until 2009, when he headed west once again, to join Stanford Linguistics. He was a co-editor at Linguistic Inquiry 2004–2006, an associate editor at Linguistics and Philosophy 2009–2012, and has been an Action Editor at TACL since 2014. In his research, he uses computational methods to explore how emotion is expressed in language and how linguistic production and interpretation are influenced by the context of utterance. He is the author of the 2005 book The Logic of Conventional Implicatures as well as numerous scholarly papers in computational and theoretical linguistics.

Invited Speaker: Andreas Stolcke

You Talking to Me? Speech-based and Multimodal Approaches for Human versus Computer Addressee Detection

Abstract: As dialog systems become ubiquitous, we must learn how to detect when a system is spoken to, and avoid mistaking human-human speech as computer-directed input. In this talk I will discuss approaches to addressee detection in this human-human-machine dialog scenario, based on what is being said (lexical information), how it is being said (acoustic-prosodic properties), and non-speech multimodal and contextual information. I will present experimental results showing that a combination of these cues can be used effectively for human/computer address classification in several dialog scenarios.

Bio: Andreas Stolcke received a Ph.D. in computer science from the University of California at Berkeley. He was subsequently a Senior Research Engineer with the Speech Technology and Research Laboratory at SRI International, Menlo Park, CA, and is currently a Principal Researcher with the Speech and Dialog Research Group in the Microsoft Advanced Technology-Information Services group, working out of Mountain View, CA. His research interests include language modeling, speech recognition, speaker recognition, and speech understanding. He has published over 200 papers in these areas, as well as SRILM, a widely used open-source toolkit for statistical language modeling. He is a Fellow of the IEEE and of ISCA, the International Speech Communications Association.

Invited Speaker: Stefanie Tellex

Learning Models of Language, Action and Perception for Human-Robot Collaboration

Abstract: Robots can act as a force multiplier for people, whether a robot assisting an astronaut with a repair on the International Space station, a UAV taking flight over our cities, or an autonomous vehicle driving through our streets. To achieve complex tasks, it is essential for robots to move beyond merely interacting with people and toward collaboration, so that one person can easily and flexibly work with many autonomous robots. The aim of my research program is to create autonomous robots that collaborate with people to meet their needs by learning decision-theoretic models for communication, action, and perception. Communication for collaboration requires models of language that map between sentences and aspects of the external world. My work enables a robot to learn compositional models for word meanings that allow a robot to explicitly reason and communicate about its own uncertainty, increasing the speed and accuracy of human-robot communication. Action for collaboration requires models that match how people think and talk, because people communicate about all aspects of a robot's behavior, from low-level motion preferences (e.g., "Please fly up a few feet") to high-level requests (e.g., "Please inspect the building"). I am creating new methods for learning how to plan in very large, uncertain state-action spaces by using hierarchical abstraction. Perception for collaboration requires the robot to detect, localize, and manipulate the objects in its environment that are most important to its human collaborator. I am creating new methods for autonomously acquiring perceptual models in situ so the robot can perceive the objects most relevant to the human's goals. My unified decision-theoretic framework supports data-driven training and robust, feedback-driven human-robot collaboration.

Bio: Stefanie Tellex is an Assistant Professor of Computer Science and Assistant Professor of Engineering at Brown University. Her group, the Humans To Robots Lab, creates robots that seamlessly collaborate with people to meet their needs using language, gesture, and probabilistic inference, aiming to empower every person with a collaborative robot. She completed her Ph.D. at the MIT Media Lab in 2010, where she developed models for the meanings of spatial prepositions and motion verbs. Her postdoctoral work at MIT CSAIL focused on creating robots that understand natural language. She has published at SIGIR, HRI, RSS, AAAI, IROS, ICAPs and ICMI, winning Best Student Paper at SIGIR and ICMI, Best Paper at RSS, and an award from the CCC Blue Sky Ideas Initiative. Her awards include being named one of IEEE Spectrum's AI's 10 to Watch in 2013, the Richard B. Salomon Faculty Research Award at Brown University, a DARPA Young Faculty Award in 2015, and a 2016 Sloan Research Fellowship. Her work has been featured in the press on National Public Radio, MIT Technology Review, Wired UK and the Smithsonian. She was named one of Wired UK's Women Who Changed Science In 2015 and listed as one of MIT Technology Review's Ten Breakthrough Technologies in 2016.

Conference Program

Tuesday, November 1, 2016

18:30–20:00 Welcome Reception

Wednesday, November 2, 2016

07:30–17:30 Registration Day 1

08:00–08:40 ***Morning Coffee***

08:40–09:00 Session P1: Plenary Session: Opening Remarks

08:40–09:00 *Opening Remarks*
General Chair, PC Co-Chairs

09:00–10:00 Session P2: Plenary Session: Invited Talk by Christopher Potts

09:00–10:00 *Learning in Extended and Approximate Rational Speech Acts Models*
Christopher Potts

10:00–10:30 ***Coffee Break***

10:30–12:10 Session 1A: Parsing and Syntax (Long Papers)

10:30–10:55 *Span-Based Constituency Parsing with a Structure-Label System and Provably Optimal Dynamic Oracles*
James Cross and Liang Huang

10:55–11:20 *Rule Extraction for Tree-to-Tree Transducers by Cost Minimization*
Pascual Martínez-Gómez and Yusuke Miyao

11:20–11:45 *A Neural Network for Coordination Boundary Prediction*
Jessica Ficler and Yoav Goldberg

11:45–12:10 *Using Left-corner Parsing to Encode Universal Structural Constraints in Grammar Induction*
Hiroshi Noji, Yusuke Miyao and Mark Johnson

10:30–12:10 Session 1B: Information Extraction (Long Papers)

10:30–10:55 *Distinguishing Past, On-going, and Future Events: The EventStatus Corpus*
Ruihong Huang, Ignacio Cases, Dan Jurafsky, Cleo Condoravdi and Ellen Riloff

10:55–11:20 *Nested Propositions in Open Information Extraction*
Nikita Bhutani, H V Jagadish and Dragomir Radev

11:20–11:45 *A Position Encoding Convolutional Neural Network Based on Dependency Tree for Relation Classification*
Yunlun Yang, Yunhai Tong, Shulei Ma and Zhi-Hong Deng

11:45–12:10 *Learning to Recognize Discontiguous Entities*
Aldrian Obaja Muis and Wei Lu

10:30–12:10 Session 1C: Psycholinguistics / Machine Learning (Long Papers)

10:30–10:55 *Modeling Human Reading with Neural Attention*
Michael Hahn and Frank Keller

10:55–11:20 *Comparing Computational Cognitive Models of Generalization in a Language Acquisition Task*
Libby Barak, Adele E. Goldberg and Suzanne Stevenson

11:20–11:45 *Rationalizing Neural Predictions*
Tao Lei, Regina Barzilay and Tommi Jaakkola

11:45–12:10 *Deep Multi-Task Learning with Shared Memory for Text Classification*
Pengfei Liu, Xipeng Qiu and Xuanjing Huang

12:10–13:40 ***Lunch***

13:40–15:20 Session 2A: Reading Comprehension and Question Answering (Long Papers)

13:40–14:05 *Natural Language Comprehension with the EpiReader*
Adam Trischler, Zheng Ye, Xingdi Yuan, Philip Bachman, Alessandro Sordoni and Kaheer Suleman

14:05–14:30 *Creating Causal Embeddings for Question Answering with Minimal Supervision*
Rebecca Sharp, Mihai Surdeanu, Peter Jansen, Peter Clark and Michael Hammond

14:30–14:55 *Improving Semantic Parsing via Answer Type Inference*
Semih Yavuz, Izzeddin Gur, Yu Su, Mudhakar Srivatsa and Xifeng Yan

14:55–15:20 *Semantic Parsing to Probabilistic Programs for Situated Question Answering*
Jayant Krishnamurthy, Oyvind Tafjord and Aniruddha Kembhavi

13:40–15:20 Session 2B: Embeddings of Linguistic Structure (Long Papers)

13:40–14:05 *Event participant modelling with neural networks*
Ottokar Tilk, Vera Demberg, Asad Sayeed, Dietrich Klakow and Stefan Thater

14:05–14:30 *Context-Dependent Sense Embedding*
Lin Qiu, Kewei Tu and Yong Yu

14:30–14:55 *Jointly Embedding Knowledge Graphs and Logical Rules*
Shu Guo, Quan Wang, Lihong Wang, Bin Wang and Li Guo

14:55–15:20 *Learning Connective-based Word Representations for Implicit Discourse Relation Identification*
Chloé Braud and Pascal Denis

13:40–15:20 Session 2C: Sentiment and Opinion Analysis (Long Papers)

13:40–14:05 *Aspect Level Sentiment Classification with Deep Memory Network*
Duyu Tang, Bing Qin and Ting Liu

14:05–14:30 *Lifelong-RL: Lifelong Relaxation Labeling for Separating Entities and Aspects in Opinion Targets*
Lei Shu, Bing Liu, Hu Xu and Annice Kim

14:30–14:55 *Learning Sentence Embeddings with Auxiliary Tasks for Cross-Domain Sentiment Classification*
Jianfei Yu and Jing Jiang

14:55–15:20 *Attention-based LSTM Network for Cross-Lingual Sentiment Classification*
Xinjie Zhou, Xiaojun Wan and Jianguo Xiao

15:20–15:50 ***Coffee Break***

Wednesday, November 2, 2016 (continued)

15:50–17:30 Session 3A: Neural Machine Translation (Long + TACL Papers)

15:50–16:15 *[TACL] Deep Recurrent Models with Fast-Forward Connections for Neural Machine Translation*
Jie Zhou, Ying Cao, Xuguang Wang, Peng Li and Wei Xu

16:15–16:40 *Neural versus Phrase-Based Machine Translation Quality: a Case Study*
Luisa Bentivogli, Arianna Bisazza, Mauro Cettolo and Marcello Federico

16:40–17:05 *Zero-Resource Translation with Multi-Lingual Neural Machine Translation*
Orhan Firat, Baskaran Sankaran, Yaser Al-Onaizan, Fatos T. Yarman Vural and Kyunghyun Cho

17:05–17:30 *Memory-enhanced Decoder for Neural Machine Translation*
Mingxuan Wang, Zhengdong Lu, Hang Li and Qun Liu

15:50–17:30 Session 3B: Semi-supervised and Minimally Supervised Learning (Long + TACL Papers)

15:50–16:15 *Semi-Supervised Learning of Sequence Models with Method of Moments*
Zita Marinho, André F. T. Martins, Shay B. Cohen and Noah A. Smith

16:15–16:40 *[TACL] Minimally supervised models for number normalization*
Kyle Gorman and Richard Sproat

16:40–17:05 *Learning from Explicit and Implicit Supervision Jointly For Algebra Word Problems*
Shyam Upadhyay, Ming-Wei Chang, Kai-Wei Chang and Wen-tau Yih

17:05–17:30 *TweeTime : A Minimally Supervised Method for Recognizing and Normalizing Time Expressions in Twitter*
Jeniya Tabassum, Alan Ritter and Wei Xu

15:50–17:30 Session 3C: Summarization and Generation (Long Papers)

15:50–16:15 *Language as a Latent Variable: Discrete Generative Models for Sentence Compression*
Yishu Miao and Phil Blunsom

16:15–16:40 *Globally Coherent Text Generation with Neural Checklist Models*
Chloé Kiddon, Luke Zettlemoyer and Yejin Choi

16:40–17:05 *A Dataset and Evaluation Metrics for Abstractive Compression of Sentences and Short Paragraphs*
Kristina Toutanova, Chris Brockett, Ke M. Tran and Saleema Amershi

17:05–17:30 *PaCCSS-IT: A Parallel Corpus of Complex-Simple Sentences for Automatic Text Simplification*
Dominique Brunato, Andrea Cimino, Felice Dell'Orletta and Giulia Venturi

17:30–17:45 *Break*

17:45–18:15 Session P3: Plenary Session: Half Minute Madness A

18:15–20:15 Session P4: Poster Session A

[L01][DISCOURSE & DIALOGUE] *Discourse Parsing with Attention-based Hierarchical Neural Networks*
Qi Li, Tianshi Li and Baobao Chang

[L02][DISCOURSE & DIALOGUE] *Multi-view Response Selection for Human-Computer Conversation*
Xiangyang Zhou, Daxiang Dong, Hua Wu, Shiqi Zhao, Dianhai Yu, Hao Tian, Xuan Liu and Rui Yan

[L03][DISCOURSE & DIALOGUE] *Variational Neural Discourse Relation Recognizer*
Biao Zhang, Deyi Xiong, jinsong su, Qun Liu, Rongrong Ji, Hong Duan and Min Zhang

[L04][DISCOURSE & DIALOGUE] *Event Detection and Co-reference with Minimal Supervision*
Haoruo Peng, Yangqiu Song and Dan Roth

[L05][INFORMATION EXTRACTION] *Learning Term Embeddings for Taxonomic Relation Identification Using Dynamic Weighting Neural Network*
Tuan Luu Anh, Yi Tay, Siu Cheung Hui and See Kiong Ng

[L06][INFORMATION EXTRACTION] *Relation Schema Induction using Tensor Factorization with Side Information*
Madhav Nimishakavi, Uday Singh Saini and Partha Talukdar

[L07][INFORMATION EXTRACTION] *Supervised Distributional Hypernym Discovery via Domain Adaptation*
Luis Espinosa Anke, Jose Camacho-Collados, Claudio Delli Bovi and Horacio Saggion

[L08][LANGUAGE MODELING] *Latent Tree Language Model*
Tomáš Brychcín

[L09][LANGUAGE & VISION] *Comparing Data Sources and Architectures for Deep Visual Representation Learning in Semantics*
Douwe Kiela, Anita Lilla Verő and Stephen Clark

[L10][LANGUAGE & VISION] *Multimodal Compact Bilinear Pooling for Visual Question Answering and Visual Grounding*
Akira Fukui, Dong Huk Park, Daylen Yang, Anna Rohrbach, Trevor Darrell and Marcus Rohrbach

[L11][MACHINE LEARNING] *The Structured Weighted Violations Perceptron Algorithm*
Rotem Dror and Roi Reichart

[L12][MACHINE LEARNING] *How Transferable are Neural Networks in NLP Applications?*
Lili Mou, Zhao Meng, Rui Yan, Ge Li, Yan Xu, Lu Zhang and Zhi Jin

[L13][MACHINE LEARNING] *Morphological Priors for Probabilistic Neural Word Embeddings*
Parminder Bhatia, Robert Guthrie and Jacob Eisenstein

[L14][MACHINE TRANSLATION] *Automatic Cross-Lingual Similarization of Dependency Grammars for Tree-based Machine Translation*
Wenbin Jiang, Wen Zhang, Jinan Xu and Rangjia Cai

[L15][MACHINE TRANSLATION] *IRT-based Aggregation Model of Crowdsourced Pairwise Comparison for Evaluating Machine Translations*
Naoki Otani, Toshiaki Nakazawa, Daisuke Kawahara and Sadao Kurohashi

[L16][MACHINE TRANSLATION] *Variational Neural Machine Translation*
Biao Zhang, Deyi Xiong, jinsong su, Hong Duan and Min Zhang

[L17][MACHINE TRANSLATION] *Towards a Convex HMM Surrogate for Word Alignment*
Andrei Simion, Michael Collins and Cliff Stein

[L18][QUESTION ANSWERING] *Solving Verbal Questions in IQ Test by Knowledge-Powered Word Embedding*
Huazheng Wang, Fei Tian, Bin Gao, Chengjieren Zhu, Jiang Bian and Tie-Yan Liu

[L19][QUESTION ANSWERING] *Long Short-Term Memory-Networks for Machine Reading*
Jianpeng Cheng, Li Dong and Mirella Lapata

[L20][QUESTION ANSWERING] *On Generating Characteristic-rich Question Sets for QA Evaluation*
Yu Su, Huan Sun, Brian Sadler, Mudhakar Srivatsa, Izzeddin Gur, Zenghui Yan and Xifeng Yan

[L21][QUESTION ANSWERING] *Learning to Translate for Multilingual Question Answering*
Ferhan Ture and Elizabeth Boschee

[L22][QUESTION ANSWERING] *A Semiparametric Model for Bayesian Reader Identification*
Ahmed Abdelwahab, Reinhold Kliegl and Niels Landwehr

[L23][SENTIMENT ANALYSIS] *Inducing Domain-Specific Sentiment Lexicons from Unlabeled Corpora*
William L. Hamilton, Kevin Clark, Jure Leskovec and Dan Jurafsky

[L24][SENTIMENT ANALYSIS] *Attention-based LSTM for Aspect-level Sentiment Classification*
Yequan Wang, Minlie Huang, xiaoyan zhu and Li Zhao

[L25][SENTIMENT ANALYSIS] *Recursive Neural Conditional Random Fields for Aspect-based Sentiment Analysis*
Wenya Wang, Sinno Jialin Pan, Daniel Dahlmeier and Xiaokui Xiao

[L26][SENTIMENT ANALYSIS] *Extracting Aspect Specific Opinion Expressions*
Abhishek Laddha and Arjun Mukherjee

[L27][SENTIMENT ANALYSIS] *Emotion Distribution Learning from Texts*
Deyu ZHOU, Xuan Zhang, Yin Zhou, Quan Zhao and Xin Geng

[L28][SEMANTICS] *Building an Evaluation Scale using Item Response Theory*
John Lalor, Hao Wu and hong yu

[L29][SEMANTICS] *WordRank: Learning Word Embeddings via Robust Ranking*
Shihao Ji, Hyokun Yun, Pinar Yanardag, Shin Matsushima and S. V. N. Vishwanathan

[L30][SEMANTICS] *Exploring Semantic Representation in Brain Activity Using Word Embeddings*
Yu-Ping Ruan, Zhen-Hua Ling and Yu Hu

[L31][SEMANTICS] *AMR Parsing with an Incremental Joint Model*
Junsheng Zhou, Feiyu Xu, Hans Uszkoreit, Weiguang QU, Ran Li and Yanhui Gu

[L32][SOCIAL MEDIA & COMPUTATIONAL SOCIAL SCIENCE] *Identifying Dogmatism in Social Media: Signals and Models*
Ethan Fast and Eric Horvitz

[L33][SOCIAL MEDIA & COMPUTATIONAL SOCIAL SCIENCE] *Enhanced Personalized Search using Social Data*
Dong Zhou, Séamus Lawless, Xuan Wu, Wenyu Zhao and Jianxun Liu

[L34][SYNTAX & MORPHOLOGY] *Effective Greedy Inference for Graph-based Non-Projective Dependency Parsing*
Ilan Tchernowitz, Liron Yedidsion and Roi Reichart

[L35][SYNTAX & MORPHOLOGY] *Generating Abbreviations for Chinese Named Entities Using Recurrent Neural Network with Dynamic Dictionary*
Qi Zhang, Jin Qian, Ya Guo, Yaqian Zhou and Xuanjing Huang

[L36][SYNTAX & MORPHOLOGY] *Neural Network for Heterogeneous Annotations*
Hongshen Chen, Yue Zhang and Qun Liu

[L37][SYNTAX & MORPHOLOGY] *LAMB: A Good Shepherd of Morphologically Rich Languages*
Sebastian Ebert, Thomas Müller and Hinrich Schütze

[L38][SYNTAX & MORPHOLOGY] *Fast Coupled Sequence Labeling on Heterogeneous Annotations via Context-aware Pruning*
Zhenghua Li, Jiayuan Chao, Min Zhang and Jiwen Yang

[L39][SYNTAX & MORPHOLOGY] *Unsupervised Neural Dependency Parsing*
Yong Jiang, Wenjuan Han and Kewei Tu

[L40][SUMMARIZATION] *Generating Coherent Summaries of Scientific Articles Using Coherence Patterns*
Daraksha Parveen, Mohsen Mesgar and Michael Strube

[L41][SUMMARIZATION] *News Stream Summarization using Burst Information Networks*
Tao Ge, Lei Cui, Baobao Chang, Sujian Li, Ming Zhou and Zhifang Sui

[L42][TEXT MINING & APPLICATIONS] *Rationale-Augmented Convolutional Neural Networks for Text Classification*
Ye Zhang, Iain Marshall and Byron C. Wallace

[L43][TEXT MINING & APPLICATIONS] *Transferring User Interests Across Websites with Unstructured Text for Cold-Start Recommendation*
Yu-Yang Huang and Shou-De Lin

[L44][TEXT MINING & APPLICATIONS] *Speculation and Negation Scope Detection via Convolutional Neural Networks*
Zhong Qian, Peifeng Li, Qiaoming Zhu, Guodong Zhou, Zhunchen Luo and Wei Luo

[L45][TEXT MINING & APPLICATIONS] *Analyzing Linguistic Knowledge in Sequential Model of Sentence*
Peng Qian, Xipeng Qiu and Xuanjing Huang

[L46][TEXT MINING & APPLICATIONS] *Keyphrase Extraction Using Deep Recurrent Neural Networks on Twitter*
Qi Zhang, Yang Wang, Yeyun Gong and Xuanjing Huang

[L47][TEXT MINING & APPLICATIONS] *Solving and Generating Chinese Character Riddles*
Chuanqi Tan, Furu Wei, Li Dong, Weifeng Lv and Ming Zhou

[L48][TEXT MINING & APPLICATIONS] *Structured prediction models for RNN based sequence labeling in clinical text*
Abhyuday Jagannatha and hong yu

[L49][TEXT MINING & APPLICATIONS] *Learning to Represent Review with Tensor Decomposition for Spam Detection*
Xuepeng Wang, Kang Liu, Shizhu He and Jun Zhao

[L50][TEXT MINING & APPLICATIONS] *Stance Detection with Bidirectional Conditional Encoding*
Isabelle Augenstein, Tim Rocktäschel, Andreas Vlachos and Kalina Bontcheva

[S01][INFORMATION EXTRACTION] *Modeling Skip-Grams for Event Detection with Convolutional Neural Networks*
Thien Huu Nguyen and Ralph Grishman

[S02][INFORMATION EXTRACTION] *Porting an Open Information Extraction System from English to German*
Tobias Falke, Gabriel Stanovsky, Iryna Gurevych and Ido Dagan

[S03][INFORMATION EXTRACTION] *Named Entity Recognition for Novel Types by Transfer Learning*
Lizhen Qu, Gabriela Ferraro, Liyuan Zhou, Weiwei Hou and Timothy Baldwin

[S04][INFORMATION EXTRACTION] *Extracting Subevents via an Effective Two-phase Approach*
Allison Badgett and Ruihong Huang

[S05][LANGUAGE & VISION] *Gaussian Visual-Linguistic Embedding for Zero-Shot Recognition*
Tanmoy Mukherjee and Timothy Hospedales

[S06][LANGUAGE & VISION] *Question Relevance in VQA: Identifying Non-Visual And False-Premise Questions*
Arijit Ray, Gordon Christie, Mohit Bansal, Dhruv Batra and Devi Parikh

[S07][LANGUAGE & VISION] *Sort Story: Sorting Jumbled Images and Captions into Stories*
Harsh Agrawal, Arjun Chandrasekaran, Dhruv Batra, Devi Parikh and Mohit Bansal

[S08][LANGUAGE & VISION] *Human Attention in Visual Question Answering: Do Humans and Deep Networks look at the same regions?*
Abhishek Das, Harsh Agrawal, Larry Zitnick, Devi Parikh and Dhruv Batra

[S09][MACHINE LEARNING] *Recurrent Residual Learning for Sequence Classification*
Yiren Wang and Fei Tian

[S10][MACHINE LEARNING] *Richer Interpolative Smoothing Based on Modified Kneser-Ney Language Modeling*
Ehsan Shareghi, Trevor Cohn and Gholamreza Haffari

[S11][MACHINE LEARNING] *A General Regularization Framework for Domain Adaptation*
Wei Lu, Hai Leong Chieu and Jonathan Löfgren

[S12][MACHINE TRANSLATION] *Coverage Embedding Models for Neural Machine Translation*
Haitao Mi, Baskaran Sankaran, Zhiguo Wang and Abe Ittycheriah

[S13][SYNTAX & MORPHOLOGY] *Neural Morphological Analysis: Encoding-Decoding Canonical Segments*
Katharina Kann, Ryan Cotterell and Hinrich Schütze

[S14][SYNTAX & MORPHOLOGY] *Exploiting Mutual Benefits between Syntax and Semantic Roles using Neural Network*
Peng Shi, Zhiyang Teng and Yue Zhang

[S15][SEMANTICS] *The Effects of Data Size and Frequency Range on Distributional Semantic Models*
Magnus Sahlgren and Alessandro Lenci

[S16][SEMANTICS] *Multi-Granularity Chinese Word Embedding*
Rongchao Yin, Quan Wang, Peng Li, Rui Li and Bin Wang

[S17][SEMANTICS] *Numerically Grounded Language Models for Semantic Error Correction*
Georgios Spithourakis, Isabelle Augenstein and Sebastian Riedel

[S18][SEMANTICS] *Towards Semi-Automatic Generation of Proposition Banks for Low-Resource Languages*
Alan Akbik, vishwajeet kumar and Yunyao Li

[S19][SENTIMENT ANALYSIS] *A Hierarchical Model of Reviews for Aspect-based Sentiment Analysis*
Sebastian Ruder, Parsa Ghaffari and John G. Breslin

[S20][SENTIMENT ANALYSIS] *Are Word Embedding-based Features Useful for Sarcasm Detection?*
Aditya Joshi, Vaibhav Tripathi, Kevin Patel, Pushpak Bhattacharyya and Mark Carman

[S21][SENTIMENT ANALYSIS] *Weakly Supervised Tweet Stance Classification by Relational Bootstrapping*
Javid Ebrahimi, Dejing Dou and Daniel Lowd

[S22][SOCIAL MEDIA & COMPUTATIONAL SOCIAL SCIENCE] *The Gun Violence Database: A new task and data set for NLP*
Ellie Pavlick, Heng Ji, Xiaoman Pan and Chris Callison-Burch

[S23][SOCIAL MEDIA & COMPUTATIONAL SOCIAL SCIENCE] *Fluency detection on communication networks*
Tom Lippincott and Benjamin Van Durme

[S25][SOCIAL MEDIA & COMPUTATIONAL SOCIAL SCIENCE] *Characterizing the Language of Online Communities and its Relation to Community Reception*
Trang Tran and Mari Ostendorf

[S26][SPOKEN LANGUAGE PROCESSING] *Joint Transition-based Dependency Parsing and Disfluency Detection for Automatic Speech Recognition Texts*
Masashi Yoshikawa, Hiroyuki Shindo and Yuji Matsumoto

[S27][SPOKEN LANGUAGE PROCESSING] *Real-Time Speech Emotion and Sentiment Recognition for Interactive Dialogue Systems*
Dario Bertero, Farhad Bin Siddique, Chien-Sheng Wu, Yan Wan, Ricky Ho Yin Chan and Pascale Fung

[S28][SUMMARIZATION] *A Neural Network Architecture for Multilingual Punctuation Generation*
Miguel Ballesteros and Leo Wanner

[S29][SUMMARIZATION] *Neural Headline Generation on Abstract Meaning Representation*
Sho Takase, Jun Suzuki, Naoaki Okazaki, Tsutomu Hirao and Masaaki Nagata

[S30][TEXT MINING & APPLICATIONS] *Robust Gram Embeddings*
Taygun Kekec and David M. J. Tax

[S31][TEXT MINING & APPLICATIONS] *SimpleScience: Lexical Simplification of Scientific Terminology*
Yea Seul Kim, Jessica Hullman, Matthew Burgess and Eytan Adar

[S32][TEXT MINING & APPLICATIONS] *Automatic Features for Essay Scoring – An Empirical Study*
Fei Dong and Yue Zhang

Thursday, November 3, 2016

07:30–17:30 Registration Day 2

08:00–09:00 ***Morning Coffee***

09:00–10:00 Session P5: Plenary Session: Invited Talk by Stefanie Tellex

09:00–10:00 *Learning Models of Language, Action and Perception for Human-Robot Collaboration*
Stefanie Tellex

10:00–10:30 ***Coffee Break***

10:30–12:10 Session 4A: Semantics and Semantic Parsing (Long Papers)

10:30–10:55 *Semantic Parsing with Semi-Supervised Sequential Autoencoders*
Tomáš Kočiský, Gábor Melis, Edward Grefenstette, Chris Dyer, Wang Ling, Phil Blunsom and Karl Moritz Hermann

10:55–11:20 *Equation Parsing : Mapping Sentences to Grounded Equations*
Subhro Roy, Shyam Upadhyay and Dan Roth

11:20–11:45 *Automatic Extraction of Implicit Interpretations from Modal Constructions*
Jordan Sanders and Eduardo Blanco

11:45–12:10 *Understanding Negation in Positive Terms Using Syntactic Dependencies*
Zahra Sarabi and Eduardo Blanco

10:30–12:10 Session 4B: NLP for Social Science and Health (Long + TACL Papers)

10:30–10:55 *Demographic Dialectal Variation in Social Media: A Case Study of African-American English*
Su Lin Blodgett, Lisa Green and Brendan O'Connor

10:55–11:20 *Understanding Language Preference for Expression of Opinion and Sentiment: What do Hindi-English Speakers do on Twitter?*
Koustav Rudra, Shruti Rijhwani, Rafiya Begum, Kalika Bali, Monojit Choudhury and Niloy Ganguly

11:20–11:45 *Detecting and Characterizing Events*
Allison Chaney, Hanna Wallach, Matthew Connelly and David Blei

11:45–12:10 *[TACL] Large-scale Analysis of Counseling Conversations: An Application of Natural Language Processing to Mental Health*
Tim Althoff, Kevin Clark and Jure Leskovec

10:30–12:10 Session 4C: Language Models (Long + TACL Papers)

10:30–10:55 *[TACL] Fast, Small and Exact: Infinite-order Language Modelling with Compressed Suffix Trees*
Ehsan Shareghi, Matthias Petri, Gholamreza Haffari and Trevor Cohn

10:55–11:20 *Convolutional Neural Network Language Models*
Ngoc-Quan Pham, Germán Kruszewski and Gemma Boleda

11:20–11:45 *[TACL] Sparse Non-negative Matrix Language Modeling*
Joris Pelemans, Noam Shazeer and Ciprian Chelba

11:45–12:10 *Generalizing and Hybridizing Count-based and Neural Language Models*
Graham Neubig and Chris Dyer

12:10–13:40 *Lunch*

Thursday, November 3, 2016 (continued)

13:00–13:40 Session P6: SIGDAT Business Meeting

13:40–15:20 Session 5A: Text Generation (Long Papers)

13:40–14:05 *Reasoning about Pragmatics with Neural Listeners and Speakers*
Jacob Andreas and Dan Klein

14:05–14:30 *Generating Topical Poetry*
Marjan Ghazvininejad, Xing Shi, Yejin Choi and Kevin Knight

14:30–14:55 *Deep Reinforcement Learning for Dialogue Generation*
Jiwei Li, Will Monroe, Alan Ritter, Dan Jurafsky, Michel Galley and Jianfeng Gao

14:55–15:20 *Neural Text Generation from Structured Data with Application to the Biography Domain*
Rémi Lebret, David Grangier and Michael Auli

13:40–15:20 Session 5B: Discourse and Document Structure (Long Papers)

13:40–14:05 *What makes a convincing argument? Empirical analysis and detecting attributes of convincingness in Web argumentation*
Ivan Habernal and Iryna Gurevych

14:05–14:30 *Recognizing Implicit Discourse Relations via Repeated Reading: Neural Networks with Multi-Level Attention*
Yang Liu and Sujian Li

14:30–14:55 *Antecedent Selection for Sluicing: Structure and Content*
Pranav Anand and Daniel Hardt

14:55–15:20 *Intra-Sentential Subject Zero Anaphora Resolution using Multi-Column Convolutional Neural Network*
Ryu Iida, Kentaro Torisawa, Jong-Hoon Oh, Canasai Kruengkrai and Julien Kloetzer

Thursday, November 3, 2016 (continued)

13:40–15:20 Session 5C: Machine Translation and Multilingual Applications (Long Papers)

13:40–14:05 *An Unsupervised Probability Model for Speech-to-Translation Alignment of Low-Resource Languages*
Antonios Anastasopoulos, David Chiang and Long Duong

14:05–14:30 *HUME: Human UCCA-Based Evaluation of Machine Translation*
Alexandra Birch, Omri Abend, Ondřej Bojar and Barry Haddow

14:30–14:55 *Improving Multilingual Named Entity Recognition with Wikipedia Entity Type Mapping*
Jian Ni and Radu Florian

14:55–15:20 *Learning Crosslingual Word Embeddings without Bilingual Corpora*
Long Duong, Hiroshi Kanayama, Tengfei Ma, Steven Bird and Trevor Cohn

15:20–15:50 *Coffee Break*

15:50–17:30 Session 6A: Neural Sequence-to-Sequence Models (Long Papers)

Span-Based Constituency Parsing with a Structure-Label System and Provably Optimal Dynamic Oracles

James Cross and **Liang Huang**
School of EECS, Oregon State University, Corvallis, OR, USA
{james.henry.cross.iii, liang.huang.sh}@gmail.com

Abstract

Parsing accuracy using efficient greedy transition systems has improved dramatically in recent years thanks to neural networks. Despite striking results in dependency parsing, however, neural models have not surpassed state-of-the-art approaches in constituency parsing. To remedy this, we introduce a new shift-reduce system whose stack contains merely sentence spans, represented by a bare minimum of LSTM features. We also design the first provably optimal dynamic oracle for constituency parsing, which runs in amortized $O(1)$ time, compared to $O(n^3)$ oracles for standard dependency parsing. Training with this oracle, we achieve the best F_1 scores on both English and French of any parser that does not use reranking or external data.

1 Introduction

Parsing is an important problem in natural language processing which has been studied extensively for decades. Between the two basic paradigms of parsing, constituency parsing, the subject of this paper, has in general proved to be the more difficult than dependency parsing, both in terms of accuracy and the run time of parsing algorithms.

There has recently been a huge surge of interest in using neural networks to make parsing decisions, and such models continue to dominate the state of the art in dependency parsing (Andor et al., 2016). In constituency parsing, however, neural approaches are still behind the state-of-the-art (Carreras et al., 2008; Shindo et al., 2012; Thang et al., 2015); see more details in Section 5.

To remedy this, we design a new parsing framework that is more suitable for constituency parsing, and that can be accurately modeled by neural networks. Observing that constituency parsing is primarily focused on sentence spans (rather than individual words, as is dependency parsing), we propose a novel adaptation of the shift-reduce system which reflects this focus. In this system, the stack consists of sentence spans rather than partial trees. It is also factored into two types of parser actions, structural and label actions, which alternate during a parse. The structural actions are a simplified analogue of shift-reduce actions, omitting the directionality of reduce actions, while the label actions directly assign nonterminal symbols to sentence spans.

Our neural model processes the sentence once for each parse with a recurrent network. We represent parser configurations with a very small number of span features (4 for structural actions and 3 for label actions). Extending Wang and Chang (2016), each span is represented as the difference of recurrent output from multiple layers in each direction. No pre-trained embeddings are required.

We also extend the idea of dynamic oracles from dependency to constituency parsing. The latter is significantly more difficult than the former due to F_1 being a combination of precision and recall (Huang, 2008), and yet we propose a simple and extremely efficient oracle (amortized $O(1)$ time). This oracle is proved optimal for F_1 as well as both of its components, precision and recall. Trained with this oracle, our parser achieves what we believe to be the best results for any parser without reranking which was trained only on the Penn Treebank and the French Treebank, despite the fact that it is not only linear-time, but also strictly greedy.

We make the following main contributions:

- A novel factored transition parsing system where the stack elements are sentence spans rather than partial trees (Section 2).
- A neural model where sentence spans are represented as differences of output from a multi-layer bi-directional LSTM (Section 3).
- The first provably optimal dynamic oracle for

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 1–11,
Austin, Texas, November 1-5, 2016.

constituency parsing which is also extremely efficient (amortized $O(1)$ time) (Section 4).

- The best F_1 scores of any single-model, closed training set, parser for English and French.

We are also publicly releasing the source code for one implementation of our parser.[1]

2 Parsing System

We present a new transition-based system for constituency parsing whose fundamental unit of computation is the sentence span. It uses a stack in a similar manner to other transition systems, except that the stack contains sentence spans with no requirement that each one correspond to a partial tree structure during a parse.

The parser alternates between two types of actions, structural and label, where the structural actions follow a path to make the stack spans correspond to sentence phrases in a bottom-up manner, while the label actions optionally create tree brackets for the top span on the stack. There are only two structural actions: *shift* is the same as other transition systems, while *combine* merges the top two sentence spans. The latter is analogous to a reduce action, but it does not immediately create a tree structure and is non-directional. Label actions do create a partial tree on top of the stack by assigning one or more non-terminals to the topmost span.

Except for the use of spans, this factored approach is similar to the odd-even parser from Mi and Huang (2015). The fact that stack elements do not have to be tree-structured, however, means that we can create productions with arbitrary arity, and no binarization is required either for training or parsing. This also allows us to remove the directionality inherent in the shift-reduce system, which is at best an imperfect fit for constituency parsing. We do follow the practice in that system of labeling unary chains of non-terminals with a single action, which means our parser uses a fixed number of steps, $(4n-2)$ for a sentence of n words.

Figure 1 shows the formal deductive system for this parser. The stack σ is modeled as a list of strictly increasing integers whose first element is always zero. These numbers are word boundaries which define the spans on the stack. In a slight abuse of notation, however, we sometimes think of it as a list of pairs (i, j), which are the actual sentence spans, i.e., every consecutive pair of indices on the stack, initially empty. We represent stack spans by trapezoids ($_i\!\!\smile\!\!\!\frown_j$) in the figures to emphasize that they may or not have tree stucture.

nolabel	$\dfrac{\langle z,\ \sigma \,\vert\, i \,\vert\, j,\ t \rangle}{\langle z+1,\ \sigma \,\vert\, i \,\vert\, j,\ t \rangle}$ $z < (4n-1)$, odd z

Figure 1: Deductive system for the Structure/Label transition parser. The stack σ is represented as a list of integers where the span defined by each consecutive pair of elements is a sentence segment on the stack. Each X is a nonterminal symbol or an ordered unary chain. The set t contains labeled spans of the form ${}_iX_j$, which at the end of a parse, fully define a parse tree.

The parser alternates between structural actions and label actions according to the parity of the parser step z. In even steps, it takes a structural action, either combining the top two stack spans, which requires at least two spans on the stack, or introducing a new span of unit length, as long as the entire sentence is not already represented on the stack

In odd steps, the parser takes a label action. One possibility is labeling the top span on the stack, (i, j) with either a nonterminal label or an ordered unary chain (since the parser has only one opportunity to label any given span). Taking no action, designated nolabel, is also a possibility. This is essentially a null operation except that it returns the parser to an even step, and this action reflects the decision that (i, j) is not a (complete) labeled phrase in the tree. In the final step, $(4n-2)$, nolabel is not allowed

15–16	comb	label-VP	$_0\frown_1\frown_5$	$_1$VP$_5$
17–18	comb	label-S	$_0\frown_5$	$_0$S$_5$

(b) static oracle actions

Figure 2: The running example. It contains one ternary branch and one unary chain (S-VP), and NP-PRP-I and NP-NN-fish are *not* unary chains in our system. Each stack is just a list of numbers but is visualized with spans here.

since the parser must produce a tree.

Figure 2 shows a complete example of applying this parsing system to a very short sentence (*"I do like eating fish"*) that we will use throughout this section and the next. The action in step 2 is label-NP because "I" is a one-word noun phrase (parts of speech are taken as input to our parser, though it could easily be adapted to include POS tagging in label actions). If a single word is not a complete phrase (e.g., "do"), then the action after a shift is nolabel.

The ternary branch in this tree (VP → MD VBP S) is produced by our parser in a straightforward manner: after the phrase "do like" is combined in step 7, no label is assigned in step 8, successfully delaying the creation of a bracket until the verb phrase is fully formed on the stack. Note also that the unary production in the tree is created with a single action, label-S-VP, in step 14.

The static oracle to train this parser simply consists of taking actions to generate the gold tree with a "short-stack" heuristic, meaning combine first whenever combine and shift are both possible.

3 LSTM Span Features

Long short-term memory networks (LSTM) are a type of recurrent neural network model proposed by Hochreiter and Schmidhuber (1997) which are very effective for modeling sequences. They are able to capture and generalize from interactions among their sequential inputs even when separated by a long distance, and thus are a natural fit for analyzing natural language. LSTM models have proved to be a powerful tool for many learning tasks in natural language, such as language modeling (Sundermeyer et al., 2012) and translation (Sutskever et al., 2014).

LSTMs have also been incorporated into parsing in a variety of ways, such as directly encoding an entire sentence (Vinyals et al., 2015), separately modeling the stack, buffer, and action history (Dyer et al., 2015), to encode words based on their character forms (Ballesteros et al., 2015), and as an element in a recursive structure to combine dependency subtrees with their left and right children (Kiperwasser and Goldberg, 2016a).

For our parsing system, however, we need a way to model arbitrary sentence spans in the context of the rest of the sentence. We do this by representing each sentence span as the elementwise difference of the vector outputs of the LSTM outputs at different time steps, which correspond to word boundaries. If the sequential output of the recurrent network for the sentence is $f_0, ..., f_n$ in the forward direction and $b_n, ..., b_0$ in the backward direction then the span (i, j) would be represented as the concatenation of the vector differences $(f_j - f_i)$ and $(b_i - b_j)$.

The spans are represented using output from both backward and forward LSTM components, as can be seen in Figure 3. This is essentially the LSTM-Minus feature representation described by Wang and Chang (2016) extended to the bi-directional case. In initial experiments, we found that there was essentially no difference in performance between using the difference features and concatenating all end-

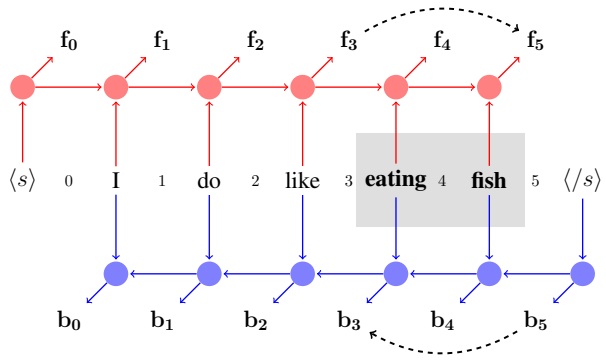

Figure 3: Word spans are modeled by differences in LSTM output. Here the span $_3$ *eating fish* $_5$ is represented by the vector differences $(\mathbf{f_5} - \mathbf{f_3})$ and $(\mathbf{b_3} - \mathbf{b_5})$. The forward difference corresponds to LSTM-Minus (Wang and Chang, 2016).

point vectors, but our approach is almost twice as fast.

This model allows a sentence to be processed once, and then the same recurrent outputs can be used to compute span features throughout the parse. Intuitively, this allows the span differences to learn to represent the sentence spans in the context of the rest of the sentence, not in isolation (especially true for LSTM given the extra hidden recurrent connection, typically described as a "memory cell"). In practice, we use a two-layer bi-directional LSTM, where the input to the second layer combines the forward and backward outputs from the first layer at that time step. For each direction, the components from the first and second layers are concatenated to form the vectors which go into the span features. See Cross and Huang (2016) for more details on this approach.

For the particular case of our transition constituency parser, we use only four span features to determine a structural action, and three to determine a label action, in each case partitioning the sentence exactly. The reason for this is straightforward: when considering a structural action, the top two spans on the stack must be considered to determine whether they should be combined, while for a label action, only the top span on the stack is important, since that is the candidate for labeling. In both cases the remaining sentence prefix and suffix are also included. These features are shown in Table 1.

The input to the recurrent network at each time step consists of vector embeddings for each word

Action	Stack	LSTM Span Features
Structural	$\sigma \mid i \mid k \mid j$	0 i k j n
Label	$\sigma \mid i \mid j$	0 i j n

Table 1: Features used for the parser. No label or tree-structure features are required.

and its part-of-speech tag. Parts of speech are predicted beforehand and taken as input to the parser, as in much recent work in parsing. In our experiments, the embeddings are randomly initialized and learned from scratch together with all other network weights, and we would expect further performance improvement from incorporating embeddings pretrained from a large external corpus.

The network structure after the the span features consists of a separate multilayer perceptron for each type of action (structural and label). For each action we use a single hidden layer with rectified linear (ReLU) activation. The model is trained on a per-action basis using a single correct action for each parser state, with a negative log softmax loss function, as in Chen and Manning (2014).

4 Dynamic Oracle

The baseline method of training our parser is what is known as a static oracle: we simply generate the sequence of actions to correctly parse each training sentence, using a short-stack heuristic (i.e., combine first whenever there is a choice of shift and combine). This method suffers from a well-documeted problem, however, namely that it only "prepares" the model for the situation where no mistakes have been made during parsing, an inevitably incorrect assumption in practice. To alleviate this problem, Goldberg and Nivre (2013) define a dynamic oracle to return the best possible action(s) at any arbitrary configuration.

In this section, we introduce an easy-to-compute optimal dynamic oracle for our constituency parser. We will first define some concepts upon which the dynamic oracle is built and then show how optimal actions can be very efficiently computed using this framework. In broad strokes, in any arbitrary parser configuration c there is a set of brackets $t^*(c)$ from the gold tree which it is still possible to reach. By following dynamic oracle actions, all of those brackets and only those brackets will be predicted.

Even though proving the optimality of our dynamic oracle (Sec. 4.3) is involved, computing the oracle actions is extremely simple (Secs. 4.2) and efficient (Sec. 4.4).

4.1 Preliminaries and Notations

Before describing the computation of our dynamic oracle, we first need to rigorously establish the desired optimality of dynamic oracle. The structure of this framework follows Goldberg et al. (2014).

Definition 1. We denote $c \vdash_\tau c'$ iff. c' is the result of action τ on configuration c, also denoted functionally as $c' = \tau(c)$. We denote $\vdash$ to be the union of $\vdash_\tau$ for all actions τ, and $\vdash^*$ to be the reflexive and transitive closure of $\vdash$.

Definition 2 (descendant/reachable trees)**.** We denote $\mathcal{D}(c)$ to be the set of final descendant trees derivable from c, i.e., $\mathcal{D}(c) = \{t \mid c \vdash^* \langle z,\ \sigma,\ t\rangle\}$. This set is also called "reachable trees" from c.

Definition 3 (F_1)**.** We define the standard F_1 metric of a tree t with respect to gold tree t_G as $\mathrm{F}_1(t) = \frac{2rp}{r+p}$, where $r = \frac{|t \cap t_\mathrm{G}|}{|t_\mathrm{G}|}, p = \frac{|t \cap t_\mathrm{G}|}{|t|}$.

The following two definitions are similar to those for dependency parsing by Goldberg et al. (2014).

Definition 4. We extend the F_1 function to configurations to define the maximum possible F_1 from a given configuration: $\mathrm{F}_1(c) = \max_{t_1 \in \mathcal{D}(c)} \mathrm{F}_1(t_1)$.

Definition 5 (oracle)**.** We can now define the desired dynamic oracle of a configuration c to be the set of actions that retrain the optimal F_1:

$$\mathit{oracle}(c) = \{\tau \mid \mathrm{F}_1(\tau(c)) = \mathrm{F}_1(c)\}.$$

This abstract oracle is implemented by $\mathit{dyna}(\cdot)$ in Sec. 4.2, which we prove to be correct in Sec. 4.3.

Definition 6 (span encompassing)**.** We say span (i, j) is encompassed by span (p, q), notated $(i, j) \preceq (p, q)$, iff. $p \le i < j \le q$.

Definition 7 (strict encompassing)**.** We say span (i, j) is strictly encompassed by span (p, q), notated $(i, j) \prec (p, q)$, iff. $(i, j) \preceq (p, q)$ and $(i, j) \neq (p, q)$. We then extend this relation from spans to brackets, and notate ${}_iX_j \prec {}_pY_q$ iff. $(i, j) \prec (p, q)$.

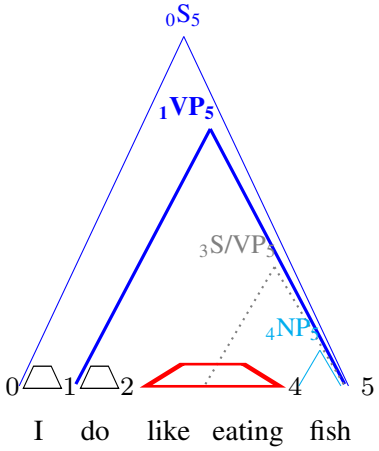

Figure 4: Reachable brackets (w.r.t. gold tree in Fig. 1) for $c = \langle 10,\ [0, 1, 2, 4],\ \{{}_0\mathrm{NP}_1\}\rangle$ which mistakenly combines "like eating". Trapezoids indicate stack spans (the top one in red), and solid triangles denote reachable brackets, with $\mathit{left}(c)$ in blue and $\mathit{right}(c)$ in cyan. The next reachable bracket, $\mathit{next}(c) = {}_1\mathbf{VP}_5$, is in bold. Brackets ${}_3\mathrm{VP}_5$ and ${}_3\mathrm{S}_5$ (in dotted triangle) cross the top span (thus unreachable), and ${}_0\mathrm{NP}_1$ is already recognized (thus not in $\mathit{reach}(c)$ either).

We next define a central concept, *reachable brackets*, which is made up of two parts, the left ones $\mathit{left}(c)$ which encompass (i, j) without crossing any stack spans, and the right ones $\mathit{right}(c)$ which are completely on the queue. See Fig. 4 for examples.

Definition 8 (reachable brackets)**.** For any configuration $c = \langle z,\ \sigma \,|\, i \,|\, j,\ t\rangle$, we define the set of reachable gold brackets (with respect to gold tree t_G) as

$$\mathit{reach}(c) = \mathit{left}(c) \cup \mathit{right}(c)$$

where the left- and right-reachable brackets are

$$\begin{aligned}\mathit{left}(c) &= \{{}_pX_q \in t_\mathrm{G} \mid (i, j) \prec (p, q),\ p \in \sigma \,|\, i\}\\ \mathit{right}(c) &= \{{}_pX_q \in t_\mathrm{G} \mid p \ge j\}\end{aligned}$$

for even z, with the $\prec$ replaced by $\preceq$ for odd z.

Special case (initial): $\mathit{reach}(\langle 0,\ [0],\ \emptyset\rangle) = t_\mathrm{G}$.

The notation $p \in \sigma \mid i$ simply means (p, q) does not "cross" any bracket on the stack. Remember our stack is just a list of span boundaries, so if p coincides with one of them, (p, q)'s left boundary is not crossing and its right boundary q is not crossing either since $q \ge j$ due to $(i, j) \prec (p, q)$.

Also note that $\mathit{reach}(c)$ is strictly disjoint from t, i.e., $\mathit{reach}(c) \cap t = \emptyset$ and $\mathit{reach}(c) \subseteq t_\mathrm{G} - t$. See Figure 6 for an illustration.

Definition 9 (next bracket)**.** For any configuration $c = \langle z,\ \sigma\,|\,i\,|\,j,\ t\rangle$, the next reachable gold bracket (with respect to gold tree t_{G}) is the smallest reachable bracket (strictly) encompassing (i, j):

$$next(c) = \min_{\prec} left(c).$$

4.2 Structural and Label Oracles

For an even-step configuration $c = \langle z,\ \sigma \mid i \mid j,\ t\rangle$, we denote the next reachable gold bracket $next(c)$ to be ${}_pX_q$, and define the dynamic oracle to be:

$$dyna(c) = \begin{cases} \{\mathsf{sh}\} & \text{if } p = i \text{ and } q > j \\ \{\mathsf{comb}\} & \text{if } p < i \text{ and } q = j \\ \{\mathsf{sh}, \mathsf{comb}\} & \text{if } p < i \text{ and } q > j \end{cases} \quad (1)$$

As a special case $dyna(\langle 0,\ [0],\ \emptyset\rangle) = \{\mathsf{sh}\}$.

Figure 5 shows examples of this policy. The key insight is, if you follow this policy, you will *not* miss the next reachable bracket, but if you do not follow it, you certainly will. We formalize this fact below (with proof omitted due to space constraints) which will be used to prove the central results later.

Lemma 1. *For any configuration c, for any $\tau \in dyna(c)$, we have $reach(\tau(c)) = reach(c)$; for any $\tau' \notin dyna(c)$, we have $reach(\tau(c)) \subsetneq reach(c)$.*

The label oracles are much easier than structural ones. For an odd-step configuration $c = \langle z,\ \sigma \mid i \mid j,\ t\rangle$, we simply check if (i, j) is a valid span in the gold tree t_G and if so, label it accordingly, otherwise no label. More formally,

$$dyna(c) = \begin{cases} \{\mathsf{label}\text{-}X\} & \text{if some } {}_iX_j \in t_G \\ \{\mathsf{nolabel}\} & \text{otherwise} \end{cases} \quad (2)$$

4.3 Correctness

To show the optimality of our dynamic oracle, we begin by defining a special tree $t^*(c)$ and show that it is optimal among all trees reachable from configuration c. We then show that following our dynamic oracle (Eqs. 1–2) from c will lead to $t^*(c)$.

Definition 10 ($t^*(c)$)**.** For any configuration $c = \langle z,\ \sigma,\ t\rangle$, we define the optimal tree $t^*(c)$ to include all reachable gold brackets and nothing else. More formally, $t^*(c) = t \cup reach(c)$.

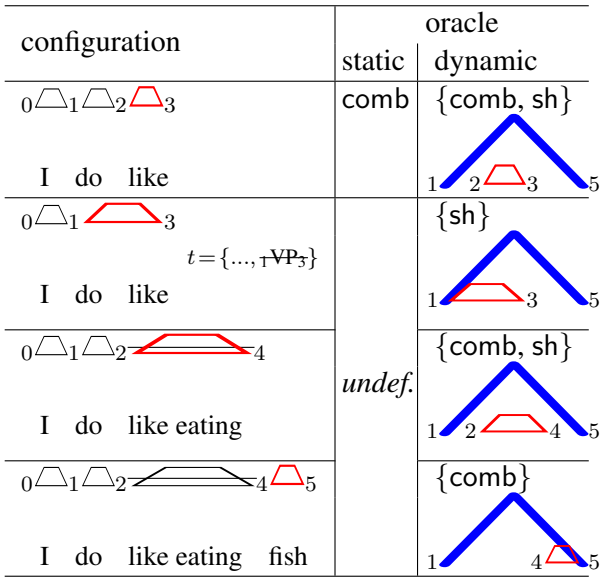

Figure 5: Dynamic oracle with respect to the gold parse in Fig. 2. The last three examples are off the gold path with strike out indicating structural or label mistakes. Trapezoids denote stack spans (top one in red) and the blue triangle denotes the next reachable bracket $next(c)$ which is ${}_1\mathrm{VP}_5$ in all cases.

We can show by induction that $t^*(c)$ is attainable:

Lemma 2. *For any configuration c, the optimal tree is a descendant of c, i.e., $t^*(c) \in \mathcal{D}(c)$.*

The following Theorem shows that $t^*(c)$ is indeed the best possible tree:

Theorem 1 (optimality of t^*)**.** *For any configuration c, $\mathrm{F}_1(t^*(c)) = \mathrm{F}_1(c)$.*

Proof. (SKETCH) Since $t^*(c)$ adds all possible additional gold brackets (the brackets in $reach(c)$), it is not possible to get higher recall. Since it adds no incorrect brackets, it is not possible to get higher pre-

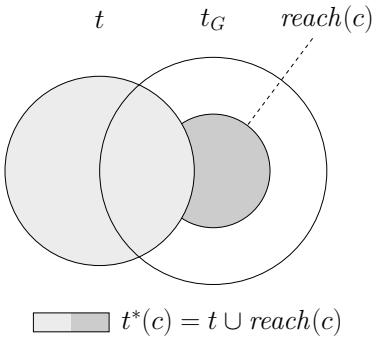

Figure 6: The optimal tree $t^*(c)$ adds all reachable brackets and nothing else. Note that $reach(c)$ and t are disjoint.

cision. Since F_1 is the harmonic mean of precision and recall, it also leads to the best possible F_1. □

Corollary 1. *For any $c = \langle z,\ \sigma,\ t\rangle$, for any $t' \in \mathcal{D}(c)$ and $t' \neq t^*(c)$, we have $\mathrm{F}_1(t') < \mathrm{F}_1(c)$.*

We now need a final lemma about the policy $dyna(\cdot)$ (Eqs. 1–2) before proving the main result.

Lemma 3. *From any $c = \langle z,\ \sigma,\ t\rangle$, for any action $\tau \in dyna(c)$, we have $t^*(\tau(c)) = t^*(c)$. For any action $\tau' \notin dyna(c)$, we have $t^*(\tau'(c)) \neq t^*(c)$.*

Proof. (SKETCH) By case analysis on even/odd z. □

We are now able to state and prove the main theoretical result of this paper (using Lemma 3, Theorem 1 and Corollary 1):

Theorem 2. *The function $dyna(\cdot)$ in Eqs. (1–2) satisfies the requirement of a dynamic oracle (Def. 5):*

$dyna(c) = oracle(c)$ for any configuration c.

4.4 Implementation and Complexity

For any configuration, our dynamic oracle can be computed in **amortized constant** time since there are only $O(n)$ gold brackets and thus bounding $|reach(c)|$ and the choice of $next(c)$. After each action, $next(c)$ either remains unchanged, or in the case of being crossed by a structural action or mislabeled by a label action, needs to be updated. This update is simply tracing the parent link to the next smallest gold bracket repeatedly until the new bracket encompasses span (i, j). Since there are at most $O(n)$ choices of $next(c)$ and there are $O(n)$ steps, the per-step cost is amortized constant time. Thus our dynamic oracle is much faster than the super-linear time oracle for arc-standard dependency parsing in Goldberg et al. (2014).

5 Related Work

Neural networks have been used for constituency parsing in a number of previous instances. For example, Socher et al. (2013) learn a recursive network that combines vectors representing partial trees, Vinyals et al. (2015) adapt a sequence-to-sequence model to produce parse trees, Watanabe and Sumita (2015) use a recursive model applying a shift-reduce system to constituency parsing with beam search, and Dyer et al. (2016) adapt the Stack-LSTM dependency parsing approach to this task. Durrett and Klein (2015) combine both neural and sparse features for a CKY parsing system. Our own previous work (Cross and Huang, 2016) use a recurrent sentence representation in a head-driven transition system which allows for greedy parsing but does not achieve state-of-the-art results.

The concept of "oracles" for constituency parsing (as the tree that is most similar to t_{G} among all possible trees) was first defined and solved by Huang (2008) in bottom-up parsing. In transition-based parsing, the dynamic oracle for shift-reduce dependency parsing costs worst-case $O(n^3)$ time (Goldberg et al., 2014). On the other hand, after the submission of our paper we became aware of a parallel work (Coavoux and Crabbé, 2016) that also proposed a dynamic oracle for their own incremental constituency parser. However, it is not optimal due to dummy non-terminals from binarization.

6 Experiments

We present experiments on both the Penn English Treebank (Marcus et al., 1993) and the French Treebank (Abeillé et al., 2003). In both cases, all state-action training pairs for a given sentence are used at the same time, greatly increasing training speed since all examples for the same sentence share the same forward and backward pass through the recurrent part of the network. Updates are performed in minibatches of 10 sentences, and we shuffle the training sentences before each epoch. The results we report are trained for 10 epochs.

The only regularization which we employ during training is dropout (Hinton et al., 2012), which is applied with probability 0.5 to the recurrent outputs. It is applied separately to the input to the second LSTM layer for each sentence, and to the input to the ReLU hidden layer (span features) for each state-action pair. We use the ADADELTA method (Zeiler, 2012) to schedule learning rates for all weights. All of these design choices are summarized in Table 2.

In order to account for unknown words during training, we also adopt the strategy described by Kiperwasser and Goldberg (2016b), where words in the training set are replaced with the unknown-word symbol UNK with probability $p_{unk} = \frac{z}{z+f(w)}$ where $f(w)$ is the number of times the word appears in the training corpus. We choose the parameter z so that the training and validation corpora have approximately the same proportion of unknown words. For the Penn Treebank, for example, we used $z = 0.8375$ so that both the validation set and the (rest of the) training set contain approximately 2.76% unknown words. This approach was helpful but not critical, improving F_1 (on dev) by about 0.1 over training without any unknown words.

6.1 Training with Dynamic Oracle

The most straightforward use of dynamic oracles to train a neural network model, where we collect all action examples for a given sentence before updating, is "training with exploration" as proposed by Goldberg and Nivre (2013). This involves parsing each sentence according to the current model and using the oracle to determine correct actions for training. We saw very little improvement on the Penn treebank validation set using this method, however. Based on the parsing accuracy on the training sentences, this appears to be due to the model overfitting the training data early during training, thus negating the benefit of training on erroneous paths.

Accordingly, we also used a method recently proposed by Ballesteros et al. (2016), which specifically addresses this problem. This method introduces stochasticity into the training data parses by randomly taking actions according to the softmax distribution over action scores. This introduces realistic mistakes into the training parses, which we found was also very effective in our case, leading to higher F_1 scores, though it noticeably sacrifices recall in favor of precision.

This technique can also take a parameter α to flatten or sharpen the raw softmax distribution. The results on the Penn treebank development set for various values of α are presented in Table 3. We were surprised that flattening the distribution seemed to be the least effective, as training accuracy (taking into account sampled actions) lagged somewhat behind validation accuracy. Ultimately, the best results were for $\alpha = 1$, which we used for final testing.

+ Explore ($\alpha=1.5$)	91.07	92.12	91.59

Table 3: Comparison of performance on PTB development set using different oracle training approaches.

6.2 Penn Treebank

Following the literature, we used the Wall Street Journal portion of the Penn Treebank, with standard splits for training (secs 2–21), development (sec 22), and test sets (sec 23). Because our parsing system seamlessly handles non-binary productions, minimal data preprocessing was required. For the part-of-speech tags which are a required input to our parser, we used the Stanford tagger with 10-way jackknifing.

Table 4 compares test our results on PTB to a range of other leading constituency parsers. Despite being a greedy parser, when trained using dynamic oracles with exploration, it achieves the best F_1 score of any closed-set single-model parser.

6.3 French Treebank

We also report results on the French treebank, with one small change to network structure. Specifically, we also included morphological features for each word as input to the recurrent network, using a small embedding for each such feature, to demonstrate that our parsing model is able to exploit such additional features.

We used the predicted morphological features, part-of-speech tags, and lemmas (used in place of word surface forms) supplied with the SPMRL 2014

data set (Seddah et al., 2014). It is thus possible that results could be improved further using an integrated or more accurate predictor for those features. Our parsing and evaluation also includes predicting POS tags for multi-word expressions as is the standard practice for the French treebank, though our results are similar whether or not this aspect is included.

We compare our parser with other recent work in Table 5. We achieve state-of-the-art results even in comparison to Björkelund et al. (2014), which utilized both external data and reranking in achieving the best results in the SPMRL 2014 shared task.

6.4 Notes on Experiments

For these experiments, we performed very little hyperparameter tuning, due to time and resource constraints. We have every reason to believe that performance could be improved still further with such techniques as random restarts, larger hidden layers, external embeddings, and hyperparameter grid search, as demonstrated by Weiss et al. (2015).

We also note that while our parser is very accurate even with greedy decoding, the model is easily adaptable for beam search, particularly since the parsing system already uses a fixed number of actions. Beam search could also be made considerably more efficient by caching post-hidden-layer feature components for sentence spans, essentially using the precomputation trick described by Chen and Manning (2014), but on a per-sentence basis.

7 Conclusion and Future Work

We have developed a new transition-based constituency parser which is built around sentence spans. It uses a factored system alternating between structural and label actions. We also describe a fast dynamic oracle for this parser which can determine the optimal set of actions with respect to a gold training tree in an arbitrary state. Using an LSTM model and only a few sentence spans as features, we achieve state-of-the-art accuracy on the Penn Treebank for all parsers without reranking, despite using strictly greedy inference.

In the future, we hope to achieve still better results using beam search, which is relatively straightforward given that the parsing system already uses a fixed number of actions. Dynamic programming (Huang and Sagae, 2010) could be especially powerful in this context given the very simple feature representation used by our parser, as noted also by Kiperwasser and Goldberg (2016b).

Abstract

Tree transducers that model expressive linguistic phenomena often require word-alignments and a heuristic rule extractor to induce their grammars. However, when the corpus of tree/string pairs is small compared to the size of the vocabulary or the complexity of the grammar, word-alignments are unreliable. We propose a general rule extraction algorithm that uses cost functions over tree fragments, and formulate the extraction as a cost minimization problem. As a by-product, we are able to introduce back-off states at which some cost functions generate right-hand-sides of previously unseen left-hand-sides, thus creating transducer rules "on-the-fly". We test the generalization power of our induced tree transducers on a QA task over a large Knowledge Base, obtaining a reasonable syntactic accuracy and effectively overcoming the typical lack of rule coverage.

1 Introduction

Tree transducers are general and solid theoretical models that have been applied to a variety of NLP tasks, such as machine translation (Knight and Graehl, 2005), text summarization (Cohn and Lapata, 2009), question answering (Jones et al., 2012), paraphrasing and textual entailment (Wu, 2005). One strategy to obtain transducer rules is by exhaustive enumeration; however, this method is ineffective when there is a high structural language variability and we wish to have an expressive model. Another strategy is to heuristically extract rules from a corpus of tree/string pairs and word-alignments, as GHKM algorithm does (Galley et al., 2004); however, word-alignments are difficult to estimate when the corpus is small. This would be the case, for example, of machine translation for low-resourced languages where there is often small numbers of parallel sentences, or in Question Answering (QA) tasks where the number of Knowledge Base (KB) identifiers (concepts) is much larger than QA datasets.

Our main contribution is an algorithm that formulates the rule extraction as a cost minimization problem, where the search for the best rules is guided by an ensemble of cost functions over pairs of tree fragments. In GHKM, a tree fragment and a sequence of words are extracted together if they are minimal and their word alignments do not fall outside of their respective boundaries. However, given that alignment violations are not allowed, the quality of the extracted rules degrades as the rate of misaligned words increases. In our framework, we can mimic GHKM by assigning an infinite cost to pairs of tree fragments that violate such conditions on word alignments and by adding a cost regularizer on the size of the tree fragments. Smoother cost functions, however, would permit controlled misalignments, contributing to generalization. Given the generality of these cost functions, we believe that the applicability of tree transducers will be extended.

A by-product of introducing these cost functions is that some of them may act as rule back-offs, where transducer rules are built "on-the-fly" when the transducer is at a predefined back-off state but there is no rule whose left-hand-side (*lhs*) matches the input subtree. These back-off states can be seen as functions that are capable of generating right-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 12–22,
Austin, Texas, November 1-5, 2016.

hand-sides (*rhs*) for unseen input subtrees.

Our rule extraction algorithm and back-off scheme are general, in the sense that they can be applied to any tree transformation task. However, in this paper, we extrinsically evaluate the quality of the extracted rules in a QA task, where the objective is to transform syntactic trees of questions into constituent trees that represent Sparql queries on Freebase, a large Knowledge Base. Implementing all components of a QA system at a sufficient level is out of the scope of this paper; for that reason, in order to evaluate our contribution in isolation, we use the FREE917 corpus released by Cai and Yates (2013), for which an entity and predicate lexicon is available[1]. We show that a tree-to-tree transducer induced using our rule extraction and back-off scheme is accurate and generalizes well, which was not previously achieved with tree transducers in semantic parsing tasks such as QA over large KBs.

2 Related Work

Tree transducers were first proposed by Rounds (1970) and Thatcher (1970), and have been greatly developed recently (Knight and Graehl, 2005). Jones et al. (2012) used tree transducers to semantically parse narrow-domain questions into Prolog queries for GeoQuery (Wong and Mooney, 2006), a small database of 700 geographical facts. Rules were exhaustively enumerated, which was possible given the small size of the database and low variability of questions. Another strategy is that of Li et al. (2013), where they used a variant of GHKM to induce tree transducers that parse into λ-SCFG. Word-to-node alignments could be reliably estimated with the IBM models (Brown et al., 1993) given, again, the small vocabulary and database size of GeoQuery. In such small-scale tasks, our rule extraction and back-off scheme offers no obvious advantage. However, when doing QA over larger and more realistic KBs (and other tasks with similar characteristics), exhaustive enumeration of rules or reliable estimations of alignments are not possible, which prevents the application of tree transducers. Thus, it is on the latter type of tasks where we focus our contribution.

A similar problem has been considered in the tree mapping literature in the form of the *tree-to-tree edit distance*. In that formulation, three edit operations are defined, namely, deleting and inserting single nodes, and replacing the label of a node. These edit operations have a cost associated to them, and the task consists of finding the minimum edit cost and its corresponding edit script[2] that transforms a source into a target tree. The problem was first solved by Tai (1979), and later Zhang and Shasha (1989) proposed a simpler and faster dynamic programming algorithm that operates in polynomial time, and that has inspired multiple variations (Bille, 2005).

However, we need edit operations that involve tree fragments (e.g., noun phrases or parts of verb phrases), rather than single nodes, when searching for the best mappings. We address this problem by searching for non-isomorphic tree mappings, in line with Eisner (2003), except that our rule extraction algorithm is guided by an ensemble of cost functions over *pairs of tree fragments*. This algorithm is capable of extracting rules more robustly than GHKM by permitting misalignments in a controlled manner. Finding a tree mapping solves simultaneously the alignment and the rule extraction problem.

There is a wide array of tree transducers with different expressive capabilities (Knight and Graehl, 2005). We consider *extended*[3] *root-to-frontier*[4] *linear*[5] transducers (Maletti et al., 2009), possibly with *deleting*[6] operations. In this paper, we syntactically parse the natural language question and transform it into a meaning representation, similarly to Ge and Mooney (2005). But instead of using Prolog formulae or λ-SCFG, we use constituent representations of $\lambda-$DCS expressions (Liang, 2013), which is a formal language convenient to represent Sparql queries where variables are eliminated by making existential quantifications implicit (see example in Figure 1).

Another challenge is to construct transducers with sufficient rule coverage, which would require billions of lexical rules that map question phrases to database entities or relations. Even if those rules were available, estimating their rule probabilities would be difficult given the small data sets of ques-

[1] The entity lexicon was released by the authors of FREE917, and the predicate lexicon is ours.

[6] Some variables on the *lhs* may not appear in the *rhs*.

tions paired with their logical representations. We solve the problem by constructing lexical rules "on-the-fly" at the decoding stage, similarly to the candidate generation stage of entity linking systems (Ling et al., 2015). Rule weights are also predicted on-the-fly given rule features and model parameters similar to Cohn and Lapata (2009).

3 Background

Tree transducers apply to general tree transformation problems, but for illustrative purposes, we use the tree pair s and t in Figure 1 (from FREE917) as a running example. s is the syntactic constituent tree of the question "how many teams participate in the uefa", whereas t is a constituent tree of an executable meaning representation in the $\lambda-$DCS formalism:

$$\texttt{count}(\texttt{Team.League.Uefa})$$

Its corresponding lambda expression is

$$\texttt{count}(\lambda x.\exists a.\texttt{Team}(x,a) \wedge \texttt{League}(a,\texttt{Uefa}))$$

which can be converted into a Sparql KB query:

$$\begin{array}{l}\texttt{SELECT COUNT}(?x)\ \texttt{WHERE}\ \{\\ \quad ?a\quad \texttt{Team}\quad\quad ?x\quad\quad .\\ \quad ?a\quad \texttt{League}\quad \texttt{Uefa}\quad .\ \}\end{array}$$

Following the terminology of Graehl and Knight (2004), we define a tree-to-tree transducer as a 5-tuple $(\mathcal{Q}, \Sigma, \Delta, q_{\text{start}}, \mathcal{R})$ where $\mathcal{Q}$ is the set of states, Σ and Δ are the sets of symbols of the input and output languages, q_{start} is the initial state, and $\mathcal{R}$ is the set of rules. For convenience, define T_Σ as the set of trees with symbols in Σ, $T_\Sigma(\mathcal{A})$ the set of trees with symbols in $\Sigma \cup \mathcal{A}$ where symbols in $\mathcal{A}$ only appear in the leaves, $\mathcal{X}$ as the set of variables $\{x_1, \ldots, x_n\}$, and $\mathcal{A}.\mathcal{B}$ for the cross-product of two sets $\mathcal{A}$ and $\mathcal{B}$. A rule $r \in \mathcal{R}$ has the form $q.t_i \xrightarrow{s} t_o$, where $q \in \mathcal{Q}$ is a state, $t_i \in T_\Sigma(\mathcal{X})$ is the left-hand-side (*lhs*) tree pattern (or elementary tree), $t_o \in T_\Delta(\mathcal{Q}.\mathcal{X})$ the right-hand-side (*rhs*), and $s \in \mathbb{R}$ the rule score.

Tree-to-tree transducers apply a sequence of rules to transform a source s into a target t tree. A root-to-frontier transducer starts at the root of the source tree and searches $\mathcal{R}$ for a rule whose i) tree pattern t_i on the *lhs* matches the root of the source tree, and ii) the state q of the rule is the initial state of the transducer. An incipient target tree is created by copying the *rhs* of the rule. Then, the transducer recursively and independently visits the subtrees of the source tree at the *lhs* variable positions of the rule from their new states, and copies the results into the same variable on the target tree.

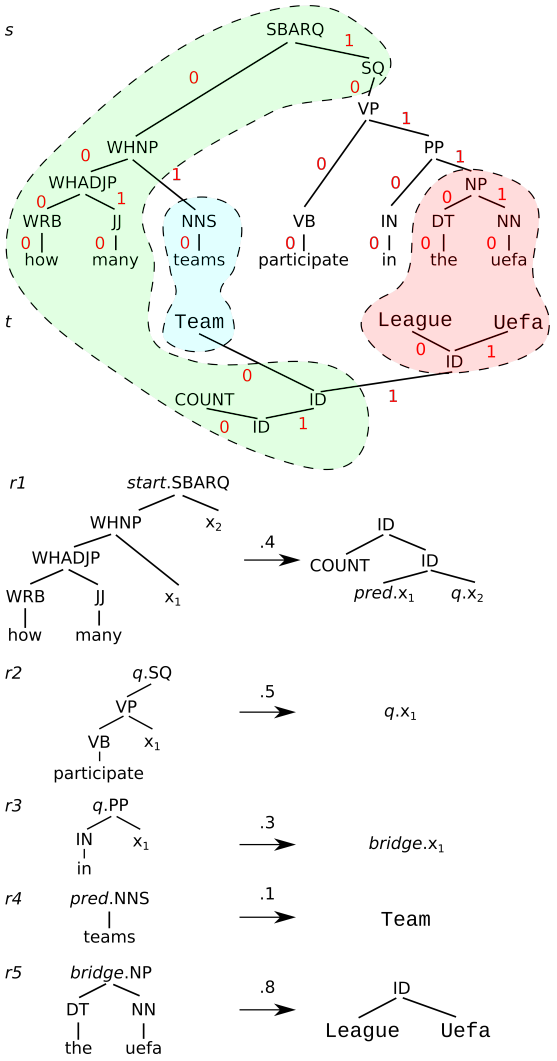

Figure 1: (s) Constituent tree of a question; (t) executable meaning representation; $r1$ - $r5$ are typical transducer rules extracted by our algorithm, where q is a generic state, *pred* and *bridge* are predicate and bridged entity back-off states.

In Figure 1, the sequential application of rules $r1$ to $r5$ is a derivation that transforms the question s into the query t. For example, rule $r1$ consumes a tree fragment of s (e.g. "how", "many", "WRB", etc.) and produces a tree fragment with terminals ("COUNT", x_1, x_2) and non-terminals ("ID") with

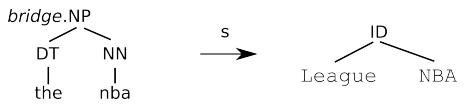
a specific structure. Rules $r2$ and $r3$ only consume but do not produce symbols (other than variables). The *rhs* of rules are target tree fragments that connect to each other at the frontier nodes (those with variables). Rules $r4$ and $r5$ are terminal rules, where $r4$ produces the predicate `Team` and rule $r5$ produces the entity `Uefa` and a disambiguating predicate `League` that has no lexical support on the source side, similarly to the role that *bridging predicates* play in Berant et al. (2013).

Given a corpus of source and target tree pairs, the learning stage aims to obtain rules such as $r1 - r5$ in Figure 1 and their associated probabilities or scores. We discuss our novel approach to rule extraction in Section 5. For the assignment of rule scores, we adopt the latent variable averaged structured perceptron, a discriminative procedure similar to Tsochantaridis et al. (2005) and Cohn and Lapata (2009). Here, we instantiate feature values $\mathbf{f}$ for every rule, and reward the weights $\mathbf{w}$ of rules that participate in a derivation (latent variable) that transforms a training source tree into a meaning representation that retrieves the correct answer.

At decoding stage, rule scores can be predicted as $s = \mathbf{w} \cdot \mathbf{f}$. However, we cannot expect to have extracted all necessary rules at the training stage given the small training data and large-scale KB. For that reason, we propose in Section 4 a novel rule back-off scheme to alleviate coverage problems.

4 Back-off rules

As an illustrative example, consider the question "how many teams participate in the nba", and the rules $r1$ to $r5$ in Figure 1. When the transducer attempts to transform the noun phrase (NP (DT the) (NN nba)), no rule's *lhs* matches it. However, since the transducer is at state *bridge* (as specified by the *rhs* of $r3$), it should be able to produce a list of bridged entities, among which the target subtree (ID `League` `NBA`) will be hopefully included. Thus, the following rule should be created for the occasion:



This mechanism produces rules "on-the-fly", allowing us to compensate low rule coverage by consuming and producing tree fragments that were not necessarily observed in the training data.

Back-off rules are produced when the transducer is at a back-off state $q_b \in \mathcal{Q}_b \subset \mathcal{Q}$, similarly as the back-off mechanisms in finite-state language models where we produce estimates (probabilities) of input structures (sequences) under less conditioning. In our scheme, a back-off state (or function) q_b produces estimates that are target structures $t_2 \in T_\Delta$ with score $s \in \mathbb{R}$, given some information of the source tree fragment $t_1 \in T_\Sigma$. That is, a function $q_b : T_\Sigma \rightarrow \{(T_\Delta, \mathbb{R}), \ldots\}$. In our QA application, we only use the leaves of the input subtree t_1 and use lexicons or entity/predicate linkers to retrieve KB entities, KB relations or a compound of a disambiguating relation and an entity from back-off states *ent*, *pred* and *bridge*, respectively. Other back-off functions would transliterate the leaves of the input tree in machine translation, or produce synonyms/hypernyms in a paraphrasing application.

We associate a score s to these newly created rules, which we learn to predict using the discriminative training procedure suggested by Tsochantaridis et al. (2005), as described in Section 3.

Back-off rules are then constructed on-demand as $q_b.t_1 \xrightarrow{s} t_2$, and the discrete set of rules $\mathcal{R}$ is augmented with them. It remains now to recognize those back-off states when inducing tree transducer grammars, which is covered in Section 5.1.

5 Rule Extraction

Given a pair of trees, our rule extraction algorithm finds a tree mapping that implicitly describes the rules that transform a source into a target tree. In the search of the best mapping, we need to explore the space of edit operations, which are substitutions of source by target tree fragments. We define cost functions for these edit operations, and formulate the tree mapping as a cost minimization problem. Whereas our tree mapping algorithm and back-off scheme are generic and can be used in any tree transformation task, cost functions depend on the application.

5.1 Cost functions

In general, cost functions are defined over edit operations, which are pairs of source and target tree fragments, $\text{cost} : T_\Sigma(\mathcal{X}) \times T_\Delta(\mathcal{Q}.\mathcal{X}) \rightarrow \mathbb{R}^{\geq 0}$, and they are equivalent to feature functions. Some cost

functions are defined over all pairs of tree fragments.

For this QA application, these are:

$$\textit{csize}(t_1, t_2) = |\text{nodes}(t_1)|^2 + |\text{nodes}(t_2)|^2$$

which acts as a tree size regularizer, returning a cost quadratic to the size of the tree fragments, thus encouraging small rules. The cost function *ccount* assigns zero cost if (i) "how" and "many" appear in t_1, and (ii) "`COUNT`" appears in t_2. If only either (i) or (ii), the cost is a positive constant. Similarly, other operators (max, min, argmax, etc.) could be recognized, but this dataset did not require them.

Other cost functions only apply to some pairs of tree fragments. These are the back-off functions described in Section 4, but instead of returning scores for every target tree fragment, they return a cost, e.g. $\textit{cent} : T_\Sigma \times T_\Delta \rightarrow \mathbb{R}^{\geq 0}$. An ensemble will produce up to three different costs for every pair of tree fragments, depending on what back-off functions were triggered. In the case of the entity cost function:

$$\begin{aligned}\gamma_{\textit{ent}}(t_1, t_2) = \lambda_1 \cdot \textit{csize}(t_1, t_2) \\ + \lambda_2 \cdot \textit{ccount}(t_1, t_2) \\ + \lambda_3 \cdot \textit{cent}(t_1, t_2)\end{aligned} \quad (1)$$

where $\lambda_i \in \mathbb{R}^{\geq 0}$ are scaling factors. In the search of the lowest-cost mapping, the labels of the cost functions that are derived from the back-off functions (e.g. $\gamma_{\textit{ent}}$, $\gamma_{\textit{pred}}$) are memorized for the pairs (t_1, t_2) for which they were defined and for which they outputted a cost. These labels are then used as back-off rule state names when constructing rules.

5.2 Tree Mapping: Optimization Problem

Intuitively, the cost of mapping a source node n_s to a target node n_t is equal to the cost of transforming a tree fragment $T_\Sigma(\mathcal{X})$ rooted at node n_s into a tree fragment $T_\Delta(\mathcal{Q}.\mathcal{X})$ rooted at node n_t, plus the sum of costs of mapping the frontier nodes rooted at the variables. In order to formalize our tree mapping, we need a more precise definition of a tree fragment where the locations of variables $\mathcal{X}$ are specified by paths. The notation to specify subtrees is taken from (Graehl and Knight, 2004), and we introduce the $\perp$ operator for convenience.

A path p is a tuple, equivalent to a Gorn address, that uniquely identifies the node of a tree by specifying the sequence of child indices to the node from the root. In the tree s of Figure 1, the path to the VP node is $(1, 0)$, whereas in t, the path to `League` is $(1, 1, 0)$. The path $p = ()$ refers to the root of a tree. We denote by $s \downarrow p$ the subtree of tree s that is rooted at path p and that has no variables. In Figure 1, the left-hand-side (*lhs*) of $r5$ is the subtree $s \downarrow (1, 0, 1, 1)$. In order to introduce variables, we generalize the notion of subtree into a tree pattern $s \downarrow p \perp \{p_1, \ldots, p_n\}$, where n variables replace subtrees $s \downarrow p_i$ at subpaths $p_i \in \{p_1, \ldots, p_n\}$. For example, the *lhs* of $r1$ can be represented with the tree pattern $s \downarrow () \perp \{(0, 1), (1)\}$, and $r2$ with $s \downarrow (1) \perp \{(1, 0, 1)\}$. Note that the order of subpaths $\{p_1, \ldots, p_n\}$ matters. A tree pattern with no subpaths $s \downarrow p \perp \{\}$ is simply a subtree $s \downarrow p$, such as the *lhs* of rules $r4$ and $r5$; a tree pattern with only one subpath equal to its path $s \downarrow p \perp \{p\}$ is a single variable, such as the *rhs* of rules $r2$ and $r3$. Note that in $s \downarrow p \perp \{p_1, \ldots, p_n\}$, all paths p_i to variables are prefixed by p, and that no variables are descendants of any other variable in the same tree pattern. In other words, $\mathbf{p} = \{p_1, \ldots, p_n\}$ are *disjoint subpaths* given p, where $\mathbf{p}$ denotes a list of paths.

We can now formalize the tree mapping algorithm as an optimization problem. Let $\gamma\left(s \downarrow p_s \perp \mathbf{p}, t \downarrow p_t \perp \mathbf{p}'\right)$ be the cost to transform a source into a target tree pattern, as defined in Equation 1. To transform $s \downarrow p_s$ into $t \downarrow p_t$, we need to find the best combination of source subtrees rooted at $\{p_1, \ldots, p_n\}$ that can be transformed at minimum cost to the best combination of target subtrees at $\{p'_1, \ldots, p'_n\}$. The transformation cost of a certain tree pattern $s \downarrow p_s \perp \{p_1, \ldots, p_n\}$ into $t \downarrow p_t \perp \{p'_1, \ldots, p'_n\}$ is equal to the cost of transforming the source tree pattern into the target tree pattern, plus the minimum cost to transform $s \downarrow p_i$ into $t \downarrow p'_i$, for $i \geq 1$. That is:

$$\begin{aligned}&\mathrm{C}\left(s \downarrow p_s, t \downarrow p_t\right) = \\ &\min_{\mathbf{p},\mathbf{p}'}\{\gamma\left(s \downarrow p_s \perp \mathbf{p}, t \downarrow p_t \perp \mathbf{p}'\right) + \\ &\qquad \sum_{i=1}^{|\mathbf{p}|} \mathrm{C}\left(s \downarrow p_i, t \downarrow p'_i\right)\}\end{aligned} \quad (2)$$

subject to $|\mathbf{p}| = |\mathbf{p}'|$, that is, source and target tree patterns having the same number of variables. Then, the cost of transforming the source into the target tree would be given by the expression

$\mathrm{C}\,(s \downarrow (), t \downarrow ())$. Since we are only interested in the pairs of source and target tree patterns that lead to the minimum cost, we keep track of subpaths $\mathbf{p}$ and $\mathbf{p}'$ of tree pattern pairs that minimize the cost.

5.3 Algorithm

5.3.1 Overview

This problem can be solved for small depths of tree patterns and a small number of variables by storing intermediate results in the computation of Eq. 2. However, an exact implementation needs to enumerate all pairs of source and target disjoint subpaths ($\mathbf{p}$ and $\mathbf{p}'$), which has a computational complexity that grows combinatorially with $|\mathbf{p}|$ (variable permutations), and exponentially with the number of descendant nodes of p_s and p_t (powerset of variables).

Instead, we use a beam search algorithm (see Algorithm 1)[7] that constructs source and target disjoint paths ($\mathbf{p}$ and $\mathbf{p}'$) hierarchically (function GENERATEDISJOINT) in a bottom-up order, for any given path pair (p_s, p_t). First, n-best solutions (pairs of disjoint paths) are computed for children; then those partial solutions are combined into their parent using the cross-product. Solutions (with their associated cost) for every pair of paths (p_s, p_t) are stored in a weighted hypergraph, from which we can extract n-best derivations (sequences of rules). In the pseudocode, we use a helper function, $\mathrm{paths}(s \downarrow p_s)$, which denotes the list of subtree paths in bottom-up order: from the leaves up to p_s (including the latter).

5.3.2 Detailed Description

For a certain path pair (p_s, p_t), there are three cases. The first case (line 34-35) considers a pair of empty disjoint subpaths $(\mathbf{p}, \mathbf{p}') = (\{\}, \{\})$, where the cost c of transforming $s \downarrow p_s \perp \{\}$ into $t \downarrow p_t \perp \{\}$ is evaluated and the empty disjoint subpaths are added to the priority queue P, indexed with p_s. Such indexing is useful to retrieve the n-best pairs of disjoint subpaths accumulated at every tree node.

The second case (line 28 to 31) evaluates the cost of transforming single-variable tree patterns: $s \downarrow p_s \perp \{p_c\}$ into $t \downarrow p_t \perp \{p'_c\}$. In this case, variables substitute entire subtrees rooted at paths p_c and p'_c on the source and target tree patterns, respectively. Note that p_c ranges over all node addresses that are descendant of p_s (including p_s), and similarly for p'_c. The pairs of disjoint subpaths $(\mathbf{p}, \mathbf{p}') = (\{p_c\}, \{p'_c\})$ are added into the priority queue, indexed by p_c.

The third case (line 16 to 26) performs the combination of subpaths hierarchically from children to parents, and incrementally across children. For every path $p_c \in \mathrm{paths}(s \downarrow p_s)$, it visits its imme-

36:   return arg min^n_(p,p'){c | (p_s, p, p', c) ∈ P}
37: end function
```

diate children p_{ic} one by one, and retrieves into C the n-best disjoint subpaths (line 18) that have already been obtained during previous iterations for p_{ic}. Then, we retrieve into A the n-best disjoint subpaths indexed at p_c, which is a list of the best subpaths that were combined from previous immediate children (the list is empty if this is the first immediate child that we visit). The cross-product of disjoint subpaths in C and A, that is $C.A$, is then evaluated and the best combinations are stored in the priority queue indexed at p_c.

As an example of a cross-product between two lists C and A of pairs of disjoint paths, let $C = \{(\mathbf{p_1}, \mathbf{p_1}'), (\mathbf{p_2}, \mathbf{p_2}')\}$ and $A = \{(\mathbf{p_3}, \mathbf{p_3}')\}$. Then the cross-product $C.A$ would be:

$$C.A = \{(\mathbf{p}_1 \cdot \mathbf{p}_3, \mathbf{p}_1' \cdot \mathbf{p}_3'), (\mathbf{p}_2 \cdot \mathbf{p}_3, \mathbf{p}_2' \cdot \mathbf{p}_3')\}$$

where $\mathbf{p}_1 \cdot \mathbf{p}_3 = \{(0,1),(0,2),(0,3),(0,4)\}$ if $\mathbf{p}_1 = \{(0,1),(0,2)\}$ and $\mathbf{p}_3 = \{(0,3),(0,4)\}$. At this stage, subpaths $\mathbf{p}_i$ or $\mathbf{p}_i'$ that are not disjoint are discarded, together with disjoint paths that produce tree patterns with depth larger than a certain user-defined threshold, or whose number of subpaths is larger than the number of variables allowed.

In line 24, the disjoint subpaths of C (in addition to their cross-product $C.A$) are also evaluated and added to the priority queue indexed by p_c, to propagate upwards in the hierarchy of solutions the decision of not combining disjoint subpaths.

Finally, GENERATEDISJOINT returns the n-best pairs of disjoint subpaths of minimum cost ($\mathbf{p}$, $\mathbf{p}'$) that accumulated in the priority queue P for path p_s.

5.3.3 Other Considerations

The n-best source and target pairs of disjoint subpaths are stored at every pair of source and target paths (p_s, p_t) (lines 2-10), forming a hypergraph, as in Figure 2. Then, with a hypergraph search (Huang and Chiang, 2007) we can retrieve at least n-best sequences of rules (derivations) that transform the source into the target tree (line 11).

To maintain diversity of partial disjoint subpaths, we divide P into a matrix of buckets with as many rows and columns as the number of non-variable terminals of the source and target tree patterns, trading memory for more effective search (Koehn, 2015). This operation is implicit in lines 24, 30 and 35.

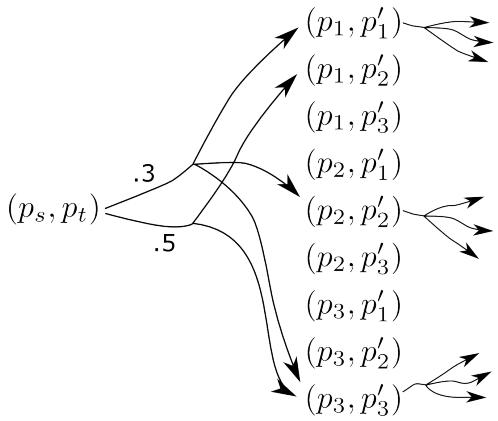

Figure 2: Hypergraph with 2-best pairs of disjoint subpaths for (p_s, p_t). Vertices are pairs of source and target paths. Hyperedges are pairs of tree patterns. The hyperedge with cost .3 denotes the pair $s \downarrow p_s \perp \{p_1, p_2, p_3\}$ and $t \downarrow p_t \perp \{p_1', p_2', p_3'\}$. The one with cost .5, $s \downarrow p_s \perp \{p_1, p_3\}$ and $t \downarrow p_t \perp \{p_2', p_3'\}$.

6 Experiments

6.1 Experiment Settings

Data The training data is a corpus of questions annotated with their logical forms that can be executed on Freebase to obtain a precise answer. For an unseen set of questions, the task is to obtain automatically their logical forms and retrieve the correct answer. Our objective is to evaluate the generalization capabilities of a transducer induced using our rule extraction on an unseen open-domain test set. We parsed questions from FREE917 into source constituent trees using the Stanford caseless model (Klein and Manning, 2003). Target constituent (meaning) representations were obtained by a simple heuristic conversion from the $\lambda-$DCS expressions released by Berant et al. (2013). We evaluate on the same training and testing split as in Berant et al. (2013). Tree pairs (2.9%) for which the gold executable meaning representation did not retrieve valid results were filtered out.

Baselines We compared to two baselines. The first one is SEMPRE (Berant et al., 2013), a state-of-the-art semantic parser that uses a target language grammar to over-generate trees, and a log-linear model to estimate the parameters that guide the decoder towards trees that generate correct answers. For FREE917, SEMPRE uses a manually-created entity lexicon released by (Cai and Yates, 2013), but an automatically generated predicate lexicon. In-

stead, our system and the second baseline use manually created entity *and* predicate lexicons, where the latter was created by selecting all words from every question that relate to the target predicate. For example, for the question "what olympics has egypt participated in", we created an entry that maps the discontinuous phrase "olympics participated in" to the predicate `OlympicsParticipatedIn`.

The second baseline is a tree-to-tree transducer whose rules are extracted using a straightforward adaptation of the GHKM algorithm (Galley et al., 2004) for pairs of trees. Word-to-concept alignments are extracted using three different strategies: i) **ghkm-g** uses the IBM models (Brown et al., 1993) as implemented in GIZA++ (Och and Ney, 2003), ii) **ghkm-m** maps KB concepts (target leaves) to as many source words as present in the entity/predicate lexicons, and iii) **ghkm-c** maps KB concepts as in ii) but only retaining the longest contiguous sequence of source words (or right-most sequence if there is a tie). Bridging predicates are assumed when a KB concept does not align (according to the lexicon) to any source word. Finally, rule state names are set according to the mechanism described in Section 5.

Our *ent*, *pred* and *bridge* cost/back-off functions assign a low cost (or high score) to source and target tree patterns with no variables whose leaves appear in either the entity or the predicate lexicons. Scaling factors λ_i (see Eq. 1) were subjectively tuned on 20 training examples. When used as back-off functions, they generate as many *rhs* as entities or predicates can be retrieved from the lexicons by at least one of the words in the source tree pattern. Bridging predicates are dispreferred by adding an extra constant cost. At back-off, this score function generates a variable predicate, acting as a wildcard in Sparql.

Our system t2t For the rule extraction, we use a beam size of 10, and we output 100 derivations for every tree pair. We do not impose any limit in the depth of *lhs* or *rhs*, or in the number of variables. To increase the coverage of our rules, we produce deleting tree transducers by replacing fully lexicalized branches that are directly attached to the root of a *lhs* with a deleting variable.

For the parameter estimation, we used 3 iterations of the latent variable averaged structured perceptron, where the number of iterations was selected on 20% of held-out training data. To assess the equality between the gold and the decoded tree, we compare their denotations. The features for the discriminative training were the *lhs* and *rhs* roots, the number of variables, deleting variables and leaves, the presence of entities or predicates in the *rhs*, the rule state and children states, and several measures of character overlaps between the leaves of the source and information associated to leaves in target tree patterns.

For decoding, we used standard techniques (Graehl and Knight, 2004) to constrain and prune weighted regular tree grammars given a tree transducer and a source tree, and used the cube-growing algorithm to generate $10,000$ derivations, converted them to Sparql queries, and retained those that were valid (either syntactically correct or that retrieved any result). We compute the accuracy of the system as the percentage of questions for which the 1-best output tree retrieves the correct answer, and the coverage as the percentage for which the correct answer is within the $10,000$ best derivations. The average rule extraction time per tree pair when using beam size 1 was 0.46 seconds (median 0.35, maximum 2.94 seconds). When using beam size 10, the average was 4.7 seconds (median 2.02, maximum 104.4 seconds), which gives us a glimpse of how the beam size influences the computational complexity for the typical tree size of FREE917 questions.

6.2 Results

Results are in Table 1. Note that although we compare our results to those obtained with SEMPRE (Berant et al., 2013), the systems cannot really be compared since Berant et al. (2013) did not have access to a manually created lexicon of predicates. When comparing the average number of entity and predicate rules that the back-off functions generate, we see that the number of predicate rules is much larger, implying a higher ambiguity. Despite this, our base system still produces promising results in terms of accuracy and coverage.

We also carried out several ablation experiments to investigate what are the characteristics of the system that contribute the most to the accuracy: In **no nbest**, we only extract one sequence of rules that transform a source into a target tree. In **no del**, we do not introduce deleting variables. In **beam 1**, we use beam size 1 in rule extraction. In **no size**, no tree size regularizer cost function is used. And in

Systems	Acc.	Cov.	# Preds.	# Ents.	# Rules

Table 1: Accuracy and coverage results; average number of predicate rules, entity rules and all rules per input tree.

no back, no rule back-offs are used. As we see, removing the back-off rule capabilities is critical in this setting and makes the QA task unfeasible. We also studied the impact of the size of the training data in the generalization of our system, by training the system in $\{100, 200, \ldots, 600\}$ examples. We found that the accuracy saturates at only 400 training instances, which might be advantageous in tasks where training resources are scarce. Finally, in order to estimate the upper bound in the coverage and accuracy of our approach on FREE917, we also run our pipeline **t2t-e** with a refined version of Cai and Yates (2013)'s entity lexicon, where 65 missing entities are added (7.8% of the total). We can observe a significant increase in the accuracy and coverage of the system, suggesting that the bottleneck may lie in the entity/predicate linking procedures.

7 Future Work

One step further in the generalization of the rule extraction is to remove the necessity of explicitly providing cost functions such as word-to-word hard-alignments or costs between tree fragments. This would allow us to remove the bias introduced by engineered cost functions and to obtain rules that are globally optimal. In this setup, the parameters of the cost functions are to be learned with the objective to maximize the likelihood on the training data or a downstream application performance. However, since rules (or tree mappings) would become hidden variables, this generalized rule extraction may require faster methods to enumerate plausible rules. Another extension would be to make the rule extraction more robust against parsing errors, using pairs of forests instead of pairs of trees, similarly as in Liu et al. (2009).

Regarding the QA application, there are two natural extensions that we want to address, namely to develop general and automatic entity and predicate linking mechanisms for large knowledge bases, and to test our approach in datasets that require higher levels of compositionality such as the QALD challenges (Unger et al., 2015) or those datasets produced by Wang et al. (2015).

8 Conclusion

We proposed to induce tree to tree transducers using a rule extraction algorithm that uses cost functions over pairs of tree fragments (instead of word-alignments), which increases the applicability of these models. Some cost functions may act as rule back-offs, generating new *rhs* given unseen *lhs*, thus producing transducer rules "on-the-fly". The scores of these rules are obtained on demand using a discriminative training procedure that estimates weights for rule features. This strategy was useful to compensate the lack of rule coverage when inducing tree transducers from small tree corpora.

As a proof-of-concept, we tested the tree transducer induced with our algorithm on a QA task over a large KB, a domain in which tree transducers have not been effective before. In this task, lexicon mappings were naturally introduced as cost functions and rule back-offs, without loss of generality. Despite using a manually created lexicon of predicates, we showed a high accuracy and coverage of non-final rules, which are promising results.

Abstract

We propose a neural-network based model for coordination boundary prediction. The network is designed to incorporate two signals: the similarity between conjuncts and the observation that replacing the whole coordination phrase with a conjunct tends to produce a coherent sentences. The modeling makes use of several LSTM networks. The model is trained solely on conjunction annotations in a Treebank, without using external resources. We show improvements on predicting coordination boundaries on the PTB compared to two state-of-the-art parsers; as well as improvement over previous coordination boundary prediction systems on the Genia corpus.

1 Introduction

Coordination is a common syntactic phenomena, appearing in 38.8% of the sentences in the Penn Treebank (PTB) (Marcus et al., 1993), and in 60.71% of the sentences in the Genia Treebank (Ohta et al., 2002). However, predicting the correct conjuncts span remain one of the biggest challenges for state-of-the-art syntactic parsers. Both the Berkeley and Zpar phrase-structure parsers (Petrov et al., 2006; Zhang and Clark, 2011) achieve F1 scores of around 69% when evaluated on their ability to recover coordination boundaries on the PTB test set. For example, in:

"He has the government's blessing to [build churches] and [spread Unificationism] in that country."

the conjuncts are incorrectly predicted by both parsers:

Berkeley: *"He has the government's blessing to [build churches] and [spread Unificationism in that country]."*
Zpar: *"He [has the government's blessing to build churches] and [spread Unificationism in that country]."*

In this work we focus on coordination boundary prediction, and suggest a specialized model for this task. We treat it as a ranking task, and learn a scoring function over conjuncts candidates such that the correct candidate pair is scored above all other candidates. The scoring model is a neural network with two LSTM-based components, each modeling a different linguistic principle: (1) conjuncts tend to be similar ("symmetry"); and (2) replacing the coordination phrase with each of the conjuncts usually result in a coherent sentence ("replacement"). The *symmetry* component takes into account the conjuncts' syntactic structures, allowing to capture similarities that occur in different levels of the syntactic structure. The *replacement* component considers the coherence of the sequence that is produced when connecting the participant parts. Both of these signals are syntactic in nature, and are learned solely based on information in the Penn Treebank. Our model substantially outperforms both the Berkeley and Zpar parsers on the coordination prediction task, while using the exact same training corpus. Semantic signals (which are likely to be based on resources external to the treebank) are also relevant for coordination disambiguation (Kawahara and Kurohashi, 2008; Hogan, 2007) and provide complementary information. We plan to incorporate such signals in future work.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 23–32,
Austin, Texas, November 1-5, 2016.

2 Background

Coordination is a very common syntactic construction in which several sentential elements (called conjuncts) are linked. For example, in:

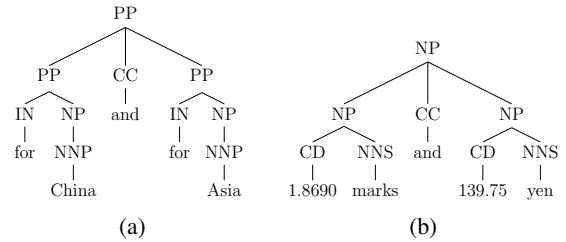
"The Jon Bon Jovi Soul Foundation [was founded in 2006] and$_1$ [exists to combat issues that force (families) and$_2$ (individuals) into economic despair]."

The coordinator *and*$_1$ links the conjuncts surrounded with square brackets and the coordinator *and*$_2$ links the conjuncts surrounded with round brackets.

Coordination between NPs and between VPs are the most common, but other grammatical functions can also be coordinated: *"[relatively active]$_{ADJP}$ but [unfocused]$_{ADJP}$"* ; *"[in]$_{IN}$ and [out]$_{IN}$ the market"*. While coordination mostly occurs between elements with the same syntactic category, cross-category conjunctions are also possible: (*"Alice will visit Earth [tomorrow]$_{NP}$ or [in the next decade]$_{PP}$"*). Less common coordinations involve non-constituent elements *"[equal to] or [higher than]"*, argument clusters (*"Alice visited [4 planets] [in 2014] and [3 more] [since then]"*), and gapping (*"[Bob lives on Earth] and [Alice on Saturn]"*) (Dowty, 1988).

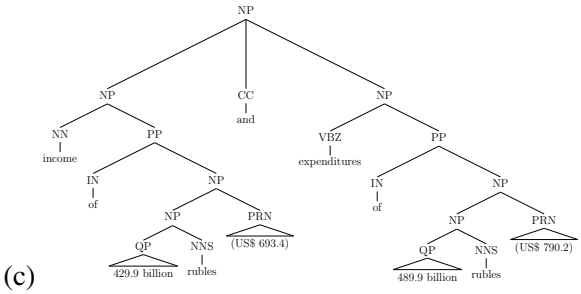
2.1 Symmetry between conjuncts

Coordinated conjuncts tend to be semantically related and have a similar syntactic structure. For example, in (a) and (b) the conjuncts include similar words (China/Asia, marks/yen) and have identical syntactic structures.



(a) (b)

Symmetry holds also in larger conjuncts, such as in:



(c)

Similarity between conjuncts was used as a guiding principle in previous work on coordination disambiguation (Hogan, 2007; Shimbo and Hara, 2007; Hara et al., 2009).

2.2 Replaceability

Replacing a conjunct with the whole coordination phrase usually produce a coherent sentence (Huddleston et al., 2002). For example, in *"Ethan has developed [new products] and [a new strategy]"*, replacement results in: *"Ethan has developed new products"*; and *"Ethan has developed a new strategy"*, both valid sentences. Conjuncts replacement holds also for conjuncts of different syntactic types, e.g.: *"inactivation of tumor-suppressor genes, [alone] or [in combination], appears crucial to the development of such scourges as cancer."*.

While both symmetry and replacebility are strong characteristics of coordination, neither principle holds universally. Coordination between syntactically dissimilar conjuncts is possible ("tomorrow and for the entirety of the next decade"), and the replacement principle fails in cases of ellipsis, gapping and others (*"The bank employs [8,000 people in Spain] and [2,000 abroad]"*).

2.3 Coordination in the PTB

Coordination annotation in the Penn Treebank (Marcus et al., 1993) is inconsistent (Hogan, 2007) and lacks internal structure for NPs with nominal modifiers (Bies et al., 1995). In addition, conjuncts in the PTB are not explicitly marked. These deficiencies led previous works on coordination disambiguation (Shimbo and Hara, 2007; Hara et al., 2009; Hanamoto et al., 2012) to use the Genia treebank of biomedical text (Ohta et al., 2002) which explicitly marks coordination phrases. However, using the Genia corpus is not ideal since it is in a specialized

domain and much smaller than the PTB. In this work we rely on a version of the PTB released by Ficler and Goldberg (2016) in which the above deficiencies are manually resolved. In particular, coordinating elements, coordination phrases and conjunct boundaries are explicitly marked with specialized function labels.

2.4 Neural Networks and Notation

We use $w_{1:n}$ to indicate a list of vectors $w_1, w_2, \ldots w_n$ and $w_{n:1}$ to indicate the reversed list. We use $\circ$ for vector concatenation. When a discrete symbol w is used as a neural network's input, the corresponding embedding vector is assumed.

A multi-layer perceptron (MLP) is a non linear classifier. In this work we take MLP to mean a classifier with a single hidden layer: $MLP(x) = V \cdot g(Wx + b)$ where x is the network's input, g is an activation function such as ReLU or Sigmoid, and W, V and b are trainable parameters. Recurrent Neural Networks (RNNs) (Elman, 1990) allow the representation of arbitrary sized sequences. In this work we use LSTMs (Hochreiter and Schmidhuber, 1997), a variant of RNN that was proven effective in many NLP tasks. LSTM$(w_{1:n})$ is the outcome vector resulting from feeding the sequence $w_{1:n}$ into the LSTM in order. A bi-directional LSTM (biLSTM) takes into account both the past $w_{1:i}$ and the future $w_{i:n}$ when representing the element in position i:

$$biLSTM(w_{1:n}, i) = LSTM_F(w_{1:i}) \circ LSTM_B(w_{n:i})$$

where $LSTM_F$ reads the sequence in its regular order and $LSTM_B$ reads it in reverse.

3 Task Definition and Architecture

Given a coordination word in a sentence, the coordination prediction task aims to returns the two conjuncts that are connected by it, or NONE if the word does not function as a coordinating conjunction of a relevant type.[1] Figure 1 provides an example.

Our system works in three phases: first, we determine if the coordinating word is indeed part of a conjunction of a desired type. We then extract a ranked list of candidate conjuncts, where a candidate is a pair of spans of the form $((i, j), (l, m))$. The candidates are then scored and the highest scoring pair is returned. Section 4 describes the scoring model, which is the main contribution of this work. The coordination classification and candidate extraction components are described in Section 5.

Sentence:
And$_1$ the city decided to treat its guests more like royalty or$_2$ rock stars than factory owners.
Expected output:
and$_1$: NONE
or$_2$: (11-11) royalty ; (12-13) rock stars

Sentence:
The president is expected to visit Minnesota, New York and$_1$ North Dakota by the end of the year.
Expected output:
and$_1$: (9-10) New York ; (12-13) North Dakota

Figure 1: The coordination prediction task.

4 Candidate Conjunctions Scoring

Our scoring model takes into account two signals, symmetry between conjuncts and the possibility of replacing the whole coordination phrase with its participating conjuncts.

4.1 The Symmetry Component

As noted in Section 2.1, many conjuncts spans have similar syntactic structure. However, while the similarity is clear to human readers, it is often not easy to formally define, such as in:

"about/IN half/NN its/PRP$ revenue/NN
and/CC
more/JJR than/IN half/NN its/PRP$ profit/NN"

If we could score the amount of similarity between two spans, we could use that to identify correct coordination structures. However, we do not know the similarity function. We approach this by training the similarity function in a data-dependent manner. Specifically, we train an encoder that encodes spans into vectors such that vectors of similar spans will have a small Euclidean distance between them. This architecture is similar to Siamese Networks, which are used for learning similarity functions in vision tasks (Chopra et al., 2005).

[1] We consider *and*, *or*, *but*, *nor* as coordination words. In case of more than two coordinated elements (conjuncts), we focus on the two conjuncts which are closest to the coordinator.

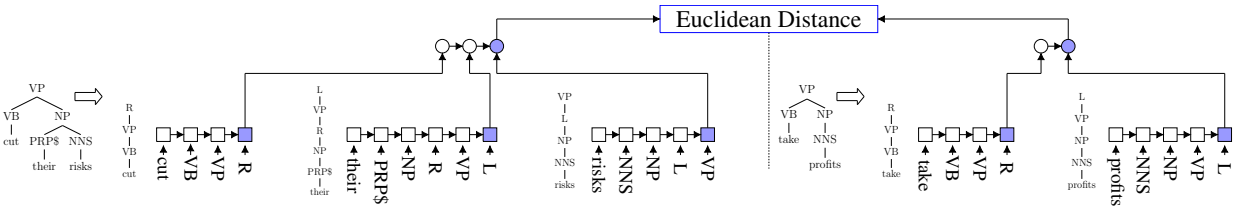


Figure 2: Illustration of the symmetry scoring component that takes into account the conjuncts syntactic structures. Each conjunct tree is decomposed into paths that are fed into the path-LSTMs (squares). The resulting vectors are fed into the symmetry LSTM function (circles). The outcome vectors (blue circles) are then fed into the euclidean distance function.

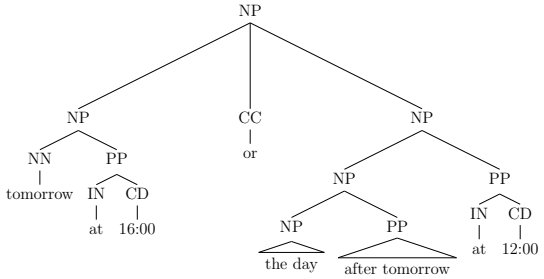
Given two spans of lengths k and m with corresponding vector sequences $u_{1:k}$ and $v_{1:m}$ we encode each sequences using an LSTM, and take the euclidean distance between the resulting representations:

$$Sym(u_{1:k}, v_{1:m}) = ||LSTM(u_{1:k}) - LSTM(v_{1:m})||$$

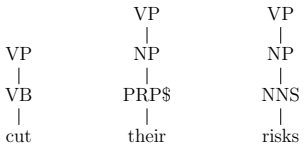
The network is trained such that the distance is minimized for compatible spans and large for incompatible ones in order to learn that vectors that represent correct conjuncts are closer than vectors that do not represent conjuncts.

What are the elements in the sequences to be compared? One choice is to take the vectors u_i to correspond to embeddings of the ith POS in the span. This approach works reasonably well, but does not consider the conjuncts' syntactic structure, which may be useful as symmetry often occurs on a higher level than POS tags. For example, in:

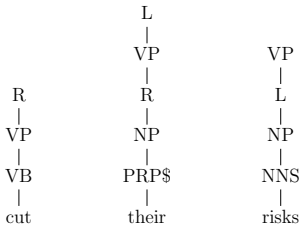


the similarity is more substantial in the third level of the tree than in the POS level.

A way to allow the model access to higher levels of syntactic symmetry is to represent each word as the projection of the grammatical functions from the word to the root.[2] For example, the projections for the first conjunct in Figure 2 are:



This decomposition captures the syntactic context of each word, but does not uniquely determine the structure of the tree. To remedy this, we add to the paths special symbols, R and L, which marks the lowest common ancestors with the right and left words respectively. These are added to the path above the corresponding nodes. For example consider the following paths which corresponds to the above syntactic structure:



The lowest common ancestor of *"their"* and *"risks"* is NP. Thus, R is added after NP in the path of *"their"* and L is added after NP in the path of *"risks"*. Similarly, L and R are added after the VP in the *"their"* and *"cut"* paths.

The path for each word is encoded using an LSTM receiving vector embeddings of the elements in the path from the word to the root. We then use the resulting encodings instead of the POS-tag embeddings as input to the LSTMs in the similarity function. Figure 2 depicts the complete process for the spans "cut their risks" and "take profits".

Using syntactic projections requires the syntactic structures of the conjuncts. This is obtained by running the Berkeley parser over the sentence and taking the subtree with the highest probability from the

[2] Similar in spirit to the spines used in Carreras et al. (2008) and Shen et al. (2003).

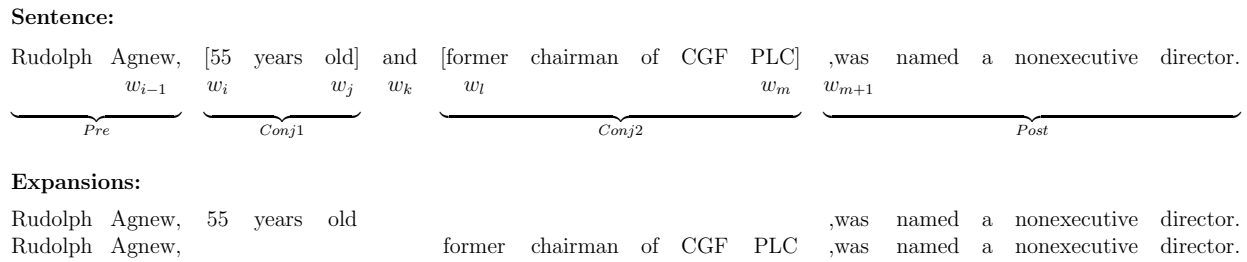


Figure 3: The correct conjuncts spans of the coordinator *and* in the sentence and the outcome expansions.

corresponding cell in the CKY chart.[3] In both approaches, the POS embeddings are initialized with vectors that are pre-trained by running word2vec (Mikolov et al., 2013) on the POS sequences in PTB training set.

4.2 The Replacement Component

The replacement component is based on the observation that, in many cases, the coordination phrase can be replaced with either one of its conjuncts while still preserving a grammatical and semantically coherent sentence (Section 2.2)

When attempting such a replacement on incorrect conjuncts, the resulting sentence is likely to be either syntactically or semantically incorrect. For example, in the following erroneous analysis: *"Rudolph Agnew, [55 years old] and [former chairman] of Consolidated Gold Fields PLC"* replacing the conjunction with the first conjunct results in the semantically incoherent sequence *"Rudolph Agnew, 55 years old of Consolidated Golden Fields, PLC"*.[4]

Our goal is to distinguish replacements resulting from correct conjuncts from those resulting from erroneous ones. To this end, we focus on the *connection points*. A connection point in a resulting sentence is the point where the sentence splits into two sequences that were not connected in the original sentence. For example, consider the sentence in Figure 3. It has four parts, marked as *Pre*, *Conj1*, *Conj2* and *Post*. Replacing the coordination phrase *Conj1 and Conj2* with *Conj2* results in a connection point between *Pre* and *Conj2*. Likewise, replacing the coordination phrase with *Conj1* results in connection point between *Conj1* and *Post*.

In order to model the validity of the connection points, we represent each connection point as the concatenation of a forward and reverse LSTMs centered around that point. Specifically, for the spans in Figure 3 the two connection points are represented as:

$LSTM_F$(Rudolph,...,old)$\circ LSTM_B$(director,...,was,,)
and
$LSTM_F$(Rudolph,Agnew,,)$\circ LSTM_B$(director,...,former)

Formally, assuming words $w_{1:n}$ in a sentence with coordination at position k and conjuncts $w_{i:j}$ and $w_{l:m}$,[5] the connection points are between $w_{1:j}$ and $w_{m+1:n}$; and between $w_{1:i-1}$ and $w_{l:n}$. The two connection points representations are then concatenated, resulting in a *replacement vector*:

$$\textsc{Repl}(w_{1:n}, i, j, l, m) = \textsc{ConPoint}(w_{1:n}, i-1, l) \circ \textsc{ConPoint}(w_{1:n}, j, m+1)$$

where:

$$\textsc{ConPoint}(w_{1:n}, i, j) = LSTM_F(w_{1:i}) \circ LSTM_B(w_{n:j})$$

We use two variants of the replacement vectors, corresponding to two levels of representation. The first variant is based on the sentence's words, while the second is based on its POS-tags.

4.3 Parser based Features

In addition to the symmetry and replacement signals, we also incorporate some scores that are derived from the Berkeley parser. As detailed in Section 5, a list of conjuncts candidates are extracted

[3] The parser's CKY chart did not include a tree for 10% of the candidate spans, which have inside probability 0 and outside probability > 0. For those, we obtained the syntactic structure by running the parser on the span words only.

[4] While uncommon, incorrect conjuncts may also result in valid sentences, e.g. *"He paid $ 7 for cold [drinks] and [pizza] that just came out of the oven."*

[5] Usually $j = k - 1$ and $l = k + 1$, but in some cases punctuation symbols may interfere.

from the CKY chart of the parser. The candidates are then sorted in descending order according to the multiplication of inside and outside scores of the candidate's spans:[6] $I_{(i,j)} \times O_{(i,j)} \times I_{(l,m)} \times O_{(l,m)}$. Each candidate $\{(i,j),(l,m)\}$ is assigned two numerical features based on this ranking: its position in the ranking, and the ratio between its score and the score of the adjacent higher-ranked candidate. We add an additional binary feature indicating whether the candidate spans are in the 1-best tree predicted by the parser. These three features are denoted as $Feats(i,j,l,m)$.

4.4 Final Scoring and Training

Finally, the score of a candidate $\{(i,j),(l,m)\}$ in a sentence with words $w_{1:n}$ and POS tags $p_{1:n}$ is computed as:

$$\begin{aligned}&\textsc{Score}(w_{1:n}, p_{1:n}, \{(i,j),(l,m)\}) = \\ &\quad MLP(\\ &\qquad Sym(v^{Path}_{i:j}, v^{Path}_{l:m}) \\ &\qquad \circ\, Repl(w_{1:n}, i, j, l, m) \\ &\qquad \circ\, Repl(p_{1:n}, i, j, l, m) \\ &\qquad \circ\, Feats(i, j, l, m)\ \ )\end{aligned}$$

where $v^{Path}_{i:j}$ and $v^{Path}_{l:m}$ are the vectors resulting from the path LSTMs, and Sym, $Repl$ and $Feats$ are the networks defined in Sections 4.1 – 4.3 above. The network is trained jointly, attempting to minimize a pairwise ranking loss function, where the loss for each training case is given by:

$$loss = max(0, 1 - (\hat{y} - y_g))$$

where $\hat{y}$ is the highest scoring candidate and y_g is the correct candidate. The model is trained on all the coordination cases in Section 2–21 in the PTB.

5 Candidates Extraction and Supporting Classifiers

Candidates Extraction We extract candidate spans based on the inside-outside probabilities assigned by the Berkeley parser. Specifically, to obtain candidates for conjunct span we collect spans that are marked with COORD, are adjacent to the coordinating word, and have non-zero inside or outside probabilities. We then take as candidates all possible pairs of collected spans. On the PTB dev set, this method produces 6.25 candidates for each coordinating word on average and includes the correct candidates for 94% of the coordinations.

Coordination Classification We decide whether a coordination word w_k in a sentence $w_{1:n}$ functions as a coordinator by feeding the biLSTM vector centered around w_k into a logistic classifier:

$$\sigma(v \cdot \text{biLSTM}(w_{1:n}, k) + b).$$

The training examples are all the coordination words (marked with CC) in the PTB training set. The model achieves 99.46 F1 on development set and 99.19 F1 on test set.

NP coordinations amount to about half of the coordination cases in the PTB, and previous work is often evaluated specifically on NP coordination. When evaluating on NP coordination, we depart from the unrealistic scenario used in most previous work where the type of coordination is assumed to be known a-priori, and train a specialized model for predicting the coordination type. For a coordination candidate $\{(i,j),(l,m)\}$ with a coordinator w_k, we predict if it is NP coordination or not by feeding a logistic classifier with a biLSTM vector centered around the coordinator and constrained to the candidate spans:

$$\sigma(v \cdot \text{biLSTM}(w_{i:m}, k) + b).$$

The training examples are coordinations in the PTB training set, where where a coordinator is considered of type NP if its head is labeled with NP or NX. Evaluating on gold coordinations results in F1 scores of 95.06 (dev) and 93.89 (test).

6 Experiments

We evaluate our models on their ability to identify conjunction boundaries in the extended Penn Treebank (Ficler and Goldberg, 2016) and Genia Treebank (Ohta et al., 2002)[7].

When evaluating on the PTB, we compare to the conjunction boundary predictions of the generative

[6] Inside-Outside probabilities (Goodman, 1998) represent the probability of a span with a given non-terminal symbol. The inside probability $I_{(N,i,j)}$ is the probability of generating words $w_i, w_{i+1}, ..., w_j$ given that the root is the non-terminal N. The outside probability $O_{(N,i,j)}$ is the probability of generating words $w_1, w_2, ..., w_{i-1}$, the non-terminal N and the words $w_{j+1}, w_{j+2}, ..., w_n$ with the root S.

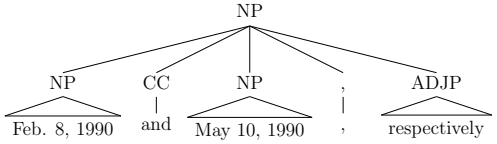
Berkeley parser (Petrov et al., 2006) and the discriminative Zpar parser (Zhang and Clark, 2011). When evaluating on the Genia treebank, we compare to the results of the discriminative coordination-prediction model of Hara et al. (2009).[8]

6.1 Evaluation on PTB

Baseline Our baseline is the performance of the Berkeley and Zpar parsers on the task presented in Section 3, namely: for a given coordinating word, determine the two spans that are being conjoined by it, and return NONE if the coordinator is not conjoining spans or conjoins spans that are not of the expected type. We convert predicted trees to conjunction predictions by taking the two phrases that are immediately adjacent to the coordinator on both sides (ignoring phrases that contain solely punctuation). For example, in the following Zpar-predicted parse tree the conjunct prediction is (*"Feb. 8, 1990"*,*"May 10, 1990"*).



Cases in which the coordination word is the left-most or right-most non-punctuation element in its phrase (e.g. `(PRN (P -)(CC and)(S it's been painful)(P -)))` are considered as no-coordination ("None").

[8] Another relevant model in the literature is (Hanamoto et al., 2012), however the results are not directly comparable as they use a slightly different definition of conjuncts, and evaluate on a subset of the Genia treebank, containing only trees that were properly converted to an HPSG formalism.

We consider two setups. In the first we are interested in all occurrences of coordination, and in the second we focus on NP coordination. The second scenario requires typed coordinations. We take the type of a parser-predicted coordination to be the type of the phrase immediately dominating the coordination word.

Evaluation Metrics We measure precision and recall compared to the gold-annotated coordination spans in the extended PTB, where an example is considered correct if both conjunct boundaries match exactly. When focusing on NPs coordinations, the type of the phrase above the CC level must match as well, and phrases of type NP/NX are considered as NP coordination.

Results Tables (1) and (2) summarize the results. The Berkeley and Zpar parsers perform similarly on the coordination prediction task. Our proposed model outperforms both parsers, with a test-set F_1 score of 72.7 (3.78 F_1 points gain over the better parser) when considering all coordinations, and test-set F_1 score of 76.1 (4.77 F_1 points gain) when considering NP coordination.

6.2 Evaluation on Genia

To compare our model to previous work, we evaluate also on the Genia treebank (Beta), a collection of constituency trees for 4529 sentences from Medline abstracts. The Genia treebank coordination annotation explicitly marks coordination phrases with a special function label (COOD), making the corpus an appealing resource for previous work on coordination boundary prediction (Shimbo and Hara, 2007; Hara et al., 2009; Hanamoto et al., 2012). Following Hara et al. (2009), we evaluate the models' ability to predict the span of the entire coordination phrase, disregarding the individual conjuncts. For example, in *"My plan is to visit Seychelles, ko Samui and Sardinia by the end of the year"* the goal is to recover *"Seychelles, ko Samui and Sardinia"*. This is a recall measure. We follow the exact protocol of Hara et al. (2009) and train and evaluate the model on 3598 coordination phrases in Genia Treebank Beta and report the micro-averaged results of a five-fold cross validation run.[9] As shown by Hara

[9] We thank Kazuo Hara for providing us with the exact details of their splits.

Sym	Correct:	Retail sales volume was [down 0.5% from the previous three months] and [up 1.2% from a year earlier].

et al. (2009), syntactic parsers do not perform well on the Genia treebank. Thus, in our symmetry component we opted to not rely on predicted tree structures, and instead use the simpler option of representing each conjunct by its sequence of POS tags. To handle coordination phrases with more than two conjuncts, we extract candidates which includes up to 7 spans and integrate the first and the last span in the model features. Like Hara et al., we use gold POS.

Results Table 3 summarizes the results. Our proposed model achieves Recall score of 64.14 (2.64 Recall points gain over Hara et al.) and significantly improves the score of several coordination types.

6.3 Technical Details

The neural networks (candidate scoring model and supporting classifiers) are implemented using the pyCNN package.[10].

In the supporting models we use words embedding of size 50 and the Sigmoid activation function. The LSTMs have a dimension of 50 as well. The models are trained using SGD for 10 iterations over the train-set, where samples are randomly shuffled before each iteration. We choose the model with the highest F1 score on the development set.

All the LSTMs in the candidate scoring model have a dimension of 50. The input vectors for the symmetry LSTM is of size 50 as well. The MLP in the candidate scoring model uses the Relu activation function, and the model is trained using the Adam optimizer. The words and POS embeddings are shared between the symmetry and replacment components. The syntactic label embeddings are for the path-encoding LSTM, We perform grid search with 5 different seeds and the following: [1] MLP hidden layer size (100, 200, 400); [2] input embeddings size for words, POS and syntactic labels (100, 300). We train for 20 iterations over the train set, randomly shuffling the examples before each iteration. We choose the model that achieves the highest F1 score on the dev set.

[10]https://github.com/clab/cnn/tree/master/pycnn

7 Analysis

Our model combines four signals: symmetry, word-level replacement, POS-level replacement and features from Berkeley parser. Table 4 shows the PTB dev-set performance of each sub-model in isolation. On their own, each of the components' signals is relatively weak, seldom outperforming the parsers. However, they provide complementary information, as evident by the strong performance of the joint model. Figure 4 lists correct and incorrect predictions by each of the components, indicating that the individual models are indeed capturing the patterns they were designed to capture – though these patterns do not always lead to correct predictions.

8 Related Work

The similarity property between conjuncts was explored in several previous works on coordination disambiguation. Hogan (2007) incorporated this principle in a generative parsing model by changing the generative process of coordinated NPs to condition on properties of the first conjunct when generating the second one. Shimbo and Hara (2007) proposed a discriminative sequence alignment model to detect similar conjuncts. They focused on disambiguation of non-nested coordination based on the learned edit distance between two conjuncts. Their work was extended by Hara et al. (2009) to handle nested coordinations as well. The discriminative edit distance model in these works is similar in spirit to our symmetry component, but is restricted to sequences of POS-tags, and makes use of a sequence alignment algorithm. We compare our results to Hara et al.'s in Section 6.2. Hanamoto et al. (2012) extended the previous method with dual decomposition and HPSG parsing. In contrast to these symmetry-directed efforts, Kawahara et al. (2008) focuses on the dependency relations that surround the conjuncts. This kind of semantic information provides an additional signal which is complementary to the syntactic signals explored in our work. Our neural-network based model easily supports incorporation of additional signals, and we plan to explore such semantic signals in future work.

9 Conclusions

We presented an neural-network based model for resolving conjuncts boundaries. Our model is based on the observation that (a) conjuncts tend to be similar and (b) that replacing the coordination phrase with a conjunct results in a coherent sentence. Our models rely on syntactic information and do not incorporate resources external to the training treebanks, yet improve over state-of-the-art parsers on the coordination boundary prediction task.

Abstract

Center-embedding is difficult to process and is known as a rare syntactic construction across languages. In this paper we describe a method to incorporate this assumption into the grammar induction tasks by restricting the search space of a model to trees with limited center-embedding. The key idea is the tabulation of *left-corner* parsing, which captures the degree of center-embedding of a parse via its stack depth. We apply the technique to learning of famous generative model, the dependency model with valence (Klein and Manning, 2004). Cross-linguistic experiments on Universal Dependencies show that often our method boosts the performance from the baseline, and competes with the current state-of-the-art model in a number of languages.

1 Introduction

Human languages in the world are divergent, but they also exhibit many striking similarities (Greenberg, 1963; Hawkins, 2014). At the level of syntax, one attractive hypothesis for such regularities is that any grammars of languages have evolved under the pressures, or biases, to avoid structures that are difficult to process. For example it is known that many languages have a preference for shorter dependencies (Gildea and Temperley, 2010; Futrell et al., 2015), which originates from the difficulty in processing longer dependencies (Gibson, 2000).

Such syntactic regularities can also be useful in applications, in particular in unsupervised (Klein and Manning, 2004; Mareček and Žabokrtský, 2012; Bisk and Hockenmaier, 2013) or weakly-supervised (Garrette et al., 2015) grammar induction tasks, where the models try to recover the syntactic structure of language without access to the syntactically annotated data, e.g., from raw or part-of-speech tagged text only. In these settings, finding better syntactic regularities universal across languages is essential, as they work as a small cue to the correct linguistic structures. A preference exploited in many previous works is favoring shorter dependencies, which has been encoded in various ways, e.g., initialization of EM (Klein and Manning, 2004), or model parameters (Smith and Eisner, 2006), and this has been the key to success of learning (Gimpel and Smith, 2012).

In this paper, we explore the utility for another universal syntactic bias that has not yet been exploited in grammar induction: a bias against center-embedding. Center-embedding is a syntactic construction on which a clause is embedded into another one. An example is "*The reporter [who the senator [who Mary met] attacked] ignored the president.*", where "*who Mary met*" is embedded in a larger relative clause. These constructions are known to cause memory overflow (Miller and Chomsky, 1963; Gibson, 2000), and also are rarely observed cross-linguistically (Karlsson, 2007; Noji and Miyao, 2014). Our learning method exploits this universal property of language. Intuitively during learning our models explore the restricted search space, which excludes linguistically implausible trees, i.e., those with deeper levels of center-embedding.

We describe how these constraints can be imposed in EM with the inside-outside algorithm. The central

idea is to tabulate *left-corner* parsing, on which its stack depth captures the degree of center-embedding of a partial parse. Each chart item keeps the current stack depth and we discard all items where the depth exceeds some threshold. The technique is general and can be applicable to any model on PCFG; in this paper, specifically, we describe how to apply the idea on the dependency model with valence (DMV) (Klein and Manning, 2004), a famous generative model for dependency grammar induction.

We focus our evaluation on grammar induction from part-of-speech tagged text, comparing the effect of several biases including the one against longer dependencies. Our main empirical finding is that though two biases, avoiding center-embedding and favoring shorter dependencies, are conceptually similar (both favor simpler grammars), often they capture different aspects of syntax, leading to different grammars. In particular our bias cooperates well with additional small syntactic cue such as the one that the sentence root tends to be a verb or a noun, with which our models compete with the strong baseline relying on a larger number of hand crafted rules on POS tags (Naseem et al., 2010).

Our contributions are: the idea to utilize left-corner parsing for a tool to constrain the models of syntax (Section 3), the formulation of this idea for DMV (Section 4), and cross-linguistic experiments across 25 languages to evaluate the universality of the proposed approach (Sections 5 and 6).

2 Left-corner parsing

We first describe (arc-eager) left-corner (LC) parsing as a push-down automaton (PDA), and then reformulate it as a grammar transform. In previous work this algorithm has been called *right-corner* parsing (e.g., Schuler et al. (2010)); we avoid this term and instead treat it as a variant of LC parsing following more recent studies, e.g., van Schijndel and Schuler (2013). The central motivation for this technique is to detect center-embedding in a parse efficiently. We describe this mechanism after providing the algorithm itself. We then give historical notes on LC parsing at the end of this section.

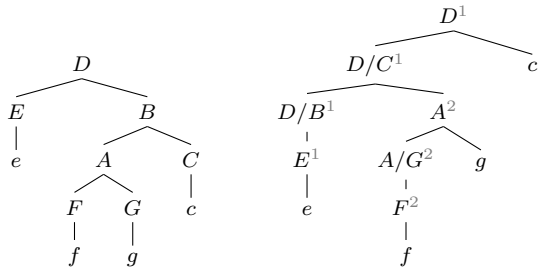
PDA Let us assume a CFG is given, and it is in CNF. We formulate LC parsing as a set of transitions between configurations, each of which is a pair of the stack and the input position (next input symbol). In Figure 1 a transition $\sigma_1 \overset{a}{\mapsto} \sigma_2$ means that the stack is changed from σ_1 to σ_2 by reading the next input symbol a. We use a vertical bar to signify the append operation, e.g., $\sigma = \sigma'|\sigma_1$ denotes σ_1 is the topmost symbol of σ. Each stack symbol is either a nonterminal, or a pair of nonterminals, e.g., A/B, which represents a subtree rooted at A and is awaiting symbol B. We also decorate each symbol with depth; for example, $\sigma^{d-1}|A^d$ means the current stack depth is d, and the depth of the topmost symbol in σ is $d-1$. The bottom symbol on the stack is always the empty symbol ε^0 with depth 0. Parsing begins with ε^0. Given the start symbol of CFG S, it finishes when S^1 is found on the stack.

The key transition here is COMP (Figure 2).[1] Basically the algorithm builds a tree by expanding the hypothesis from left to right. In COMP, a subtree rooted at A is combined with the second top subtree (D/B) on the stack. This can be done by first *predicting* that A's parent symbol is B and its sibling is C; then it unifies two different Bs to combine them. PRED is simpler, and it just predicts the parent and sibling symbols of A. The input symbols are read by SHIFT and SCAN: SHIFT addes a new element on the stack while SCAN fills in the predicted sibling symbol. For an example, Figure 3 shows how

[1] van Schijndel and Schuler (2013) employ different transition names, e.g., L- and L+; we avoid them as they are less informative.

Step	Transition	Stack	Next input symbol
0		ε	e
1	SHIFT	E^1	f
2	PRED	D/B^1	f
3	SHIFT	$D/B^1\ F^2$	g
4	PRED	$D/B^1\ A/G^2$	g
5	SCAN	$D/B^1\ A^2$	c
6	COMP	D/C^1	c
7	SCAN	D^1	

Figure 3: Sequence of transitions in LC PDA to parse the tree in Figure 4(a).



(a) (b)

Figure 4: An example of LC transform: (a) the original parse; and (b) the transformed parse.

this PDA works for parsing a tree in Figure 4(a).

Grammar transform The algorithm above can be reformulated as a grammar transform, which becomes the starting point for our application to grammar induction. This can be done by extracting the operated top symbols on the stack in each transition:

SHIFT: $A^d \rightarrow a \quad (A \rightarrow a \in P)$;
SCAN: $B^d \rightarrow B/A^d\ a \quad (A \rightarrow a \in P)$;
PRED: $B/C^d \rightarrow A^d \quad (B \rightarrow A\ C \in P)$;
COMP: $D/C^d \rightarrow D/B^d\ A^{d+1} \quad (B \rightarrow A\ C \in P)$.

where a rule on the right side is a condition given the set of rules P in the CFG.

Figure 4 shows an example of this transform. The essential point is that each CFG rule in the transformed parse (b) corresponds to a transition in the original algorithm (Figure 1). For example a rule $D/C^1 \rightarrow D/B^1\ A^2$ in the parse indicates that the stack configuration $D/B^1|A^2$ occurs during parsing (just corresponding to the step 5 in Figure 3) and COMP is then applied. This can also be seen as an instantiation of Figure 2.

Stack depth and center-embedding We use the term *center-embedding* to distinguish just the tree structures, i.e., ignoring symbols. That is, the tree in Figure 4(a) is the minimal, one degree of center-embedded tree, where the constituent rooted at A is embedded into a larger constituent rooted at D. Multiple, or degree ≥ 2 of center-embedding occurs if this constituent is also embedded into another larger constituent.

Note that it is only COMP that consumes the top *two* symbols on the stack. This means that a larger stack depth occurs only when COMP is needed. Furthermore, from Figure 2 COMP always induces a subtree involving new center-embedding, and this is the underlying mechanism that the stack depth of the algorithm captures the degree of center-embedding.

One thing to note is that to precisely associate the stack depth and the degree of center-embedding the depth calculation in COMP should be revised as:

$$\text{COMP: } D/C^d \rightarrow D/B^d\ A^{d'} \quad (B \rightarrow A\ C \in P)$$
$$d' = \begin{cases} d & (\textsc{SpanLen}(A) = 1) \\ d+1 & (\text{otherwise}), \end{cases} \quad (1)$$

where $\textsc{SpanLen}(A)$ calculates the span length of the constituent rooted at A, which is 2 in Figure 4(b). This modification is necessary since COMP for a single token occurs for building purely right-branching structures.[2] Formally, then, given a tree with degree λ of center-embedding the largest stack depth d^* during parsing this tree is: $d^* = \lambda + 1$.

Schuler et al. (2010) found that on English treebanks larger stack depth such as 3 or 4 rarely occurs while Noji and Miyao (2014) validated the language universality of this observation through cross-linguistic experiments. These suggest we may utilize LC parsing as a tool for exploiting universal syntactic biases as we discuss in Section 3.

Historical notes Rosenkrantz and Lewis (1970) first presented the idea of LC parsing as a grammar transform. This is *arc-standard*, and has no relevance to center-embedding; Resnik (1992) and Johnson (1998) formulated an *arc-eager* variant by extending this algorithm. The presented algorithm here is the same as Schuler et al. (2010), and is slightly different from Johnson (1998). The difference is in the start and end conditions: while

[2] Schuler et al. (2010) skip this subtlety by only concerning stack depth after PRED or COMP. We do not take this approach since ours allows a flexible extension described in Section 3.

our parser begins with an empty symbol, Johnson's parser begins with the predicted start symbol, and finishes with an empty symbol.

3 Learning with structural constraints

Now we discuss how to utilize LC parsing for grammar induction in general. An important observation in the above transform is that if we perform chart parsing, e.g., CKY, we can detect center-embedded trees efficiently in a chart. For example, by setting a threshold of stack depth δ, we can eliminate any parses involving center-embedding up to degree $\delta-1$. Note that in a probabilistic setting, each weight of a transformed rule comes from the corresponding underlying CFG rule (i.e., the condition).

For learning, our goal is to estimate θ of a generative model $p(z, x|\theta)$ for parse z and its yields (words) x. We take an EM-based simplest approach, and multiply the original model by a constraint factor $f(z, x) \in [0, 1]$ to obtain a new model:

$$p'(z, x|\theta) \propto p(z, x|\theta) f(z, x), \tag{2}$$

and then optimize θ based on $p'(z, x|\theta)$. This is essentially the same approach as Smith and Eisner (2006). As shown in Smith (2006), when training with EM we can increase the likelihood of $p'(z, x|\theta)$ by just using the expected counts from an E-step on the unnormalized distribution $p(z, x|\theta) f(z, x)$.

We investigate the following constraints in our experiments:

$$f(z, x) = \begin{cases} 0 & (d^*_z > \delta) \\ 1 & (\text{otherwise}), \end{cases} \tag{3}$$

where d^*_z is the largest stack depth for z in LC parsing and δ is the threshold. This is a hard constraint, and can easily be achieved by removing all chart items (of LC transformed grammar) on which the depth of the symbol exceeds δ. For example, when $\delta = 1$ the model only explores trees without center-embedding, i.e., right- or left-linear trees.

Length-based constraints By $\delta = 2$, the model is allowed to explore trees with one degree of center-embedding. Besides these simple ones, we also investigate relaxing $\delta = 1$ that results in an intermediate between $\delta = 1$ and 2. Specifically, we relax the depth calculation in COMP (Eq. 1) as follows:

$$d' = \begin{cases} d & (\textsc{SpanLen}(A) \leq \xi) \\ d + 1 & (\text{otherwise}), \end{cases} \tag{4}$$

where $\xi \geq 1$ controls the minimal length of a span regarded as *embedded* into another one. For example, when $\xi = 2$, the parse in Figure 4(a) is *not* regarded as center-embedded because the span length of the constituent reduced by COMP (i.e., A) is 2.

This modification is motivated with our observation that in many cases center-embedded constructions arise due to embedding of small chunks, rather than clauses. An example is "*... prepared [the cat 's] dinner*", where "*the cat 's*" is center-embedded in our definition. For this sentence, by relaxing the condition with, e.g., $\xi = 3$, we can suppress the increase of stack depth. We treat ξ as a hyperparameter in our experiments, and in practice, we find that this relaxed constraint leads to higher performance.

4 Dependency grammar induction

In this section we discuss how we can formulate the dependency model with valence (DMV) (Klein and Manning, 2004), a famous generative model for *dependency* grammar induction, on LC parsing. Though as we will see, applying LC parsing for a dependency model is a little involved compared to simple PCFG models, dependency models have been the central for the grammar induction tasks, and we consider it is most appropriate for assessing effectiveness of our approach.

DMV is a head-outward generative model of a dependency tree, controlled by two types of multinomial distributions. For *stop* $\in \{\textsc{stop}, \neg\textsc{stop}\}$, $\theta_{\textsc{s}}(\textit{stop}|h, \textit{dir}, \textit{adj})$ is a Bernoulli random variable to decide whether or not to attach further dependents in *dir* $\in \{\leftarrow, \rightarrow\}$ direction. The adjacency *adj* $\in \{\textsc{true}, \textsc{false}\}$ is the key factor to distinguish the distributions of the first and the other dependents, which is TRUE if h has no dependent yet in *dir* direction. Another type of parameter is $\theta_{\textsc{a}}(a|h, \textit{dir})$, a probability that h takes a as a dependent in *dir* direction.

For this particular model, we take the following approach to formulate it in LC parsing: 1) converting a dependency tree into a binary CFG parse; 2) applying LC transform on it; and 3) encoding DMV

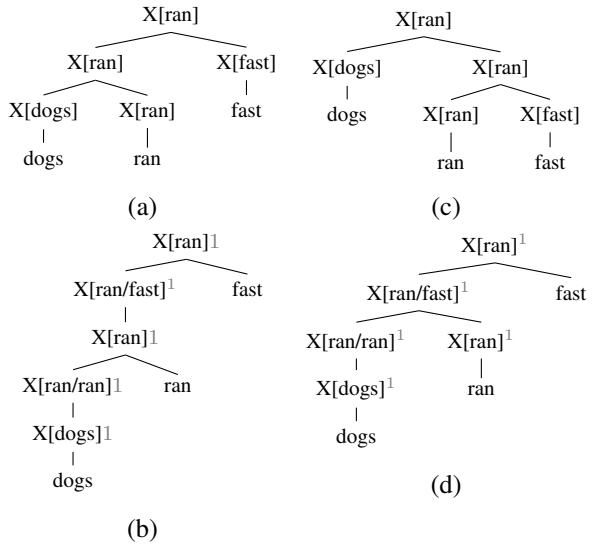


Figure 5: Two CFG parses for "dogs ran fast" and the results of LC transform ((a) → (b); (c) → (d)). X[a/b] is an abbreviation for X[a]/X[b].

parameters into each CFG rule of the transformed grammar.[3] Below we discuss a problem for (1) and (2), and then consider parameterization.[4]

Spurious ambiguity The central issue for applying LC parsing is the *spurious ambiguity* in dependency grammars. That is, there are more than one (binary) CFG parses corresponding to a given dependency tree. This is problematic mainly for two reasons: 1) we cannot specify the degree of center-embedding in a dependency tree uniquely; and 2) this one-to-many mapping prevents the inside-outside algorithm to work correctly (Eisner, 2000).

As a concrete example, Figures 5(a) and 5(c) show two CFG parses corresponding to the dependency tree *dogs*↶*ran*↷*fast*. We approach this problem by first providing a grammar transform, which generates all valid LC transformed parses (e.g., Figures 5(b) and 5(d)) and then restricting the grammar

[3]Another approach might be just applying the technique in Section 3 to some PCFG that encodes DMV, e.g., Headden III et al. (2009). The problem with this approach, in particular with split-head grammars (Johnson, 2007), is that the calculated stack depth no longer reflects the degree of center-embedding in the original parse correctly. As we discuss later, instead, we can speed up inference by applying head-splitting *after* obtaining the LC transformed grammar.

[4]Technical details including the chart algorithm for split-head grammars can be found in the Ph.D. thesis of the first author (Noji, 2016).

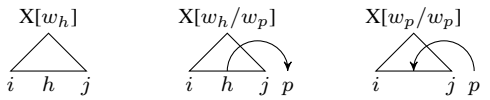

Figure 6: The senses of the symbols as a chart item. X[w_h/w_p] *predicts* the next dependent outside of the span while X[w_p/w_p] predicts the head.

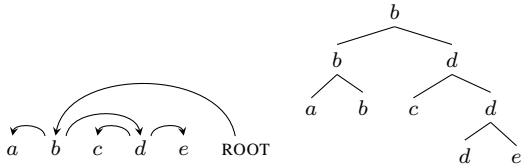

Figure 7: Implicit binarization of the restricted grammar. For each token, if its parent is in the right side (e.g., b), it attaches all left children first. The behavior is opposed when the parent is in its left (e.g., d). A dummy root token is placed at the end.

for generating particular parses only.

Naive method Let us begin with the grammar below, which suffers from the spurious ambiguity:

SHIFT: $\mathrm{X}[w_h]^d \to w_h$
SCAN: $\mathrm{X}[w_h]^d \to \mathrm{X}[w_h/w_p]^d\ w_p$
L-PRED: $\mathrm{X}[w_p/w_p]^d \to \mathrm{X}[w_h]^d\ (w_h \curvearrowleft w_p)$;
R-PRED: $\mathrm{X}[w_h/w_p]^d \to \mathrm{X}[w_h]^d\ (w_h \curvearrowright w_p)$;
L-COMP: $\mathrm{X}[w_h/w_p]^d \to \mathrm{X}[w_h/w_p]^d \mathrm{X}[w_a]^{d'}\ (w_a \curvearrowleft w_p)$;
R-COMP: $\mathrm{X}[w_h/w_a]^d \to \mathrm{X}[w_h/w_p]^d \mathrm{X}[w_p]^{d'}\ (w_p \curvearrowright w_a)$.

Here X[a/b] denotes X[a]/X[b] while w_h denotes the h-th word in the sentence w. We can interpret these rules as the operations on chart items (Figure 6). Note that only PRED and COMP create new dependency arcs and we divide them depending on the direction of the created arcs (L and R). d' is calculated by Eq. 4. Note also that for L-COMP and R-COMP h might equal p; X[ran/fast]^1 → X[ran/ran]^1 X[ran]^2 in Figure 5(d) is such a case for R-COMP.

Removing spurious ambiguity We can show that by restricting conditions for some rules, the spurious ambiguity can be eliminated (the proof is omitted).

1. Prohibit R-COMP when $h = p$;
2. Assume the span of $\mathrm{X}[w_p]^{d'}$ is (i, j) ($i \le p \le j$). Then allow R-COMP only when $i = p$.

Intuitively, these conditions constraint the order that each word collects its left and right children. For

example, by the condition 1, this grammar is prohibited to generate the parse of Figure 5(d).

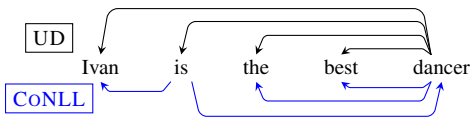
Binarization Note that two CFG parses in Figures 5(a) and 5(c) differ in how we *binarize* a given dependency tree. This observation indicates that our restricted grammar *implicitly* binarizes a dependency tree, and the incurred stack depth (or the degree of center-embedding) is determined based on the structure of the binarized tree. Specifically, we can show that the presented grammar performs *optimal* binarization; i.e., it *minimizes* the incurred stack depth. Figure 7 shows an example, which is not regarded as center-embedded in our procedure. In summary, our method detects center-embedding for a dependency tree, but the degree is determined based on the structure of the binarized CFG parse.

Parameterization We can encode DMV parameters into each rule. A new arc is introduced by one of {L/R}-{PRED/COMP}, and the stop probabilities can be assigned appropriately in each rule by calculating the valence from indices in the rule. For example, after L-PRED, w_h does not take any right dependents so $\theta_{\mathrm{S}}(stop|w_h, \rightarrow, h = j)$, where j is the right span index of $\mathrm{X}[w_h]$, is multiplied.

Improvement Though we omit the details, we can improve the time complexity of the above grammar from $O(n^6)$ to $O(n^4)$ applying the technique similar to Eisner and Satta (1999) without changing the binarization mechanism mentioned above. We implemented this improved grammar.

5 Experimental setup

A sound evaluation metric in grammar induction is known as an open problem (Schwartz et al., 2011; Bisk and Hockenmaier, 2013), which essentially arises from the ambiguity in the notion of head. For example, Universal dependencies (UD) is the recent standard in annotation and prefers content words to be heads, but as shown below this is very different from the conventional style, e.g., the one in CoNLL shared tasks (Johansson and Nugues, 2007):



The problem is that both trees are *correct* under some linguistic theories but the standard metric, unlabeled attachment score (UAS), only takes into account the annotation of the current gold data.

Our goal in this experiment is to assess the effect of our structural constraints. To this end, we try to eliminate such arbitrariness in our evaluation as much as possible in the following way:

- We experiment on UD, in which every treebank follows the consistent UD style annotation.
- We restrict the model to explore only trees that follow the UD style annotation during learning[5], by prohibiting every function word[6] in a sentence to have any dependents.
- We calculate UAS in a standard way.

We use UD of version 1.2. Some treebanks are very small, so we select the top 25 largest languages. The input to the model is coarse universal POS tags. Punctuations are stripped off. All models are trained on sentences of length ≤ 15 and tested on ≤ 40.

Initialization Much previous work of dependency grammar induction relies on the technique called harmonic initialization, which also biases the model towards shorter dependencies (Klein and Manning, 2004). Since our focus is to see the effect of structural constraints, we do not try this and initialize models uniformly. However, we add a baseline model with this initialization in our comparison to see the relative strength of our approach.

Models For the baseline, we employ a variant of DMV with *features* (Berg-Kirkpatrick et al., 2010), which is simple yet known to boost the performance well. The feature templates are almost the same; the only change is that we add backoff features for STOP probabilities that ignore both direction and adjacency, which we found slightly improves the performance in a preliminary experiment. We set the regularization parameter to 10 though in practice we found the model is less sensitive to this value. We run 100 iterations of EM for each setting. The dif-

[5] We remove the restriction at test time though we found it does not affect the performance.

[6] A word with one of the following POS tags: ADP, AUX, CONJ, DET, PART, and SCONJ.

ference of each model is then the type of constraints imposed during the E-step[7], or initialization:

- Baseline (FUNC): Function word constraints;
- HARM: FUNC with harmonic initialization;
- DEP: FUNC + stack depth constraints (Eq. 3);
- LEN: FUNC + soft dependency length bias, which we describe below.

For DEP, we use $\delta = 1.\xi$ to denote the relaxed maximum depth allowing span length up to ξ (Eq. 4).

LEN is the previously explored structural bias (Smith and Eisner, 2006), which penalizes longer dependencies by modifying each attachment score:

$$\theta'_{\text{A}}(a|h, dir) = \theta_{\text{A}}(a|h, dir) \cdot e^{-\gamma \cdot (|h-a|-1)}, \quad (5)$$

where γ (≥ 0) determines the strength of the bias and $|h - a|$ is (string) distance between h and a.

Note that DEP and LEN are closely related; generally center-embedded constructions are accompanied by longer dependencies so LEN also penalizes center-embedding implicitly. However, the opposite is not true and there exist many constructions with longer dependencies without center-embedding. By comparing these two settings, we discuss the worth of focusing on constraining center-embedding relative to the simpler bias on dependency length.

Finally we also add the system of Naseem et al. (2010) in our comparison. This system encodes many manually crafted rules between POS tags with the posterior regularization technique. For example, the model is encouraged to find NOUN → ADJ relationship. Our systems cannot access to these core grammatical rules so it is our strongest baseline.[8]

Constraining root word We also see the effects of the constraints when a small amount of grammatical rule is provided. In particular, we restrict the candidate root words of the sentence to a noun or a verb; similar rules have been encoded in past work such as Gimpel and Smith (2012) and the CCG induction system of Bisk and Hockenmaier (2013).

[7]We again remove the restrictions at decoding as we observed that the effects are very small.

[8]We encode the customized rules that follow UD scheme. The following 13 rules are used: ROOT → VERB, ROOT → NOUN, VERB → NOUN, VERB → ADV, VERB → VERB, VERB → AUX, NOUN → ADJ, NOUN → DET, NOUN → NUM, NOUN → NOUN, NOUN → CONJ, NOUN → ADP, ADJ → ADV.

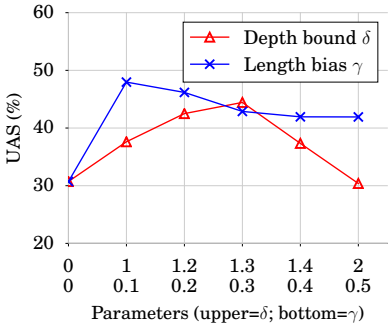


Figure 8: UAS for various settings on (UD) WSJ.

Hyperparameters Selecting hyperparameters in multilingual grammar induction is difficult; some works tune values for each language based on the development set (Smith and Eisner, 2006; Bisk et al., 2015), but this violates the assumption of unsupervised learning. We instead follow many works (Mareček and Žabokrtský, 2012; Naseem et al., 2010) and select the values with the English data. For this, we use the WSJ data, which we obtain in UD style from the Stanford CoreNLP (ver. 3.6.0).[9]

6 Experiments

WSJ Figure 8 shows the result on WSJ. Both DEP and LEN have one parameter: the maximum depth δ, and γ (Eq. 5), and the figure shows the sensitivity on them. Note that x-axis = 0 represents FUNC.

For LEN, we can see the optimal parameter γ is 0.1, and degrades the performance when increasing the value; i.e., the small bias is the best. For DEP, we find the best setting is 1.3, i.e., allowing embedded constituents of length 3 or less ($\xi = 3$ in Eq. 4). We can see that allowing depth 2 degrades the performance, indicating that depth 2 allows too many trees and does not reduce the search space effectively.[10]

Multilingual results Table 1 shows the main multilingual results. When we see "No root constraint" block, we notice that our DEP boosts the performance in many languages (e.g., Bulgarian, French,

[9]Note that the English data in UD is Web Treebank (Silveira et al., 2014), not the standard WSJ Penn treebank.

[10]We see the same effects when training with longer sentences (e.g., length ≤ 20). This is probably because a looser constraint does nothing for shorter sentences. In other words, the model can restrict the search space only for longer sentences, which are relatively small in the data.

Indonesian, and Portuguese), though LEN performs equally well and in average, LEN performs slightly better. Harmonic initialization does not work well.

We then move on to the settings with the constraint on root tags. Interestingly, in these settings DEP performs the best. The model competes with Naseem et al.'s system in average, and outperforms it in many languages, e.g., Bulgarian, Czech, etc. LEN, on the other hand, decreases the average score.

Analysis Why does DEP perform well in particular with the restriction on root candidates? To shed light on this, we inspected the output parses of English with no root constraints, and found that the types of errors are very different across constraints.

Figure 9 shows a typical example of the difference. One difference between trees is in the constructions of phrase "On ... pictures". LEN predicts that "On the next two" comprises a constituent, which modifies "pictures" while DEP predicts that "the ... pictures" comprises a constituent, which is correct, although the head of the determiner is incorrectly predicted. On the other hand, LEN works well to find more primitive dependency arcs between POS tags, such as arcs from verbs to nouns, which are often incorrectly recognized by DEP.

These observations may partially answer the

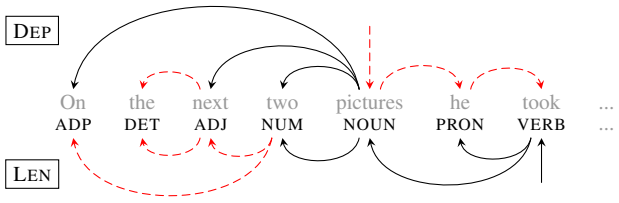

Figure 9: A comparison of output parses by DEP and LEN (with no root constraints). Dashed arcs are misclassified ones.

	Prec.	Recall	F1
FUNC (English)	11.6	18.4	14.1
DEP (English)	**22.4**	**37.1**	**27.9**
LEN (English)	21.6	31.0	25.5
FUNC (Avg.)	22.5	30.0	25.6
DEP (Avg.)	**27.8**	**34.5**	**30.5**
LEN (Avg.)	24.0	33.7	27.9
FUNC + ROOT (Avg.)	22.0	29.4	25.0
DEP + ROOT (Avg.)	**28.1**	**35.2**	**31.0**
LEN + ROOT (Avg.)	21.8	31.2	25.6

Table 2: Unlabeled bracket scores in various settings. Avg. is the average score across languages.

question above. The main source of improvements by DEP is detections of constituents, but this constraint itself does not help to resolve some core dependency relationships, e.g., arcs from verbs to nouns. The constraint on root POS tags is thus orthogonal to this approach, and it may help to find such core dependencies. On the other hand, the dependency length bias is the most effective to find basic dependency relationships between POS tags while the resulting tree may involve implausible constituents. Thus the effect of the length bias seems somewhat overlapped with the root POS constraints, which may be the reason why they do not well collaborate with each other.

Bracket scores We verify the above intuition quantitatively. To this end, we convert both the predicted and gold dependency trees into the unlabeled bracket structures, and then compare them on the standard PARSEVAL metrics. This bracket tree is not binarized; for example, we extract (X a b (X c d)) from the tree $a \curvearrowleft b \curvearrowright c \curvearrowleft d$. Table 2 shows the results, and we can see that DEP always performs the best, showing that DEP leads to the models that find better constituent structures. Of particular note

	UAS	F1
DEP	48.1	**30.5**
LEN	48.5	27.9
DEP+LEN	**49.2**	27.0

Table 3: Average scores of DEP, LEN, and the combination.

is in Enlgish the bracket and dependency scores are only loosely correlated. In Table 1, UASs for FUNC, DEP, and LEN are 37.2, 39.8, and 52.1, respectively, though F1 of DEP is substantially higher. This suggests that DEP often finds more linguistically plausible structures even when the improvement in UAS is modest. We conjecture that this performance change between constraints essentially arise due to the nature of DEP, which eliminates center-embedding, i.e., implausible *constituent* structures, rather than dependency arcs.

Combining DEP and LEN These results suggest DEP and LEN capture different aspects of syntax. To furuther understand this difference, we now evaluate the models with *both* constraints. Table 3 shows the average scores across languages (without root constraints). Interestingly, the combination (DEP+LEN) performs the best in UAS while the worst in bracket F1. This indicates the ability of DEP to find good constituent boundaries is diminished by combining LEN. We feel the results are expected observing that center-embedded constructions are a special case of longer dependency constructions. In other words, LEN is a stronger constraint than DEP in that the structures penalized by DEP are only a subset of structures penalized by LEN. Thus when LEN and DEP are combined LEN overwhelms, and the advantage of DEP is weakened. This also suggests not penalizing all longer dependencies is important for learning accurate grammars. The improvement of UAS suggests there are also collaborative effects in some aspect.

7 Conclusion

We have shown that a syntactic constraint that eliminates center-embedding is helpful in dependency grammar induction. In particular, we found that our method facilitates to find linguistically correct constituent structures, and given an additional cue on dependency, the models compete with the system relying on a significant amount of prior linguistic knowledge. Future work includes applying our DEP constraint into other PCFG-based grammar induction tasks beyond dependency grammars. In particular, it would be fruitful to apply our idea into constituent structure induction for which, to our knowledge, there has been no successful PCFG-based learning algorithm. As discussed in de Marcken (1999) one reason for the failures of previous work is the lack of necessary syntactic biases, and our approach could be useful to alleviate this issue. Finally, though we have focused on unsupervised learning for simplicity, we believe our syntactic bias also leads to better learning in more practical scenarios, e.g., weakly supervised learning (Garrette et al., 2015).

Abstract

Determining whether a major societal event has already happened, is still on-going, or may occur in the future is crucial for event prediction, timeline generation, and news summarization. We introduce a new task and a new corpus, *EventStatus*, which has 4500 English and Spanish articles about civil unrest events labeled as PAST, ON-GOING, or FUTURE. We show that the temporal status of these events is difficult to classify because local tense and aspect cues are often lacking, time expressions are insufficient, and the linguistic contexts have rich semantic compositionality. We explore two approaches for event status classification: (1) a feature-based SVM classifier augmented with a novel induced lexicon of *future-oriented* verbs, such as "threatened" and "planned", and (2) a convolutional neural net. Both types of classifiers improve event status recognition over a state-of-the-art TempEval model, and our analysis offers linguistic insights into the semantic compositionality challenges for this new task.

1 Introduction

When a major societal event is mentioned in the news (e.g., civil unrest, terrorism, natural disaster), it is important to understand whether the event has already happened (PAST), is currently happening (ON-GOING), or may happen in the future (FUTURE). We introduce a new task and corpus for studying the temporal/aspectual properties of major events. The **EventStatus corpus** consists of 4500 English and Spanish news articles about *civil unrest events*, such as protests, demonstrations, marches, and strikes, in which each event is annotated as PAST, ON-GOING, or FUTURE (sublabeled as PLANNED, ALERT or POSSIBLE). This task bridges event extraction research and temporal research in the tradition of TIMEBANK (Pustejovsky et al., 2003) and TempEval (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013). Previous corpora have begun this association: TIMEBANK, for example, includes temporal relations linking events with Document Creation Times (DCT). But the EventStatus task and corpus offers several new research directions.

First, major societal events are often discussed before they happen, or while they are still happening, because they have the potential to impact a large number of people. News outlets frequently report on impending natural disasters (e.g., hurricanes), anticipated disease outbreaks (e.g., Zika virus), threats of terrorism, and plans or warnings of potential civil unrest (e.g., strikes and protests). Traditional event extraction research has focused primarily on recognizing events that have already happened. Furthermore, the linguistic contexts of on-going and future events involve complex compositionality, and features like explicit time expressions are less useful. Our results demonstrate that a state-of-the-art TempEval system has difficulty identifying on-going and future events, mislabeling examples like these:

(1) *The metro workers' strike in Bucharest has entered the fifth day.* (On-Going)
(2) *BBC unions demand more talks amid threat of new strikes.* (Future)
(3) *Pro-reform groups have called for nationwide protests on polling day.* (Future)

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 44–54,
Austin, Texas, November 1-5, 2016.

Second, we intentionally created the EventStatus corpus to concentrate on one particular event frame (class of events): civil unrest. In contrast, previous temporally annotated corpora focus on a wide variety of events. Focusing on one frame (semantic depth instead of breadth) makes this corpus analogous to domain-specific event extraction data sets, and therefore appropriate for evaluating rich tasks like event extraction and temporal question answering, which require more knowledge about event frames and schemata than might be represented in large broad corpora like TIMEBANK (UzZaman et al., 2012; Llorens et al., 2015).

Third, the EventStatus corpus focuses on specific instances of high-level events, in contrast to the low-level and often non-specific or generic events that dominate other temporal datasets.[1] Mentions of specific events are much more likely to be realized in non-finite form (as nouns or infinitives, such as "the strike" or "to protest") than randomly selected event keywords. In breadth-based corpora like the EventCorefBank (ECB) corpus (Bejan and Harabagiu, 2008), 34% of the events have non-finite realization; in TIMEBANK, 45% of the events have non-finite realization. By contrast, in a frame-based corpus like ACE2005 (ACE, 2005), 59% of the events have non-finite forms. In the EventStatus corpus, 80% of the events have non-finite forms. Whether this is due to differences in labeling or to intrinsic properties of these events, the result is that they are much harder to label because tense and aspect are less available than for events realized as finite verbs.

Fourth, the EventStatus data set is multilingual: we collected data from both English and Spanish texts, allowing us to compare events representing the same event frame across two languages that are known to differ in their typological properties for describing events (Talmy, 1985).

Using the new EventStatus corpus, we investigate two approaches for recognizing the temporal status of events. We create a SVM classifier that incorporates features drawn from prior TempEval work (Bethard, 2013; Chambers et al., 2014; Llorens et al., 2010) as well as a new automatically induced lexicon of 411 English and 348 Spanish "future-oriented" matrix verbs—verbs like "threaten" and "fear" whose complement clause or nominal direct object argument is likely to describe a future event. We show that the SVM outperforms a state-of-the-art TempEval system and that the induced lexicon further improves performance for both English and Spanish. We also introduce a Convolutional Neural Network (CNN) to detect the temporal status of events. Our analysis shows that it successfully models semantic compositionality for some challenging temporal contexts. The CNN model again improves performance in both English and Spanish, providing strong initial results for this new task and corpus.

2 The EventStatus Corpus

For major societal events, it can be very important to know whether the event has ended or if it is still in progress (e.g., are people still rioting in the streets?). And sometimes events are anticipated before they actually happen, such as labor strikes, marches and parades, social demonstrations, political events (e.g., debates and elections), and acts of war. The EventStatus corpus represents the *temporal status* of an event as one of five categories:

Past: An event that has started and has ended. There should be no reason to believe that it may still be in progress.
On-going: An event that has started and is still in progress or likely to resume[2] in the immediate future. There should be no reason to believe that it has ended.
Future Planned: An event that has not yet started, but a person or group has planned for or explicitly committed to an instance of the event in the future. There should be near certainty it will happen.
Future Alert: An event that has not yet started, but a person or group has been threatening, warning, or advocating for a future instance of the event.
Future Possible: An event that has not yet started, but the context suggests that its occurrence is a live possibility (e.g., it is anticipated, feared, hinted at, or is mentioned conditionally).

The three subtypes of future events are important

[1] For example in TIMEBANK almost half the annotated events (3720 of 7935) are hypothetical or generic, i.e., PERCEPTION, REPORTING, ASPECTUAL, I_ACTION, STATE or I_STATE rather than the specific OCCURRENCE.

[2] For example, demonstrators have gone home for the day but are expected to return in the morning.

	Past
[EN]	Today's *demonstration* ended without violence.
	An estimated 2,000 people *protested* against the government in Peru.
[SP]	Terminó la *manifestación* de los kurdos en la UNESCO de París.
	On-going
[EN]	Negotiations continue with no end in sight for the 2 week old *strike*.
	Yesterday's rallies have caused police to fear more today.
[SP]	Pacifistas latinoamericanos no cesan sus *protestas* contra guerra en Irak.
	Future Planned
[EN]	77 percent of German steelworkers voted to *strike* to raise their wages.
	Peace groups have already started organizing mass *protests* in Sydney.
[SP]	Miedo en la City en víspera de masivas *protestas* que la toman por blanco.
	Future Alert
[EN]	Farmers have threatened to hold *demonstrations* on Monday.
	Nurses are warning they intend to walkout if conditions don't improve.
[SP]	Indigenas hondureños amenazan con declararse en *huelga* de hambre.
	Future Possible
[EN]	Residents fear *riots* if the policeman who killed the boy is acquitted.
	The military is preparing for possible protests at the G8 summit.
[SP]	Policía Militar analiza la posibilidad de decretar una *huelga* nacional.

Table 1: Examples of event status categories for civil unrest events, showing two examples in English [EN] and one in Spanish [SP].

in marking not just temporal status but also what we might call predictive status. Events very likely to occur are distinguished from events whose occurrence depends on other contingencies (Future Planned vs. Alert/Possible). Warnings or mentions of a potential event by a likely actor are further distinguished from events whose occurrence is more open-ended (Future Alert vs. Possible). The status of future events is not due just to lexical semantics or local context but also other qualifiers in the sentence (e.g. "may"), the larger discourse context, and world knowledge. The annotation guidelines are formulated with that in mind. The categories for future events are not incompatible with one another but are meant to be informationally ordered (e.g. "future alert" implies "future possible"). Annotators are instructed to go for the strongest implication supported by the overall context. Table 1 presents examples of each category in news reports about civil unrest events, with the event keywords in *italics*.

2.1 EventStatus Annotations

The EventStatus dataset consists of English and Spanish news articles. We manually identified 6 English words[3] and 13 Spanish words[4] and phrases associated with civil unrest events, and added their morphological variants. We then randomly selected 2954 and 1491[5] news stories from the English Gigaword 5th Ed. (Parker et al., 2011) and Spanish Gigaword 3rd Ed. (Mendon et al., 2011) corpora, respectively, that contain at least one civil unrest phrase. Events of a specific type are very sparsely distributed in a large corpus like the Gigaword, so we used keyword matching just as a first pass to identify candidate event mentions.

[3]The English keywords are "protest", "strike", "march", "rally", "riot" and "occupy". These correspond to the most frequent words in the relevant frame in the Media Frames corpus (Card et al., 2015). Because "march" most commonly refers to the month, we removed the word itself and only kept its other morphological variations.

[4]Spanish keywords: "marchar", "protestar", "amotinar(se)", "manifestar(se)", "huelga", "manifestación", "disturbio", "motín", "ocupar * la calle", "tomar * la calle", "salir * las calles", "lanzarse a las calles", "cacerolas vacías", "cacerolazo", "cacerolada". Asterisks could be replaced by up to 4 words. The last three terms are common expressions for protest marches in many countries of Latin America and Spain.

[5]46 (out of 3000) and 9 (out of 1500) stories were removed due to keyword errors.

	Past	Ongoing	Future (Plan,Alert,Possible)	Multiple	Not Event
EN	1735	583	292 (197,48,47)	28	186
SP	1545	739	360 (279,61,30)	21	72

Table 2: Counts of Temporal Status Labels in EventStatus.

Because many keyword instances don't refer to a specific event, primarily due to lexical ambiguity and generic descriptions (e.g., *"Protests are often facilitated by ..."*), we used a two-stage annotation process. First, we extracted sentences containing at least one key phrase, and had three human annotators judge whether the sentence describes a specific civil unrest event. Next, for each sentence that mentions a specific event, the annotators assigned an event status to every civil unrest key phrase in that sentence. In both annotation phases, we asked the annotators to consider the context of the entire article.

In the first annotation phase, the average pairwise inter-annotator agreement (Cohen's κ) among the annotators was $\kappa = 0.84$ on the English data and 0.70 on the Spanish data. We then assigned the majority label among the three annotators to each sentence. In the English data, of the 5085 sentences with at least one key phrase, 2492 (49%) were judged to be about a specific civil unrest event. In the Spanish data, 3249 sentences contained at least one key phrase and 2466 (76%) described a specific event.

In the second phase, the annotators assigned one of the five temporal status categories listed in Section 2 to each event keyword in a relevant sentence. In addition, we provided a *Not Event* label.[6] Occasionally, a single instance of a keyword can refer to multiple events (e.g., *"Both last week's and today's protests..."*), so we permitted multiple labels to be assigned to an event phrase. However this happened for only 28 cases in English and 21 cases in Spanish.

The average pairwise inter-annotator agreement among the three human annotators for the temporal status labels was κ=.78 for English and κ=.80 for Spanish. We used the majority label among the three annotators as the gold status. In total, 2907 English and 2807 Spanish event phrases exist in the relevant sentences and were annotated. However there were 83 English cases (≈2.9%) and 70 Spanish cases (≈2.5%) where the labels among the three annotators were all different, so we discarded these cases. Table 2 shows the final distribution of labels in the EventStatus corpus. The EventStatus corpus[7] is available through the LDC.

[6] A sentence can contain multiple keyword instances. So even in a relevant sentence, some instances may not refer to a specific event.

2.2 Linguistic Properties of Event Mentions

Next, we investigated the linguistic properties of the event status categories, lumping together the 3 future subcategories. Table 3 shows the distribution of syntactic forms of the event mentions in two commonly used event datasets, ACE2005 (ACE, 2005) and EventCorefBank (Bejan and Harabagiu, 2008), and our new EventStatus corpus. In the introduction, we mentioned the high frequency of non-finite event expressions; Table 3 provides the evidence: non-finite forms (nouns and infinitives) constitute 59% in ACE2005, 34% in EventCorefBank, and a very high 80% of the events in the EventStatus dataset. The distribution is even more skewed for future events, which are 95% (English) and 96% (Spanish) realized by non-finite surface forms.

	Finite Verbs	Nouns	Inf. Verbs	Other

Table 3: Number and % (in parentheses) of event mentions by syntactic form. PA = Past; OG = On-going; FU = Future

2.3 Future Oriented Verbs

We observed that many future event mentions are preceded by a set of lexical (non-aux) verbs that we call *future oriented verbs*, such as "threatened" in (4) and "fear" in (5). These verbs project the events in the lower clause into the future.

[7] http://faculty.cse.tamu.edu/huangrh/EventStatus_corpus.html

(4) *They threatened to protest if Kmart does not acknowledge their request for a meeting.*

(5) *People fear renewed rioting during the coming days.*

Categories of future oriented verbs include mental activity ("anticipate", "expect"), affective ("fear", "worry"), planning ("plan", "prepare", "schedule"), threatening ("threaten", "advocate", "warn"), and inchoative verbs ("start", "initiate", and "launch"). We found that these categories correlate with the predictive status of the events they embed. We drew on these insights to induce a lexicon of future oriented verbs.

We harvested matrix verbs whose complement unambiguously describes a future event using two heuristics. One heuristic looks for examples with a tense conflict between the matrix verb and its complement: a matrix verb in the past tense (like "planned" below) whose complement event is an infinitive verb or deverbal noun modified by a future time expression (like "tomorrow" or "next week"), hence in the future (e.g., "strike" below): [8]

(6) *The union planned to strike next week.*

Future events are often marked by conditional clauses, so the second heuristic considers an event to be future if it was post-modified by a conditional clause (beginning with "if" or "unless"):

(7) *The union threatened to strike if their appeal was rejected.*

Finally, to increase precision, we only harvested a verb as future-oriented if it functioned as a matrix both in sentences with an embedded future time expression and in sentences with a conditional clause.

Future Oriented Verb Categories: We ran the algorithm on the English and Spanish Gigaword corpora (Parker et al., 2011; Mendon et al., 2011), obtaining 411 English verbs and 348 Spanish verbs. To better understand the structure of the learned lexicon, we mapped each English verb to Framenet (Baker et al., 1998); 86% (355) of the English verbs occurred in Framenet, in 306 unique frames. We clustered these into 102 frames[9] and grouped the Spanish verbs following English Framenet, identifying 67 categories. (Some learned verbs, such as "poise" , "slate" , "compel" and "hesitate", had a clear future orientation but didn't exist in Framenet.) Table 4 shows examples of learned verbs for English and their categories.

Commitment: threaten, vow, promise, pledge, commit, declare, claim, volunteer, anticipate
Coming_to_be: enter, emerge, plunge, kick, mount reach, edge, soar, promote, increase, climb, double
Purpose: plan, intend, project, aim, object, target
Permitting: allow, permit, approve, subpoena
Experiencer_subj: fear, scare, hate
Waiting: expect, wait
Scheduling: arrange, schedule
Deciding: decide, opt, elect, pick, select, settle
Request: ask, urge, order, encourage, demand, appeal, request, summon, implore, advise, invite
Evoking: raise, press, back, recall, pressure, force, rush, pull, drag, respond

Table 4: Examples from Future Oriented Verb Lexicon

In the next sections we propose two classifiers, an SVM classifier using standard TempEval features plus our new future-oriented lexicon, and a Convolutional Neural Net, as a pilot exploration of what features and architecture work well for the EventStatus task. For these studies we combine the Future Planned, Future Alert and Future Possible categories into a single Future event status because we first wanted to establish how well classifiers can detect the primary temporal distinctions between Past vs. Ongoing vs. Future. The future subcategories are, of course, relatively smaller and we expect that the most effective approach will be to design a classifier that sits on top of the primary classifier to further subcategorize the Future instances. We leave the task of subcategorizing future events for later work.

[8] For English, we extract events linked by the "xcomp" dependency using the Stanford dependency parser (Marneffe et al., 2006), with a future time expression attached to the second event with the "tmod" relation. For Spanish, we consider two events related if they are at most 5 words apart, and the second event is modified by a time expression, at most 5 words apart.

[9] By merging frames that share frame elements (e.g., "Purpose" and "Project" share the frame element "plan")

3 SVM Event Status Model

Our first classifier is a linear SVM classifier.[10] We trained three binary classifiers (one per class) using one-vs.-rest, and label an event mention with the class that assigned the highest score to the mention. We used features inspired by prior TempEval work and by the previous analysis, including words, tense and aspect features, time expressions, and the new future-oriented verb lexicon. We also experimented with other features used by TempEval systems (including bigrams, POS tags, and two-hop dependency features), but they did not improve performance.[11]

Bag-Of-Words Features: For bag-of-words unigram features we used a window size of 7 (7 left and 7 right) for the English data and 6 for the Spanish data; this size was optimized on the tuning sets.

Tense, Aspect and Time Expressions: Because these features are known to be the most important for relating events to document creation time (Bethard, 2013; Llorens et al., 2010), we used TIPSem (Llorens et al., 2010) to generate the tense and aspect of events and find time expressions in both languages. TIPSem infers the tense and aspect of nominal and infinitival event mentions using heuristics without relying on syntactic dependencies. For the English data set, we also generated syntactic dependencies using Stanford CoreNLP (Marneffe et al., 2006) and applied several rules to create additional tense and aspect features based on the governing words of event mentions[12]. Time indication features are created by comparing document creation time to time expressions linked to an event mention detected by TIPSem. If TIPSem detects no linked time expressions for an event mention, we take the nearest time expression in the same sentence.

Governing Words: Governing words have been useful in prior work. Our version of the feature pairs the governing word of an event mention with the dependency relation in between. We used Stanford CoreNLP (Marneffe et al., 2006) to generate dependencies for the English data. For the Spanish data, we used Stanford CoreNLP to generate Part-of-Speech tags[13] and then applied the MaltParser (Nivre et al., 2004) to generate dependencies.

4 Convolutional Neural Network Model

Convolutional neural networks (CNNs) have been shown to be effective in modeling natural language semantics (Collobert et al., 2011). We were especially keen to find out whether the convolution operations of CNNs can model the semantic compositionality needed to detect temporal-aspectual status. For our experiments, we trained a simple CNN with one convolution layer followed by one max pooling layer (Kim, 2014; Collobert et al., 2011),

The convolution layer has 300 hidden units. In each unit, the same affine transformation is applied to every consecutive 5 words (a filter instance) in the input sequence of words. A different affine transformation is applied to each hidden unit. After each affine transformation, a Rectified Linear Units (ReLU) (Nair and Hinton, 2010) non-linearity is applied. For each hidden unit, the max pooling layer selects the maximum value from the pool of real values generated from each filter instance.

After the max pooling layer, a *softmax* classifier predicts probabilites for each of the three classes, Past, Ongoing and Future. To alleviate overfitting of the CNN model, we applied dropout (Hinton et al., 2012) on the convolution layer and the following pooling layer with a keeping rate of 0.5.

Our experiments used the 300-dimension English word2vec embeddings[14] trained on 100 billion words of Google News. We trained our own 300-dimension Spanish embeddings, running word2vec (Mikolov et al., 2013) over both Spanish Gigaword (Mendon et al., 2011)— tokenized using Stanford CoreNLP SpanishTokenizer (Manning et al., 2014)— and the pre-tokenized Spanish Wikipedia dump (Al-Rfou et al., 2013). The vectors were then tuned during backpropagation for our specific task.

[10] Trained using LIBSVM (Chang and Lin, 2011) with linear kernels (polynomial kernels yielded worse performance).

[11] Previous TempEval work reported that those additional features were useful when computing temporal relations between two events but not when relating an event to the Document Creation Time, for which tense, aspect, and time expression features were the most useful (Llorens et al., 2010; Bethard, 2013).

[12] We did not imitate this procedure for Spanish because the quality of our generated Spanish dependencies is poor.

[13] Stanford CoreNLP has no support for generating syntactic dependencies for Spanish.

Table 5: Label Distributions in the Test Set

5 Evaluations

For all subsequent evaluations, we use gold event mentions. We randomly sampled around 20% of the annotated documents as the parameter tuning set and used the rest as the test set. Rather than training once on a distinct training set, all our experiment results are based on 10-fold cross validation on the test set, (1191 Spanish documents, 2364 English documents; see Table 5 for the distribution of event mentions).

5.1 Comparing with a TempEval System

We begin with a baseline: applying a TempEval system to classify each event. Most of our features are already drawn from TempEval, but our goal was to see if an off-the-shelf system could be directly applied to our task. We chose TIPSem (Llorens et al., 2010), a CRF system trained on TimeBank that uses linguistic features, has achieved top performance in TempEval competitions for both English and Spanish (Verhagen et al., 2010), and can compute the relation of each event with the Document Creation Time. We applied TIPSem to our test set, mapping the DCT relations to our three event status classes[15].

Row 1 of Tables 6 and 7 shows TIPSem results. The columns show results for each category separately, as well as macro-average and micro-average results across the three categories. Each cell shows the Recall/Precision/F-score numbers. Since TIPSem linked relatively few event mentions to the DCT, we next leveraged the transitivity of temporal relations (UzZaman et al., 2012; Llorens et al., 2015), linking an event to a DCT if the temporal relation between another event in the same sentence and the DCT is transferable. For instance, if event A is AFTER its DCT, and event B is AFTER event A, then event B is also AFTER the DCT.[16] Row 2 shows the results of TIPSem with temporal transitivity.

Even augmented by transitivity, TIPSem fails to detect many Ongoing (**OG**) and Future (**FU**) events; most mislabeled OG and FU events were nominal. Confusion matrices (Table 8) show that most of the

[15]We used the obvious mappings from TIPSem relations: "BEFORE" to "PA", "AFTER" to "FU" , and "INCLUDES" (for English) and "OVERLAP" (for Spanish) to "OG".

[16]Some transitivity rules are ambiguous: if event A is AFTER DCT, event B INCLUDES event A, event B can be AFTER or INCLUDES DCT. We ran experiments and chose rules that improved performance the most for TipSem.

missed OG events were labeled as Past (PA) while FU events were commonly mislabeled as both PA and OG. Below are some examples of OG and FU events mislabeled as PA:

(8) Jego said Sunday on arriving in Guadeloupe that he would stay as long as it took to bring an end to the strike organised by the Collective against Extreme Exploitation (LKP). (OG)

(9) A massive protest planned for Kathmandu on Tuesday has been re-baptised a victory parade. (FU)

	Predicted (EN)			Predicted (SP)		
	PA	**OG**	**FU**	**PA**	**OG**	**FU**
Gold **PA**	718	96	15	653	231	6
Gold **OG**	156	35	11	196	160	10
Gold **FU**	72	30	7	78	72	26

Table 8: Confusion Matrices for TIPSem (with transitivity).

SVM Results Next, we compare TIPSem's results with our SVM classifier. An issue is that TIPSem identifies only 72% and 78% of the gold event mentions, for English and Spanish respectively[17]. To have a fair comparison, we applied the SVM to only the event mentions that TipSem recognized. Row 3 shows these results for the SVM classifier using its full feature set. The SVM outperforms TipSem on all three categories, for both languages, with the largest improvements on Future events.

Next, we ran ablation experiments with the SVM to evaluate the impact of different subsets of its features. For these experiments, we applied the SVM to all gold event mentions, thus Rows 1-3 of Tables 6 and 7 report on fewer event mentions than rows 4-8. Row 4 shows results using only bag-of-words features[18]. Row 5 shows results when additionally including the tense, aspect, and time features provided by TIPSem (Llorens et al., 2010). Unsurprisingly, in both languages[19] these features improve over just bag-of-word features.

Row 6 further adds governing word features. These improve English performance, especially for On-Going events. For Spanish, governing word features slightly decrease performance, likely due to the poor quality of the Spanish dependencies.

Row 7 adds the future oriented lexicon features[20]. For both English and Spanish, the future oriented lexicon increased overall performance, and (as expected) especially for Future events.

CNN Results Row 8 shows the results using CNN models. For English and Spanish, the same window (7 words for English, 6 words for Spanish) was used to compute bag-of-word features for SVMs as for training the CNN models. For English, the CNN model further increased recall and precision across all three classes. The CNN improved Spanish performance on both Past and On-going events, but the SVM outperformed the CNN for Future events when the future oriented lexicon features were included.

6 Analysis

To better understand whether the CNN model's strong performance was related to handling compositionality, we examined some English examples that were correctly recognized by the CNN model but mislabeled by the SVM classifier with bag-of-words features. The examples below (event mentions are in *italics*) suggest that the CNN may be capturing the compositional impact of local cues like "possibility" or "since":

(10) Raising the possibility of a *strike* on New Year's Eve, the president of New York City's largest union is calling for a 30 percent raise over three years. (FU)

(11) The lockout was announced in the wake of a go-slow and partial *strike* by the union since July 12 after management turned down its demand. (OG)

We also conducted an error analysis by randomly sampling and then analyzing 50 of the 473 errors by the CNN model. Many cases (26/50) are ambiguous from the sentence alone, requiring discourse information. The first example below is caused by the well-known "double access" ambiguity of the complement of a communication verb (Smith, 1978; Abusch, 1997; Giorgi, 2010).

(12) Chavez also said he discussed the *strike* with UN Secretary General Kofi Annan and told him the strike organizers were "terrorists." (OG)

[17] We were not able to decouple TipSem's event recognition component and force it to process all event mentions.

[18] Replacing each word feature with a word2vec embedding resulted in slightly worse performance.

[19] We always obtain even recall and precision for the micro average metric because we only apply classifiers to event mentions that refer to a civil unrest event.

[20] For Spanish, we removed the governing word features because of the poor quality of the Spanish dependencies.

(13) Students and teachers *protest* over education budget (PA)

In 9/50 cases, the contexts that imply temporal status are complex and fall out of our ± 7 word range, e.g.,:

(14) Protesters on Saturday also *occupied* two gymnastics halls near Gorleben which are to be used as accommodation for police. They were later forcibly dispersed by policemen. (PA)

The remaining 15/50 cases contain enough local cues to be solvable by humans, but both the CNN and SVM models nonetheless failed:

(15) Eastern leaders have grown weary of the *protest* movement led mostly by Aymara. (OG)

7 Related Work

Our work overlaps with two communities of tasks and corpora: the task of classifying temporal order between event mentions and Document Creation Time (DCT) in TempEval (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013), and the task of extracting events, associated with corpora such as ACE2005 (ACE, 2005) and the EventCorefBank (ECB) (Bejan and Harabagiu, 2008). By studying the events in a particular frame (civil unrest), but focusing on their temporal status, our work has the potential to draw these communities together. Most event extraction work (Freitag, 1998; Appelt et al., 1993; Ciravegna, 2001; Chieu and Ng, 2002; Riloff and Jones, 1999; Roth and Yih, 2001; Zelenko et al., 2003; Bunescu and Mooney, 2007) has focused on extracting event slots or frames for past events and assigning dates. The TempEval task of linking events to DCT has not focused on events that tend to have non-finite realizations, nor has it focused on subtypes of future events. Our work, including the corpus and the future-oriented verb lexicon, has the potential to benefit related tasks like generating event timelines from news articles (Allan et al., 2000; Yan et al., 2011) or social media sources (Li and Cardie, 2014; Ritter et al., 2012), or exploring the psychological implications of future oriented language (Nie et al., 2015; Schwartz et al., 2015).

8 Conclusions

We have proposed a new task of recognizing the past, on-going, or future temporal status of major events, introducing a new resource for studying events in two languages. Besides its importance for studying time and aspectuality, the EventStatus dataset offers a rich resource for any future investigation of information extraction from major societal events.

The strong performance of the convolutional net system suggests the power of latent representations to model temporal compositionality, and points to extensions of our work using deeper and more powerful networks.

Finally, our investigation of the role of context and semantic composition in conveying temporal information also has implications for our understanding of temporality and aspectuality and their linguistic expression. Many of the errors made by our CNN system are complex ambiguities, like the double access readings, that cannot be solved without information from the wider discourse context. Our work can thus also be seen as a call for the further use of rich discourse information in the computational study of temporal processing.

9 Acknowledgments

We want to thank the Stanford NLP group and especially Danqi Chen for valuable inputs, and Michael Zeleznik for helping us refine the categories and for masterfully orchestrating the annotation efforts. We also thank Luke Zettlemoyer and all our reviewers for providing useful comments. Abstract

The challenges of Machine Reading and Knowledge Extraction at a web scale require a system capable of extracting diverse information from large, heterogeneous corpora. The Open Information Extraction (OIE) paradigm aims at extracting assertions from large corpora without requiring a vocabulary or relation-specific training data. Most systems built on this paradigm extract binary relations from arbitrary sentences, ignoring the context under which the assertions are correct and complete. They lack the expressiveness needed to properly represent and extract complex assertions commonly found in the text. To address the lack of representation power, we propose NESTIE, which uses a nested representation to extract higher-order relations, and complex, interdependent assertions. Nesting the extracted propositions allows NESTIE to more accurately reflect the meaning of the original sentence. Our experimental study on real-world datasets suggests that NESTIE obtains comparable precision with better minimality and informativeness than existing approaches. NESTIE produces 1.7-1.8 times more minimal extractions and achieves 1.1-1.2 times higher informativeness than CLAUSIE.

1 Introduction

Syntactic analyses produced by syntactic parsers are a long way from representing the full meaning of the sentences parsed. In particular, they cannot support questions like "*Who did what to whom?*", "*Where did what happen?*". Owing to the large, heterogeneous corpora available at web scale, traditional approaches to information extraction (Brin, 1998; Agichtein and Gravano, 2000) fail to scale to the millions of relations found on the web. As a response, the paradigm of Open Information Extraction (OIE) (Banko et al., 2007) has seen a rise in interest as it eliminates the need for domain knowledge or relation-specific annotated data. OIE systems use a collection of patterns over the surface form or dependency tree of a sentence to extract propositions of the form `(arg1,rel,arg2)`.

However, state-of-the-art OIE systems, REVERB (Fader et al., 2011) and OLLIE (Schmitz et al., 2012) focus on extracting binary assertions and suffer from three key drawbacks. First, lack of expressivity of representation leads to significant information loss for higher-order relations and complex assertions. This results in incomplete, uninformative and incoherent prepositions. Consider Example 1 in Figure 1. Important contextual information is either ignored or is subsumed in over-specified argument and relation phrases. It is not possible to fix such nuances by post-processing the propositions. This affects downstream applications like Question Answering (Fader et al., 2014) which rely on correctness and completeness of the propositions.

Second, natural language frequently includes relations presented in a non-canonical form that cannot be captured by a small set of extraction patterns that only extract relation mediated by verbs or a subset of verbal patterns. Consider Example 2 in Figure 1 that asserts, "*Rozsa Hill is the third hill near the river*", "*Rozsa Hill is Rose Hill*" and "*Rozsa Hill lies north of Castle Hill*". A verb-mediated pattern would extract

Figure 1: Example propositions from OIE systems: REVERB (R), OLLIE (O) and NESTIE(N).

a triple, `(the third hill, lies north of, Castle Hill)` that is less informative than a triple, `(Rozsa, lies, north of Castle Hill)` which is not mediated by a verb in the original sentence. Furthermore, these propositions are not complete. Specifically, queries of the form '*What is the other name of Rozsa Hill?*", "*Where is Rozsa Hill located?*", "*Which is the third hill near the river?*" will either return no answer or return an uninformative answer with these propositions. Since information is encoded at various granularity levels, there is a need for a representation rich enough to express such complex relations and sentence constructions.

Third, OIE systems tend to extract propositions with long argument phrases that are not minimal and are difficult to disambiguate or aggregate for downstream applications. For instance, the argument phrase, *body which was found by U.S. military police*, is less likely to be useful than the argument phrase, *body* in Example 3 in Figure 1.

In this paper we present NESTIE, which overcomes these limitations by 1) expanding the proposition representation to nested expressions so additional contextual information can be captured, 2) expanding the syntactic scope of relation phrases to allow relations mediated by other syntactic entities like nouns, adjectives and nominal modifiers. NESTIE bootstraps a small set of extraction patterns that cover simple sentences and learns broad-coverage relation-independent patterns. We believe that it is possible to adapt OIE systems that extract verb-based relations to process assertions denoting events with many arguments, and learn other non-clausal relations found in the text. With weakly-supervised learning techniques, patterns encoding these relations can be learned from a limited amount of data containing sentence equivalence pairs.

This article is organized as follows. We provide background on OIE in Sec. 2 followed by an overview of our proposed solution in Sec. 3. We then discuss how the extraction patterns for nested representations are learned in Sec. 4. In Sec. 5, we compare NESTIE against alternative methods on two datasets: Wikipedia and News. In Sec. 6, we discuss related work on pattern-based information extraction.

2 Background

The key goal of OIE is to obtain a shallow semantic representation of the text in the form of tuples consisting of argument phrases and a phrase that expresses the relation between the arguments. The phrases are identified automatically using domain-independent syntactic and lexical constraints. Some OIE systems are:

TextRunner (Yates et al., 2007) **WOE** (Wu and Weld, 2010): They use a sequence-labeling graphical model on extractions labeled automatically using heuristics or distant supervision. Consequently, long-range dependencies, holistic and lexical aspects of relations tend to get ignored.

ReVerb (Fader et al., 2011): Trained with shallow syntactic features, REVERB uses a logistic regression classifier to extract relations that begin with a

verb and occur between argument phrases.

Ollie (Schmitz et al., 2012): Bootstrapping from REVERB extractions, OLLIE learns syntactic and lexical dependency parse-tree patterns for extraction. Some patterns reduce higher order relations to ReVerb-style relation phrases. Also, representation is extended optionally to capture contextual information about conditional truth and attribution for extractions.

ClausIE (Del Corro and Gemulla, 2013): Using linguistic knowledge and a small set of domain-independent lexica, CLAUSIE identifies and classifies clauses into clause types, and then generates extractions based on the clause type. It relies on a predefined set of rules on how to extract assertions instead of learning extraction patterns. Also, it doesn't capture the relations between the clauses.

There has been some work in open-domain information extraction to extract higher-order relations. KRAKEN (Akbik and Löser, 2012) uses a predefined set of rules based on dependency parse to identify fact phrases and argument heads within fact phrases. But unlike alternative approaches, it doesn't canonicalize the fact phrases. There is another body of work in natural language understanding that shares tasks with OIE. AMR parsing (Banarescu et al.,), semantic role labeling (SRL) (Toutanova et al., 2008; Punyakanok et al., 2008) and frame-semantic parsing (Das et al., 2014). In these tasks, verbs or nouns are analyzed to identify their arguments. The verb or noun is then mapped to a semantic frame and roles of each argument in the frame are identified. These techniques have gained interest with the advent of hand-constructed semantic resources like PropBank and FrameNet (Kingsbury and Palmer, 2002; Baker et al., 1998). Generally, the verb/noun and the semantically labeled arguments correspond to OIE propositions and, therefore, the two tasks are considered similar. Systems like SRL-IE (Christensen et al., 2010) explore if these techniques can be used for OIE. However, while OIE aims to identify the relation/predicate between a pair of arguments, frame-based techniques aim to identify arguments and their roles with respect to a predicate. Hence, the frames won't correspond to propositions when both the arguments cannot be identified for a binary relation or when the correct argument is buried in long argument phrases.

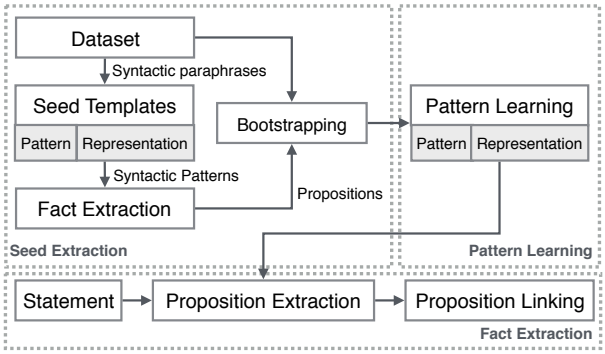

Figure 2: System Architecture of NESTIE.

3 Task Definition and NestIE Overview

Task: We focus on the task of OIE, where the system takes a natural language statement and extracts the supported assertions. This is achieved by using an extractor that uses nested representations to extract propositions and a linker that connects extracted propositions to capture context.

Proposition-based Extractor: We propose a framework to extend open-domain binary-relation extractors to extract n-ary and complex relations. As not all assertions can be expressed as `(arg1,rel,arg2)`, we learn syntactic patterns for relations that are expressed as nested templates like, `(arg1,rel,(arg2,rel2,arg3))`, `((arg1,rel,arg2),rel2,arg3)`.

Proposition Linking: In practice, it is infeasible to enumerate simple syntactic pattern templates that capture the entire meaning of a sentence. Also, increasing the complexity of templates would lead to sparsity issues while bootstrapping. We assume that there is a finite set of inter-proposition relations that can be captured using a small set of rules which take into account the structural properties of the propositions and syntactic dependencies between the relation phrases of the propositions.

System Evaluation: To compare NESTIE to other alternative methods, we conduct an experimental study on two real-world datasets: Wikipedia and News. Propositions from each system are evaluated for correctness, minimality, and informativeness.

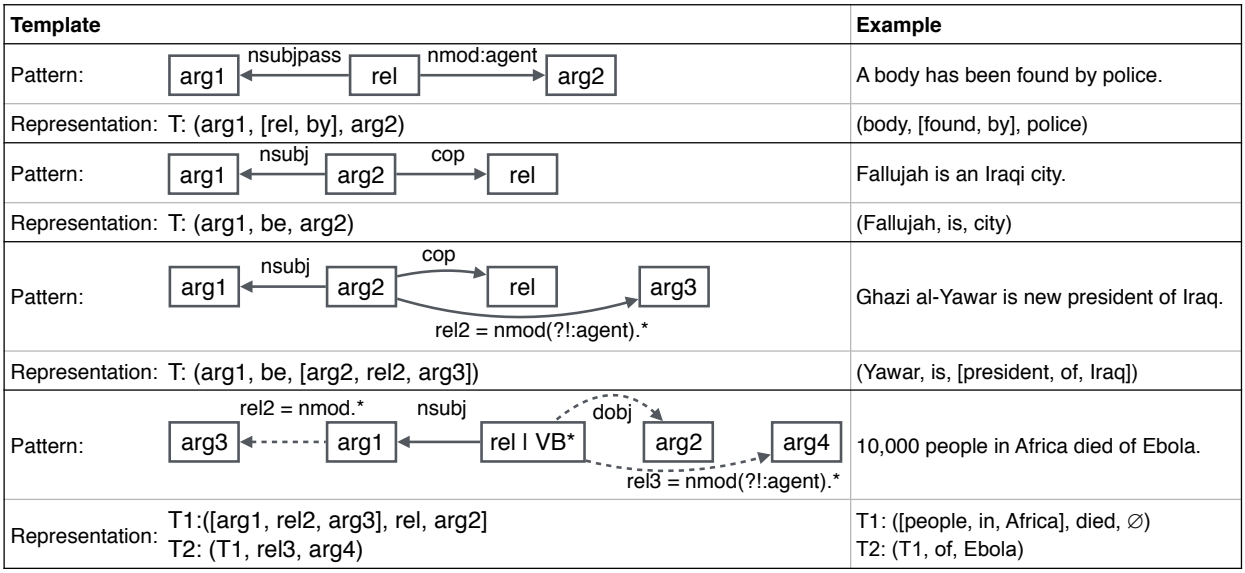

Figure 3: Seed templates and corresponding representation.

4 Proposition Extraction

Figure 2 illustrates the system architecture of NESTIE. First, a set of high-precision seed templates is used to extract propositions. A template maps a dependency parse-tree pattern to a triple representation such as `(arg1,rel,arg2)` for binary relations, or a nested triple representation such as `((arg1,rel,arg2),rel2,arg3)` for n-ary relations. Furthermore, an argument is allowed to be a sequence of words, "`arg2 rel2 arg3`" to capture its nominal modifiers. Then, using a RTE dataset that contains syntactic paraphrases, NESTIE learns equivalent parse-tree patterns for each template in the seed set. These patterns are used to extract propositions which are then linked.

4.1 Constructing Seed Set

We use a set of 13 hand-written templates. Each template maps an extraction pattern for a simple sentence to corresponding representation. A subset of these templates is shown in Figure 3. To create a seed set of propositions, we use the RTE dataset which is comprised of statements and their entailed hypotheses. We observed that most of the hypotheses were syntactic variants of the facts in their corresponding statements. These hypotheses were also short with a single, independent clause. These shared sentence constructions could be captured with a small set of templates. We iteratively create templates until at least one proposition could be extracted for each hypothesis. The propositions from the hypotheses form the set for bootstrapping.

For each seed proposition extracted from a hypothesis, the statement entailing the hypothesis contains all the content words of the proposition and expresses the same information as the proposition. However, there is a closed class of words, such as prepositions, a subset of adverbs, determiners, verbs etc. that does not modify the underlying meaning of the hypothesis or the statement and can be considered auxiliary. These were ignored while constructing the seed set.

Example 1 Consider a statement-hypothesis pair,
Statement: *Paul Bremer, the top U.S. civilian administrator in Iraq, and Iraq's new president, Ghazi al-Yawar, visited the northern Iraqi city of Kirkuk.*
Hypothesis: *Ghazi al-Yawar is the president of Iraq.*
The hypothesis is entailed in the statement. The seed templates extract propositions from the hypothesis: `(al-Yawar,is,president`, `(al-Yawar,is,president of Iraq)`, and `(al-Yawar,is president of,Iraq)`.

Bootstrapping is a popular technique to generate positive training data for information extraction (Collins and Singer, 1999; Hoffmann et al., 2011). We extend the bootstrapping techniques employed

in OLLIE and RENOUN, for n-ary and complex relations. First, instead of learning dependency parse-tree patterns connecting the heads of the argument phrases and the relation phrase connecting them, we learn the dependency parse-tree patterns connecting the heads of all argument and relation phrases in the template. This allows greater coverage of context for the propositions and prevents the arguments/relations from being over-specified and/or uninformative. Second, some of the relations in the representation are derived from the type of dependency, e.g. type of nominal modifier. As these relations are implicit, and might not be present in the paraphrase, they are ignored for learning. Intuitively, with such constraints, paraphrases "*Mary gave John a car*" and "*Mary gave a car to John*" can map to the same representation.

4.2 Extraction Pattern Learning

The biggest challenge in information extraction is the multitude of ways in which information can be expressed. Since it is not possible to enumerate all the different syntactic variations of an assertion, there is a need to learn general patterns that encode the various ways of expressing the assertion. In particular, we learn the various syntactic patterns that can encode the same information as the seed patterns and hence can be mapped to same representation.

NESTIE tries to learn the different ways in which the content words of a seed proposition from a hypothesis can be expressed in the statement that entails this hypothesis. We use the Stanford dependency parser (De Marneffe et al., 2006) to parse the statement and identify the path connecting the content words in the parse tree. If such a path exists, we retain the syntactic constraints on the nodes and edges in the path and ignore the surface forms of the nodes in the path. This helps generalize the learned patterns to unseen relations and arguments. NESTIE could learn 183 templates from the 13 seed templates. Figure 4 shows a subset of these patterns.

Example 2 Consider dependency parse-subtree of the statement and hypothesis from Example 1,
Statement: $Iraq \xrightarrow{\text{poss}} president \xrightarrow{\text{appos}} al-Yawar$
Hypothesis: $al-Yawar \xleftarrow{\text{nsubj}} president \xrightarrow{\text{of}} Iraq$
A seed extraction pattern maps the parse-tree of the hypothesis to the representation, `(arg1, be, arg2)`, returning proposition, `(al-Yawar,is,president of Iraq)`. With bootstrapping, the syntactic pattern from the statement is mapped to the same representation.

4.3 Pattern Matching

Once the extraction patterns are learned, we use these patterns to extract propositions from new unseen sentences. We first parse a new sentence and match the patterns against the parse tree. As the patterns only capture the heads of the arguments and relations, we expand the extracted propositions to increase the coverage of context of the arguments as in the original sentence.

Example 3 In the statement from Example 1, the extraction patterns capture the dependency path connecting the head words: `Iraq`, `administrator` and `Paul Bremer`. However, to capture the contextual information, further qualification of the argument node, `administrator`, is required.

Following this observation, we expand the arguments on `nmod`, `amod`, `compound`, `nummod`, `det`, `neg` edges. We expand the relations on `advmod`, `neg`, `aux`, `auxpass`, `cop`, `nmod` edges. Only the dependency edges not captured in the pattern are considered for expansion. Also, the order of words from the original sentence is retained in the argument phrases.

4.4 Proposition Linking

NESTIE uses a nested representation to capture the context of extracted propositions. The context could include condition, attribution, belief, order, reason and more. Since it is not possible to generate or learn patterns that can express these complex assertions as a whole, NESTIE links the various propositions from the previous step to generate nested propositions that are complete and closer in meaning to the original statement.

The proposition linking module is based on the assumption that the inter-proposition relation can be inferred from the dependency parse of the sentence from which propositions were extracted. Some of the rules employed to link the propositions are:

- The relation of proposition P1 has a relationship to the relation of proposition P2.

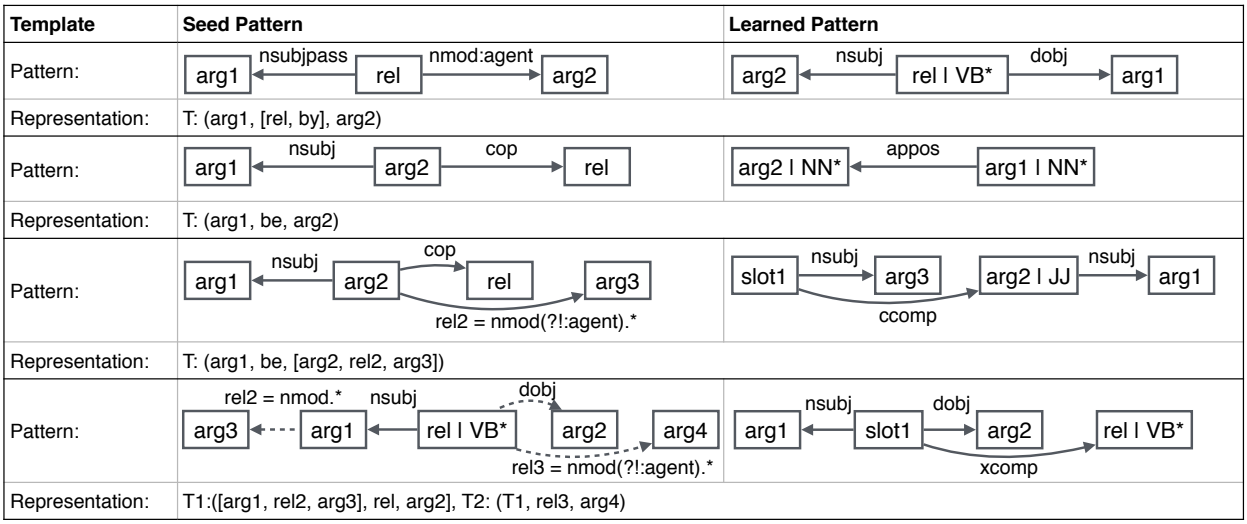

Figure 4: Syntactic Patterns learned using bootstrapping.

Consider the statement, "The accident happened after the chief guest had left the event." and propositions, P1: `(accident, happen, ϕ)` and P2: `(chief guest, had left, event)`. Using dependency edge, `nmod:after`, the linking returns `(P1,after,P2)`.

- Proposition P1 is argument in proposition P2.

Consider the statement, "A senior official said the body appeared to have been thrown from a vehicle." and propositions, P1: `(body,appeared to have been thrown from,vehicle)` and P2: `(senior official,said,ϕ)`. The linking updates P2 to `(senior official,said,P1)`.

- An inner nested proposition is replaced with a more descriptive alternative proposition.

We use dependency parse patterns to link propositions. We find correspondences between: a `ccomp` edge and a clausal complement, an `advcl` edge and a conditional, a `nmod` edge and a relation modifier. For clausal complements, a null argument in the source proposition is updated with the target proposition. For conditionals and nominal modifiers, a new proposition is created with the source and target propositions as arguments. The relation of the new proposition is derived from the target of the `mark` edge from the relation head of target proposition.

4.5 Comparison with Ollie

NESTIE uses an approach similar to OLLIE and WOE to learn dependency parse based syntactic patterns. However, there are significant differences. First, OLLIE and WOE rely on extractions from REVERB and Wikipedia info-boxes respectively for bootstrapping. Most of these relations are binary. On the contrary, our algorithm is based on high-confidence seed templates that are more expressive and hence learn patterns expressing different ways in which the proposition as a whole can be expressed. Though the arguments in OLLIE can be expanded to include the n-ary arguments, NESTIE encodes them in the seed templates and learns different ways of expressing these arguments. Also, similar to OLLIE, NESTIE can extract propositions that are not just mediated by verbs.

5 Experiments

We conducted an experimental study to compare NESTIE to other state-of-the-art extractors. We found that it achieves higher informativeness and produces more correct and minimal propositions than other extractors.

5.1 Experimental Setup

We used two datasets released by (Del Corro and Gemulla, 2013) in our experiments: 200 random sentences from Wikipedia, and 200 random sentences from New York Times (NYT). We compared

Dataset		Reverb	Ollie	ClausIE	NestIE
NYT dataset	Avg. Informativeness	1.437/5	2.09/5	2.32/5	**2.762/5**
	Correct	187/275 (0.680)	359/529 (0.678)	527/882 (0.597)	469/914 (0.513)
	Minimal (among correct)	161/187 (0.861)	238/359 (0.663)	199/527 (0.377)	**355/469 (0.757)**
Wikipedia dataset	Avg. Informativeness	1.63/5	2.267/5	2.432/5	**2.602/5**
	Correct	194/258 (0.752)	336/582 (0.577)	453/769 (0.589)	415/827 (0.501)
	Minimal (among correct)	171/194 (0.881)	256/336 (0.761)	214/453 (0.472)	**362/415 (0.872)**

Figure 5: Informativeness and number of correct and minimal extractions as fraction of total extractions.

NESTIE against three OIE systems: REVERB, OLLIE and CLAUSIE. Since the source code for each of the extractors was available, we independently ran the extractors on the two datasets. Next, to make the extractions comparable, we configured the extractors to generate triple propositions. REVERB and CLAUSIE extractions were available as triples by default. OLLIE extends its triple proposition representation. So, we generated an additional extraction for each of the possible extensions of a proposition. NESTIE uses a nested representation. So, we simply extracted the innermost proposition in a nested representation as a triple and allowed the subject and the object in the outer proposition to contain a *reference* to the inner triple. By preserving references the context of a proposition is retained while allowing for queries at various granularity levels.

We manually labeled the extractions obtained from all extractors to 1) maintain consistency, 2) additionally, assess if extracted triples were informative and minimal. Some extractors use heuristics to identify arguments and/or relation phrase boundaries, which leads to over-specific arguments that render the extractions unusable for other downstream applications. To assess the usability of extractions, we evaluated them for minimality (Bast and Haussmann, 2013). Furthermore, the goal of our system is to extract as many propositions as possible and lose as little information as possible. We measure this as *informativeness* of the set of the extractions for a sentence. Since computing informativeness as a percentage of text contained in at least one extraction could be biased towards long extractions, we used an explicit rating scale to measure informativeness.

Two CS graduate student labeled each extraction for correctness (0 or 1) and minimality (0 or 1). For each sentence, they label the set of extractions for informativeness (0-5). An extraction is marked correct if it is asserted in the text and correctly captures the contextual information. An extraction is considered minimal if the arguments are not over-specified i.e. they don't subsume another extraction or have conjunctions or are excessively long. Lastly, they rank the set of extractions on a scale of 0-5 (0 for bad, 5 for good) based on the coverage of information in the original sentence. The agreement between labelers was measured in terms of Cohens Kappa.

5.2 Comparative Results

The results of our experimental study are summarized in Figure 5 which shows the number of correct and minimal extractions, as well as the total number of extractions for each extractor and dataset. For each dataset, we also report the macro-average of informativeness reported by the labelers. We found moderate inter-annotator agreement: 0.59 on correctness and 0.53 on minimality for both the datasets. Each extractor also includes a confidence score for the propositions. But since each extractor has its unique method to find confidence, we compare the precision over all the extractions instead of a subset of high-confidence extractions.

NESTIE produced many more extractions, and more informative extractions than other systems. There appears to be a trade-off between informativeness and correctness (which are akin to recall and precision, respectively). CLAUSEIE is the system with results closer to NESTIE than other systems. However, the nested representation and proposition linking used by NESTIE produce substantially more (1.7-1.8 times more) minimal extractions than CLAUSEIE, which generates propositions from the constituents of the clause. Learning non-verb medi-

ated extraction patterns and proposition linking also increase the syntactic scope of relation expressions and context. This is also reflected in the average informativeness score of the extractions. NESTIE achieves 1.1-1.9 times higher informativeness score than the other systems.

We believe that nested representation directly improves minimality, independent of other aspects of extractor design. To explore this idea, we conducted experiments on OLLIE, which does not expand the context of the arguments heuristically unlike other extractors. Of the extractions labeled correct but not minimal by the annotators on the Wikipedia dataset, we identified extractions that satisfy one of: 1) has an argument for which there is an equivalent extraction (nested extractions), 2) shares the same subject with another extraction whose relation phrase contains the relation and object of this extraction (n-ary extractions), 3) has an object with conjunction. Any such extractions can be made minimal and informative with a nested representation. 73.75% of the non-minimal correct extractions met at least one of these conditions, so by a post-processing step, we could raise the minimality score of OLLIE by 17.65%, from 76.1% to 93.75%.

5.3 Error Analysis of NestIE

We did a preliminary analysis of the errors made by NESTIE. We found that in most of the cases (about 33%-35%), extraction errors were due to incorrect dependency parsing. This is not surprising as NESTIE relies heavily on the parser for learning extraction patterns and linking propositions. An incorrect parse affects NESTIE more than other systems which are not focused on extracting finer grained information and can trade-off minimality for correctness. An incorrect parse not only affects the pattern matching but also proposition linking which either fails to link two propositions or produces an incorrect proposition.

Example 4 Consider the statement, "*A day after strong winds stirred up the Hauraki Gulf and broke the mast of Team New Zealand, a lack of wind caused Race 5 of the America's Cup to be abandoned today.*". The statement entails following assertions:

A1: "strong winds stirred up the Hauraki Gulf"

A2: "strong winds broke the mast of Team New Zealand"

A3: "a lack of wind caused Race 5 of the America's Cup to be abandoned"

A1 and A2 are parsed correctly. A3 is parsed incorrectly with `Race 5` as object of the verb `caused`. Some extractors either don't capture A3 or return an over-specified extraction, *(a lack of wind, caused, Race 5 of the America 's Cup to be abandoned today)*. Such an extraction is correct but not minimal.

To maintain minimality, NESTIE aims to extract propositions, P1: *(Race 5 of the America 's Cup, be abandoned, ϕ)* and P2: *(a lack of wind, caused, P1)*. However, it fails because of parser errors. It extracts incorrect proposition, P3: *(a lack of wind, caused, Race 5)* corresponding to A3 and links it to propositions for A1 and A2. Linking an incorrect proposition generates more incorrect propositions which hurt the system performance.

However, we hope this problem can be alleviated to some extent as parsers become more robust. Another approach could be to use clause segmentation to first identify clause boundaries and then use NESTIE on reduced clauses. As the problem becomes more severe for longer sentences, we wish to explore clause processing for complex sentences in future.

Another source of errors was under-specified propositions. Since our nested representation allows null arguments for intransitive verb phrases and for linking propositions, failure to find an argument/proposition results in an under-specified extraction. We found that 27% of the errors were because of null arguments. However, by ignoring extractions with null arguments we found that precision increases by only 4%-6% (on Wikipedia). This explains that many of the extractions with empty arguments were correct, and need special handling. Other sources of errors were: aggressive generalization of an extraction pattern to unseen relations (24%), unidentified dependency types while parsing long, complex sentences (21%), and errors in expanding the scope of arguments and linking extractions (20%).

6 Related Work

As OIE has gained popularity to extract propositions from large corpora of unstructured text, the problem of the extractions being uninformative and incomplete has surfaced. A recent paper (Bast and Haussmann, 2014) pointed out that a significant fraction of the extracted propositions is not informative. A simple inference algorithm was proposed that uses generic rules for each semantic class of predicate to derive new triples from extracted triples. Though it improved the informativeness of extracted triples, it did not alleviate the problem of lost context in complex sentences. We, therefore, create our own extractions.

Some recent works (Bast and Haussmann, 2013; Angeli et al., 2015) have tried to address the problem of long and uninformative extractions in open-domain information extraction by finding short entailment or clusters of semantically related constituents from a longer utterance. These clusters are reduced to triples using schema mapping to known relation types or using a set of hand-crafted rules. NESTIE shares similar objectives but uses bootstrapping to learn extraction patterns.

Bootstrapping and pattern learning has a long history in traditional information extraction. Systems like DIPRE (Brin, 1998), SNOWBALL (Agichtein and Gravano, 2000), NELL (Mitchell, 2010), and OLLIE bootstrap based on seed instances of a relation and then learn patterns for extraction. We follow a similar bootstrapping algorithm to learn extraction patterns for n-ary and nested propositions.

Using a nested representation to express complex and n-ary assertions has been studied in closed-domain or ontology-aided information extraction. Yago (Suchanek et al., 2008) and (Nakashole and Mitchell, 2015) extend binary relations to capture temporal, geospatial and prepositional context information. We study such a representation for open-domain information extraction.

7 Conclusions

We presented NESTIE, a novel open information extractor that uses nested representation for expressing complex propositions and inter-propositional relations. It extends the bootstrapping techniques of previous approaches to learn syntactic extraction patterns for the nested representation. This allows it to obtain higher informativeness and minimality scores for extractions at comparable precision. It produces 1.7-1.8 times more minimal extractions and achieves 1.1-1.2 times higher informativeness than CLAUSEIE. Thus far, we have tested our bootstrap learning and proposition linking approaches only on a small dataset. We believe that its performance will improve with larger datasets. NESTIE can be seen as a step towards a system that has a greater awareness of the context of each extraction and provides informative extractions to downstream applications.

Abstract

With the renaissance of neural network in recent years, relation classification has again become a research hotspot in natural language processing, and leveraging parse trees is a common and effective method of tackling this problem. In this work, we offer a new perspective on utilizing syntactic information of dependency parse tree and present a position encoding convolutional neural network (PECNN) based on dependency parse tree for relation classification. First, tree-based position features are proposed to encode the relative positions of words in dependency trees and help enhance the word representations. Then, based on a redefinition of "context", we design two kinds of tree-based convolution kernels for capturing the semantic and structural information provided by dependency trees. Finally, the features extracted by convolution module are fed to a classifier for labelling the semantic relations. Experiments on the benchmark dataset show that PECNN outperforms state-of-the-art approaches. We also compare the effect of different position features and visualize the influence of tree-based position feature by tracing back the convolution process.

1 Introduction

Relation classification focuses on classifying the semantic relations between pairs of marked entities in given sentences (Hendrickx et al., 2010). It is a fundamental task which can serve as a pre-existing system and provide prior knowledge for information extraction, natural language understanding, information retrieval, etc. However, automatic recognition of semantic relation is challenging. Traditional feature based approaches rely heavily on the quantity and quality of hand-crafted features and lexical resources, and it is time-consuming to select an optimal subset of relevant features in order to maximize performance. Though kernel based methods get rid of the feature selection process, they need elaborately designed kernels and are also computationally expensive.

Recently, with the renaissance of neural network, deep learning techniques have been adopted to provide end-to-end solutions for many classic NLP tasks, such as sentence modeling (Socher, 2014; Kim, 2014) and machine translation (Cho et al., 2014). Recursive Neural Network (RNN) (Socher et al., 2012) and Convolutional Neural Network (CNN) (Zeng et al., 2014) have proven powerful in relation classification. In contrast to traditional approaches, neural network based methods own the ability of automatic feature learning and alleviate the problem of severe dependence on human-designed features and kernels.

However, previous researches (Socher et al., 2012) imply that some features exploited by traditional methods are still informative and can help enhance the performance of neural network in relation classification. One simple but effective approach is to concatenate lexical level features to features extracted by neural network and directly pass the combined vector to classifier. In this way, Socher et al. (2012), Liu et al. (2015) achieve better performances when considering some external features produced

by existing NLP tools. Another more sophisticated method adjusts the structure of neural network according to the parse trees of input sentences. The results of (Li et al., 2015) empirically suggest syntactic structures from recursive models might offer useful power in relation classification. Besides relation classification, parse tree also gives neural network a big boost in other NLP tasks (Mou et al., 2015; Tai et al., 2015).

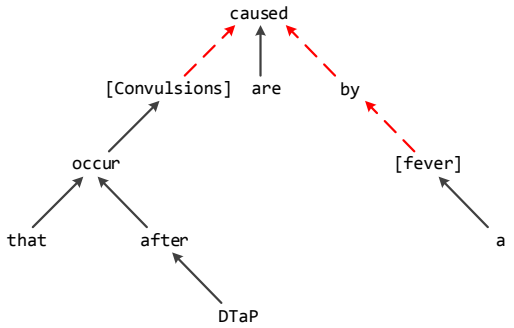

Figure 1: A dependency tree example. Words in square brackets are marked entities. The red dashed-line arrows indicate the path between two entities.

Dependency parse tree is valuable in relation classification task. According to our observation, dependency tree usually shortens the distances between pairs of marked entities and helps trim off redundant words, when comparing with plain text. For example, in the sentence shown in Figure 1, two marked entities span the whole sentence, which brings much noise to the recognition of their relation. By contrast, in the dependency tree corresponding to the sentence, the path between two marked entities comprises only four words and extracts a key phrase "caused by" that clearly implies the relation of entities. This property of dependency tree is ubiquitous and consistent with the Shortest Path Hypothesis which is accepted by previous studies (Bunescu and Mooney, 2005; Xu et al., 2015a; Xu et al., 2015b).

To better utilize the powerful neural network and make the best of the abundant linguistic knowledge provided by parse tree, we propose a position encoding convolutional neural network (PECNN) based on dependency parse tree for relation classification. In our model, to sufficiently benefit from the important property of dependency tree, we introduce the position feature and modify it in the context of parse tree. Tree-based position features encode the relative positions between each word and marked entities in a dependency tree, and help the network pay more attention to the key phrases in sentences. Moreover, with a redefinition of "context", we design two kinds of tree-based convolution kernels for capturing the structural information and salient features of sentences.

To sum up, our contributions are:

1) We propose a novel convolutional neural network with tree-based convolution kernels for relation classification.

2) We confirm the feasibility of transferring the position feature from plain text to dependency tree, and compare the performances of different position features by experiments.

3) Experimental results on the benchmark dataset show that our proposed method outperforms the state-of-the-art approaches. To make the mechanism of our model clear, we also visualize the influence of tree-based position feature on relation classification task.

2 Related Work

Recent studies usually present the task of relation classification in a supervised perspective, and traditional supervised approaches can be divided into feature based methods and kernel methods.

Feature based methods focus on extracting and selecting relevant feature for relation classification. Kambhatla (2004) leverages lexical, syntactic and semantic features, and feeds them to a maximum entropy model. Hendrickx et al. (2010) show that the winner of SemEval-2010 Task 8 used the most types of features and resources, among all participants. Nevertheless, it is difficult to find an optimal feature set, since traversing all combinations of features is time-consuming for feature based methods.

To remedy the problem of feature selection mentioned above, kernel methods represent the input data by computing the structural commonness between sentences, based on carefully designed kernels. Mooney and Bunescu (2005) split sentences into subsequences and compute the similarities using the proposed subsequence kernel. Bunescu and

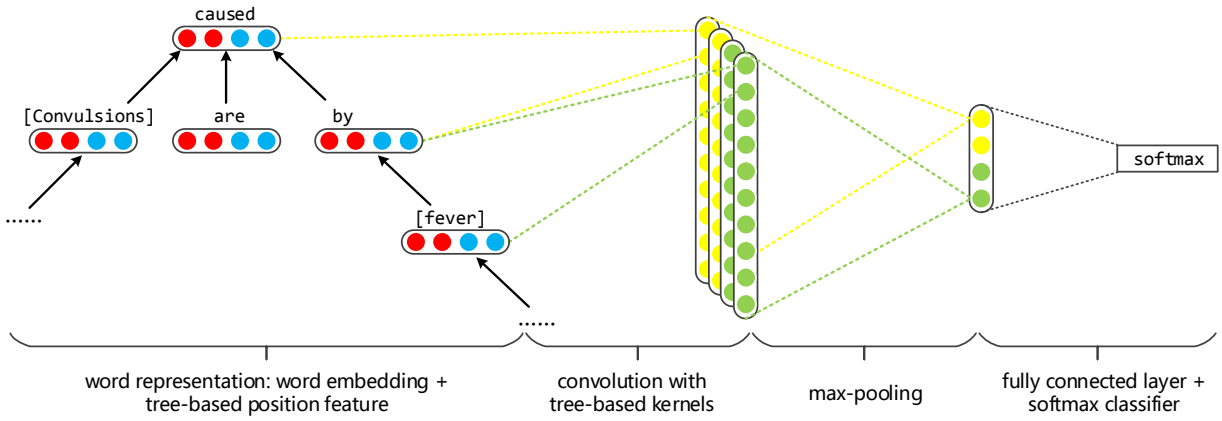

Figure 2: The framework of PECNN. The red and blue circles represent the word embeddings and tree-based position features of words. The yellow and green circles stand for the feature maps extracted by two kinds of convolution kernels respectively.

Mooney (2005) propose a dependency tree kernel and extract information from the Shortest Dependency Path (SDP) between marked entities. Since kernel methods require similarity computation between input samples, they are relatively computationally expensive when facing large-scale datasets.

Nowadays, deep neural network based approaches have become the main solutions to relation classification. Among them, some handle this task by modifying sentence modeling methods. Socher et al. (2012) build RNN on constituency trees of sentences, and apply the model to relation recognition task. Zeng et al. (2014) propose the use of position feature for improving the performance of CNN in relation classification. dos Santos et al. (2015) diminish the impact of noisy class by using a pairwise ranking loss function based CNN. Meanwhile, inspired by the ideas of traditional methods, some recent researches concentrate on mining information from the SDP. Xu et al. (2015b) use a multichannel LSTM network to model the SDP in given sentences. Liu et al. (2015) reserve the subtrees attached to the SDP and propose an augmented SDP based CNN. Neural network based methods offer the advantage of automatic feature learning and also scale well with large amounts of data.

3 Proposed Model

Given a sentence s with two marked entities $e1$ and $e2$, we aim to identify the semantic relation between $e1$ and $e2$ in relation classification. As the set of target relations is predefined, this task can be formulated as a multi-class classification problem. In this section, we detailedly describe our proposed model designed for this problem.

3.1 Framework

The schematic illustration of the framework is shown in Figure 2.

First, the dependency tree of a sentence is generated by the Stanford Parser (Klein and Manning, 2003). For each word in the tree, its word embedding and tree-based position features are concatenated as its representation. The position feature of a word is determined by the relative position between the word and marked entities in the dependency tree.

Next, with tree-based kernels, convolution operations are conducted on each node of the dependency tree. Compared with plain text, dependency tree could provide a word with more meaningful context, thus making tree-based kernel more effective. After convolution, we apply max-pooling over the extracted feature maps to capture the most important features.

At last, the output of max-pooling layer, i.e. the feature vector of input sentence, is fed to a softmax classifier for labelling the semantic relation of entities in each sentence.

3.2 Word Represetation

The representation of a word is composed of two parts: word embedding and tree-based position feature.

3.2.1 Word Embedding

Distributed representation of words in a vector space help learning algorithms to achieve better performance in NLP tasks (Mikolov et al., 2013). Such representation is usually called word embedding in recent works. High-quality word embedding is able to capture precise syntactic and semantic information by training unsupervisedly on large-scale corpora.

In our model, we initialize the word embeddings by pretraining them on a large corpus and further fine-tune them in training phase.

3.2.2 Tree-based Position Feature

Position Feature (PF) is first proposed by (Collobert et al., 2011) for semantic role labeling. (Zeng et al., 2014) exploit position feature as a substitute for traditional structure features in relation classification. The main idea of position feature is to map each discrete distance to a real-valued vector. It is similar to word embedding, except that words are replaced by discrete distances. For instance, let us examine again the sentence shown in Figure 1,

$$[\text{Convulsions}]_{e1} \text{ that occur after DTaP are caused by a } [\text{fever}]_{e2}.$$

the relative distances of *caused* to *Convulsions* and *fever* are respectively 6 and -3. Each relative distance is further mapped to a d_{pf} (a hyperparameter) dimensional vector, which is randomly initialized. Supposing $\boldsymbol{pf}_6$ and $\boldsymbol{pf}_{-3}$ are the corresponding vectors of distance 6 and -3, the position feature of *caused* is given by concatenating these two vectors $[\boldsymbol{pf}_6, \boldsymbol{pf}_{-3}]$.

Position feature on plain text proves to be informative (dos Santos et al., 2015), while it may suffer from several problems. According to our case study, adverbs or unrelated entities that appear between two entities in a sentence could significantly affect the performance of position feature, as these words only change the relative distance to entities without providing any more useful information for relation classification. Similarly, position feature often fails to handle sentences in which marked entities are too far from each other.

On the other hand, dependency tree focuses on the action and agents in a sentence (Socher et al., 2014), which is valuable for relation classification. As we have mentioned above, dependency tree is able to shorten the distances between pairs of marked entities and help trim off redundant words. Therefore, it is straightforward and reasonable to transfer the position feature from plain text to dependency tree.

We propose two kinds of Tree-based Position Feature which we refer as TPF1 and TPF2.

TPF1 encodes the relative distances of current word to marked entities in dependency trees. The "relative distance" here refers to the length of the shortest dependency path between current word and target entity. The sign of the distance is used to distinguish whether current word is a descendant of target entity. After calculating the relative distances of words in the tree, we can get their TPF1 by mapping relative distances to corresponding vectors, which is the same as the PF in plain text.

To more precisely describe the position of a word, TPF2 incorporates more information given by dependency tree. TPF2 represents the relative positions between current word and marked entities by encoding their shortest paths. For a word and an entity, the shortest path between them can be separated by their lowest common ancestor, and the lengths of the two sub-paths are sufficient for encoding the shortest path and the relative position between the word and the entity. As a result, we formally represent the relative position using a 2-tuple, in which two elements are the lengths of the two separated sub-paths respectively. Thereafter, each unique relative position is mapped to a real-valued vector.

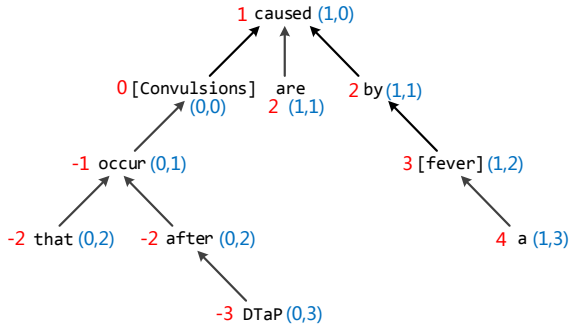

Figure 3: Example of Tree-based Position Features. The red numbers are relative distances in TPF1. The blue 2-tuples are relative positions in TPF2.

For example, in Figure 3, the path between *Convulsions* and *by* is *Convulsions*→ *caused*←*by*. In

TPF1, the relative distance of *by* to *Convulsions* is 2, the length of this path. In TPF2, the lowest common ancestor *caused* splits the path into two subpaths of length 1, so the relative position between *Convulsions* and *by* is $(1, 1)$ (encoded in 2-tuple). More examples of the tree-based position features are shown in Figure 3.

TPF1 and TPF2 both offer good strategies for encoding word position in dependency tree. TPF2 is more fine-grained than TPF1 and TPF1 is a simplified version of TPF2.

In our model, for each word in dependency trees, its word embedding and tree-based position feature are concatenated to form its representation, which is subsequently fed to the convolutional layer.

3.3 Convolution Methods

In the classic CNN architecture of (Collobert et al., 2011) and its variants (Kim, 2014), a convolution window covers a word and its context, i.e. its neighboring words. Thus convolution only captures local features around each word. Words that are not in a same window will not interact, even if they are syntactically related.

Compared with plain text, dependency tree could provide a word with more meaningful context. In a dependency tree, words are connected if they are in some dependency relationship. To capitalize on these syntactic information, we regard the parent and children of a word (i.e. nodes neighboring this word) as its new context. Changing the definition of "context" leads to modification of convolution kernel. To implement this idea, we design two kinds of tree-based kernels (Kernel-1 and Kernel-2), and apply them to sentences in dependency tree form.

Formally, for a word x in the dependency tree, let p be its parent and $c_1, \cdots, c_n$ be its n children. Their vector representation are respectively denoted by $\boldsymbol{x}, \boldsymbol{p}, \boldsymbol{c}_1, \cdots, \boldsymbol{c}_n \in \mathbb{R}^d$. The convolution process of Kernel-1 is formulated as

$$\begin{aligned} \boldsymbol{z}^1_{xi} =& g(W^1_x \cdot \boldsymbol{x} + W^1_p \cdot \boldsymbol{p} + W^1_c \cdot \boldsymbol{c}_i) \\ & for \quad i = 1, \cdots, n \end{aligned} \tag{1}$$

where $\boldsymbol{z}^1_{xi} \in \mathbb{R}^{n_1}$ and n_1 is the number of Kernel-1, and $W^1_x, W^1_p, W^1_c \in \mathbb{R}^{n_1 \times d}$ are weight parameters corresponding to the word, its parent and children respectively. g is the non-linear activation function. For leaf nodes which have no child, i.e. $n = 0$, we assign each of them a child of which the vector representation is $\mathbf{0}$. For the root node, $\boldsymbol{p}$ is set to be $\mathbf{0}$.

Similarly, the output of Kernel-2 is given by

$$\begin{aligned} \boldsymbol{z}^2_{xi} =& g(W^2_x \cdot \boldsymbol{x} + W^2_{lc} \cdot \boldsymbol{c}_i + W^2_{rc} \cdot \boldsymbol{c}_{i+1}) \\ & for \quad i = 1, \cdots, n-1 \end{aligned} \tag{2}$$

where $\boldsymbol{z}^2_{xi} \in \mathbb{R}^{n_2}$ and n_2 is the number of Kernel-2, and $W^2_x, W^2_{lc}, W^2_{rc} \in \mathbb{R}^{n_2 \times d}$ are weight parameters associated with the word and its two neighboring children. If $n \leq 1$, we simply add one or two $\mathbf{0}$ children, just like the zero padding strategy.

Kernel-1 aims at extracting features from words of multiple levels in dependency tree, while Kernel-2 focuses on mining the semantic information between words which share the same parent. Kernel-1 and Kernel-2 both consider 3 words at a time because the experimental results of previous researches (Zeng et al., 2014; dos Santos et al., 2015) suggest that trigram features are relatively more useful in relation classification. And it is also straightforward to extend these kernels to a larger size and apply them to other tasks.

After convolution with tree-based kernels, we apply a global max-pooling operation over extracted features by taking the maximum value in each dimension, which is formulated as

$$\boldsymbol{h}^1 = \operatorname*{elemax}_{x,i} \boldsymbol{z}^1_{xi} \tag{3}$$

$$\boldsymbol{h}^2 = \operatorname*{elemax}_{x,i} \boldsymbol{z}^2_{xi} \tag{4}$$

where $\boldsymbol{h}^1 \in \mathbb{R}^{n_1}$, $\boldsymbol{h}^2 \in \mathbb{R}^{n_2}$, and elemax is the operation which gives the element-wise maximum of all input vectors. As a consequence, the output of convolution process is $[\boldsymbol{h}^1, \boldsymbol{h}^2]$, the combination of features extracted by two kinds of kernels.

3.4 Output and Training Objective

After convolution, the extracted feature is further passed to a fully connected softmax layer whose output is the probability distribution over all types of relations.

Since we treat the relation classification task as a multi-class classification problem, the training objective is the cross-entropy error. For regularization, we apply dropout (Srivastava et al., 2014) to the feature vector extracted by convolution and penalize the fully connected layer with l_2 regularizer as well.

Some other dependency tree based methods like (Liu et al., 2015), (Xu et al., 2015a) and (Xu et al., 2015b), all focus on using different kinds of neural networks to model the shortest dependency path (SDP) between entities. By contrast, PECNN extracts features from the whole dependency tree, so that the information out of SDP will be taken into consideration as well. The empirical results of (dos Santos et al., 2015) suggest that when position features exist, modeling the full sentence yields a better performance than only using the subsentence between entities. With the help of tree-based position feature, our model is capable of evaluating the importance of different parts of dependency trees and tends to pay relatively more attention to SDP.

Some methods enhancing their performances by proposing dataset-specific strategies. dos Santos et al. (2015) treat the class *Other* as a special class and omit its embedding. Xu et al. (2015a) take the relation dimensionality into account and introduce a negative sampling strategy to double the number of training samples, which can be regarded as data augmentation. These strategies do not conflict with our model, but we decide not to integrate them into our methods as we aim to offer a general and effective feature extraction model for relation classification.

4 Experiments

4.1 Dataset and Evaluation Metric

To evaluate our method, we conduct experiments on the SemEval2010 Task 8 dataset which is a widely used benchmark for relation classification. The dataset contains $8,000$ training sentences and $2,717$ test sentences. In each sentence, two entities are marked as target entities.

The predefined target relations include 9 directed relations and an undirected *Other* class. The 9 directed relations are *Cause-Effect, Component-Whole*, *Content-Container*, *Entity- Destination*, *Entity-Origin*, *Instrument-Agency*, *Member-Collection*, *Message-Topic* and *Product-Producer*. "Directed" here means, for example, *Cause-Effect*(e_1, e_2) and *Cause-Effect*(e_2, e_1) are two different relations. In another word, the directionality of relation also matters. And sentences that do not belong to any directed relation are labelled as *Other*. Therefore, relation classification on this dataset is a 19-class classification problem.

Following previous studies, we use the official evaluation metric, macro-averaged F1-score with directionality taken into account and the *Other* class ignored.

4.2 Training Details

Since there is no official validation set, 10% of the training sentences are taken out for hyperparameter tuning and early stopping.

When converting sentences to dependency trees, we note that some prepositions such as "by", "in" and "of", might be important clues to relation classification. To reserve these valuable information, we use the Stanford Parser **without** the *collapsed* option.

In the dataset, there are some entities consisting of multiple words, which make the calculation of relative position ambiguous. To solve this problem, we take the last word as the representation of an entity, as the last word is usually the predominant word.

For word embeddings, we initialize them using the 300-dimensional `word2vec` vectors[1]. The vectors are trained on 100 billion words from Google News. Words not present in the `word2vec` vectors are initialized by sampling each dimension from a uniform distribution (Kim, 2014). Tree-based position features are 50-dimensional and initialized randomly. Therefore the representation of each word has dimensionality of 400.

We use ReLU as the activation function. The number of convolution kernels is 500 for each kind, $1,000$ in total. The dropout rate is 0.5, and the coefficient of l_2 penalty of fully connected layer is set to 10^{-6}. These parameters are selected through grid search on validation set. The network is trained with the Adadelta update rule (Zeiler, 2012). The network is implemented with Theano (Theano Development Team, 2016).

4.3 Results

The performances of our proposed model and other state-of-the-art methods are shown in Table 1.

First, we compare PECNN with the following baselines when no external lexical feature is used.

Socher et al. (2012) assign a vector and a matrix to each word for the purpose of semantic composition, and build recursive neural network along constituency tree (MVRNN). It is noteworthy that this work is the first one who confirms the feasibility of applying neural network to relation classification.

Following the ideas of (Collobert et al., 2011), Zeng et al. (2014) first solve relation classification using convolutional neural network (CNN). The position feature introduced by them proves effective. dos Santos et al. (2015) build a similar CNN called CR-CNN but replace the objective function with a pairwise ranking loss. By treating the noisy class *Other* as a **special** class, this method achieves an $F1$ of 84.1. The $F1$ score is 82.7 if no special treatment is applied.

The rest two baselines focus on modeling the Shortest Dependency Paths (SDP) between marked entities. Xu et al. (2015a)) (depLCNN) integrate the relation directionality into CNN and achieve an $F1$ of 84.0 with a data augmentation strategy called negative sampling. Without such data augmentation, their $F1$ score is 81.9. Xu et al. (2015b) (SDP-LSTM) represent heterogeneous features as embeddings and propose a multichannel LSTM based recurrent neural network for picking up information along the SDP. Their $F1$ score is 83.0 when only word embedding is used as the word representation.

Without considering any external lexical feature and dataset-specific strategy, our model achieve an $F1$ of 84.0, suggesting that tree-based position features and kernels are effective. Comparing with the CNN based on plain text, our model benefits from dependency tree based network and obtain a notable

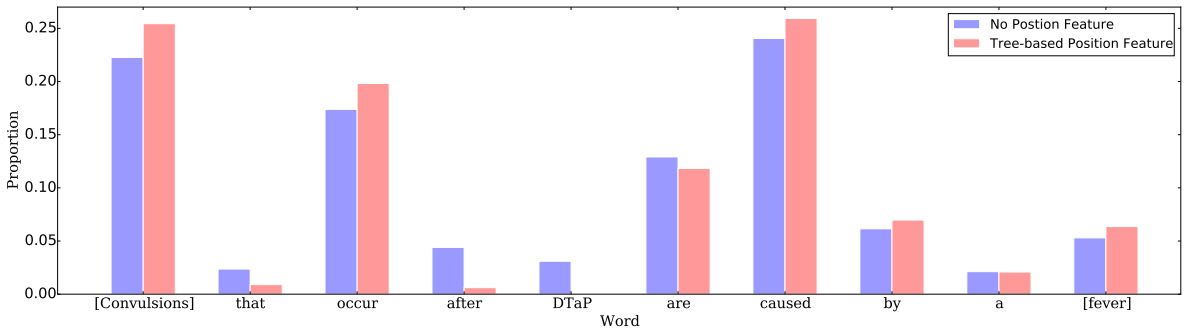

Figure 4: Visualization of the effect of tree-based position feature. The proportions of words change with the use of tree-based position feature.

improvement.

When external lexical features are available, we take two more baselines into account. The first one (SVM) is a typical example of traditional feature-based methods which rely largely on hand-crafted features. Benefitting from various features and resources, this method won the SemEval 2010 Task 8 by a large margin (Hendrickx et al., 2010). Liu et al. (2015) (DepNN) reserve the subtrees attached to the SDP and propose an augmented SDP based CNN.

Most of these baselines concatenate external lexical features to features extracted by neural network and directly pass the combined vector to classifier. SDP-LSTM represents lexical features as embeddings and enhances its word representation. For fair comparison, we add three features (POS tags, NER tags and WordNet hypernyms of marked entities) to the vector extracted by our model and retrain the network. Thus, our model achieves an $F1$ of 84.6 and outperforms all existing baselines in a fair condition where no data augmentation strategy is adopted. The enhancement we gain from external features is less, comparing with other baselines. This implies that our model is able to mine useful features from limited resources, even no extra information is available.

4.4 Effect of Different Position Features

Position Feature	$F1$
plain text PF	83.21
TPF1	83.99
TPF2	83.90

Table 2: Comparison of different position features.

Table 2 summarizes the performances of proposed model when different position features are exploited. To concentrate on studying the effect of position features, we do not involve lexical features in this section. As the table shows, the position feature on plain text is still effective in our model and we accredit its satisfactory result to the dependency information and tree-based kernels. The $F1$ scores of tree-based position features are higher since they are "specially designed" for our model.

Contrary to our expectation, the more fine-grained TPF2 does not yield a better performance than TPF1, and two kinds of TPF give fairly close results. One possible reason is that the influence of a more elaborated definition of relative position is minimal. As most sentences in this dataset are of short length and their dependency trees are not so complicated, replacing TPF1 with TPF2 usually brings little new structural information and thus results in a similar $F1$ score.

However, though the performances of different position features are close, tree-based position feature is an essential part of our model. The $F1$ score is severely reduced to 75.22 when we remove the tree-based position feature in PECNN.

4.5 Effect of Tree-based Position Feature

For shallow CNN in NLP, visualization offers clear and convincing explanations for the mechanism of neural networks (dos Santos and Gatti, 2014; Mou et al., 2015). Moreover, it is easy to implement.

Note that in the max-pooling step, for each kernel, we select the feature which has the largest value. This feature corresponds to 3 words in the convolu-

tion step, and we regard them as the most relevant words extracted by this kernel, with respect to the sentence . Since there are $1,000$ kernels in total, we count $3,000$ words ($\mathbf{0}$ will be ignored) and calculate the proportion of each different word. Intuitively, the more important a word is in this task, the larger its proportion will be.

In Figure 4, we compare the proportions of words in the example sentence when tree-based position feature (TPF) is used and not. As we can see, the proportions of two entities, *Convulsions* and *fever*, and the phrase *caused by* all increase visibly with the presence of TPF, suggesting that TPF is effective in helping the neural network pay more attention to the crucial words and phrases in a sentence. The word *occur* is also picked up by our model since it is an important candidate clue to relation classification. Meanwhile, the influence of irrelevant entity *DTaP* is remarkably diminished as expected.

5 Conclusion

This work presents a dependency parse tree based convolutional neural network for relation classification. We propose tree-based position features to encode the relative positions of words in a dependency tree. Meanwhile, tree-based convolution kernels are designed to gather semantic and syntactic information in dependency trees. Experimental results prove the effectiveness of our model. Comparing with plain text based CNN, our proposed kernels and position features boost the performance of network by utilizing dependency trees in a new perspective.

Learning to Recognize Discontiguous Entities

Aldrian Obaja Muis **Wei Lu**
Singapore University of Technology and Design
{aldrian_muis,luwei}@sutd.edu.sg

Abstract

This paper focuses on the study of recognizing discontiguous entities. Motivated by a previous work, we propose to use a novel hypergraph representation to jointly encode discontiguous entities of unbounded length, which can overlap with one another. To compare with existing approaches, we first formally introduce the notion of *model ambiguity*, which defines the difficulty level of interpreting the outputs of a model, and then formally analyze the theoretical advantages of our model over previous existing approaches based on linear-chain CRFs. Our empirical results also show that our model is able to achieve significantly better results when evaluated on standard data with many discontiguous entities.

1 Introduction

Building effective automatic named entity recognition (NER) systems that is capable of extracting useful semantic shallow information from texts has been one of the most important tasks in the field of natural language processing. An effective NER system can typically play an important role in certain downstream NLP tasks such as relation extraction, event extraction, and knowledge base construction (Hasegawa et al., 2004; Al-Rfou and Skiena, 2012).

Most traditional NER systems are capable of extracting entities[1] as short spans of texts. Two basic assumptions are typically made when extracting entities: 1) entities do not overlap with one another, and 2) each entity consists of a contiguous sequence of words. These assumptions allow the task to be modeled as a sequence labeling task, for which many existing models are readily available, such as linear-chain CRFs (McCallum and Li, 2003).

EGD showed [***hiatal hernia***]$_1$ and vertical [***laceration***]$_2$ in distal [***esophagus***]$_2$ with [***blood in*** [***stomach***]$_4$]$_3$ and overlying [***lac***]$_4$.

Figure 1: Discontiguous entities in a medical domain. Words annotated with the same index are part of the same entity. Note that entity 3 and entity 4 overlap with one another.

While the above two assumptions are valid for most cases, they are not always true. For example, in the entity *University of New Hampshire* of type *ORG* there exists another entity *New Hampshire* of type *LOC*. This violates the first assumption above, yet it is crucial to extract both entities for subsequent tasks such as relation extraction and knowledge base construction. Researchers therefore have proposed to tackle the above issues in NER using more sophisticated models (Finkel and Manning, 2009; Lu and Roth, 2015). Such efforts still largely rely on the second assumption.

Unfortunately, the second assumption is also not always true in practice. There are also cases where the entities are composed of multiple discontiguous sequences of words, such as in disorder mention recognition in clinical texts (Pradhan et al., 2014b), where the entities (disorder mentions in this case) may be discontiguous. Consider the example shown in Figure 1. In this example there are four enti-

[1]Or sometimes *mentions* are considered, which can be named, nominal or pronominal references to entities (Florian et al., 2004). In this paper we use "mentions" and "entities" interchangeably.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 75–84,
Austin, Texas, November 1-5, 2016.

ties, the first one, ***hiatal hernia***, is a conventional contiguous entity. The second one, ***laceration ... esophagus***, is a discontiguous entity, consisting of two parts. The third and fourth ones, ***blood in stomach*** and ***stomach ... lac*** (for *stomach laceration*), are overlapping with each other, with the fourth being discontiguous at the same time.

For such discontiguous entities which can potentially overlap with other entities in complex manners, existing approaches such as those based on simple sequence tagging models have difficulties handling them accurately. This stems from the fact that there is a very large number of possible entity combinations in a sentence when the entities can be discontiguous and overlapping.

Motivated by this, in this paper we propose a novel model that can better represent both contiguous and discontiguous entities which can overlap with one another. Our major contributions can be summarized as follows:

- We propose a novel model that is able to represent both contiguous and discontiguous entities.
- Theoretically, we introduce the notion of *model ambiguity* for quantifying the ambiguity of different NER models that can handle discontiguous entities. We present a study and make comparisons about different models' ambiguity under this theoretical framework.
- Empirically, we demonstrate that our model can significantly outperform conventional approaches designed for handling discontiguous entities on data which contains many discontiguous entities.

2 Related Work

Learning to recognize named entities is a popular task in the field of natural language processing. A survey by Nadeau (2007) lists several approaches in NER, including Hidden Markov Models (HMM) (Bikel et al., 1997), Decision Trees (Sekine, 1998), Maximum Entropy Models (Borthwick and Sterling, 1998), Support Vector Machines (SVM) (Asahara and Matsumoto, 2003), and also semi-supervised and unsupervised approaches. Ratinov (2009) utilizes averaged perceptron to solve this problem and also focused on four key design decisions, achieving state-of-the-art in MUC-7 dataset. These approaches work on standard texts, such as news articles, and the entities to be recognized are defined to be contiguous and non-overlapping.

Noticing that many named entities contain other named entities inside them, Finkel and Manning (2009) proposed a model that is capable of extracting nested named entities by representing the sentence as a constituency parse tree, with named entities as phrases. As a parsing-based model, the approach has a time complexity that is cubic in the number of words in the sentence.

Recently, Lu and Roth (2015) proposed a model that can represent overlapping entities. In addition to supporting nested entities, theoretically this model can also represent overlapping entities where neither is nested in another. The model represents each sentence as a hypergraph with nodes indicating entity types and boundaries. Compared to the previous model, this model has a lower time complexity, which is linear in the number of words in the sentence.

All the above models focus on NER in conventional texts, where the assumption of contiguous entities is valid. In the past few years, there is a growing body of works on recognizing disorder mentions in clinical text. These disorder mentions may be discontiguous and also overlapping. To tackle such an issue, a research group from University of Texas Health Science Center at Houston (Tang et al., 2013; Zhang et al., 2014; Xu et al., 2015) first utilized a conventional linear-chain CRF to recognize disorder mention parts by extending the standard BIO (*Begin, Inside, Outside*) format, and next did some postprocessing to combine different components. Though effective, as we will see later, such a model comes with some drawbacks. Nevertheless, their work motivated us to perform further analysis on this issue and propose a novel model specifically designed for discontiguous entity extraction.

3 Models

3.1 Linear-chain CRF Model

Before we present our approach, we would like to spend some time to discuss a simple approach based on linear-chain CRFs (Lafferty et al., 2001). This approach is primarily based on the system by Tang et al. (2013), and this will be the baseline system

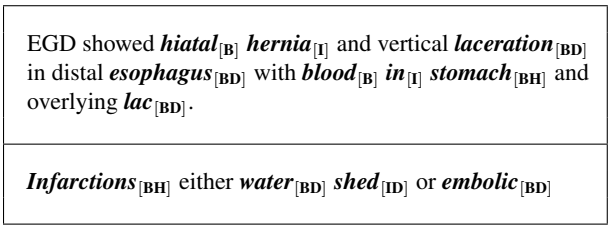

Figure 2: Entity encoding in the linear-chain model. **Top**: for the example in Fig 1. **Bottom**: for the second example in Fig 4. The **O** labels are not shown.

that we will make comparison with in later sections.

The problem is regarded as a sequence prediction task, where each word is assigned a label similar to BIO format often used for NER. We used the encoding used by Tang et al. (2013), which uses 7 tags to handle entities that can be discontiguous and overlapping. Specifically, we used **B**, **I**, **O**, **BD**, **ID**, **BH**, and **IH** to denote **B**eginning of entity, **I**nside entity, **O**utside of entity, **B**eginning of **D**iscontiguous entity, **I**nside of **D**iscontiguous entity, **B**eginning of **H**ead, and **I**nside of **H**ead. To encode a sentence in this format, first we identify the contiguous word sequences which are parts of multiple entities. We call these *head components* and we label each word inside each component with **BH** (for the first word in *each component*) or **IH**. Then we find contiguous word sequences which are parts of a discontiguous entity, which we call the *body components*. Words inside those components which have not been labeled are labeled with **BD** (for the first word in *each component*) or **ID**. Finally, words that are parts of a contiguous entity are called *contiguous component*, and, if they have not been labeled, are labeled as **B** (for the first word in *each component*) or **I**.

This encoding is lossy, since the information on which parts constitute the same entity is lost. The top example in Figure 2 is the encoding of the example shown in Figure 1. During decoding, based on the labels only it is not entirely clear whether "***laceration***" should be combined with "***esophagus***" or with "***stomach***" to form a single mention. For the bottom example, we cannot deduce that "***Infarctions***" alone is a mention, since there is no difference in the encoding of a sentence with only two mentions {"***Infarctions ... water shed***", "***Infarctions ... embolic***"} or having three mentions with "***Infarctions***" as another mention, since in both cases, the word "***Infarctions***" is labeled with **BH**.

Also, it should be noted that some of the label sequences are not valid. For example, a sentence in which there is only one word labeled as **BD** is invalid, since a discontiguous entity requires at least two words to be labeled as **BD** or **BH**. This is, however, a possible output from the linear CRF model, due to the Markov assumption inherent in linear CRF models. Later we see that our models do not have this problem.

3.2 Our Model

Linear-chain CRF models are limited in their representational power when handling complex entities, especially when they can be discontiguous and can overlap with one another. While recent models have been proposed to effectively handle overlapping entities, how to effectively handle discontiguous entities remains a research question to be answered. Motivated by previous efforts on handling overlapping entities (Lu and Roth, 2015), in this work we propose a model based on hypergraphs that can better represent entities that can be discontiguous and at the same time be overlapping with each other.

Unlike the previous work (Lu and Roth, 2015), we establish a novel theoretical framework to formally quantify the ambiguity of our hypergraph-based models and justify their effectiveness by making comparisons with the linear-chain CRF approach.

Now let us introduce our novel hypergraph representation. A hypergraph can be used to represent entities of different types and their combinations in a given sentence. Specifically, a hypergraph is constructed as follows. For the word at position k, we have the following nodes:

- $\mathbf{A}^k$: this node represents all entities that begin with the current or a future word (to the right of the current word).
- $\mathbf{E}^k$: this node represents all entities that begin with the current word.
- $\mathbf{T}_t^k$: this node represents entities of certain specific type t that begin with the current word. There is one $\mathbf{T}_t^k$ for each different type.
- $\mathbf{B}_{t,i}^k$: this node indicates that the current word is part of the i-th component of an entity of type t.
- $\mathbf{O}_{t,i}^k$: this node indicates that the current word appears in between $(i\text{-}1)$-th and i-th components of an entity of type t.

There is also a special leaf node, $\mathbf{X}$-node, which indicates the end (*i.e.*, right boundary) of an entity.

The nodes are connected by directed hyperedges, which for the purpose of explaining our models are defined as those edges that connect one node, called the parent node, to one or more child nodes. For ease of notation, in the rest of this paper we use *edge* to refer to directed hyperedge.

The edges Each $\mathbf{A}^k$ is a parent to $\mathbf{E}^k$ and $\mathbf{A}^{k+1}$, encoding the fact that the set of all entities at position k is the union of the set of entities starting **e**xactly at current position ($\mathbf{E}^k$) with the set of entities starting at or **a**fter position $k+1$ ($\mathbf{A}^{k+1}$).

Each $\mathbf{E}^k$ is a parent to $\mathbf{T}^k_1, \ldots, \mathbf{T}^k_T$, where T is the total number of possible types that we consider. Each $\mathbf{T}^k_t$ has two edges where it serves as a parent, within one it is parent to $\mathbf{B}^k_{t,0}$ and within another it is to $\mathbf{X}$. These edges encode the fact that at position k, either there is an entity of type t that begins with the current word (to $\mathbf{B}^k_{t,0}$), or there is no entity of type t that begins with the current word (to $\mathbf{X}$).

In the full hypergraph, each $\mathbf{B}^k_{t,i}$ is a parent to $\mathbf{B}^{k+1}_{t,i}$ (encoding the fact that the next word also belongs to the same component of the same entity), to $\mathbf{O}^{k+1}_{t,i+1}$ (encoding the fact that this word is part of a discontiguous entity, and the next word is the first word separating current component and the next component), and to $\mathbf{X}$ (representing that the entity ends at this word). Also there are edges with all possible combinations of $\mathbf{B}^{k+1}_{t,i}$, $\mathbf{O}^{k+1}_{t,i+1}$, and $\mathbf{X}$ as the child nodes, representing overlapping entities. For example, the edge $\mathbf{B}^k_{t,i} \rightarrow (\mathbf{B}^{k+1}_{t,i}, \mathbf{X})$ denotes that there is an entity which continues to the next word (the edge to $\mathbf{B}^{k+1}_{t,i}$), while there is another entity ending at k-th word (the edge to $\mathbf{X}$). In total there are 7 edges in which $\mathbf{B}^k_{t,i}$ is a parent, which are:

- $\mathbf{B}^k_{t,i} \rightarrow (\mathbf{X})$
- $\mathbf{B}^k_{t,i} \rightarrow (\mathbf{O}^{k+1}_{t,i+1})$
- $\mathbf{B}^k_{t,i} \rightarrow (\mathbf{O}^{k+1}_{t,i+1}, \mathbf{X})$
- $\mathbf{B}^k_{t,i} \rightarrow (\mathbf{B}^{k+1}_{t,i})$
- $\mathbf{B}^k_{t,i} \rightarrow (\mathbf{B}^{k+1}_{t,i}, \mathbf{X})$
- $\mathbf{B}^k_{t,i} \rightarrow (\mathbf{B}^{k+1}_{t,i}, \mathbf{O}^{k+1}_{t,i+1})$
- $\mathbf{B}^k_{t,i} \rightarrow (\mathbf{B}^{k+1}_{t,i}, \mathbf{O}^{k+1}_{t,i+1}, \mathbf{X})$

Analogously, $\mathbf{O}^k_{t,i}$ has three edges that connect to $\mathbf{O}^{k+1}_{t,i}$, $\mathbf{B}^{k+1}_{t,i+1}$, and both. Note that $\mathbf{O}^k_{t,i}$ is not a parent to $\mathbf{X}$ by definition.

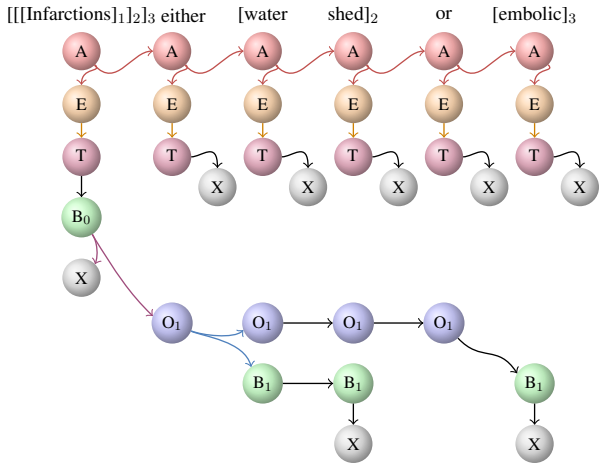

Figure 3: The hypergraph for SHARED model for the second example in Figure 4. The type information in $\mathbf{T}$, $\mathbf{B}$, and $\mathbf{O}$-nodes is not shown. The $\mathbf{X}$-node is drawn multiple times for better visualization.

During testing, the model will predict a **subgraph** which will result in the predicted entities after decoding. We call this subgraph representing certain entity combination ***entity-encoded hypergraph***.

For example, Figure 3 shows the entity-encoded hypergraph of our model encoding the three mentions in the second example in Figure 4. The edge from the $\mathbf{T}$-node for the first word to the $\mathbf{B}$-node for the first word shows that there is at least one entity starting with this word. The three places where an $\mathbf{X}$-node is connected to a $\mathbf{B}$-node show the end of the three entities. Note that this hypergraph clearly shows the presence of the three mentions without ambiguity, unlike a linear-chain encoding of this example where it cannot be inferred that "***Infarctions***" alone is a mention, as discussed previously. In this paper, we set the maximum number of components to be 3 since the dataset does not contain any mention with more than 3 components.

Also note that this model supports discontiguous and overlapping mentions of different types since each type has its own set of $\mathbf{O}$-nodes and $\mathbf{B}$-nodes, unlike the linear-chain model, which supports only overlapping mentions of the same type.

We also experimented with a variant of this model, where we split the $\mathbf{T}$-nodes, $\mathbf{B}$-nodes, and $\mathbf{O}$-nodes further according to the number of components. We split $\mathbf{B}^k_{t,i}$ into $\mathbf{B}^k_{t,i,j}$, $i = 1 \ldots j, j =$

$1 \ldots 3$ which represents that the word is part of the i-th component of a mention with total j components. Similarly we split $\mathbf{O}^k_{t,i}$ into $\mathbf{O}^k_{t,i,j}$ and $\mathbf{T}^k_t$ into $\mathbf{T}^k_{t,j}$. We call the original version SHARED model, and this variant SPLIT model. The motivation for this variant is that the majority of overlaps in the data are between discontiguous and contiguous entities, and so splitting the two cases – one component (contiguous) and more (discontiguous) – will reduce ambiguity for those cases.

These models are still ambiguous to some degree, for example when an $\mathbf{O}$-node has two child nodes and two parents, we cannot decide which of the parent node is paired with which child node. However, in this paper we argue that:

- This model is less ambiguous compared to the linear-chain model, as we will show later theoretically and empirically.
- Every output of our model is a valid prediction, unlike the linear-chain model since this model will always produce a valid path from $\mathbf{T}$-nodes to the $\mathbf{X}$-nodes representing some entities.

We will also show through experiments that our models can encode the entities more accurately.

3.3 Interpreting Output Structures

Both the linear-chain CRF model and our models are still ambiguous to some degree, so we need to handle the ambiguity in interpreting the output structures into entities. For all models, we define two general heuristics: ENOUGH and ALL. The ENOUGH heuristic handles ambiguity by trying to produce a minimal set of entities which encodes to the one produced by the model, while ALL heuristic handles ambiguity by producing the union of all possible entity combinations that encode to the one produced by the model. For more details on how these heuristics are implemented for each model, please refer to the supplementary material.

3.4 Training

For both models, the training follows a log-linear formulation, by maximizing the loglikelihood of the training data $\mathcal{D}$:

$$\mathcal{L}(\mathcal{D}) = \sum_{(\mathbf{x},\mathbf{y})\in\mathcal{D}} \left[\sum_{e\in\mathcal{E}(\mathbf{x},\mathbf{y})} \left[\mathbf{w}^T \mathbf{f}(e)\right] - \log Z_{\mathbf{w}}(\mathbf{x}) \right] - \lambda ||\mathbf{w}||^2$$

Here $(\mathbf{x}, \mathbf{y})$ is a training instance consisting of the sentence $\mathbf{x}$ and the entity-encoded hypergraph $\mathbf{y} \in \mathcal{Y}$ where $\mathcal{Y}$ is the set of all possible mention-encoded hypergraphs. The vector $\mathbf{w}$ consists of feature weights, which are the model parameters to be learned. The set $\mathcal{E}(\mathbf{x}, \mathbf{y})$ consists of all edges present in the entity-encoded hypergraph $\mathbf{y}$ for input $\mathbf{x}$. The function $\mathbf{f}(e)$ returns the features defined over the edge e, $Z_{\mathbf{w}}(\mathbf{x})$ is the normalization term which gives the sum of scores over all possible entity-encoded hypergraphs in $\mathcal{Y}$ that is relevant to the input $\mathbf{x}$, and finally λ is the ℓ_2-regularization parameter.

4 Model Ambiguity

The main aim of this paper is to assess how well each model can represent the discontiguous entities, even in the presence of overlapping entities.

In this section, we will theoretically compare the models' ambiguity, which is defined as the average number of mention combinations that map to the same encoding in a model. Now, to compare two models, instead of calculating the ambiguity directly, we can calculate the ***relative ambiguity*** between the two models directly by comparing the number of *canonical encodings* in the two models.

A canonical encoding is a fixed, selected representation of a particular set of mentions in a sentence, among (possibly) several alternative representations. Several alternatives may be present due to the ambiguity of the encoding-decoding process and also since the output of the model is not restricted to a specific rule. For example, for the text "John Smith", a model trained in BIO format might output "B-PER I-PER" or "I-PER I-PER", and both will still mean that "John Smith" is a person, although the "correct" encoding would of course be "B-PER I-PER", which is selected as the canonical encoding. Intuitively, a canonical encoding is a formal way to say that we only consider the "correct" encodings.

A model with larger number of canonical encodings will, on average, have less ambiguity compared to the one with smaller number of canonical encodings. Subsequently, a model with less ambiguity will be more precise in predicting entities.

Let $\mathcal{M}_{\text{LI}}(n), \mathcal{M}_{\text{SH}}(n), \mathcal{M}_{\text{SP}}(n)$ denote the number of canonical encodings of the linear-chain, SHARED, and SPLIT model, respectively, for a sen-

tence with n words. Then we formally define the relative ambiguity of model M_1 over model M_2, $\mathcal{A}_r(M_1, M_2)$, as follows:

$$\mathcal{A}_r(M_1, M_2) = \lim_{n\to\infty} \frac{\log \sum_{i=1}^{n} \mathcal{M}_{M_2}(i)}{\log \sum_{i=1}^{n} \mathcal{M}_{M_1}(i)} \quad (1)$$

$\mathcal{A}_r(M_1, M_2) > 1$ means model M_1 is more ambiguous than M_2. Now, we claim the following:

Theorem 4.1. $\mathcal{A}_r(\text{LI}, \text{SH}) > 1$

We provide a proof sketch below. Due to space limitation, we cannot provide the full dynamic programming calculation. We refer the reader to the supplementary material for the details.

Proof Sketch The number of canonical encodings in the linear-chain model is less than 7^n since there are 7 possible tags for each of the n words and not all of the 7^n tag sequences are canonical encodings. So we have $\mathcal{M}_{\text{LI}}(n) < 7^n$ and thus we can derive $\log \sum_{i=1}^{n} \mathcal{M}_{\text{LI}}(i) < 3n \log 2$.

For our models, by employing some dynamic programming adapted from the inside algorithm (Baker, 1979), we can calculate the growth order of the number of canonical encodings for SHARED model to arrive at a conclusion that $\forall n > n_0,\ \sum_{i=1}^{n} \mathcal{M}_{\text{SH}}(i) > C \cdot 2^{10n}$ for some constants n_0, C. Then we have:

$$\mathcal{A}_r(\text{LI}, \text{SH}) \geq \lim_{n\to\infty} \frac{\log C + 10n \log 2}{3n \log 2} = \frac{10}{3} > 1 \quad (2)$$

□

Theorem 4.1 says that the linear-chain model is more ambiguous compared to our SHARED model. Similarly, we can also establish $\mathcal{A}_r(\text{SH}, \text{SP}) > 1$. Later we also see this empirically from experiments.

5 Experiments

5.1 Data

To allow us to conduct experiments to empirically assess different models' capability in handling entities that can be discontiguous and can potentially overlap with one another, we need a text corpus annotated with entities which can be discontiguous and overlapping with other entities. We found the largest of such corpus to be the dataset from the task to recognize disorder mentions in clinical text, initially organized by ShARe/CLEF eHealth Evaluation Lab (SHEL) in 2013 (Suominen et al., 2013) and continued in SemEval-2014 (Pradhan et al., 2014a).

The definition of the task is to recognize mentions of concepts that belong to the Unified Medical Language System (UMLS) semantic group *disorders* from a set of clinical texts. Each text has been annotated with a list of disorder mentions by two professional coders trained for this task, followed by an open adjudication step (Suominen et al., 2013).

Unfortunately, even in this dataset, only 8.95% of the mentions are discontiguous. Working directly on such data would prevent us from understanding the true effectiveness of different models when handling entities which can be discontiguous and overlapping. In order to truly understand how different models behave on data with discontiguous entities, we consider a subset of the data where we consider those sentences which contain at least one discontiguous entity. We call the resulting subset the "Discontiguous" subset of the "Original" dataset. Later we will also still use the training data of the "Original" dataset in the experiments.

Note that this "Discontiguous" subset still contains contiguous entities since a sentence usually contains more than one entity. The subset is a balanced dataset with 53.61% of the entities being discontiguous and the rest contiguous. We then split this dataset into training, development, and test set, according to the split given in SemEval 2014 setting (henceforth LARGE dataset). To see the impact of dataset size, we also experiment on a subset of the LARGE dataset, following the SHEL 2013 setting, with the development set in the LARGE dataset used as test set (henceforth SMALL dataset). The training and development set of the SMALL dataset comes from a random 80% (Tr80) and 20% (Tr20) split of the training set in LARGE dataset.

The statistics of the datasets, including the number of overlaps between the entities in the "All" column, are shown in Table 1.

We note that this dataset only contains one type of entity. In later experiments, in order to evaluate the models on multiple types, we create another dataset where we split the entities based on the entity-level semantic category. This information is available for some entities through the Concept Unique Identifier (CUI) annotation in the data. In total we have three types: two types (type `A` and `B`) based on the semantic category, and one type (type `N`) for those entities

Split	#Sentences	Number of mentions				#Overlaps	
		1 part	2 parts	3 parts	Total	All	Diff
Train	534	544	607	44	1,195	205	58
- Tr80	416	448	476	33	957	164	48
- Tr20	118	96	131	11	238	41	10
Dev	303	357	421	18	796	240	28
Test	430	584	610	16	1,210	327	61

Table 1: The statistics of the data. Tr80 and Tr20 refers to the 80% and 20% partitions of the full training data.

having no semantic category information[2]. See the supplementary material for more details. The number of overlaps between different types is shown in the "Diff" column in Table 1. Except for a handful overlaps in development set, all overlaps involve at least one discontiguous entity. Our main result will still be based on the dataset with one type of entity.

The patient had blood in his mouth and on his tongue, pupils were pinpoint and reactive.
- ***blood in his mouth***
- ***blood . . . on his tongue***
- ***pupils . . . pinpoint***

Infarctions either water shed or embolic
- ***Infarctions***
- ***Infarctions . . . water shed***
- ***Infarctions . . . embolic***

You see blood or dark/black material when you vomit or have a bowel movement.
- ***blood . . . vomit***
- ***blood . . . bowel movement***
- ***dark . . . material . . . vomit***
- ***dark . . . bowel movement***
- ***black material . . . vomit***
- ***black material . . . bowel movement***

Figure 4: Examples of discontiguous and overlapping mentions, taken from the dataset.

Figure 4 shows some examples of the mentions. The first example shows two discontiguous mentions that do not overlap. The second example shows a typical discontiguous and overlapping case. The last example shows a very hard case of overlapping and discontiguous mentions, as each of the components in {***blood***, ***dark***, ***black material***} is paired with each of the word in {***vomit***, ***bowel movement***}, resulting in six mentions in total, with one having three components (***dark . . . material . . . vomit***).

5.2 Features

Motivated by the features used by Zhang et al. (2014), for both the linear-chain CRF model and our models we use the following features: neighbouring words with relative position information (we consider previous and next k words, where k=1, 2, 3), neighbouring words with relative position information paired with the current word, word n-grams containing the current word (n=2,3), POS tag for the current word, POS tag n-grams containing the current word (n=2,3), orthographic features (prefix, suffix, capitalization, lemma), note type (discharge summary, echo report, radiology, and ECG report), section name (*e.g.* Medications, Past Medical History)[3], Brown cluster, and word-level semantic category information[4]. We used Stanford POS tagger (Toutanova et al., 2003) for POS tagging, and NLP4J package[5] for lemmatization. For Brown cluster features, following Tang et al. (2013), we used 1,000 clusters from the combination of training, development, and test set, and used all the subpaths of the cluster IDs as features.

5.3 Experimental Setup

We evaluated the three models on the SMALL dataset and the LARGE dataset.

Note that in both the SMALL and LARGE dataset, about half of all mentions are discontiguous, both in training and test set. We also want to see whether training on a set where the majority of the mentions are contiguous will affect the performance on recognizing discontiguous mentions. So we also performed another experiment where we trained each model on the original training set where the majority of the entities are contiguous. We refer to this original dataset as "Train-Orig" (it contains 10,405 sentences, including those with no entities) and the

[2]It is tempting to just ignore these entities since the N type does not convey any specific information about the entities in it. However, due to the dataset size, excluding this type will lead to very small number of interactions between types. So we decided to keep this type

[3]Section names were determined by some heuristics, refer to the supplementary material for more information

[4]This is standard information that can be extracted from UMLS. See (Zhang et al., 2014) for more details.

Table 2: Results on the two datasets and two different training data after optimizing regularization hyperparameter λ in development set. The -ENH and -ALL suffixes refer to the ENOUGH and ALL heuristics. The best result in each column is put in boldface.

earlier one as "Train-Disc".

First we trained each model on the training set, varying the regularization hyperparameter λ,[6] then the λ with best result in the development set using the respective ENOUGH heuristic for each model is chosen for final result in the test set.

For each experiment setting, we show precision (P), recall (R) and F1 measure. Precision is the percentage of the mentions predicted by the model which are correct, recall is the percentage of mentions in the dataset correctly discovered by the model, and F1 measure is the harmonic mean of precision and recall.

5.4 Results and Discussions

The full results are recorded in Table 2.

We see that in general our models have higher precision compared to the linear-chain baseline. This is expected, since our models have less ambiguity, which means that from a given output structure it is easier in our model to get the correct interpretation. We will explore this more in Section 5.5.

The ALL heuristic, as expected, results in higher recall, and this is more pronounced in the linear-chain model, with up to 4% increase from the ENOUGH heuristic, achieving the highest recall in three out of four settings. The high recall of the ALL heuristic in the linear-chain model can be explained by the high level of ambiguity the model has. Since it has more ambiguity compared to our models, one label sequence predicted by the model produces a lot of entities, and so it is more likely to overlap with the gold entities. But this has the drawback of very low precision as we can see in the result.

We see switching from one heuristic to the other does not affect the results of our models much. Looking at the output of our models, they tend to produce output structures with less ambiguity, which causes little difference in the two heuristics.

One example where the baseline made a mistake is the sentence: "Ethanol Intoxication and withdrawal". The gold mentions are "Ethanol Intoxication" and "Ethanol withdrawal". But the linear-chain model labeled it as "$[\text{Ethanol}]_{[B]}$ $[\text{Intoxication}]_{[I]}$ and $[\text{withdrawal}]_{[BD]}$", which is inconsistent since there is only one discontiguous component. Our models do not have this issue because in our models every subgraph that may be predicted translates to valid mention combinations, as discussed in Section 3.2.

In the "Train-Orig" column, we see that all models can recognize discontiguous entities better when given more data, even though the majority of the entities in "Train-Orig" are contiguous.

5.5 Experiments on Ambiguity

To see the ambiguity of each model empirically, we run the decoding process for each model given the gold output structure, which is the true label sequence for the linear-chain model and the true mention-encoded hypergraph for our models.

We used the entities from the training and development sets for this experiment, and we compare the "Original" datasets with the "Discontiguous" subset to see that the ambiguity is more pronounced when there are more discontiguous entities. Then we show the precision and recall errors (defined as $1 - P$ and $1 - R$, respectively) in Table 3.

Since the ALL heuristics generates all possible mentions from the given encoding, theoretically it should give perfect recall. However, due to errors in the training data, there are mentions which can-

[6] Taken from the set $\{0.125, 0.25, 0.5, 1.0, 2.0\}$

	Discontiguous		Original	
	Prec Err	Rec Err	Prec Err	Rec Err
LI-ALL	63.66%	0.30%	23.81%	0.17%
SH-ALL	1.73%	0.30%	0.35%	0.17%
SP-ALL	1.05%	0.30%	0.22%	0.17%
LI-ENH	2.74%	3.82%	0.52%	0.90%

SP-ENH	0.75%	0.90%	0.17%	0.28%

Table 3: Precision and recall errors (%) of each model in the "Discontiguous" and "Original" datasets when given the gold output structure (label sequence in linear-chain model, hypergraph in our models). Lower numbers are better.

Type	#Ent	Linear-chain			SHARED			SPLIT		
		P	R	F	P	R	F	P	R	F
A	289	69.8	59.9	64.4	79.4	56.1	65.7	81.0	56.1	66.3
B	418	50.0	34.0	40.5	56.8	29.0	38.4	58.2	28.0	37.8
N	503	62.1	37.8	47.0	84.8	43.3	57.4	84.9	42.4	56.5
Total	1210	60.3	41.7	49.3	74.3	41.4	53.2	75.5	40.7	52.9

Table 4: Results on the LARGE dataset when entities are split into three types: A, B, and N. #Ent is the number of entities

not be properly encoded in the models[7]. Removing these errors results in perfect recall (0% recall error). This means that all models are complete: they can encode any mention combinations.

We see however, a very huge difference on the precision error between the linear-chain model and our models, even more when most of the entities are discontiguous. For the discontiguous subset with the ALL heuristic, the linear-chain model produced 5,463 entities, while the SHARED and SPLIT model produced 2,020 and 2,006 entities, respectively. The total number of gold entities is 1,991. This means one encoding in the linear-chain model produces much more distinct mention combinations compared to our model, which again shows that the linear-chain model has more ambiguity. Similarly, we can deduce that the SHARED model has slightly more ambiguity compared to the SPLIT model. This confirms our theoretical result presented previously.

It is also worth noting that in the ENOUGH heuristic our models have smaller errors compared to the linear-chain model, showing that when both models can predict the true output structure (the correct label sequence for the baseline model and mention-encoded hypergraph for our models), it is easier in our models to get the desired mention combinations.

5.6 Experiments on Multiple Entity Types

We used the LARGE dataset with the multiple-type entities for this experiment. We ran our two models and the linear-chain CRF model with the ENOUGH heuristic on this multi-type dataset, in the same setting as Train-Orig in previous experiments, and the result is shown in Table 4. We used the best lambda from the main experiment for this experiment.

There is a performance drop compared to the LARGE-Train-Orig results in Table 2, which is expected since the presence of multiple types make the task harder. But in general we still see that our models are still better than the baseline, especially the SPLIT model, which shows that in the presence of multiple types, our models can still work better than the baseline model.

6 Conclusions and Future Work

In this paper we proposed new models that can better represent discontiguous entities that can be overlapping at the same time. We validated our claims through theoretical analysis and empirical analysis on the models' ambiguity, as well as their performances on the task of recognizing disorder mentions on datasets with a substantial number of discontiguous entities. When the true output structure is given, which is still ambiguous in all models, our models show that it is easier to produce the desired mention combinations compared to the linear-chain CRF model with reasonable heuristics. We note that an extension similar to semi-Markov or weak semi-Markov (Muis and Lu, 2016) is possible for our models. We leave this for future investigations.

The supplementary material and our implementations for the models are available at:

Abstract

When humans read text, they fixate some words and skip others. However, there have been few attempts to explain skipping behavior with computational models, as most existing work has focused on predicting reading times (e.g., using surprisal). In this paper, we propose a novel approach that models both skipping and reading, using an unsupervised architecture that combines a neural attention with autoencoding, trained on raw text using reinforcement learning. Our model explains human reading behavior as a tradeoff between precision of language understanding (encoding the input accurately) and economy of attention (fixating as few words as possible). We evaluate the model on the Dundee eye-tracking corpus, showing that it accurately predicts skipping behavior and reading times, is competitive with surprisal, and captures known qualitative features of human reading.

1 Introduction

Humans read text by making a sequence of fixations and saccades. During a fixation, the eyes land on a word and remain fairly static for 200–250 ms. Saccades are the rapid jumps that occur between fixations, typically lasting 20–40 ms and spanning 7–9 characters (Rayner, 1998). Readers, however, do not simply fixate one word after another; some saccades go in reverse direction, and some words are fixated more than once or skipped altogether.

A range of computational models have been developed to account for human eye-movements in reading (Rayner and Reichle, 2010), including models of saccade generation in cognitive psychology, such as EZ-Reader (Reichle et al., 1998, 2003, 2009), SWIFT (Engbert et al., 2002, 2005), or the Bayesian Model of Bicknell and Levy (2010). More recent approaches use machine learning models trained on eye-tracking data to predict human reading patterns (Nilsson and Nivre, 2009, 2010; Hara et al., 2012; Matthies and Søgaard, 2013). Both types of models involve theoretical assumptions about human eye-movements, or at least require the selection of relevant eye-movement features. Model parameters have to be estimated in a supervised way from eye-tracking corpora.

Unsupervised approaches, that do not involve training the model on eye-tracking data, have also been proposed. A key example is *surprisal*, which measures the predictability of a word in context, defined as the negative logarithm of the conditional probability of the current word given the preceding words (Hale, 2001; Levy, 2008). Surprisal is computed by a language model, which can take the form of a probabilistic grammar, an n-gram model, or a recurrent neural network. While surprisal has been shown to correlate with word-by-word reading times (McDonald and Shillcock, 2003a,b; Demberg and Keller, 2008; Frank and Bod, 2011; Smith and Levy, 2013), it cannot explain other aspects of human reading, such as reverse saccades, re-fixations, or skipping. Skipping is a particularly intriguing phenomenon: about 40% of all words are skipped (in the Dundee corpus, see below), without apparent detriment to text understanding.

In this paper, we propose a novel model architecture that is able to explain which words are skipped and which ones are fixated, while also predicting

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 85–95,
Austin, Texas, November 1-5, 2016.

reading times for fixated words. Our approach is completely unsupervised and requires only unlabeled text for training.

Compared to language as a whole, reading is a recent innovation in evolutionary terms, and people learning to read do not have access to competent readers' eye-movement patterns as training data. This suggests that human eye-movement patterns emerge from general principles of language processing that are independent of reading. Our starting point is the *Tradeoff Hypothesis*: Human reading optimizes a tradeoff between *precision* of language understanding (encoding the input accurately) and *economy* of attention (fixating as few words as possible). Based on the Tradeoff Hypothesis, we expect that humans only fixate words to the extent necessary for language understanding, while skipping words whose contribution to the overall meaning can be inferred from context.

In order to test these assumptions, this paper investigates the following questions:

1. Can the Tradeoff Hypothesis be implemented in an unsupervised model that predicts skipping and reading times in *quantitative* terms? In particular, can we compute surprisal based only on the words that are actually fixated?

2. Can the Tradeoff Hypothesis explain known *qualitative* features of human fixation patterns? These include dependence on word frequency, word length, predictability in context, a contrast between content and function words, and the statistical dependence of the current fixation on previous fixations.

To investigate these questions, we develop a generic architecture that combines neural language modeling with recent ideas on integrating recurrent neural networks with mechanisms of attention, which have shown promise both in NLP and in computer vision. We train our model end-to-end on a large text corpus to optimize a tradeoff between minimizing input reconstruction error and minimizing the number of words fixated. We evaluate the model's reading behavior against a corpus of human eye-tracking data. Apart from the unlabeled training corpus and the generic architecture, no further assumptions about language structure are made – in particular, no lexicon or grammar or otherwise labeled data is required.

Our unsupervised model is able to predict human skips and fixations with an accuracy of 63.7%. This compares to a baseline of 52.6% and a supervised accuracy of 69.9%. For fixated words, the model significantly predicts human reading times in a linear mixed effects analysis. The performance of our model is comparable to surprisal, even though it only fixates 60.4% of all input words. Furthermore, we show that known qualitative features of human fixation sequences emerge in our model without additional assumptions.

2 Related Work

A range of attention-based neural network architectures have recently been proposed in the literature, showing promise in both NLP and computer vision (e.g., Mnih et al., 2014; Bahdanau et al., 2015). Such architectures incorporate a mechanism that allows the network to dynamically focus on a restricted part of the input. Attention is also a central concept in cognitive science, where it denotes the focus of cognitive processing. In both language processing and visual processing, attention is known to be limited to a restricted area of the visual field, and shifts rapidly through eye-movements (Henderson, 2003).

Attention-based neural architectures either employ *soft attention* or *hard attention*. Soft attention distributes real-valued attention values over the input, making end-to-end training with gradient descent possible. Hard attention mechanisms make discrete choices about which parts of the input to focus on, and can be trained with reinforcement learning (Mnih et al., 2014). In NLP, soft attention can mitigate the difficulty of compressing long sequences into fixed-dimensional vectors, with applications in machine translation (Bahdanau et al., 2015) and question answering (Hermann et al., 2015). In computer vision, both types of attention can be used for selecting regions in an image (Ba et al., 2015; Xu et al., 2015).

3 The NEAT Reading Model

The point of departure for our model is the Tradeoff Hypothesis (see Section 1): Reading optimizes a tradeoff between precision of language understand-

ing and economy of attention. We make this idea explicit by proposing NEAT (NEural Attention Tradeoff), a model that reads text and attempts to reconstruct it afterwards. While reading, the network chooses which words to process and which words to skip. The Tradeoff Hypothesis is formalized using a training objective that combines accuracy of reconstruction with economy of attention, encouraging the network to only look at words to the extent that is necessary for reconstructing the sentence.

3.1 Architecture

We use a neural sequence-to-sequence architecture (Sutskever et al., 2014) with a hard attention mechanism. We illustrate the model in Figure 1, operating on a three-word sequence $\boldsymbol{w}$. The most basic components are the *reader*, labeled R, and the *decoder*. Both of them are recurrent neural networks with Long Short-Term Memory (LSTM, Hochreiter and Schmidhuber, 1997) units. The recurrent reader network is expanded into time steps $R_0, \ldots, R_3$ in the figure. It goes over the input sequence, reading one word w_i at a time, and converts the word sequence into a sequence of vectors $h_0, \ldots, h_3$. Each vector h_i acts as a fixed-dimensionality encoding of the word sequence $w_1, \ldots, w_i$ that has been read so far. The last vector h_3 (more generally h_N for sequence length N), which encodes the entire input sequence, is then fed into the input layer of the decoder network, which attempts to reconstruct the input sequence $\boldsymbol{w}$. It is also realized as a recurrent neural network, collapsed into a single box in the figure. It models a probability distribution over word sequences, outputting a probability distribution $P_{Decoder}(w_i|\boldsymbol{w}_{1,\ldots,i-1}, h_N)$ over the vocabulary in the i-th step, as is common in neural language modeling (Mikolov et al., 2010). As the decoder has access to the vector representation created by the reader network, it ideally is able to assign the highest probability to the word sequence $\boldsymbol{w}$ that was actually read. Up to this point, the model is a standard sequence-to-sequence architecture reconstructing the input sequence, that is, performing autoencoding.

As a basic model of human processing, NEAT contains two further components. First, experimental evidence shows that during reading, humans constantly make predictions about the upcoming input (e.g., Van Gompel and Pickering, 2007). As a model of this behavior, the reader network at each time step outputs a probability distribution P_R over the lexicon. This distribution describes which words are likely to come next (i.e., the reader network performs language modeling). Unlike the modeling performed by the decoder, P_R, via its recurrent connections, has access to the previous context only.

Second, we model skipping by stipulating that only some of the input words w_i are fed into the reader network R, while R receives a special vector representation, containing no information about the input word, in other cases. These are the words that are skipped. In NEAT, at each time step during reading, the *attention module* A decides whether the next word is shown to the reader network or not. When humans skip a word, they are able to identify it using *parafoveal preview* (Rayner, 2009). Thus, we can assume that the choice of which words to skip takes into account not only the prior context but also a preview of the word itself. We therefore allow the attention module to take the input word into account when making its decision. In addition, the attention module has access to the previous state h_{i-1} of the reader network, which summarizes what has been read so far. To allow for interaction between skipping and prediction, we also give the attention module access to the probability of the input word according to the prediction P_R made at the last time step. If we write the decision made by A as $\omega_i \in \{0,1\}$, where $\omega_i = 1$ means that word w_i is shown to the reader and 0 means that it is not, we can write the probability of showing word w_i as:

$$\begin{aligned} &P(\omega_i = 1|\boldsymbol{\omega}_{1\ldots i-1}, \boldsymbol{w}) \\ &= P_A(w_i, h_{i-1}, P_R(w_i|\boldsymbol{w}_{1\ldots i-1}, \boldsymbol{\omega}_{1\ldots i-1})) \end{aligned} \quad (1)$$

We implement A as a feed-forward network, followed by taking a binary sample ω_i.

We obtain the *surprisal* of an input word by taking the negative logarithm of the conditional probability of this word given the context words that precede it:

$$\mathrm{Surp}(w_i|\boldsymbol{w}_{1\ldots i-1}) = -\log P_R(w_i|\boldsymbol{w}_{1\ldots i-1}, \boldsymbol{\omega}_{1\ldots i-1}) \quad (2)$$

As a consequence of skipping, not all input words are accessible to the reader network. Therefore, the

probability and surprisal estimates it computes crucially only take into account the words that have actually been fixated. We will refer to this quantity as the *restricted surprisal*, as opposed to *full surprisal*, which is computed based on all prior context words.

The key quantities for predicting human reading are the fixation probabilities in equation (1), which model fixations and skips, and restricted surprisal in equation (2), which models the reading times of the words that are fixated.

3.2 Model Objective

Given network parameters θ and a sequence $\boldsymbol{w}$ of words, the network stochastically chooses a sequence $\boldsymbol{\omega}$ according to (1) and incurs a loss $L(\boldsymbol{\omega}|\boldsymbol{w},\theta)$ for language modeling and reconstruction:

$$\begin{aligned} L(\boldsymbol{\omega}|\boldsymbol{w},\theta) = &-\sum_i \log P_R(w_i|\boldsymbol{w}_{1,\ldots,i-1},\boldsymbol{\omega}_{1,\ldots,i-1};\theta) \\ &-\sum_i \log P_{Decoder}(w_i|\boldsymbol{w}_{1,\ldots,i-1};h_N;\theta) \end{aligned} \tag{3}$$

where $P_R(w_i,\ldots)$ denotes the output of the reader after reading w_{i-1}, and $P_{Decoder}(w_i|\ldots;h_N)$ is the output of the decoder at time $i-1$, with h_N being the vector representation created by the reader network for the entire input sequence.

To implement the Tradeoff Hypothesis, we train NEAT to solve language modeling and reconstruction with minimal attention, i.e., the network minimizes the expected loss:

$$Q(\theta) := \mathrm{E}_{\boldsymbol{w},\boldsymbol{\omega}}\left[L(\boldsymbol{\omega}|\boldsymbol{w},\theta) + \alpha\cdot\|\boldsymbol{\omega}\|_{\ell_1}\right] \tag{4}$$

where word sequences $\boldsymbol{w}$ are drawn from a corpus, and $\boldsymbol{\omega}$ is distributed according to $P(\boldsymbol{\omega}|\boldsymbol{w},\theta)$ as defined in (1). In (4), $\|\boldsymbol{\omega}\|_{\ell_1}$ is the number of words shown to the reader, and $\alpha > 0$ is a hyperparameter. The term $\alpha\cdot\|\boldsymbol{\omega}\|_{\ell_1}$ encourages NEAT to attend to as few words as possible.

Note that we make no assumption about linguistic structure – the only ingredients of NEAT are the neural architecture, the objective (4), and the corpus from which the sequences $\boldsymbol{w}$ are drawn.

3.3 Training

We follow previous approaches to hard attention in using a combination of gradient descent and reinforcement learning, and separate the training of the recurrent networks from the training of A. To train the reader R and the decoder, we temporarily remove the attention network A, set $\boldsymbol{\omega} \sim \mathrm{Binom}(n,p)$ (n sequence length, p a hyperparameter), and minimize $\mathrm{E}[L(\boldsymbol{w}|\theta,\boldsymbol{\omega})]$ using stochastic gradient descent, sampling a sequence $\boldsymbol{\omega}$ for each input sequence. In effect, NEAT is trained to perform reconstruction and language modeling when there is noise in the input. After R and the decoder have been trained, we fix their parameters and train A using the REINFORCE rule (Williams, 1992), which performs stochastic gradient descent using the estimate

$$\frac{1}{|B|}\sum_{\boldsymbol{w}\in B;\boldsymbol{\omega}} \left(L(\boldsymbol{\omega}|\boldsymbol{w},\theta) + \alpha\cdot\|\boldsymbol{\omega}\|_{\ell_1}\right)\partial_{\theta_A}\left(\log P(\boldsymbol{\omega}|\boldsymbol{w},\theta)\right) \tag{5}$$

for the gradient $\partial_{\theta_A} Q$. Here, B is a minibatch, $\boldsymbol{\omega}$ is sampled from $P(\boldsymbol{\omega}|\boldsymbol{w},\theta)$, and $\theta_A \subset \theta$ is the set of parameters of A. For reducing the variance of this estimator, we subtract in the i-th step an estimate of the expected loss:

$$\begin{aligned} U(\boldsymbol{w},\boldsymbol{\omega}_{1\ldots i-1}) := \mathrm{E}_{\boldsymbol{\omega}_{i\ldots N}}[&L(\boldsymbol{\omega}_{1\ldots i-1}\boldsymbol{\omega}_{i\ldots N}|\boldsymbol{w},\theta) \\ &+ \alpha\cdot\|\boldsymbol{\omega}\|_{\ell_1}] \end{aligned} \tag{6}$$

We compute the expected loss using an LSTM that we train simultaneously with A to predict $L + \alpha\|\boldsymbol{\omega}\|_{\ell_1}$ based on $\boldsymbol{w}$ and $\boldsymbol{\omega}_{1\ldots i-1}$. To make learning more stable, we add an entropy term encouraging the distribution to be smooth, following Xu et al. (2015). The parameter updates to A are thus:

$$\begin{aligned} \sum_{\boldsymbol{w},\boldsymbol{\omega}}\sum_i &\left(L(\boldsymbol{\omega}|\boldsymbol{w},\theta) + \alpha\|\boldsymbol{\omega}\|_{\ell_1} - U(\boldsymbol{w},\boldsymbol{\omega}_{1\ldots i-1})\right) \\ &\cdot \partial_{\theta_A}\left(log\ P(\omega_i|\boldsymbol{\omega}_{1\ldots i-1},\boldsymbol{w},\theta)\right) \\ -\gamma\,\partial_{\theta_A}&\left(\sum_{\boldsymbol{w},\boldsymbol{\omega}}\sum_i \mathrm{H}[P(\omega_i|\boldsymbol{\omega}_{1,\ldots,i-1},\boldsymbol{w},\theta)]\right) \end{aligned} \tag{7}$$

where γ is a hyperparameter, and H the entropy.

4 Methods

Our aim is to evaluate how well NEAT predicts human fixation behavior and reading times. Furthermore, we want show that known qualitative properties emerge from the Tradeoff Hypothesis, even though no prior knowledge about useful features is hard-wired in NEAT.

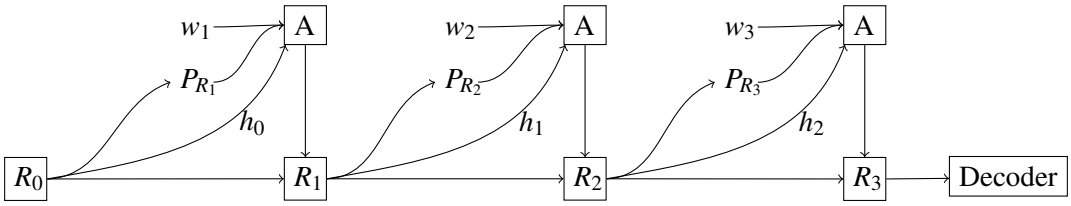

Figure 1: The architecture of the proposed model, reading a three-word input sequence w_1, w_2, w_3. R is the reader network and P_R the probability distribution it computes in each time step. A is the attention network. At each time step, the input, its probability according to P_R, and the previous state h_{i-1} of R are fed into A, which then decides whether the word is read or skipped.

4.1 Training Setup

For both the reader and the decoder networks, we choose a one-layer LSTM network with 1,000 memory cells. The attention network is a one-layer feed-forward network. For the loss estimator U, we use a bidirectional LSTM with 20 memory cells. Input data is split into sequences of 50 tokens, which are used as the input sequences for NEAT, disregarding sentence boundaries. Word embeddings have 100 dimensions, are shared between the reader and the attention network, and are only trained during the training of the reader. The vocabulary consists of the 10,000 most frequent words from the training corpus. We trained NEAT on the training set of the *Daily Mail* section of the corpus described by Hermann et al. (2015), which consists of 195,462 articles from the *Daily Mail* newspaper, containing approximately 200 million tokens. The recurrent networks and the attention network were each trained for one epoch. For initialization, weights are drawn from the uniform distribution. We set $\alpha = 5.0$, $\gamma = 5.0$, and used a constant learning rate of 0.01 for A.

4.2 Corpus

For evaluation, we use the English section of the Dundee corpus (Kennedy and Pynte, 2005), which consists of 20 texts from *The Independent*, annotated with eye-movement data from ten English native speakers. Each native speakers read all 20 texts and answered a comprehension question after each text. We split the Dundee corpus into a development and a test set, with texts 1–3 constituting the development set. The development set consists of 78,300 tokens, and the test set of 281,911 tokens. For evaluation, we removed the datapoints removed by Demberg and Keller (2008), mainly consisting of words at the beginning or end of lines, outliers, and cases of track loss. Furthermore, we removed datapoints where the word was outside of the vocabulary of the model, and those datapoints mapped to positions 1–3 or 48–50 of a sequence when splitting the data. After preprocessing, 62.9% of the development tokens and 64.7% of the test tokens remained. To obtain the number of fixations on a token and reading times, we used the eye-tracking measures computed by Demberg and Keller (2008). The overall fixation rate was 62.1% on the development set, and 61.3% on the test set.

The development set was used to run preliminary versions of the human evaluation studies, and to determine the human skipping rate (see Section 5). All the results reported in this paper were computed on the test set, which remained unseen until the model was final.

5 Results and Discussion

Throughout this section, we consider the following baselines for the attention network: *random attention* is defined by $\boldsymbol{\omega} \sim \text{Binom}(n, p)$, with $p = 0.62$, the human fixation rate in the development set. For *full attention*, we take $\boldsymbol{\omega} = 1$, i.e., all words are fixated. We also derive fixation predictions from *full surprisal*, *word frequency*, and *word length* by choosing a threshold such that the resulting fixation rate matches the human fixation rate on the development set.

5.1 Quantitative Properties

By averaging over all possible fixation sequences, NEAT defines for each word in a sequence a probability that it will be fixated. This probability is not efficiently computable, so we approximate it by sampling a sequence $\boldsymbol{\omega}$ and taking the probabilities $P(\omega_i = 1 | \omega_{1\ldots i-1}, \boldsymbol{w})$ for $i = 1, \ldots, 50$. These sim-

ulated fixation probabilities can be interpreted as defining a distribution of attention over the input sequence. Figure 2 shows heatmaps of the simulated and human fixation probabilities, respectively, for the beginning of a text from the Dundee corpus. While some differences between simulated and human fixation probabilities can be noticed, there are similarities in the general qualitative features of the two heatmaps. In particular, function words and short words are less likely to be fixated than content words and longer words in both the simulated and the human data.

Reconstruction and Language Modeling We first evaluate NEAT intrinsically by measuring how successful the network is at predicting the next word and reconstructing the input while minimizing the number of fixations. We compare perplexity on reconstruction and language modeling for $\boldsymbol{\omega} \sim P(\boldsymbol{\omega}|\boldsymbol{w}, \theta)$. In addition to the baselines, we run NEAT on the fixations generated by the human readers of the Dundee corpus, i.e., we use the human fixation sequence as $\boldsymbol{\omega}$ instead of the fixation sequence generated by A to compute perplexity. This will tell us to what extent the human behavior minimizes the NEAT objective (4).

The results are given in Table 1. In all settings, the fixation rates are similar (60.4% to 62.1%) which makes the perplexity figures directly comparable. While NEAT has a higher perplexity on both tasks compared to full attention, it considerably outperforms random attention. It also outperforms the word length, word frequency, and full surprisal baselines. The perplexity on human fixation sequences is similar to that achieved using word frequency. Based on these results, we conclude that REINFORCE successfully optimizes the objective (4).

Likelihood of Fixation Data Human reading behavior is stochastic in the sense that different runs of eye-tracking experiments such as the ones recorded in the Dundee corpus yield different eye-movement sequences. NEAT is also stochastic, in the sense that, given a word sequence $\mathbf{w}$, it defines a probability distribution over fixation sequences $\boldsymbol{\omega}$. Ideally, this distribution should be close to the actual distribution of fixation sequences produced by humans reading the sequence, as measured by perplexity.

We find that the perplexity of the fixation sequences produced by the ten readers in the Dundee corpus under NEAT is 1.84. A perplexity of 2.0 corresponds to the random baseline $\text{Binom}(n, 0.5)$, and a perplexity of 1.96 to random attention $\text{Binom}(n, 0.62)$. As a lower bound on what can achieved with models disregarding the context, using the human fixation rates for each word as probabilities, we obtain a perplexity of 1.68.

	Acc	$F1_{fix}$	$F1_{skip}$
NEAT	63.7	70.4	53.0
Supervised Models			
Nilsson and Nivre (2009)	69.5	75.2	62.6
Matthies and Søgaard (2013)	69.9	72.3	66.1
Human Performance and Baselines			
Random Baseline	52.6	62.1	37.9
Full Surprisal	64.1	70.7	53.6
Word Frequency	67.9	74.0	58.3
Word Length	68.4	77.1	49.0
Human	69.5	76.6	53.6

Table 2: Evaluation of fixation sequence predictions against human data. For the human baseline, we predicted the n-th reader's fixations by taking the fixations of the $n+1$-th reader (with missing values replaced by reader average), averaging the resulting scores over the ten readers.

Accuracy of Fixation Sequences Previous work on supervised models for modeling fixations (Nilsson and Nivre, 2009; Matthies and Søgaard, 2013) has been evaluated by measuring the overlap of the fixation sequences produced by the models with those in the Dundee corpus. For NEAT, this method of evaluation is problematic as differences between model predictions and human data may be due to differences in the rate of skipping, and due to the inherently stochastic nature of fixations. We therefore derive model predictions by rescaling the simulated fixation probabilities so that their average equals the fixation rate in the development set, and then greedily take the maximum-likelihood sequence. That is, we predict a fixation if the rescaled probability is greater than 0.5, and a skip otherwise. As in previous work, we report the accuracy of fixations and skips, and also separate F1 scores for fixations and skips. As lower and upper bounds, we use the random baseline $\boldsymbol{\omega} \sim \text{Binom}(n, 0.62)$ and the agreement of the ten human readers, respectively. The re-

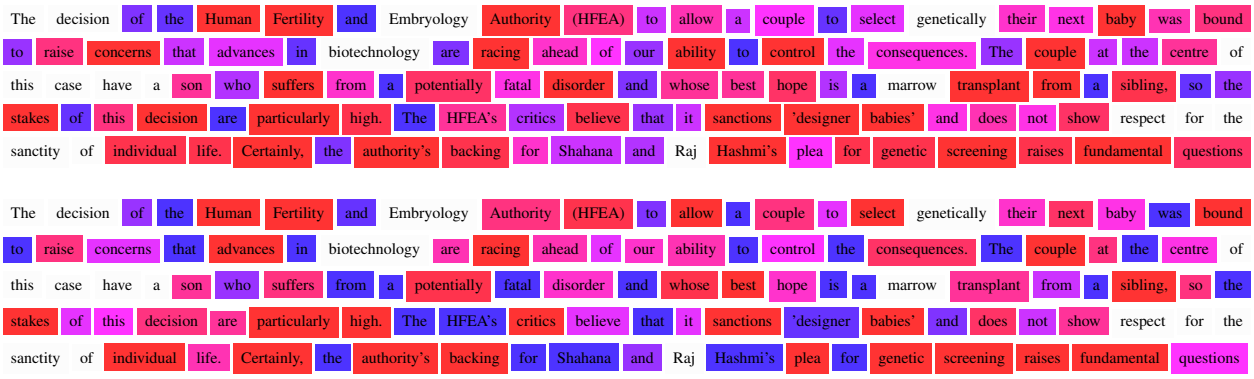

Figure 2: Top: Heatmap showing human fixation probabilities, as estimated from the ten readers in the Dundee corpus. In cases of track loss, we replaced the missing value with the corresponding reader's overall fixation rate. Bottom: Heatmap showing fixation probabilities simulated by NEAT. Color gradient ranges from blue (low probability) to red (high probability); words without color are at the beginning or end of a sequence, or out of vocabulary.

	NEAT	Rand. Att.	Word Len.	Word Freq.	Full Surp.	Human	Full Att.
Language Modeling	180	333	230	219	211	218/170	107
Reconstruction	4.5	56	40	39	34	39/31	1.6
Fixation Rate	60.4%	62.1%	62.1%	62.1%	62.1%	61.3%/72.0%	100%

Table 1: Performance on language modeling and reconstruction as measured by perplexity. Random attention is an upper bound on perplexity, while full attention is a lower bound. For the human baseline, we give two figures, which differ in the treatment of missing data. The first figure is obtained when replacing missing values with a random variable $\omega \sim \text{Binom}(n, 0.61)$; the second results from replacing missing values with 1.

sults are shown in Table 2. NEAT clearly outperforms the random baseline and shows results close to full surprisal (where we apply the same rescaling and thresholding as for NEAT). This is remarkable given that NEAT has access to only 60.4% of the words in the corpus in order to predict skipping, while full surprisal has access to all the words.

Word frequency and word length perform well, almost reaching the performance of supervised models. This shows that the bulk of skipping behavior is already explained by word frequency and word length effects. Note, however, that NEAT is completely unsupervised, and does not know that it has to pay attention to word frequency; this is something the model is able to infer.

Restricted Surprisal and Reading Times To evaluate the predictions NEAT makes for reading times, we use linear mixed-effects models containing restricted surprisal derived from NEAT for the Dundee test set. The mixed models also include a set of standard baseline predictors, viz., word length, log word frequency, log frequency of the previous word, launch distance, landing position, and the position of the word in the sentence. We treat participants and items as random factors. As the dependent variable, we take first pass duration, which is the sum of the durations of all fixations from first entering the word to first leaving it. We compare against *full surprisal* as an upper bound and against *random surprisal* as a lower bound. Random surprisal is surprisal computed by a model with random attention; this allows us to assess how much surprisal degrades when only 60.4% of all words are fixated, but no information is available as to which words should be fixated. The results in Table 3 show that restricted surprisal as computed by NEAT, full surprisal, and random surprisal are all significant predictors of reading time.

In order to compare the three surprisal estimates, we therefore need a measure of effect size. For this, we compare the model fit of the three mixed effects models using deviance, which is defined as the difference between the log likelihood of the model under consideration minus the log likelihood of the baseline model, multiplied by -2. Higher de-

	β	SE	*t*

MSE		57	450

Table 4: Actual and simulated fixation probabilities (in %) by PoS tag, with the ranks given in brackets, and correlations and mean squared error relative to human data.

viance indicates greater improvement in model fit over the baseline model. We find that the mixed model that includes restricted surprisal achieves a deviance of 867, compared to the model containing only the baseline features. With full surprisal, we obtain a deviance of 980. On the other hand, the model including random surprisal achieves a lower deviance of 832.

This shows that restricted surprisal as computed by NEAT not only significantly predicts reading times, it also provides an improvement in model fit compared to the baseline predictors. Such an improvement is also observed with random surprisal, but restricted surprisal achieves a greater improvement in model fit. Full surprisal achieves an even greater improvement, but this is not unexpected, as full surprisal has access to all words, unlike NEAT or random surprisal, which only have access to 60.4% of the words.

5.2 Qualitative Properties

We now examine the second key question we defined in Section 1, investigating the qualitative features of the simulated fixation sequences. We will focus on comparing the predictions of NEAT with that of word frequency, which performs comparably at the task of predicting fixation sequences (see Section 5.1). We show NEAT nevertheless makes relevant predictions that go beyond frequency.

Fixations of Successive Words While predictors derived from word frequency treat the decision whether to fixate or skip words as independent, humans are more likely to fixate a word when the previous word was skipped (Rayner, 1998). This effect is also seen in NEAT. More precisely, both in the human data and in the simulated fixation data, the conditional fixation probability $P(\omega_i = 1|\omega_{i-1} = 1)$ is lower than the marginal probability $P(\omega_i = 1)$. The ratio of these probabilities is 0.85 in the human data, and 0.81 in NEAT. The threshold predictor derived from word frequency also shows this effect (as the frequencies of successive words are not independent), but it is weaker (ratio 0.91).

To further test the context dependence of NEAT's fixation behavior, we ran a mixed model predicting the fixation probabilities simulated by NEAT, with items as random factor and the log frequency of word i as predictor. Adding ω_{i-1} as a predictor results in a significant improvement in model fit (deviance = 4,798, $t = 71.3$). This shows that NEAT captures the context dependence of fixation sequences to an extend that goes beyond word frequency alone.

Parts of Speech Part of speech categories are known to be a predictor of fixation probabilities, with content words being more likely to be fixated than function words (Carpenter and Just, 1983). In Table 4, we give the simulated fixation probabilities and the human fixation probabilities estimated from the Dundee corpus for the tags of the Universal PoS tagset (Petrov et al., 2012), using the PoS annotation of Barrett et al. (2015). We again compare with the probabilities of a threshold predictor derived from word frequency.[1] NEAT captures the differences between PoS categories well, as evidenced by the high correlation coefficients. The content word categories ADJ, ADV, NOUN, VERB and X consistently show higher probabilities than the function word categories. While the correlation coefficients for word frequency are very similar, the numerical values of the simulated probabilities are closer to the human ones than those derived from word frequency, which tend towards more extreme values. This difference can be seen clearly if we compare the mean squared error, rather than the correlation, with the human fixation probabilities (last row of Table 4).

Correlations with Known Predictors In the literature, it has been observed that skipping correlates with predictability (surprisal), word frequency, and word length (Rayner, 1998, p. 387). These correlations are also observed in the human skipping data derived from Dundee, as shown in Table 5. (Human fixation probabilities were obtained by averaging over the ten readers in Dundee.)

Comparing the known predictors of skipping with NEAT's simulated fixation probabilities, similar correlations as in the human data are observed. We observe that the correlations with surprisal are stronger in NEAT, considering both restricted surprisal and full surprisal as measures of predictability.

6 Conclusions

We investigated the hypothesis that human reading strategies optimize a tradeoff between precision of language understanding and economy of attention. We made this idea explicit in NEAT, a neural reading architecture with hard attention that can be trained end-to-end to optimize this tradeoff. Experiments on the Dundee corpus show that NEAT provides accurate predictions for human skipping behavior. It also predicts reading times, even though it only has access to 60.4% of the words in the corpus in order to estimate surprisal. Finally, we found that known qualitative properties of skipping emerge in our model, even though they were not explicitly included in the architecture, such as context dependence of fixations, differential skipping rates across parts of speech, and correlations with other known predictors of human reading behavior.

[1] We omit the tag "." for punctuation, as punctuation characters are not treated as separate tokens in Dundee.

	Human	NEAT

Abstract

Natural language acquisition relies on appropriate generalization: the ability to produce novel sentences, while learning to restrict productions to acceptable forms in the language. Psycholinguists have proposed various properties that might play a role in guiding appropriate generalizations, looking at learning of verb alternations as a testbed. Several computational cognitive models have explored aspects of this phenomenon, but their results are hard to compare given the high variability in the linguistic properties represented in their input. In this paper, we directly compare two recent approaches, a Bayesian model and a connectionist model, in their ability to replicate human judgments of appropriate generalizations. We find that the Bayesian model more accurately mimics the judgments due to its richer learning mechanism that can exploit distributional properties of the input in a manner consistent with human behaviour.

1 Introduction

Native speakers of a language are mostly able to generalize appropriately beyond the observed data while avoiding overgeneralizations. A testbed area for studying generalization behavior in language acquisition is verb alternations – i.e., learning the patterns of acceptability of alternative constructions for expressing similar meanings. For example, English speakers readily use a new verb like *text* in both the double-object (DO) construction ("text me the details") and the prepositional-dative (PD) ("text the details to me") – an instance of the dative alternation. However, speakers avoid overgeneralizing the DO construction to verbs such as *explain* that resist its use ("?explain me the details"), even though they occur with analogous arguments in the PD alternative ("explain the details to me"). Psycholinguistic studies have focused on the possible properties of natural language that enable such generalization while constraining it to acceptable forms.

Initially, children are linguistically conservative: they generally use verbs in constructions that are very close to exemplars in the input (Lieven et al., 1997; Akhtar, 1999; Tomasello, 2003; Boyd and Goldberg, 2009). Children reach adult-like competence by gradually forming more general associations of constructions to meaning that allow them to extend verb usages to unwitnessed forms. Much work has emphasized the role of verb classes that capture the regularities across semantically-similar verbs, enabling appropriate generalization (e.g., Pinker, 1989; Fisher, 1999; Levin, 1993; Ambridge et al., 2008). Usage-based approaches have argued that such class-based behaviour can arise in learning through the clustering of observed usages that share semantic and syntactic properties (e.g., Bybee, 2010; Tomasello, 2003; Goldberg, 2006).

A number of studies also reveal that the statistical properties of the language play a central role in limiting generalization (e.g., Bresnan and Ford, 2010; Ambridge et al., 2012, 2014). Individual verbs often show statistical biases that favor their appearance in one construction over another (Ford et al., 1982; MacDonald et al., 1994; Garnsey et al., 1997; Trueswell et al., 1993; Losiewicz, 1992; Gahl and Garnsey, 2004). For example, while both *give* and *push* can occur in either DO or PD constructions,

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 96–106,
Austin, Texas, November 1-5, 2016.

give strongly favors the DO construction ("give me the box"), while *push* strongly favors the PD ("push the box to me") (Wasow, 2002). Generally, the more frequent a verb is overall, the less likely speakers are to extend it to an unobserved construction (Braine and Brooks, 1995). In addition, when a verb repeatedly occurs in one construction when an alternative construction could have been appropriate, speakers appear to learn that the verb is inappropriate in the alternative, regardless of its overall frequency (Goldberg, 2011).

Given these observations, it has been argued that both the semantic and statistical properties of a verb underlie its degree of acceptability in alternating constructions (e.g., Braine and Brooks, 1995; Theakston, 2004; Ambridge et al., 2014). Recently, Ambridge and Blything (2015) propose a computational model designed to study the role of verb semantics and frequency in the acquisition of the dative alternation. However, they only evaluate their model preferences for one of the two constructions, which does not provide a full picture of the alternation behaviour; moreover, they incorporate certain assumptions about the input that may not match the properties of naturalistic data.

In this paper, we compare the model of Ambridge and Blything (2015) to the Bayesian model of Barak et al. (2014) that offers a general framework of verb construction learning. We replicate the approach taken in Ambridge and Blything (2015) in order to provide appropriate comparisons, but we also extend the experimental settings and analysis to enable a more fulsome evaluation, on data with more naturalistic statistical properties. Our results show that the Bayesian model provides a better fit to the psycholinguistic data, which we suggest is due to its richer learning mechanism: its two-level clustering approach can exploit distributional properties of the input in a manner consistent with human generalization behaviour.

2 Related Work

Acquisition of the dative alternation – use of the DO and PD constructions with analogous semantic arguments – has been studied in several computational cognitive models because it illustrates how people learn to appropriately generalize linguistic constructions in the face of complex, interacting factors. As noted by Ambridge et al. (2014), such models should capture influences of the verb such as its semantic properties, its overall frequency, and its frequency in various constructions.

A focus of computational models has been to show under what conditions a learner generalizes to the DO construction having observed a verb in the PD, and vice versa. For example, the hierarchical Bayesian models of Perfors et al. (2010) and Parisien and Stevenson (2010) show the ability to generalize from one construction to the other. However, both models are limited in their semantic representations. Perfors et al. (2010) use semantic properties that directly (albeit noisily) encode the knowledge of the alternating and non-alternating (DO-only or PD-only) classes. The model of Parisien and Stevenson (2010) addresses this limitation by learning alternation classes from the data (including the dative), but it uses only syntactic slot features that can be gleaned automatically from a corpus. In addition, both models use batch processing, failing to address how learning to generalize across an alternation might be achieved incrementally.

Alishahi and Stevenson (2008) presents an incremental Bayesian model shown to capture various aspects of verb argument structure acquisition (Alishahi and Pyykkoïen, 2011; Barak et al., 2012, 2013b; Matusevych et al., 2016), but the model is unable to mimic alternation learning behaviour. Barak et al. (2014) extends this construction-learning model to incrementally learn both constructions and classes of alternating verbs, and show the role of the classes in learning the dative. However, like Parisien and Stevenson (2010), the input to the model in this study is limited to syntactic properties, not allowing for a full analysis of the relevant factors that influence acquisition of alternations.

Ambridge and Blything (2015) propose the first computational model of this phenomenon to include a rich representation of the verb/construction semantics, drawn from human judgments. In evaluation, however, they only report the ability of the model to predict the DO usage (i.e., only one pair of the alternation), which does not give the full picture of the alternation behaviour. Moreover, their assumptions about the nature of the input – including the use of raw vs. log frequencies and the treatment of

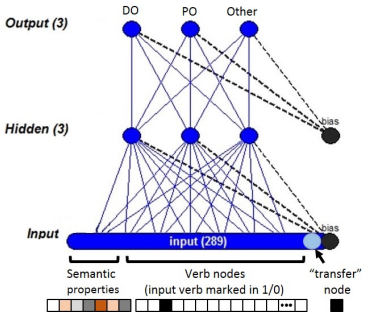

Figure 1: A visual representation of the feed-forward network used by the AB model. (The figure is adapted from output of the OXlearn package of Ruh and Westermann (2009).) The input nodes correspond to the semantic properties of the verbs, the verb lexemes, and a "transfer" node (explained in the text). The output nodes correspond to the target constructions.

non-dative construction usages – differ from earlier models, making it difficult to compare the results.

In this paper, we compare the models of Ambridge and Blything (2015) and Barak et al. (2014), using the same input settings for each, so that, for the first time, two computational models of this generalization phenomenon can be directly compared. Moreover, in contrast to Ambridge and Blything (2015) and in line with the other studies mentioned above, we evaluate the ability of the models to generate both the DO and the PD alternates, on a per verb basis, in order to more accurately assess the fit to human judgments.

3 The Computational Models

In this section, we give an overview of the connectionist model of Ambridge and Blything (2015), hereafter the AB model, and the Bayesian model of Barak et al. (2014), hereafter the BFS model, followed by a comparison of their relevant properties.

3.1 Overview of the Connectionist Model

The AB connectionist model of Ambridge and Blything (2015) aims to predict the preference of a verb for each of three target constructions, on the basis of verb semantics and the observed distribution of verbs in those constructions in the input. Figure 1 provides an illustration of the 3-layer feed-forward network, trained using backpropagation. Each input to the model consists of lexical and semantic features of a verb and its usage. The target output is a 1-hot pattern across output nodes, each of which represents the use of the verb in the associated construction. The possible constructions are DO, PD, or *other*, representing all other constructions the verb appears in. Training presents the slate of input features with the appropriate output node activated representing the construction the verb appears in. In a full sweep of training, the model observes all verbs in proportion to their frequency in the input; for each verb, the proportion of training trials with 1 in each of the output nodes corresponds to the frequency of the verb in each of those constructions. During testing, only the input nodes are activated (corresponding to a verb and its semantics), and the activation of output nodes reveals the learned proportional activation rate corresponding to the degree of verb bias toward either the DO or the PD (or *other*).

The structure of the AB model encodes some assumptions regarding the information and learning mechanisms available to the learner. The model incorporates awareness of individual verbs by having a node per verb in the input to distinguish the usage of each verb and its accompanying features. Each verb is also represented by a vector of semantic features that capture properties relevant to its meaning when used in one of the two dative constructions (based on elicited human judgments from Ambridge et al., 2014). The "transfer" input node encodes the ability to distinguish the semantic properties of the dative constructions from other constructions: i.e., this node is set to 1 for a DO or PD usage, and to 0 otherwise. Representing the construction of the input usage (DO, PD, or *other*) on the output nodes reflects the formalization of the learning as an association of semantic and lexical features with a syntactic pattern, and the knowledge of the model is demonstrated by activating the construction output nodes in response to a lexical/semantic input.

3.2 Overview of the Bayesian Model

The BFS of model Barak et al. (2014) is a Bayesian clustering model that simultaneously and incrementally learns both constructions and verb classes in a two-level design; see Figure 2 for an illustration of each level. In learning, the model processes an input sequence of verb usages, represented as collections of semantic and syntactic features, one usage at a time. The first step of processing each input aims to

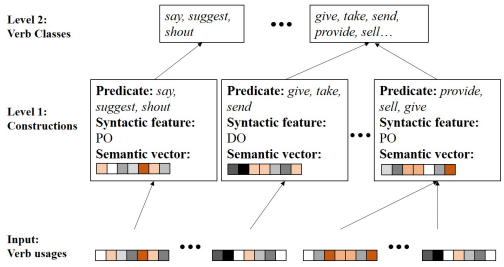

Figure 2: A visual representation of the the Bayesian model, with sample input features for verb usages, construction level, and verb class level.

find the best cluster at level one as:

$$\text{BestCluster}(F_i) = \underset{k \in Clusters}{\text{argmax}}\ P(k|F_i) \quad (1)$$

where F_i is the set of features for input i, and k ranges over all existing clusters and a new one. The number of possible clusters is not set in advanced, and thus at any step the best choice may be to start a new cluster (of size 1) with this input.

Using Bayes rule:

$$P(k|F_i) = \frac{P(k)P(F_i|k)}{P(F_i)} \propto P(k)P(F_i|k) \quad (2)$$

The prior probability of a cluster $P(k)$ is proportional to the number of verb usages clustered to k so far, thus assigning a higher prior to larger clusters. The likelihood $P(F_i|k)$ is estimated based on the match of feature values in the current verb usage to those aggregated in the cluster, where the quality of the match depends on the frequency and vector similarity of the two sets of features.

The clusters at this level correspond to constructions of the language – i.e., probabilistic associations of form and meaning. For example, a cluster emerges from semantically-similar verbs like *tell* and *ask*, in a particular syntax, such as the DO. Creating a new cluster – forming a new construction – depends on both the likelihood and the prior. Early on, the $P(F_i|k)$ term has more influence and differences in feature values between a new usage and existing clusters will often trigger a new cluster. Later, the model will favour adding a new input to an existing cluster – even if it makes it more heterogeneous – because the $P(k)$ term prefers larger clusters as the number of observed inputs increases. This mechanism mimics human language learning behavior of moving from more verb-specific constructions to more general constructions (Tomasello, 2003).

Each verb can occur in several clusters in the first level based on its association with various semantic and syntactic features. For instance, the alternating verb *give* can occur in one cluster associating a transfer meaning with PD syntax and in a second cluster associating a transfer meaning with DO syntax. To capture the common behaviour of such alternating verbs – where verbs with similar meanings occur across the same set of clusters – the model represents the similarity in distributional properties of the verbs in a second level of representation, which captures such verb class behaviours.

Formally, after each clustering decision in the first level, the model calculates the current frequency distribution of the input verb over all level-one clusters. This distribution vector is used as input for the second level: the model measures the similarity of this vector to the weighted average distribution represented by each second-level cluster, adding the input verb's distribution to the most similar one:

$$\text{BestClass}(d_{v_t}) = \underset{c \in Classes}{\text{argmax}}\ (1 - D_{\text{JS}}(d_c \| d_{v_t})) \quad (3)$$

where d_{v_t} is the current distribution of the verb v over the clusters (i.e., at time t), c ranges over all the classes in the second level, d_c is the weighted average of c given the distributions of its member verb tokens, and D_{JS} is the Jensen–Shannon divergence. As in the first level, the model may create a new cluster in the second level if none of the existing clusters is similar enough to d_{v_t}.

The resulting second-level clusters capture verb class behavior by grouping verbs that share a pattern of usages across constructions, e.g., alternating verbs that occur with the DO and PD syntax. These clusters encode a snapshot of the distribution of each verb each time it occurs in the input, reflecting the need of the language learner to incrementally update their knowledge of the distributional behavior of the verb across constructions.

3.3 Comparison of the Models

Both models capture the semantic and statistical properties of language proposed as possible factors in the ability to learn an alternation appropri-

ately – i.e., to generalize to new uses but not overgeneralize to inappropriate verbs. Semantic influences are reflected in the use of meaning features, and each model incorporates the key idea behind statistical preemption (Goldberg, 1995), namely that semantically-appropriate constructions compete with one another. The statistical effects of overall verb frequency and of frequency of the verb-in-construction are captured by inputting each verb in proportion to its frequency with each construction.

The models have a crucial difference in how they reflect the influence of the various features in learning alternations. As a feed-forward network, the AB model learns the weight of the semantic features given the entire set of input, and uses these weightings to shape the prediction of a verb's preference for each of the syntactic constructions (represented by the target output nodes). The BFS model does not explicitly weight features, but the influence of a feature is determined by its local context within a cluster. For example, if the value of a feature has high frequency in a cluster – e.g., the cluster records usages with only the DO syntax – the predictions based on this cluster would strongly prefer matching usages based on this feature value; a less-frequent feature would have less influence on this cluster's predictions, but could have more influence in a cluster where it is more represented. This property, along with the representation of an open-ended set of constructions (level one clusters) and verb classes (level two clusters), enables the model to capture rich interactions among the lexical, semantic, and syntactic features. We evaluate the role of these differences in the fit of each model to the task.

4 Experimental Setup

4.1 Input and Training

We base the learning and evaluation on the 281 distinct verbs used in Ambridge and Blything (2015), which had been determined to occur in the double object (DO) and/or the preposition-dative (PD) (Pinker, 1989; Levin, 1993). Following Ambridge and Blything (2015), we consider a third (artificial) construction labeled as *other* that corresponds to *all* non-DO and non-PD usages of a verb. The models are trained on usages of the verbs in proportion to their frequencies in the British National Corpus (BNC) (Leech, 1992). Table 1 summarizes the per-construction frequency data for the verbs.[1] Note that 98 of the verbs can occur in the DO and/or PD but have no such occurrences in the BNC; these verbs unseen in the dative are important for judging the appropriate generalization behavior of the models.

		Raw freq			Log freq		
	#Verbs	DO	PD	*other*	DO	PD	*other*
PD	101	0	93	9964	0	3	5
DO	7	49	0	877	2	0	4
Alt	75	325	1144	13332	3	3	7
Uns	98	0	0	716	0	0	4

Table 1: Frequency data for the dative verbs in the BNC for non-alternating **PD**-only and **DO**-only verbs, **ALT**ernating verbs, and **UNS**een dative-taking verbs that do not occur with the dative constructions in the BNC.

The input to the models include: the lexeme of the verb, the semantic features of the verb, a "transfer" feature marking the common meaning of the dative constructions, and (in training only) a syntactic feature. The syntactic feature indicates whether a verb is used with the DO, PD, or *other* construction; in the AB model, this is given as the target output node in training. The verb semantic features are those used in Ambridge and Blything (2015). These vectors are based on the ratings of each verb on 18 meaning properties relevant to use of the verb in the dative (e.g., "The verb specifies the means of transfer" Ambridge et al., 2014), subject to Principal Component Analysis by Ambridge and Blything (2015), yielding a vector of 7 dimensions. The transfer feature is 1 for a verb usage in one of the two dative constructions, and 0 for the *other* construction, to indicate the shared transfer meaning conveyed by the DO and the PD. The input to each model is generated automatically to correspond to the BNC frequencies of each verb in each of the constructions.

It should be noted that, while we adopt the semantic features of Ambridge and Blything (2015), they reflect the meaning within the two dative constructions and may be less applicable to the *other* construction. In addition, we found that there are alternating and non-alternating verbs that have very similar semantic vectors, indicating that these fea-

[1] The full list of verbs and their frequencies can be found in Ambridge and Blything (2015).

tures may not sufficiently distinguish the alternation behaviours.

The models are trained with sufficient input to converge on stable behavior. We follow Ambridge and Blything (2015) in training and testing the AB model using the OXlearn MATLAB package (Ruh and Westermann, 2009); the input is generated using a random seed, in random input order without replacements, and the model is trained with a learning rate of 0.01 for 1K sweeps for log frequencies; 100K sweeps for raw frequencies. We train the BFS model using the input generation method described by Barak et al. (2014), with the features as above. The model is trained on 5K input verb usages (in proportion to their frequencies in the constructions).

4.2 Evaluation of the Models

As in Ambridge and Blything (2015), to test the model preferences for the DO or PD, the models are presented with an input consisting of a verb lexeme, its semantic features, and the transfer feature set to 1 (i.e., this is a "transfer" semantics suitable for a dative construction). For the AB model, we measure preferences for each construction as the activation rate of each of the corresponding output nodes, as in Ambridge and Blything (2015). In the BFS model, the preference for each construction is measured as its likelihood over the learned clusters given the verb and its semantic features. Formally, the prediction in the Bayesian model is:

$$P(s|F_{\text{test}}) = \sum_{k \in Clusters} P(s|k)P(k|F_{\text{test}}) \quad (4)$$

where s is the predicted syntactic construction (DO or PD) and F_{test} is the set of test features representing a verb v and its corresponding semantic features. $P(s|k)$ is the probability of the syntactic pattern feature having the value s in cluster k, calculated as the proportional occurrences of s in k. $P(k|F_{\text{test}})$ is the probability of cluster k given test features F_{test}, calculated as in Eqn. (2). Following Barak et al. (2014), we calculate $P(k|F_{\text{test}})$ in two ways, using just the constructions (level one) or both the classes (level two) and the constructions, to see whether verb class knowledge improves performance. Using solely the construction level, the probability of k reflects the frequency with which usages of verb v occur in cluster k. Using the verb class level in addition, the distribution of the verb over classes in the second level is combined with the distribution of those classes over the constructions in level one, to get the likelihood of k.

These model preferences of the verbs for a dative construction are compared, using Pearson correlation, to the DO/PD acceptability judgment data collected from adult participants by Ambridge et al. (2014). Note that Ambridge and Blything (2015) only evaluate their model's preferences for verbs to take the DO construction. To fully understand the preference and generalization patterns, we also analyze the results for the PD preference. Even more importantly, we calculate the *difference* between the preferences for the DO and the PD constructions *per verb*, and compare these to analogous scores for the human data, as suggested by Ambridge et al. (2014). The DO−PD difference scores, which we will refer to as the **verb bias score**, are crucial because, as in the human data, it is these scores that accurately capture a learner's relative preference for a construction *given a particular verb*.

5 Experiments and Analysis of Results

We examine the ability of each model to match the dative construction preferences of human judgments, as described just above, under two different experimental scenarios. In Section 5.1, we follow the experimental settings of Ambridge and Blything (2015). We replicate their results on the AB model showing correlation with human DO preferences, but find that only the BFS model achieves a significant correlation with the crucial verb bias score that appropriately assesses per-verb preference. We adjust the experimental settings in Section 5.2 to use more naturalistic input data – by training in proportion to raw frequencies and excluding the artificial *other* construction – achieving an improvement in the verb bias score for both models.

5.1 Exp 1: Log Freq Input; 3 Constructions

Results. We first evaluated the models under the experimental conditions of Ambridge and Blything (2015), providing input corresponding to the verbs in 3 constructions (DO, PD, and *other*), in proportion to their log frequencies; see Table 2. We replicate the positive correlation of the AB model over

	AB (Connectionist)	BFS (Bayesian)	
		Level 1	Level 2
DO	**0.54**	0.24	0.29
PD	0.39	0.30	**0.50**
DO-PD	[-0.02]	0.48	**0.53**

Table 2: Pearson correlation values between human and model preferences for each construction and the verb-bias score (DO−PD); training on log frequencies and 3 constructions. All correlations significant with p-value < 0.001, except the one value in square brackets. Best result for each row is marked in boldface.

the ratings for the DO construction found in Ambridge and Blything (2015). In addition, our analysis shows that the AB model produces a significant positive correlation with the PD acceptability rating. However, the AB model has no correlation with the verb bias score. Although the model ranks the separate verb preferences for DO and PD similarly to humans, the model does not produce the same relative preference *for individual verbs*. For example, the human data rank *give* with high acceptability in both the DO and the PD, with a higher value for the DO construction. Although the AB model has a high preference for both constructions for *give* (compared with other verbs), the model erroneously prefers *give* in the PD construction.

The BFS model also produces preferences for verbs in each construction that have a significant positive correlation with human judgments. While the AB model shows better correlation with the DO judgments, the BFS model correlates more strongly with the PD judgments. Importantly, in contrast to the AB model, the verb bias score of the BFS model also significantly correlates with the judgment data. That is, the BFS model provides a better prediction of the preference per verb, which is key to producing a verb in the appropriate syntax.

Analysis. We can explain these results by looking more closely at the properties of the input and the differences in the learning mechanisms of each model. Following Ambridge and Blything (2015), the input presents an artificial *other* construction in proportion to the frequency of the verbs with all non-dative constructions. The very high frequency of this single artificial construction (see *other* in Table 1) results in higher predictions of it for any of the verbs, even though the "transfer" feature in test inputs has a value intended to signal one of the dative constructions. As a result, the preferences for the dative constructions in both models have a very small range of values, showing relatively small differences.

The BFS model is also affected by the relatively compressed semantic space of the input, which is exacerbated by the use of log frequencies to guide the input. As noted earlier, we found that the semantic features of alternating verbs can be highly similar to non-alternating verbs – e.g., *give* (alternating) and *pull* (PO-only) have similar semantic vectors. With such input, the model cannot form sufficiently distinct first-level clusters based on the semantics, particularly when the data is presented with such a flat distribution (note the small differences in log frequencies in Table 1). Visual inspection reveals that these clusters in the model largely form around syntactic constructions, with mixed semantic properties. Despite this, the first-level clusters capture a strong enough association between individual verbs and their constructions to yield a good correlation of the verb bias score with human judgments, and drawing on the second-level (verb-class) clusters improves the results.

Conclusions. The use of an artificial high-frequency non-dative construction (*other*), and the use of log frequencies, seem to mask the influence of the semantic and syntactic properties on learning the verb-bias for each verb. Previous psycholinguistic data and computational models have found that a skewed naturalistic distribution of the input is helpful in learning constructions, due to the high-frequency verbs establishing appropriate construction-meaning associations (Casenhiser and Goldberg, 2005; Borovsky and Elman, 2006; Barak et al., 2013b; Matusevych et al., 2014). To allow a more direct analysis of the role of statistical and semantic properties in learning and generalizing the dative, we adjust the input to the models in the next section.

Results. Here we perform the same type of experiments, but using input in proportion to the raw frequencies of the verbs (instead of log frequencies) over occurrences only in the two dative constructions (with no *other* construction). Since 98 of the 281 verbs do not occur with either dative construc-

tion in the BNC, this also allows us to more stringently test the generalization ability of the models, by considering their behavior when ˜$1/3$ of the verbs are unseen in training.

Table 3 presents the correlation results for the two models' preferences for each construction and the verb bias score; we also show the correlation plots for the verb bias score in Figure 3. The AB model does not correlate with the judgments for the DO. However, the model produces significant positive correlations with the PD judgments and with the verb bias score. The BFS model, on the other hand, achieves significant positive correlations on all measures, by both levels. As in the earlier experiments, the best correlation with the verb bias score is produced by the second level of the BFS model, as Figure 3 demonstrates.

Analysis. As shown by Barak et al. (2013b), the Bayesian model is better at learning the distribution pattern of each verb class given a skewed distribution, as in the raw frequencies here. The model learns an association of each construction to the frequently-observed meaning of high-frequency verbs. For example, the semantics of the DO is most strongly influenced by the semantics of its most frequently occurring instance: *give*. The accuracy of preference judgments benefits from the entrenchment of the relevant meaning with the construction. This supports appropriate generalization – e.g., because *reward* is semantically similar to *give*, it has a good fit to the human preference judgments even though it is unseen with the dative (see Figure 3). But the same factor can serve to limit generalization – e.g., because the unseen verb *mail* is semantic *dissimilar* to a frequent PD-only verb like *pull*, its preference for the PD syntax is limited, giving it a

good match to human judgments by preventing its overgeneralization (see Figure 3).

The AB model can also take advantage of high frequency verbs biasing the preference toward the frequently observed association. However, the semantic similarity across verbs within alternating or non-alternating classes is less effective in this model. The representation of the lexemes as 281 nodes in the input (compared to less than a dozen other nodes) make the learning more verb specific, reducing the ability of the model to generalize to the unattested verbs.

Conclusions. The success of the BFS model, and especially the results using both constructions and classes, point to the role of probabilistic constructions and verb classes in generalizing exist-

ing knowledge while avoiding overgeneralizations. Moreover, the use of a skewed distribution reveals the role of the high verb-in-construction frequency in guiding the association of construction and meaning (see Ambridge et al., 2014, for discussion). Yet both models would benefit from a richer semantic representation that better captures the distinctive properties of verbs across various constructions.

6 Discussion

This paper presents a comparative analysis of two computational cognitive models on the sample task of learning the dative alternation. This study enables an evaluation of the psycholinguistic plausibility of each model for the given task when facing identical input and experimental settings. Adopting the semantic representation of Ambridge and Blything (2015), our input incorporates both semantic and syntactic properties over a large number of verbs. By providing the first direct comparison between two existing models of this phenomenon, we are the first to demonstrate the complex interaction of various linguistic properties in the input, and how rich learning mechanisms are required in order to achieve generalizations compatible with human judgments in this area. Moreover, comparison of learning mechanisms and of input properties can inform CL/NLP more generally by shedding light on potential factors in achieving humanlike behaviours.

We find that the Bayesian model of BFS significantly correlates with human judgments on the 3 key evaluation measures. Importantly, this model outperforms the connectionist model of AB in the correlation with the verb-bias score (the per-verb difference between DO and PD preference), which points to its advantage in choosing the more appropriate construction per verb. We argue that the fit of the model relies on a rich learning mechanism that exploits distributional properties of naturalistic input.

The AB model has a streamlined design to support learning a particular semantic-syntactic association underlying the dative alternation. While the BFS model is richer computationally, its properties were motivated in earlier work explaining many human behaviours. When we consider more natural input, the simple input[semantics]–output[syntax] association mechanism of the AB model is unable to capture the necessary interactions among the verb semantic properties, the syntactic usages, and their patterns across different types of verbs. By contrast, the two-level design of the BFS model captures these interactions. The first level learns the verb-semantics-syntax associations as clusters of similar configurations of those features. The second level captures the commonalities of behaviour of sets of verbs by forming classes of verbs that have similar distributional patterns over the first-level clusters. We also observe that the replication of adult-like language competence relies on several naturalistic properties of the input: skewed distribution, and a rich semantic representation combined with syntactic information. The skewed input enables the formation of clusters representing more entrenched associations, which are biased towards high-frequency verbs associated with certain semantic and syntactic features.

Given the role of these linguistic properties, the results here call for additional analysis and development of the input to computational cognitive models. The predictions may be improved given more realistic syntactic and semantic information about the verb usages. On the syntax side, the input should reflect the distribution of verbs across more syntactic constructions, as statistical patterns over such usages can indirectly indicate aspects of a verb's semantics (cf. Barak et al., 2013a). In the future, we aim to analyze the role of fuller syntactic distributions in restricting overgeneralization patterns. Moreover, the semantic annotations used here replicate the settings originally tested for the AB model, which correspond to the verb as used in the relevant constructions. This contrasts with typical automated extractions of verb-meaning representation (e.g., word2vec, Mikolov et al., 2013), which capture a more general verb meaning across all its usages. In preliminary experiments, we have found an advantage in using word2vec representations in addition to the semantic properties reported here. We aim to further analyze manual and automated methods for semantic feature extraction in future work.

Acknowledgments

We are grateful to Ben Ambridge for helpful discussion of his model and for sharing his data with us.

Rationalizing Neural Predictions

Tao Lei, Regina Barzilay and Tommi Jaakkola

Abstract

Prediction without justification has limited applicability. As a remedy, we learn to extract pieces of input text as justifications – rationales – that are tailored to be short and coherent, yet sufficient for making the same prediction. Our approach combines two modular components, generator and encoder, which are trained to operate well together. The generator specifies a distribution over text fragments as candidate rationales and these are passed through the encoder for prediction. Rationales are never given during training. Instead, the model is regularized by desiderata for rationales. We evaluate the approach on multi-aspect sentiment analysis against manually annotated test cases. Our approach outperforms attention-based baseline by a significant margin. We also successfully illustrate the method on the question retrieval task.[1]

1 Introduction

Many recent advances in NLP problems have come from formulating and training expressive and elaborate neural models. This includes models for sentiment classification, parsing, and machine translation among many others. The gains in accuracy have, however, come at the cost of interpretability since complex neural models offer little transparency concerning their inner workings. In many applications, such as medicine, predictions are used to drive critical decisions, including treatment options. It is necessary in such cases to be able to verify and understand the underlying basis for the decisions. Ideally, complex neural models would not only yield improved performance but would also offer interpretable justifications – rationales – for their predictions.

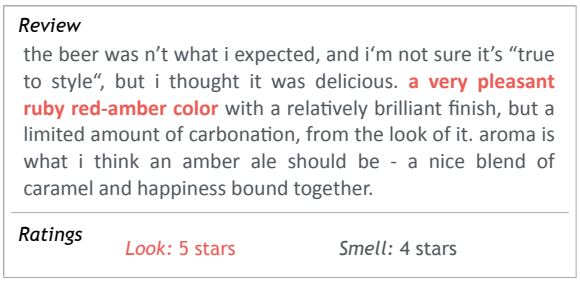

Figure 1: An example of a review with ranking in two categories. The rationale for Look prediction is shown in bold.

In this paper, we propose a novel approach to incorporating rationale generation as an integral part of the overall learning problem. We limit ourselves to extractive (as opposed to abstractive) rationales. From this perspective, our rationales are simply subsets of the words from the input text that satisfy two key properties. First, the selected words represent short and coherent pieces of text (e.g., phrases) and, second, the selected words must alone suffice for prediction as a substitute of the original text. More concretely, consider the task of multi-aspect sentiment analysis. Figure 1 illustrates a product review along with user rating in terms of two categories or aspects. If the model in this case predicts five star rating for color, it should also identify the phrase *"a very pleasant ruby red-amber color"* as the rationale underlying this decision.

In most practical applications, rationale genera-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 107–117,
Austin, Texas, November 1-5, 2016.

tion must be learned entirely in an unsupervised manner. We therefore assume that our model with rationales is trained on the same data as the original neural models, without access to additional rationale annotations. In other words, target rationales are never provided during training; the intermediate step of rationale generation is guided only by the two desiderata discussed above. Our model is composed of two modular components that we call the generator and the encoder. Our generator specifies a distribution over possible rationales (extracted text) and the encoder maps any such text to task specific target values. They are trained jointly to minimize a cost function that favors short, concise rationales while enforcing that the rationales alone suffice for accurate prediction.

The notion of what counts as a rationale may be ambiguous in some contexts and the task of selecting rationales may therefore be challenging to evaluate. We focus on two domains where ambiguity is minimal (or can be minimized). The first scenario concerns with multi-aspect sentiment analysis exemplified by the beer review corpus (McAuley et al., 2012). A smaller test set in this corpus identifies, for each aspect, the sentence(s) that relate to this aspect. We can therefore directly evaluate our predictions on the sentence level with the caveat that our model makes selections on a finer level, in terms of words, not complete sentences. The second scenario concerns with the problem of retrieving similar questions. The extracted rationales should capture the main purpose of the questions. We can therefore evaluate the quality of rationales as a compressed proxy for the full text in terms of retrieval performance. Our model achieves high performance on both tasks. For instance, on the sentiment prediction task, our model achieves extraction accuracy of 96%, as compared to 38% and 81% obtained by the bigram SVM and a neural attention baseline.

2 Related Work

Developing sparse interpretable models is of considerable interest to the broader research community(Letham et al., 2015; Kim et al., 2015). The need for interpretability is even more pronounced with recent neural models. Efforts in this area include analyzing and visualizing state activation (Hermans and Schrauwen, 2013; Karpathy et al., 2015; Li et al., 2016), learning sparse interpretable word vectors (Faruqui et al., 2015b), and linking word vectors to semantic lexicons or word properties (Faruqui et al., 2015a; Herbelot and Vecchi, 2015).

Beyond learning to understand or further constrain the network to be directly interpretable, one can estimate interpretable proxies that approximate the network. Examples include extracting "if-then" rules (Thrun, 1995) and decision trees (Craven and Shavlik, 1996) from trained networks. More recently, Ribeiro et al. (2016) propose a model-agnostic framework where the proxy model is learned only for the target sample (and its neighborhood) thus ensuring locally valid approximations. Our work differs from these both in terms of what is meant by an explanation and how they are derived. In our case, an explanation consists of a concise yet sufficient portion of the text where the mechanism of selection is learned jointly with the predictor.

Attention based models offer another means to explicate the inner workings of neural models (Bahdanau et al., 2015; Cheng et al., 2016; Martins and Astudillo, 2016; Chen et al., 2015; Xu and Saenko, 2015; Yang et al., 2015). Such models have been successfully applied to many NLP problems, improving both prediction accuracy as well as visualization and interpretability (Rush et al., 2015; Rocktäschel et al., 2016; Hermann et al., 2015). Xu et al. (2015) introduced a stochastic attention mechanism together with a more standard soft attention on image captioning task. Our rationale extraction can be understood as a type of stochastic attention although architectures and objectives differ. Moreover, we compartmentalize rationale generation from downstream encoding so as to expose knobs to directly control types of rationales that are acceptable, and to facilitate broader modular use in other applications.

Finally, we contrast our work with rationale-based classification (Zaidan et al., 2007; Marshall et al., 2015; Zhang et al., 2016) which seek to improve prediction by relying on richer annotations in the form of human-provided rationales. In our work, rationales are never given during training. The goal is to learn to generate them.

3 Extractive Rationale Generation

We formalize here the task of extractive rationale generation and illustrate it in the context of neural models. To this end, consider a typical NLP task where we are provided with a sequence of words as input, namely $\mathbf{x} = \{x_1, \cdots, x_l\}$, where each $x_t \in \mathbb{R}^d$ denotes the vector representation of the i-th word. The learning problem is to map the input sequence $\mathbf{x}$ to a target vector in $\mathbb{R}^m$. For example, in multi-aspect sentiment analysis each coordinate of the target vector represents the response or rating pertaining to the associated aspect. In text retrieval, on the other hand, the target vectors are used to induce similarity assessments between input sequences. Broadly speaking, we can solve the associated learning problem by estimating a complex parameterized mapping $\mathbf{enc}(\mathbf{x})$ from input sequences to target vectors. We call this mapping an *encoder*. The training signal for these vectors is obtained either directly (e.g., multi-sentiment analysis) or via similarities (e.g., text retrieval). The challenge is that a complex neural encoder $\mathbf{enc}(\mathbf{x})$ reveals little about its internal workings and thus offers little in the way of justification for why a particular prediction was made.

In extractive rationale generation, our goal is to select a subset of the input sequence as a *rationale*. In order for the subset to qualify as a rationale it should satisfy two criteria: 1) the selected words should be interpretable and 2) they ought to suffice to reach nearly the same prediction (target vector) as the original input. In other words, a rationale must be short and sufficient. We will assume that a short selection is interpretable and focus on optimizing sufficiency under cardinality constraints.

We encapsulate the selection of words as a *rationale generator* which is another parameterized mapping $\mathbf{gen}(\mathbf{x})$ from input sequences to shorter sequences of words. Thus $\mathbf{gen}(\mathbf{x})$ must include only a few words and $\mathbf{enc}(\mathbf{gen}(\mathbf{x}))$ should result in nearly the same target vector as the original input passed through the encoder or $\mathbf{enc}(\mathbf{x})$. We can think of the generator as a tagging model where each word in the input receives a binary tag pertaining to whether it is selected to be included in the rationale. In our case, the generator is probabilistic and specifies a distribution over possible selections.

The rationale generation task is entirely unsupervised in the sense that we assume no explicit annotations about which words should be included in the rationale. Put another way, the rationale is introduced as a latent variable, a constraint that guides how to interpret the input sequence. The encoder and generator are trained jointly, in an end-to-end fashion so as to function well together.

4 Encoder and Generator

We use multi-aspect sentiment prediction as a guiding example to instantiate the two key components – the encoder and the generator. The framework itself generalizes to other tasks.

Encoder $\mathbf{enc}(\cdot)$: Given a training instance $(\mathbf{x}, \mathbf{y})$ where $\mathbf{x} = \{x_t\}_{t=1}^{l}$ is the input text sequence of length l and $\mathbf{y} \in [0, 1]^m$ is the target m-dimensional sentiment vector, the neural encoder predicts $\tilde{\mathbf{y}} = \mathbf{enc}(\mathbf{x})$. If trained on its own, the encoder would aim to minimize the discrepancy between the predicted sentiment vector $\tilde{\mathbf{y}}$ and the gold target vector $\mathbf{y}$. We will use the squared error (i.e. L_2 distance) as the sentiment loss function,

$$\mathcal{L}(\mathbf{x}, \mathbf{y}) = \|\tilde{\mathbf{y}} - \mathbf{y}\|_2^2 = \|\mathbf{enc}(\mathbf{x}) - \mathbf{y}\|_2^2$$

The encoder could be realized in many ways such as a recurrent neural network. For example, let $\mathbf{h}_t = f_e(\mathbf{x}_t, \mathbf{h}_{t-1})$ denote a parameterized recurrent unit mapping input word $\mathbf{x}_t$ and previous state $\mathbf{h}_{t-1}$ to next state $\mathbf{h}_t$. The target vector is then generated on the basis of the final state reached by the recurrent unit after processing all the words in the input sequence. Specifically,

$$\mathbf{h}_t = f_e(\mathbf{x}_t, \mathbf{h}_{t-1}), \;\; t = 1, \ldots, l$$
$$\tilde{\mathbf{y}} = \sigma_e(\mathbf{W}^e \mathbf{h}_l + \mathbf{b}^e)$$

Generator $\mathbf{gen}(\cdot)$: The rationale generator extracts a subset of text from the original input $\mathbf{x}$ to function as an interpretable summary. Thus the rationale for a given sequence $\mathbf{x}$ can be equivalently defined in terms of binary variables $\{\mathbf{z}_1, \cdots, \mathbf{z}_l\}$ where each $\mathbf{z}_t \in 0, 1$ indicates whether word $\mathbf{x}_t$ is selected or not. From here on, we will use $\mathbf{z}$ to specify the binary selections and thus $(\mathbf{z}, \mathbf{x})$ is the actual rationale generated (selections, input). We will use generator $\mathbf{gen}(\mathbf{x})$ as synonymous with a

probability distribution over binary selections, i.e., $\mathbf{z} \sim \mathbf{gen}(\mathbf{x}) \equiv p(\mathbf{z}|\mathbf{x})$ where the length of $\mathbf{z}$ varies with the input $\mathbf{x}$.

In a simple generator, the probability that the t^{th} word is selected can be assumed to be conditionally independent from other selections given the input $\mathbf{x}$. That is, the joint probability $p(\mathbf{z}|\mathbf{x})$ factors according to

$$p(\mathbf{z}|\mathbf{x}) = \prod_{t=1}^{l} p(\mathbf{z}_t|\mathbf{x}) \quad \text{(independent selection)}$$

The component distributions $p(\mathbf{z}_t|\mathbf{x})$ can be modeled using a shared bi-directional recurrent neural network. Specifically, let $\overrightarrow{f}()$ and $\overleftarrow{f}()$ be the forward and backward recurrent unit, respectively, then

$$\overrightarrow{\mathbf{h}_t} = \overrightarrow{f}(\mathbf{x}_t, \overrightarrow{\mathbf{h}_{t-1}})$$
$$\overleftarrow{\mathbf{h}_t} = \overleftarrow{f}(\mathbf{x}_t, \overleftarrow{\mathbf{h}_{t+1}})$$
$$p(\mathbf{z}_t|\mathbf{x}) = \sigma_z(\mathbf{W}^z[\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}] + \mathbf{b}^z)$$

Independent but context dependent selection of words is often sufficient. However, the model is unable to select phrases or refrain from selecting the same word again if already chosen. To this end, we also introduce a dependent selection of words,

$$p(\mathbf{z}|\mathbf{x}) = \prod_{t=1}^{l} p(\mathbf{z}_t|\mathbf{x}, \mathbf{z}_1 \cdots \mathbf{z}_{t-1})$$

which can be also expressed as a recurrent neural network. To this end, we introduce another hidden state $\mathbf{s}_t$ whose role is to couple the selections. For example,

$$p(\mathbf{z}_t|\mathbf{x}, \mathbf{z}_{1,t-1}) = \sigma_z(\mathbf{W}^z[\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}; \mathbf{s}_{t-1}] + \mathbf{b}^z)$$
$$\mathbf{s}_t = f_z([\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}; \mathbf{z}_t], \mathbf{s}_{t-1})$$

Joint objective: A rationale in our definition corresponds to the selected words, i.e., $\{\mathbf{x}_k|\mathbf{z}_k = 1\}$. We will use $(\mathbf{z}, \mathbf{x})$ as the shorthand for this rationale and, thus, $\mathbf{enc}(\mathbf{z}, \mathbf{x})$ refers to the target vector obtained by applying the encoder to the rationale as the input. Our goal here is to formalize how the rationale can be made short and meaningful yet function well in conjunction with the encoder. Our generator and encoder are learned jointly to interact well but they are treated as independent units for modularity.

The generator is guided in two ways during learning. First, the rationale that it produces must suffice as a replacement for the input text. In other words, the target vector (sentiment) arising from the rationale should be close to the gold sentiment. The corresponding loss function is given by

$$\mathcal{L}(\mathbf{z}, \mathbf{x}, \mathbf{y}) = \|\mathbf{enc}(\mathbf{z}, \mathbf{x}) - \mathbf{y}\|_2^2$$

Note that the loss function depends directly (parametrically) on the encoder but only indirectly on the generator via the sampled selection.

Second, we must guide the generator to realize short and coherent rationales. It should select only a few words and those selections should form phrases (consecutive words) rather than represent isolated, disconnected words. We therefore introduce an additional regularizer over the selections

$$\Omega(\mathbf{z}) = \lambda_1\|\mathbf{z}\| + \lambda_2 \sum_t |\mathbf{z}_t - \mathbf{z}_{t-1}|$$

where the first term penalizes the number of selections while the second one discourages transitions (encourages continuity of selections). Note that this regularizer also depends on the generator only indirectly via the selected rationale. This is because it is easier to assess the rationale once produced rather than directly guide how it is obtained.

Our final cost function is the combination of the two, $\text{cost}(\mathbf{z}, \mathbf{x}, \mathbf{y}) = \mathcal{L}(\mathbf{z}, \mathbf{x}, \mathbf{y}) + \Omega(\mathbf{z})$. Since the selections are not provided during training, we minimize the expected cost:

$$\min_{\theta_e, \theta_g} \sum_{(\mathbf{x},\mathbf{y}) \in D} \mathbb{E}_{\mathbf{z} \sim \mathbf{gen}(\mathbf{x})} \left[\text{cost}(\mathbf{z}, \mathbf{x}, \mathbf{y})\right]$$

where θ_e and θ_g denote the set of parameters of the encoder and generator, respectively, and D is the collection of training instances. Our joint objective encourages the generator to compress the input text into coherent summaries that work well with the associated encoder it is trained with.

Minimizing the expected cost is challenging since it involves summing over all the possible choices of rationales $\mathbf{z}$. This summation could potentially be made feasible with additional restrictive assumptions about the generator and encoder. However, we assume only that it is possible to efficiently sample from the generator.

Doubly stochastic gradient We now derive a sampled approximation to the gradient of the expected cost objective. This sampled approximation is obtained separately for each input text $\mathbf{x}$ so as to work well with an overall stochastic gradient method. Consider therefore a training pair $(\mathbf{x}, \mathbf{y})$. For the parameters of the generator θ_g,

$$\begin{aligned}
&\frac{\partial \mathbb{E}_{\mathbf{z}\sim\mathbf{gen}(\mathbf{x})}\left[\text{cost}(\mathbf{z},\mathbf{x},\mathbf{y})\right]}{\partial \theta_g} \\
&= \sum_{\mathbf{z}} \text{cost}(\mathbf{z},\mathbf{x},\mathbf{y}) \cdot \frac{\partial p(\mathbf{z}|\mathbf{x})}{\partial \theta_g} \\
&= \sum_{\mathbf{z}} \text{cost}(\mathbf{z},\mathbf{x},\mathbf{y}) \cdot \frac{\partial p(\mathbf{z}|\mathbf{x})}{\partial \theta_g} \cdot \frac{p(\mathbf{z}|\mathbf{x})}{p(\mathbf{z}|\mathbf{x})}
\end{aligned}$$

Using the fact $(\log f(\theta))' = f'(\theta)/f(\theta)$, we get

$$\begin{aligned}
&\sum_{\mathbf{z}} \text{cost}(\mathbf{z},\mathbf{x},\mathbf{y}) \cdot \frac{\partial p(\mathbf{z}|\mathbf{x})}{\partial \theta_g} \cdot \frac{p(\mathbf{z}|\mathbf{x})}{p(\mathbf{z}|\mathbf{x})} \\
&= \sum_{\mathbf{z}} \text{cost}(\mathbf{z},\mathbf{x},\mathbf{y}) \cdot \frac{\partial \log p(\mathbf{z}|\mathbf{x})}{\partial \theta_g} \cdot p(\mathbf{z}|\mathbf{x}) \\
&= \mathbb{E}_{z\sim\mathbf{gen}(\mathbf{x})}\left[\text{cost}(\mathbf{z},\mathbf{x},\mathbf{y}) \frac{\partial \log p(\mathbf{z}|\mathbf{x})}{\partial \theta_g}\right]
\end{aligned}$$

The last term is the expected gradient where the expectation is taken with respect to the generator distribution over rationales $\mathbf{z}$. Therefore, we can simply sample a few rationales $\mathbf{z}$ from the generator $\mathbf{gen}(\mathbf{x})$ and use the resulting average gradient in an overall stochastic gradient method. A sampled approximation to the gradient with respect to the encoder parameters θ_e can be derived similarly,

$$\begin{aligned}
&\frac{\partial \mathbb{E}_{\mathbf{z}\sim\mathbf{gen}(\mathbf{x})}\left[\text{cost}(\mathbf{z},\mathbf{x},\mathbf{y})\right]}{\partial \theta_e} \\
&= \sum_{\mathbf{z}} \frac{\partial \text{cost}(\mathbf{z},\mathbf{x},\mathbf{y})}{\partial \theta_e} \cdot p(\mathbf{z}|\mathbf{x}) \\
&= \mathbb{E}_{z\sim\mathbf{gen}(\mathbf{x})}\left[\frac{\partial \text{cost}(\mathbf{z},\mathbf{x},\mathbf{y})}{\partial \theta_e}\right]
\end{aligned}$$

Choice of recurrent unit We employ recurrent convolution (RCNN), a refinement of local-ngram based convolution. RCNN attempts to learn n-gram features that are not necessarily consecutive, and average features in a dynamic (recurrent) fashion. Specifically, for bigrams (filter width $n = 2$) RCNN computes $\mathbf{h}_t = f(\mathbf{x}_t, \mathbf{h}_{t-1})$ as follows

Number of reviews	1580k
Avg length of review	144.9
Avg correlation between aspects	63.5%
Max correlation between two aspects	79.1%
Number of annotated reviews	994

Table 1: Statistics of the beer review dataset.

$$\begin{aligned}
\lambda_t &= \sigma(\mathbf{W}^{\lambda}\mathbf{x}_t + \mathbf{U}^{\lambda}\mathbf{h}_{t-1} + \mathbf{b}^{\lambda}) \\
\mathbf{c}_t^{(1)} &= \lambda_t \odot \mathbf{c}_{t-1}^{(1)} + (1-\lambda_t) \odot (\mathbf{W}_1\mathbf{x}_t) \\
\mathbf{c}_t^{(2)} &= \lambda_t \odot \mathbf{c}_{t-1}^{(2)} + (1-\lambda_t) \odot (\mathbf{c}_{t-1}^{(1)} + \mathbf{W}_2\mathbf{x}_t) \\
\mathbf{h}_t &= \tanh(\mathbf{c}_t^{(2)} + \mathbf{b})
\end{aligned}$$

RCNN has been shown to work remarkably in classification and retrieval applications (Lei et al., 2015; Lei et al., 2016) compared to other alternatives such CNNs and LSTMs. We use it for all the recurrent units introduced in our model.

5 Experiments

We evaluate the proposed joint model on two NLP applications: (1) multi-aspect sentiment analysis on product reviews and (2) similar text retrieval on AskUbuntu question answering forum.

5.1 Multi-aspect Sentiment Analysis

Dataset We use the BeerAdvocate[2] review dataset used in prior work (McAuley et al., 2012).[3] This dataset contains 1.5 million reviews written by the website users. The reviews are naturally multi-aspect – each of them contains multiple sentences describing the *overall* impression or one particular aspect of a beer, including *appearance*, *smell* (aroma), *palate* and the *taste*. In addition to the written text, the reviewer provides the ratings (on a scale of 0 to 5 stars) for each aspect as well as an overall rating. The ratings can be fractional (e.g. 3.5 stars), so we normalize the scores to $[0, 1]$ and use them as the (only) supervision for regression.

McAuley et al. (2012) also provided sentence-level annotations on around 1,000 reviews. Each sentence is annotated with one (or multiple) aspect label, indicating what aspect this sentence covers.

[2] www.beeradvocate.com

[3] http://snap.stanford.edu/data/web-BeerAdvocate.html

Method	Appearance		Smell		Palate	
	% precision	% selected	% precision	% selected	% precision	% selected
SVM	38.3	13	21.6	7	24.9	7
Attention model	80.6	13	88.4	7	65.3	7
Generator (independent)	94.8	13	93.8	7	79.3	7
Generator (recurrent)	96.3	14	95.1	7	80.2	7

Table 2: Precision of selected rationales for the first three aspects. The precision is evaluated based on whether the selected words are in the sentences describing the target aspect, based on the sentence-level annotations. Best training epochs are selected based on the objective value on the development set (no sentence annotation is used).

	D	d	l	$\|\theta\|$	MSE
SVM	260k	-	-	2.5M	0.0154
SVM	1580k	-	-	7.3M	0.0100
LSTM	260k	200	2	644k	0.0094
RCNN	260k	200	2	323k	**0.0087**

Table 3: Comparing neural encoders with bigram SVM model. MSE is the mean squared error on the test set. D is the amount of data used for training and development. d stands for the hidden dimension, l denotes the depth of network and $|\theta|$ denotes the number of parameters (number of features for SVM).

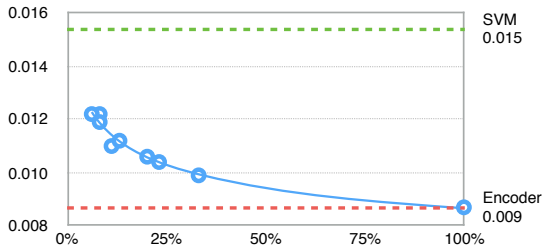

Figure 2: Mean squared error of all aspects on the test set (y-axis) when various percentages of text are extracted as rationales (x-axis). 220k training data is used.

We use this set as our test set to evaluate the precision of words in the extracted rationales.

Table 1 shows several statistics of the beer review dataset. The sentiment correlation between any pair of aspects (and the overall score) is quite high, getting 63.5% on average and a maximum of 79.1% (between the *taste* and *overall* score). If directly training the model on this set, the model can be confused due to such strong correlation. We therefore perform a preprocessing step, picking "less correlated" examples from the dataset.[4] This gives us a de-correlated subset for each aspect, each containing about 80k to 90k reviews. We use 10k as the development set. We focus on three aspects since the fourth aspect *taste* still gets $> 50\%$ correlation with the overall sentiment.

Sentiment Prediction Before training the joint model, it is worth assessing the neural encoder separately to check how accurately the neural network predicts the sentiment. To this end, we compare neural encoders with bigram SVM model, training medium and large SVM models using 260k and all 1580k reviews respectively. As shown in Table 3, the recurrent neural network models outperform the SVM model for sentiment prediction and also require less training data to achieve the performance. The LSTM and RCNN units obtain similar test error, getting 0.0094 and 0.0087 mean squared error respectively. The RCNN unit performs slightly better and uses less parameters. Based on the results, we choose the RCNN encoder network with 2 stacking layers and 200 hidden states.

To train the joint model, we also use RCNN unit with 200 states as the forward and backward recurrent unit for the generator $\mathbf{gen}()$. The dependent generator has one additional recurrent layer. For this layer we use 30 states so the dependent version still has a number of parameters comparable to the independent version. The two versions of the generator have 358k and 323k parameters respectively.

Figure 2 shows the performance of our joint dependent model when trained to predict the sentiment of all aspects. We vary the regularization λ_1 and λ_2 to show various runs that extract different amount of text as rationales. Our joint model gets performance close to the best encoder run (with full text) when few words are extracted.

[4] Specifically, for each aspect we train a simple linear regression model to predict the rating of this aspect given the ratings of the other four aspects. We then keep picking reviews with largest prediction error until the sentiment correlation in the selected subset increases dramatically.

a beer that is not sold in my neck of the woods , but managed to get while on a roadtrip . poured into an imperial pint glass with a generous head that sustained life throughout . nothing out of the ordinary here , but a good brew still . body was kind of heavy , but not thick . the hop smell was excellent and enticing . very drinkable

very dark beer . pours a nice finger and a half of creamy foam and stays throughout the beer . smells of coffee and roasted malt . has a major coffee-like taste with hints of chocolate . if you like black coffee , you will love this porter . creamy smooth mouthfeel and definitely gets smoother on the palate once it warms . it 's an ok porter but i feel there are much better one 's out there .

i really did not like this . it just seemed extremely watery . i dont ' think this had any carbonation whatsoever . maybe it was flat , who knows ? but even if i got a bad brew i do n't see how this would possibly be something i 'd get time and time again . i could taste the hops towards the middle , but the beer got pretty nasty towards the bottom . i would never drink this again , unless it was free . i 'm kind of upset i bought this .

a : poured a nice dark brown with a tan colored head about half an inch thick , nice red/garnet accents when held to the light . little clumps of lacing all around the glass , not too shabby . not terribly impressive though s : smells like a more guinness-y guinness really , there are some roasted malts there , signature guinness smells , less burnt though , a little bit of chocolate ... ... m : relatively thick , it is n't an export stout or imperial stout , but still is pretty hefty in the mouth , very smooth , not much carbonation . not too shabby d : not quite as drinkable as the draught , but still not too bad . i could easily see drinking a few of these .

Figure 3: Examples of extracted rationales indicating the sentiments of various aspects. The extracted texts for appearance, smell and palate are shown in red, blue and green color respectively. The last example is shortened for space.

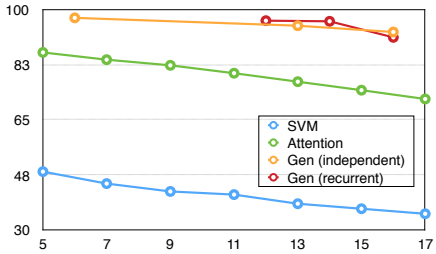

Figure 4: Precision (y-axis) when various percentages of text are extracted as rationales (x-axis) for the appearance aspect.

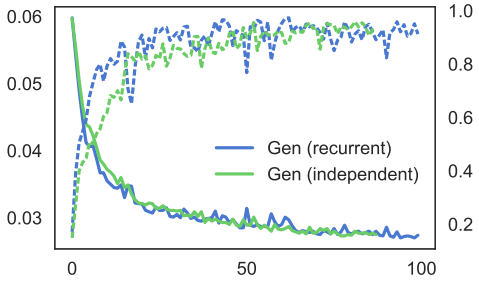

Figure 5: Learning curves of the optimized cost function on the development set and the precision of rationales on the test set. The smell (aroma) aspect is the target aspect.

Rationale Selection To evaluate the supporting rationales for each aspect, we train the joint encoder-generator model on each de-correlated subset. We set the cardinality regularization λ_1 between values $\{2e-4, 3e-4, 4e-4\}$ so the extracted rationale texts are neither too long nor too short. For simplicity, we set $\lambda_2 = 2\lambda_1$ to encourage local coherency of the extraction.

For comparison we use the bigram SVM model and implement an attention-based neural network model. The SVM model successively extracts unigram or bigram (from the test reviews) with the highest feature. The attention-based model learns a normalized attention vector of the input tokens (using similarly the forward and backward RNNs), then the model averages over the encoder states accordingly to the attention, and feed the averaged vector to the output layer. Similar to the SVM model, the attention-based model can selects words based on their attention weights.

Table 2 presents the precision of the extracted rationales calculated based on sentence-level aspect annotations. The λ_1 regularization hyper-parameter is tuned so the two versions of our model extract similar number of words as rationales. The SVM and attention-based model are constrained similarly for comparison. Figure 4 further shows the precision when different amounts of text are extracted. Again, for our model this corresponds to changing the λ_1 regularization. As shown in the table and the figure, our encoder-generator networks extract text pieces describing the target aspect with high precision, ranging from 80% to 96% across the three aspects appearance, smell and palate. The SVM baseline performs poorly, achieving around 30% accuracy. The attention-based model achieves reasonable but worse performance than the rationale generator, suggesting the potential of directly modeling rationales as explicit extraction.

Figure 5 shows the learning curves of our model for the smell aspect. In the early training epochs, both the independent and (recurrent) dependent selection models fail to produce good rationales, getting low precision as a result. After a few epochs of exploration however, the models start to achieve high accuracy. We observe that the dependent version learns more quickly in general, but both versions obtain close results in the end.

Finally we conduct a qualitative case study on the extracted rationales. Figure 3 presents several reviews, with highlighted rationales predicted by the model. Our rationale generator identifies key phrases or adjectives that indicate the sentiment of a particular aspect.

5.2 Similar Text Retrieval on QA Forum

Dataset For our second application, we use the real-world AskUbuntu[5] dataset used in recent work (dos Santos et al., 2015; Lei et al., 2016). This set contains a set of 167k unique questions (each consisting a question title and a body) and 16k user-identified similar question pairs. Following previous work, this data is used to train the neural encoder that learns the vector representation of the input question, optimizing the cosine distance (i.e. cosine similarity) between similar questions against random non-similar ones. We use the "one-versus-all" hinge loss (i.e. positive versus other negatives) for the encoder, similar to (Lei et al., 2016). During development and testing, the model is used to score 20 candidate questions given each query question, and a total of 400×20 query-candidate question pairs are annotated for evaluation[6].

Task/Evaluation Setup The question descriptions are often long and fraught with irrelevant details. In this set-up, a fraction of the original question text should be sufficient to represent its content, and be used for retrieving similar questions. Therefore, we will evaluate rationales based on the accuracy of the question retrieval task, assuming that better rationales achieve higher performance. To put this performance in context, we also report the accuracy when full body of a question is used, as well as titles alone. The latter constitutes an upper bound on the model performance as in this dataset titles provide short, informative summaries of the question content. We evaluate the rationales using the mean average precision (MAP) of retrieval.

	MAP (dev)	MAP (test)	%words
Full title	56.5	60.0	10.1
Full body	54.2	53.0	89.9
Independent	55.7	53.6	9.7
	56.3	52.6	19.7
Dependent	56.1	54.6	11.6
	56.5	55.6	32.8

Table 4: Comparison between rationale models (middle and bottom rows) and the baselines using full title or body (top row).

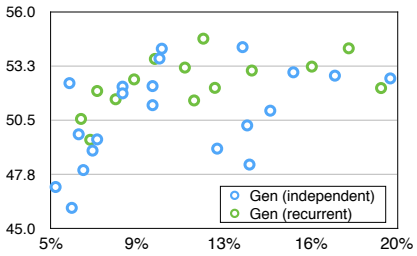

Figure 6: Retrieval MAP on the test set when various percentages of the texts are chosen as rationales. Data points correspond to models trained with different hyper-parameters.

Results Table 4 presents the results of our rationale model. We explore a range of hyper-parameter values[7]. We include two runs for each version. The first one achieves the highest MAP on the development set, The second run is selected to compare the models when they use roughly 10% of question text (7 words on average). We also show the results of different runs in Figure 6. The rationales achieve the MAP up to 56.5%, getting close to using the titles. The models also outperform the baseline of using the noisy question bodies, indicating the the models' capacity of extracting short but important fragments.

Figure 7 shows the rationales for several questions in the AskUbuntu domain, using the recurrent version with around 10% extraction. Interestingly, the model does not always select words from the question title. The reasons are that the question body can contain the same or even complementary information useful for retrieval. Indeed, some rationale fragments shown in the figure are error messages,

which are typically not in the titles but very useful to identify similar questions.

6 Discussion

We proposed a novel modular neural framework to automatically generate concise yet sufficient text fragments to justify predictions made by neural networks. We demonstrated that our encoder-generator framework, trained in an end-to-end manner, gives rise to quality rationales in the absence of any explicit rationale annotations. The approach could be modified or extended in various ways to other applications or types of data.

Choices of $\mathbf{enc}(\cdot)$ and $\mathbf{gen}(\cdot)$. The encoder and generator can be realized in numerous ways without changing the broader algorithm. For instance, we could use a convolutional network (Kim, 2014; Kalchbrenner et al., 2014), deep averaging network (Iyyer et al., 2015; Joulin et al., 2016) or a boosting classifier as the encoder. When rationales can be expected to conform to repeated stereotypical patterns in the text, a simpler encoder consistent with this bias can work better. We emphasize that, in this paper, rationales are flexible explanations that may vary substantially from instance to another. On the generator side, many additional constraints could be imposed to further guide acceptable rationales.

Dealing with Search Space. Our training method employs a REINFORCE-style algorithm (Williams, 1992) where the gradient with respect to the parameters is estimated by sampling possible rationales. Additional constraints on the generator output can be helpful in alleviating problems of exploring potentially a large space of possible rationales in terms of their interaction with the encoder. We could also apply variance reduction techniques to increase stability of stochastic training (cf. (Weaver and Tao, 2001; Mnih et al., 2014; Ba et al., 2015; Xu et al., 2015)).

7 Acknowledgments

We thank Prof. Julian McAuley for sharing the review dataset and annotations. We also thank MIT NLP group and the reviewers for their helpful comments. Abstract

Neural network based models have achieved impressive results on various specific tasks. However, in previous works, most models are learned separately based on single-task supervised objectives, which often suffer from insufficient training data. In this paper, we propose two deep architectures which can be trained jointly on multiple related tasks. More specifically, we augment neural model with an external memory, which is shared by several tasks. Experiments on two groups of text classification tasks show that our proposed architectures can improve the performance of a task with the help of other related tasks.

1 Introduction

Neural network based models have been shown to achieved impressive results on various NLP tasks rivaling or in some cases surpassing traditional models, such as text classification (Kalchbrenner et al., 2014; Socher et al., 2013; Liu et al., 2015a), semantic matching (Hu et al., 2014; Liu et al., 2016a), parser (Chen and Manning, 2014) and machine translation (Bahdanau et al., 2014).

Usually, due to the large number of parameters these neural models need a large-scale corpus. It is hard to train a deep neural model that generalizes well with size-limited data, while building the large scale resources for some NLP tasks is also a challenge. To overcome this problem, these models often involve an unsupervised pre-training phase. The final model is fine-tuned on specific task with respect to a supervised training criterion. However, most pre-training methods are based on unsupervised objectives (Collobert et al., 2011; Turian et al., 2010; Mikolov et al., 2013), which is effective to improve the final performance, but it does not directly optimize the desired task.

Multi-task learning is an approach to learn multiple related tasks simultaneously to significantly improve performance relative to learning each task independently. Inspired by the success of multi-task learning (Caruana, 1997), several neural network based models (Collobert and Weston, 2008; Liu et al., 2015b) are proposed for NLP tasks, which utilized multi-task learning to jointly learn several tasks with the aim of mutual benefit. The characteristic of these multi-task architectures is they share some lower layers to determine common features. After the shared layers, the remaining layers are split into multiple specific tasks.

In this paper, we propose two deep architectures of sharing information among several tasks in multi-task learning framework. All the related tasks are integrated into a single system which is trained jointly. More specifically, inspired by Neural Turing Machine (NTM) (Graves et al., 2014) and memory network (Sukhbaatar et al., 2015), we equip task-specific long short-term memory (LSTM) neural network (Hochreiter and Schmidhuber, 1997) with an external shared memory. The external memory has capability to store long term information and knowledge shared by several related tasks. Different with NTM, we use a deep fusion strategy to integrate the information from the external memory into task-specific LSTM, in which a fusion gate controls the

Austin, Texas, November 1-5, 2016.

information flowing flexibly and enables the model to selectively utilize the shared information.

We demonstrate the effectiveness of our architectures on two groups of text classification tasks. Experimental results show that jointly learning of multiple related tasks can improve the performance of each task relative to learning them independently.

Our contributions are of three-folds:

- We proposed a generic multi-task framework, in which different tasks can share information by an external memory and communicate by a reading/writing mechanism. Two proposed models are complementary to prior multi-task neural networks.
- Different with Neural Turing Machine and memory network, we introduce a deep fusion mechanism between internal and external memories, which helps the LSTM units keep them interacting closely without being conflated.
- As a by-product, the fusion gate enables us to better understand how the external shared memory helps specific task.

2 Neural Memory Models for Specific Task

In this section, we briefly describe LSTM model, and then propose an external memory enhanced LSTM with deep fusion.

2.1 Long Short-term Memory

Long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997) is a type of recurrent neural network (RNN) (Elman, 1990), and specifically addresses the issue of learning long-term dependencies. LSTM maintains an internal memory cell that updates and exposes its content only when deemed necessary.

Architecturally speaking, the memory state and output state are explicitly separated by activation gates (Wang and Cho, 2015). However, the limitation of LSTM is that it lacks a mechanism to index its memory while writing and reading (Danihelka et al., 2016).

While there are numerous LSTM variants, here we use the LSTM architecture used by (Jozefowicz et al., 2015), which is similar to the architecture of (Graves, 2013) but without peep-hole connections.

We define the LSTM *units* at each time step t to be a collection of vectors in $\mathbb{R}^d$: an *input gate* $\mathbf{i}_t$, a *forget gate* $\mathbf{f}_t$, an *output gate* $\mathbf{o}_t$, a *memory cell* $\mathbf{c}_t$ and a hidden state $\mathbf{h}_t$. d is the number of the LSTM units. The elements of the gating vectors $\mathbf{i}_t$, $\mathbf{f}_t$ and $\mathbf{o}_t$ are in $[0, 1]$.

The LSTM is precisely specified as follows.

$$\begin{bmatrix} \tilde{\mathbf{c}}_t \\ \mathbf{o}_t \\ \mathbf{i}_t \\ \mathbf{f}_t \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} \left(\mathbf{W}_p \begin{bmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{bmatrix} + \mathbf{b}_p \right), \quad (1)$$

$$\mathbf{c}_t = \tilde{\mathbf{c}}_t \odot \mathbf{i}_t + \mathbf{c}_{t-1} \odot \mathbf{f}_t, \quad (2)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t), \quad (3)$$

where $\mathbf{x}_t \in \mathbb{R}^m$ is the input at the current time step; $\mathbf{W} \in \mathbb{R}^{4h \times (d+m)}$ and $\mathbf{b}_p \in \mathbb{R}^{4h}$ are parameters of affine transformation; σ denotes the logistic sigmoid function and $\odot$ denotes elementwise multiplication.

The update of each LSTM unit can be written precisely as follows:

$$(\mathbf{h}_t, \mathbf{c}_t) = \mathbf{LSTM}(\mathbf{h}_{t-1}, \mathbf{c}_{t-1}, \mathbf{x}_t, \theta_p). \quad (4)$$

Here, the function $\mathbf{LSTM}(\cdot, \cdot, \cdot, \cdot)$ is a shorthand for Eq. (1-3), and θ_p represents all the parameters of LSTM.

2.2 Memory Enhanced LSTM

LSTM has an internal memory to keep useful information for specific task, some of which may be beneficial to other tasks. However, it is non-trivial to share information stored in internal memory.

Recently, there are some works to augment LSTM with an external memory, such as neural Turing machine (Graves et al., 2014) and memory network (Sukhbaatar et al., 2015), called memory enhanced LSTM (ME-LSTM). These models enhance the low-capacity internal memory to have a capability of modelling long pieces of text (Andrychowicz and Kurach, 2016).

Inspired by these models, we introduce an external memory to share information among several tasks. To better control shared information and understand how it is utilized from external memory, we propose a deep fusion strategy for ME-LSTM.

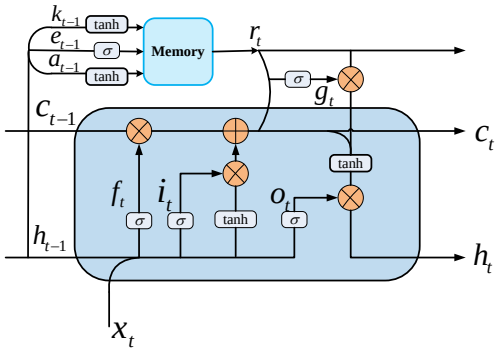

Figure 1: Graphical illustration of the proposed ME-LSTM unit with deep fusion of internal and external memories.

As shown in Figure 1, ME-LSTM consists the original LSTM and an external memory which is maintained by reading and writing operations. The LSTM not only interacts with the input and output information but accesses the external memory using selective read and write operations.

The external memory and corresponding operations will be discussed in detail below.

External Memory The form of external memory is defined as a matrix $\mathbf{M} \in \mathbb{R}^{K \times M}$, where K is the number of memory segments, and M is the size of each segment. Besides, K and M are generally instance-independent and pre-defined as hyper-parameters.

At each step t, LSTM emits output $\mathbf{h}_t$ and three key vectors $\mathbf{k}_t$, $\mathbf{e}_t$ and $\mathbf{a}_t$ simultaneously. $\mathbf{k}_t$, $\mathbf{e}_t$ and $\mathbf{a}_t$ can be computed as

$$\begin{bmatrix} \mathbf{k}_t \\ \mathbf{e}_t \\ \mathbf{a}_t \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \tanh \end{bmatrix} (\mathbf{W}_m \mathbf{h}_t + \mathbf{b}_m) \tag{5}$$

where $\mathbf{W}_m$ and $\mathbf{b}_m$ are parameters of affine transformation.

Reading The read operation is to read information $\mathbf{r}_t \in \mathbb{R}^M$ from memory $\mathbf{M}_{t-1}$.

$$\mathbf{r}_t = \alpha_t \mathbf{M}_{t-1}, \tag{6}$$

where $\mathbf{r}_t$ denotes the reading vector and $\alpha_t \in \mathbb{R}^K$ represents a distribution over the set of segments of memory $\mathbf{M}_{t-1}$, which controls the amount of information to be read from and written to the memory.

Each scalar $\alpha_{t,k}$ in attention distribution α_t can be obtained as:

$$\alpha_{t,k} = \text{softmax}(g(\mathbf{M}_{t-1,k}, \mathbf{k}_{t-1})) \tag{7}$$

where $\mathbf{M}_{t-1,k}$ represents the k-th row memory vector, and $\mathbf{k}_{t-1}$ is a key vector emitted by LSTM.

Here $g(\mathbf{x}, \mathbf{y})$ ($\mathbf{x} \in \mathbb{R}^M, \mathbf{y} \in \mathbb{R}^M$) is a align function for which we consider two different alternatives:

$$g(\mathbf{x}, \mathbf{y}) = \begin{cases} \mathbf{v}^T \tanh(\mathbf{W}_a[\mathbf{x}; \mathbf{y}]) \\ \mathbf{cosine}(x, y) \end{cases} \tag{8}$$

where $\mathbf{v} \in \mathbb{R}^M$ is a parameter vector.

In our current implementation, the similarity measure is cosine similarity.

Writing The memory can be written by two operations: erase and add.

$$\mathbf{M}_t = \mathbf{M}_{t-1}(\mathbf{1} - \alpha_t \mathbf{e}_t^\mathbf{T}) + \alpha_t \mathbf{a}_t^\mathbf{T}, \tag{9}$$

where $\mathbf{e}_t, \mathbf{a}_t \in \mathbb{R}^M$ represent erase and add vectors respectively.

To facilitate the following statements, we re-write the writing equation as:

$$\mathbf{M}_t = \mathbf{f}_{write}(\mathbf{M}_{t-1}, \alpha_t, \mathbf{h}_t). \tag{10}$$

Deep Fusion between External and Internal Memories After we obtain the information from external memory, we need a strategy to comprehensively utilize information from both external and internal memory.

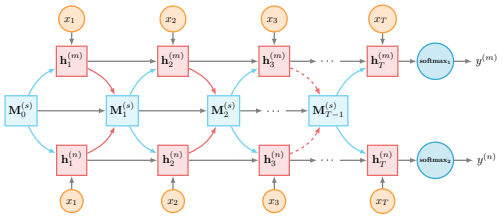
To better control signals flowing from external memory, inspired by (Wang and Cho, 2015), we propose a deep fusion strategy to keep internal and external memories interacting closely without being conflated.

In detail, the state $\mathbf{h}_t$ of LSTM at step t depends on both the read vector $\mathbf{r}_t$ from external memory, and internal memory c_t, which is computed by

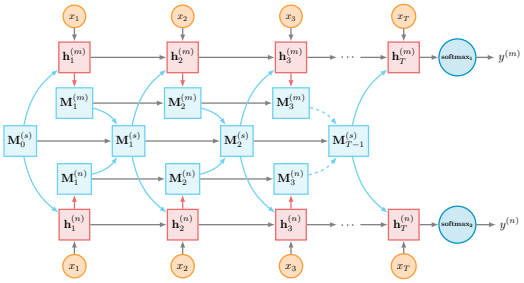
$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t + \mathbf{g}_t \odot (\mathbf{W}_f \mathbf{r}_t)), \tag{11}$$

where $\mathbf{W}_f$ is parameter matrix, and $\mathbf{g}_t$ is a fusion gate to select information from external memory, which is computed by

$$\mathbf{g}_t = \sigma(\mathbf{W}_r \mathbf{r}_t + \mathbf{W}_c \mathbf{c}_t), \tag{12}$$



(a) Global Memory Architecture



(b) Local-Global Hybrid Memory Architecture

Figure 2: Two architectures for modelling text with multi-task learning.

where $\mathbf{W}_r$ and $\mathbf{W}_c$ are parameter matrices.

Finally, the update of external memory enhanced LSTM unit can be written precisely as

$$(\mathbf{h}_t, \mathbf{M}_t, \mathbf{c}_t) = \textbf{ME-LSTM}(\mathbf{h}_{t-1}, \mathbf{M}_{t-1}, \mathbf{c}_{t-1}, \mathbf{x}_t, \theta_p, \theta_q), \quad (13)$$

where θ_p represents all the parameters of LSTM internal structure and θ_q represents all the parameters to maintain the external memory.

Overall, the external memory enables ME-LSTM to have larger capability to store more information, thereby increasing the ability of ME-LSTM. The read and write operations allow ME-LSTM to capture complex sentence patterns.

3 Deep Architectures with Shared Memory for Multi-task Learning

Most existing neural network methods are based on supervised training objectives on a single task (Collobert et al., 2011; Socher et al., 2013; Kalchbrenner et al., 2014). These methods often suffer from the limited amounts of training data. To deal with this problem, these models often involve an unsupervised pre-training phase. This unsupervised pre-training is effective to improve the final performance, but it does not directly optimize the desired task.

Motivated by the success of multi-task learning (Caruana, 1997), we propose two deep architectures with shared external memory to leverage supervised data from many related tasks. Deep neural model is well suited for multi-task learning since the features learned from a task may be useful for other tasks. Figure 2 gives an illustration of our proposed architectures.

ARC-I: Global Shared Memory In ARC-I, the input is modelled by a task-specific LSTM and external shared memory. More formally, given an input text x, the task-specific output $\mathbf{h}_t^{(m)}$ of task m at step t is defined as

$$(\mathbf{h}_t^{(m)}, \mathbf{M}_t^{(s)}, \mathbf{c}_t^{(m)}) = \textbf{ME-LSTM}(\mathbf{h}_{t-1}^{(m)}, \mathbf{M}_{t-1}^{(s)}, \mathbf{c}_{t-1}^{(m)}, \mathbf{x}_t, \theta_p^{(m)}, \theta_q^{(s)}), \quad (14)$$

where $\mathbf{x}_t$ represents word embeddings of word x_t; the superscript s represents the parameters are shared across different tasks; the superscript m represents that the parameters or variables are task-specific for task m.

Here all tasks share single global memory $\mathbf{M}^{(s)}$, meaning that all tasks can read information from it and have the duty to write their shared or task-specific information into the memory.

$$\mathbf{M}_t^{(s)} = \mathbf{f}_{write}(\mathbf{M}_{t-1}^{(s)}, \alpha_t^{(s)}, \mathbf{h}_t^{(m)}) \quad (15)$$

After calculating the task-specific representation of text $\mathbf{h}_T^{(m)}$ for task m, we can predict the probability distribution over classes.

ARC-II: Local-Global Hybrid Memory In ARC-I, all tasks share a global memory, but can also record task-specific information besides shared information. To address this, we allocate each task a local task-specific external memory, which can further write shared information to a global memory for all tasks.

More generally, for task m, we assign each task-specific LSTM with a local memory $\mathbf{M}^{(m)}$, followed by a global memory $\mathbf{M}^{(s)}$, which is shared across different tasks.

The read and write operations of the local and global memory are defined as

$$\mathbf{r}_t^{(m)} = \alpha_t^{(m)} \mathbf{M}_t^{(m)}, \quad (16)$$

Dataset		Type	Train Size	Dev. Size	Test Size	Class	Avg. Length	Vocabulary Size
Movie	SST-1	Sen.	8544	1101	2210	5	19	18K
	SST-2	Sen.	6920	872	1821	2	18	15K
	SUBJ	Sen.	9000	-	1000	2	21	21K
	IMDB	Doc.	25,000	-	25,000	2	294	392K
Product	Books	Doc.	1400	200	400	2	181	27K
	DVDs	Doc.	1400	200	400	2	197	29K
	Electronics	Doc.	1400	200	400	2	117	14K
	Kitchen	Doc.	1400	200	400	2	98	12K

Table 1: Statistics of two multi-task datasets. Each dataset consists of four related tasks.

$$\mathbf{M}_t^{(m)} = \mathbf{f}_{write}(\mathbf{M}_{t-1}^{(m)}, \alpha_t^{(m)}, \mathbf{h}_t^{(m)}), \quad (17)$$

$$\mathbf{r}_t^{(s)} = \alpha_{t-1}^{(s)} \mathbf{M}_{t-1}^{(s)}, \quad (18)$$

$$\mathbf{M}_t^{(s)} = \mathbf{f}_{write}(\mathbf{M}_{t-1}^{(s)}, \alpha_t^{(s)}, \mathbf{r}_t^{(m)}), \quad (19)$$

where the superscript s represents the parameters are shared across different tasks; the superscript m represents that the parameters or variables are task-specific for task m.

In ARC-II, the local memories enhance the capacity of memorizing, while global memory enables the information flowing from different tasks to interact sufficiently.

4 Training

The task-specific representation $\mathbf{h}^{(m)}$, emitted by the deep muti-task architectures, is ultimately fed into the corresponding task-specific output layers.

$$\hat{\mathbf{y}}^{(m)} = \mathrm{softmax}(\mathbf{W}^{(m)}\mathbf{h}^{(m)} + \mathbf{b}^{(m)}), \quad (20)$$

where $\hat{\mathbf{y}}^{(m)}$ is prediction probabilities for task m.

Given M related tasks, our global cost function is the linear combination of cost function for all tasks.

$$\phi = \sum_{m=1}^{M} \lambda_m L(\hat{y}^{(m)}, y^{(m)}) \quad (21)$$

where λ_m is the weights for each task m respectively.

Computational Cost Compared with vanilla LSTM, our proposed two models do not cause much extra computational cost while converge faster. In our experiment, the most complicated ARC-II, costs 2 times as long as vanilla LSTM.

	Movie Reviews	Product Reviews
Embedding dimension	100	100
Hidden layer size	100	100
External memory size	(50,20)	(50,20)

Regularization	0	$1E{-}5$

Table 2: Hyper-parameters of our models.

5 Experiment

In this section, we investigate the empirical performances of our proposed architectures on two multi-task datasets. Each dataset contains several related tasks.

5.1 Datasets

The used multi-task datasets are briefly described as follows. The detailed statistics are listed in Table 1.

Movie Reviews The movie reviews dataset consists of four sub-datasets about movie reviews.

- **SST-1** The movie reviews with five classes in the Stanford Sentiment Treebank[1] (Socher et al., 2013).
- **SST-2** The movie reviews with binary classes. It is also from the Stanford Sentiment Treebank.
- **SUBJ** The movie reviews with labels of subjective or objective (Pang and Lee, 2004).
- **IMDB** The IMDB dataset[2] consists of 100,000 movie reviews with binary classes (Maas et al., 2011). One key aspect of this dataset is that each movie review has several sentences.

Tree-LSTM (Tai et al., 2015)		**50.6**	86.9	-	-	-

Table 3: Accuracies of our models on movie reviews tasks against state-of-the-art neural models. The last column gives the improvements relative to LSTM and ME-LSTM respectively. **NBOW**: Sums up the word vectors and applies a non-linearity followed by a softmax classification layer. **RAE**: Recursive Autoencoders with pre-trained word vectors from Wikipedia (Socher et al., 2011). **MV-RNN**: Matrix-Vector Recursive Neural Network with parse trees (Socher et al., 2012). **RNTN**: Recursive Neural Tensor Network with tensor-based feature function and parse trees (Socher et al., 2013). **DCNN**: Dynamic Convolutional Neural Network with dynamic k-max pooling (Kalchbrenner et al., 2014; Denil et al., 2014). **CNN-multichannel**: Convolutional Neural Network (Kim, 2014). **Tree-LSTM**: A generalization of LSTMs to tree-structured network topologies (Tai et al., 2015).

Product Reviews This dataset[3], constructed by Blitzer et al. (2007), contains Amazon product reviews from four different domains: Books, DVDs, Electronics and Kitchen appliances. The goal in each domain is to classify a product review as either positive or negative. The datasets in each domain are partitioned randomly into training data, development data and testing data with the proportion of 70%, 20% and 10% respectively.

5.2 Competitor Methods for Multi-task Learning

The multi-task frameworks proposed by previous works are various while not all can be applied to the tasks we focused. Nevertheless, we chose two most related neural models for multi-task learning and implement them as strong competitor methods .

- MT-CNN: This model is proposed by Collobert and Weston (2008) with convolutional layer, in which lookup-tables are shared partially while other layers are task-specific.
- MT-DNN: The model is proposed by Liu et al. (2015b) with bag-of-words input and multi-layer perceptrons, in which a hidden layer is shared.

[3] https://www.cs.jhu.edu/~mdredze/datasets/sentiment/

5.3 Hyperparameters and Training

The networks are trained with backpropagation and the gradient-based optimization is performed using the Adagrad update rule (Duchi et al., 2011).

The word embeddings for all of the models are initialized with the 100d GloVe vectors (840B token version, (Pennington et al., 2014)) and fine-tuned during training to improve the performance. The other parameters are initialized by randomly sampling from uniform distribution in $[-0.1, 0.1]$. The mini-batch size is set to 16.

For each task, we take the hyperparameters which achieve the best performance on the development set via an small grid search over combinations of the initial learning rate $[0.1, 0.01]$, l_2 regularization $[0.0, 5E{-}5, 1E{-}5]$. For datasets without development set, we use 10-fold cross-validation (CV) instead. The final hyper-parameters are set as Table 2.

5.4 Multi-task Learning of Movie Reviews

We first compare our proposed models with the baseline system for single task classification. Table 3 shows the classification accuracies on the movie reviews dataset. The row of "Single Task" shows the results of LSTM and ME-LSTM for each individual task. With the help of multi-task learning, the performances of these four tasks are improved by 1.8% (ARC-I) and 2.9% (ARC-II) on average relative to LSTM. We can find that the architecture of local-global hybrid external memory has better performances. The reason is that the global memory in ARC-I could store some task-specific information besides shared information, which maybe noisy to other tasks. Moreover, both of our proposed models outperform MT-CNN and MT-DNN, which indicates the effectiveness of our proposed shared mechanism. To give an intuitive evaluation of these results, we also list the following state-of-the-art neural models. With the help of utilizing the shared information of several related tasks, our results outperform most of state-of-the-art models. Although Tree-LSTM outperforms our method on SST-1, it needs an external parser to get the sentence topological structure. It is worth noticing that our models are generic and compatible with the other LSTM based models. For example, we can easily extend our models to incorporate the Tree-LSTM model.

5.5 Multi-task Learning of Product Reviews

Table 4 shows the classification accuracies on the tasks of product reviews. The row of "Single Task" shows the results of the baseline for each individual task. With the help of global shared memory (ARC-I), the performances of these four tasks are improved by an average of 2.9%(2.6%) compared with LSTM(ME-LSTM). ARC-II achieves best performances on three sub-tasks, and its average improvement is 3.7%(3.5%). Compared with MT-CNN and MT-DNN, our models achieve a better performance. We think the reason is that our models can not only share lexical information but share complicated patterns of sentences by reading/writing operations of external memory. Furthermore, these results on product reviews are consistent with that on movie reviews, which shows our architectures are robust.

5.6 Case Study

To get an intuitive understanding of what is happening when we use shared memory to predict the class of text, we design an experiment to compare and analyze the difference between our models and vanilla LSTM, thereby demonstrating the effectiveness of our proposed architectures.

We sample two sentences from the SST-2 validation dataset, and the changes of the predicted sentiment score at different time steps are shown in Figure 3, which are obtained by vanilla LSTM and ARC-I respectively. Additionally, both models are bidirectional for better visualization. To get more insights into how the shared external memory influences the specific task, we plot and observe the evolving activation of fusion gates through time, which controls signals flowing from a shared external memory to task-specific output, to understand the behaviour of neurons.

For the sentence "*It is a cookie-cutter movie, a cut-and-paste job.*", which has a negative sentiment, while the standard LSTM gives a wrong prediction due to not understanding the informative words "*cookie-cutter*" and "*cut-and-paste*".

In contrast, our model makes a correct prediction and the reason can be inferred from the activation of fusion gates. As shown in Figure 3-(c), we can see clearly the neurons are activated much when they take input as "*cookie-cutter*" and "*cut-and-paste*", which indicates much information in shared memory has be passed into LSTM, therefore enabling the model to give a correct prediction.

Another case "*If you were not nearly moved to tears by a couple of scenes , you 've got ice water in your veins*", a subjunctive clause introduced by "*if*", has a positive sentiment.

As shown in Figure 3-(b,d), vanilla LSTM failed to capture the implicit meaning behind the sentence, while our model is sensitive to the pattern "*If ... were not ...*" and has an accurate understanding of the sentence, which indicates the shared memory mechanism can not only enrich the meaning of certain words, but teach some information of sentence structure to specific task.

Model		Books	DVDs	Electronics	Kitchen	AvgΔ
Single Task	LSTM	78.0	79.5	81.2	81.8	-
	ME-LSTM	77.5	80.2	81.5	82.1	-
Multi-task	ARC-I	81.2	82.0	84.5	**84.3**	+(2.9/2.6)
	ARC-II	**82.8**	**83.0**	**85.5**	84.0	+(3.7/3.5)
	MT-CNN	80.2	81.0	83.4	83.0	-
	MT-DNN	79.7	80.5	82.5	82.8	-

The red horizontal line gives a border between the positive and negative sentiments. (c)(d) Visualization of the fusion gate's activation.

6 Related Work

Neural networks based multi-task learning has been proven effective in many NLP problems (Collobert and Weston, 2008; Glorot et al., 2011; Liu et al., 2015b; Liu et al., 2016b). In most of these models, the lower layers are shared across all tasks, while top layers are task-specific.

Collobert and Weston (2008) used a shared representation for input words and solved different traditional NLP tasks within one framework. However, only one lookup table is shared, and the other lookup tables and layers are task-specific.

Liu et al. (2015b) developed a multi-task DNN for learning representations across multiple tasks. Their multi-task DNN approach combines tasks of query classification and ranking for web search. But the input of the model is bag-of-word representation, which loses the information of word order.

More recently, several multi-task encoder-decoder networks were also proposed for neural machine translation (Dong et al., 2015; Luong et al., 2015; Firat et al., 2016), which can make use of cross-lingual information.

Unlike these works, in this paper we design two neural architectures with shared memory for multi-task learning, which can store useful information across the tasks. Our architectures are relatively loosely coupled, and therefore more flexible to expand. With the help of shared memory, we can obtain better task-specific sentence representation by utilizing the knowledge obtained by other related tasks.

7 Conclusion and Future Work

In this paper, we introduce two deep architectures for multi-task learning. The difference with the previous models is the mechanisms of sharing information among several tasks. We design an external

memory to store the knowledge shared by several related tasks. Experimental results show that our models can improve the performances of several related tasks by exploring common features.

In addition, we also propose a deep fusion strategy to integrate the information from the external memory into task-specific LSTM with a fusion gate.

In future work, we would like to investigate the other sharing mechanisms of neural network based multi-task learning.

Abstract

We present EpiReader, a novel model for machine comprehension of text. Machine comprehension of unstructured, real-world text is a major research goal for natural language processing. Current tests of machine comprehension pose questions whose answers can be inferred from some supporting text, and evaluate a model's response to the questions. EpiReader is an end-to-end neural model comprising two components: the first component proposes a small set of candidate answers after comparing a question to its supporting text, and the second component formulates hypotheses using the proposed candidates and the question, then reranks the hypotheses based on their estimated concordance with the supporting text. We present experiments demonstrating that EpiReader sets a new state-of-the-art on the CNN and Children's Book Test benchmarks, outperforming previous neural models by a significant margin.

1 Introduction

When humans reason about the world, we tend to formulate a variety of hypotheses and counterfactuals, then test them in turn by physical or thought experiments. The philosopher Epicurus first formalized this idea in his Principle of Multiple Explanations: if several theories are consistent with the observed data, retain them all until more data is observed. In this paper, we argue that the same principle can be applied to machine comprehension of natural language. We propose a deep neural comprehension model, trained end-to-end, that we call EpiReader.

Comprehension of natural language by machines, at a near-human level, is a prerequisite for an extremely broad class of useful applications of artificial intelligence. Indeed, most human knowledge is collected in the natural language of text. Machine comprehension (MC) has therefore garnered significant attention from the machine learning research community. Machine comprehension is typically evaluated by posing a set of questions based on a supporting text passage, then scoring a system's answers to those questions. Such tests are objectively gradable and may assess a range of abilities, from basic understanding to causal reasoning to inference (Richardson et al., 2013).

In the past year, two large-scale MC datasets have been released: the CNN/Daily Mail corpus, consisting of news articles from those outlets (Hermann et al., 2015), and the Children's Book Test (CBT), consisting of short excerpts from books available through Project Gutenberg (Hill et al., 2016). The size of these datasets (on the order of 10^5 distinct questions) makes them amenable to data-intensive deep learning techniques. Both corpora use Cloze-style questions (Taylor, 1953), which are formulated by replacing a word or phrase in a given sentence with a placeholder token. The task is then to find the answer that "fills in the blank".

In tandem with these corpora, a host of neural machine comprehension models has been developed (Weston et al., 2015b; Hermann et al., 2015; Hill et al., 2016; Kadlec et al., 2016; Chen et al., 2016). We compare EpiReader to these earlier models through training and evaluation on the CNN and

Austin, Texas, November 1-5, 2016.

CBT datasets.[1]

EpiReader factors into two components. The first component extracts a small set of potential answers based on a shallow comparison of the question with its supporting text; we call this the *Extractor*. The second component reranks the proposed answers based on deeper semantic comparisons with the text; we call this the *Reasoner*. We can summarize this process as *Extract* $\rightarrow$ *Hypothesize* $\rightarrow$ *Test*[2]. The semantic comparisons implemented by the Reasoner are based on the concept of *recognizing textual entailment* (RTE) (Dagan et al., 2006), also known as natural language inference. This process is computationally demanding. Thus, the Extractor serves the important function of filtering a large set of potential answers down to a small, tractable set of likely candidates for more thorough testing. The two-stage process is an analogue of *structured prediction cascades* (Weiss and Taskar, 2010), wherein a sequence of increasingly complex models progressively filters the output space in order to trade off between model complexity and limited computational resources. We demonstrate that this cascade-like framework is applicable to machine comprehension and can be trained end-to-end with stochastic gradient descent.

The Extractor follows the form of a pointer network (Vinyals et al., 2015), and uses a differentiable attention mechanism to indicate words in the text that potentially answer the question. This approach was used (on its own) for question answering with the Attention Sum Reader (Kadlec et al., 2016). The Extractor outputs a small set of answer candidates along with their estimated probabilities of correctness. The Reasoner forms hypotheses by inserting the candidate answers into the question, then estimates the concordance of each hypothesis with each sentence in the supporting text. We use these estimates as a measure of the evidence for a hypothesis, and aggregate evidence over all sentences. In the end, we combine the Reasoner's evidence with the Extractor's probability estimates to produce a final ranking of the answer candidates.

[1]The CNN and Daily Mail datasets were released together and have the same form. The Daily Mail dataset is significantly larger; therefore, models consistently score higher when trained/tested on it.

[2]The Extractor performs extraction, while the Reasoner both hypothesizes and tests.

This paper is organized as follows. In Section 2 we formally define the problem to be solved and give some background on the datasets used in our tests. In Section 3 we describe EpiReader, focusing on its two components and how they combine. Section 4 discusses related work, and Section 5 details our experimental results and analysis. We conclude in Section 6.

2 Problem definition, notation, datasets

EpiReader's task is to answer a Cloze-style question by reading and comprehending a supporting passage of text. The training and evaluation data consist of tuples $(\mathcal{Q}, \mathcal{T}, a^*, A)$, where $\mathcal{Q}$ is the question (a sequence of words $\{q_1, ...q_{|\mathcal{Q}|}\}$), $\mathcal{T}$ is the text (a sequence of words $\{t_1, ..., t_{|\mathcal{T}|}\}$), A is a set of possible answers $\{a_1, ..., a_{|A|}\}$, and $a^* \in A$ is the correct answer. All words come from a vocabulary V, and $A \subset \mathcal{T}$. In each question, there is a placeholder token indicating the missing word to be filled in.

2.1 Datasets

CNN This corpus is built using articles scraped from the CNN website. The articles themselves form the text passages, and questions are generated synthetically from short summary statements that accompany each article. These summary points are (presumably) written by human authors. Each question is created by replacing a named entity in a summary point with a placeholder token. All named entities in the articles and questions are replaced with anonymized tokens that are shuffled for each $(\mathcal{Q}, \mathcal{T})$ pair. This forces the model to rely only on the text, rather than learning world knowledge about the entities during training. The CNN corpus (henceforth CNN) was presented by Hermann et al. (2015).

Children's Book Test This corpus is constructed similarly to CNN, but from children's books available through Project Gutenberg. Rather than articles, the text passages come from book excerpts of 20 sentences. Since no summaries are provided, a question is generated by replacing a single word in the next (i.e. 21st) sentence. The corpus distinguishes questions based on the type of word that is replaced: named entity, common noun, verb, or preposition. Like Kadlec et al. (2016), we focus only on the first two classes since Hill et al. (2016) showed that stan-

dard LSTM language models already achieve human-level performance on the latter two. Unlike in the CNN corpora, named entities are not anonymized and shuffled in the Children's Book Test (CBT). CBT was presented by Hill et al. (2016).

The different methods of construction for questions in each corpus mean that CNN and CBT assess different aspects of comprehension. The summary points of CNN are a condensed paraphrasing of information in the text; thus, determining the correct answer relies mostly on recognizing textual entailment. On the other hand, CBT is about story prediction. It is a comprehension task insofar as comprehension is likely necessary for story prediction, but comprehension alone may not be sufficient. Indeed, there are some CBT questions that are unanswerable given the preceding context.

3 EpiReader

3.1 Overview and intuition

EpiReader explicitly leverages the observation that the answer to a question is often a word or phrase from the related text passage. This condition holds for the CNN and CBT datasets. EpiReader's first module, the Extractor, can thus select a small set of candidate answers by pointing to their locations in the supporting passage. This mechanism is detailed in Section 3.2, and was used previously by the Attention Sum Reader (Kadlec et al., 2016). Pointing to candidate answers removes the need to apply a softmax over the entire vocabulary as in Weston et al. (2015b), which is computationally more costly and uses less-direct information about the context of a predicted answer in the supporting text.

EpiReader's second module, the Reasoner, begins by formulating hypotheses using the extracted answer candidates. It generates each hypothesis by replacing the placeholder token in the question with an answer candidate. Cloze-style questions are ideally-suited to this process, because inserting the correct answer at the placeholder location produces a well-formed, grammatical statement. Thus, the correct hypothesis will "make sense" to a language model.

The Reasoner then tests each hypothesis individually. It compares a hypothesis to the text, split into sentences, to measure textual entailment, and then aggregates entailment over all sentences. This computation uses a pair of convolutional encoder networks followed by a recurrent neural network. The convolutional encoders generate abstract representations of the hypothesis and each text sentence; the recurrent network estimates and aggregates entailment. This is described formally in Section 3.3. The end-to-end EpiReader model, combining the Extractor and Reasoner modules, is depicted in Figure 1.

Throughout our model, words will be represented with trainable embeddings (Bengio et al., 2000). We represent these embeddings using a matrix $\mathbf{W} \in \mathbb{R}^{D \times |V|}$, where D is the embedding dimension and $|V|$ is the vocabulary size.

3.2 The Extractor

The Extractor is a Pointer Network (Vinyals et al., 2015). It uses a pair of bidirectional recurrent neural networks, $f(\theta_T, \mathbf{T})$ and $g(\theta_Q, \mathbf{Q})$, to encode the text passage and the question. θ_T represents the parameters of the text encoder, and $\mathbf{T} \in \mathbb{R}^{D \times N}$ is a matrix representation of the text (comprising N words), whose columns are individual word embeddings $\mathbf{t}_i$. Likewise, θ_Q represents the parameters of the question encoder, and $\mathbf{Q} \in \mathbb{R}^{D \times N_Q}$ is a matrix representation of the question (comprising N_Q words), whose columns are individual word embeddings $\mathbf{q}_j$.

We use a recurrent neural network with gated recurrent units (GRU) (Bahdanau et al., 2015) to scan over the columns (i.e. word embeddings) of the input matrix. We selected the GRU because it is computationally simpler than Long Short-Term Memory (Hochreiter and Schmidhuber, 1997), while still avoiding the problem of vanishing/exploding gradients often encountered when training recurrent networks.

The GRU's hidden state gives a representation of the ith word conditioned on preceding words. To include context from proceeding words, we run a second GRU over $\mathbf{T}$ in the reverse direction. We refer to the combination as a biGRU. At each step the biGRU outputs two d-dimensional encoding vectors, one for the forward direction and one for the backward direction. We concatenate these to yield a vector $f(\mathbf{t}_i) \in \mathbb{R}^{2d}$. The question biGRU is similar, but we form a single-vector representation of the question by concatenating the final forward state with the final backward state, which we denote $g(\mathbf{Q}) \in \mathbb{R}^{2d}$.

As in Kadlec et al. (2016), we model the probability that the ith word in text $\mathcal{T}$ answers question $\mathcal{Q}$

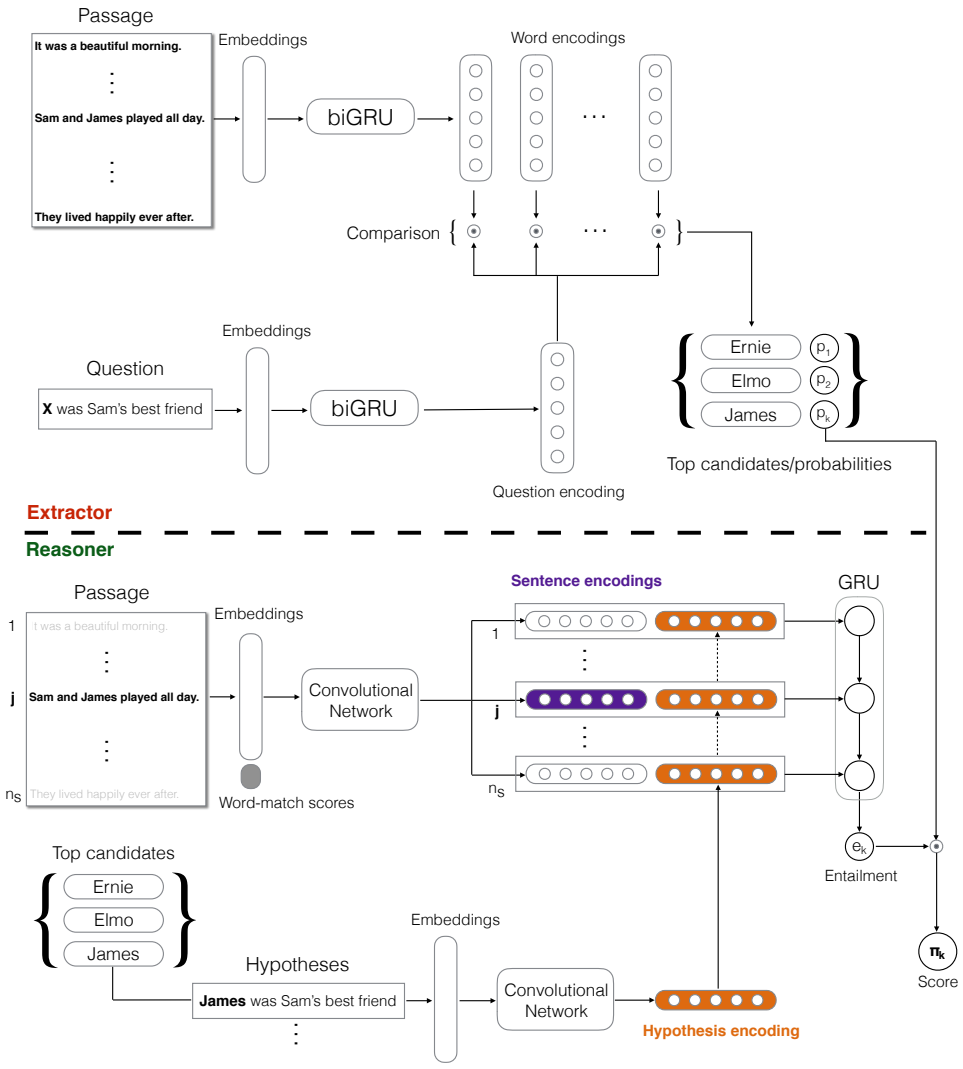

Figure 1: The complete EpiReader framework. The Extractor is above, the Reasoner below. Propagating the Extractor's probability estimates forward and combining them with the Reasoner's entailment estimates renders the model end-to-end differentiable.

using

$$s_i \propto \exp(f(\mathbf{t}_i) \cdot g(\mathbf{Q})), \tag{1}$$

which takes the inner product of the text and question representations followed by a softmax. In many cases unique words repeat in a text. Therefore, we compute the total probability that word w is the correct answer using a sum:

$$P(w \,|\, \mathcal{T}, \mathcal{Q}) = \sum_{i:\ t_i = w} s_i. \tag{2}$$

This probability is evaluated for each unique word in $\mathcal{T}$. Finally, the Extractor outputs the set $\{p_1, ..., p_K\}$ of the K highest word probabilities from 2, along with the corresponding set of K most probable answer words $\{\hat{a}_1, ..., \hat{a}_K\}$.

3.3 The Reasoner

The indicial selection involved in gathering $\{\hat{a}_1, ..., \hat{a}_K\}$, which is equivalent to a K-best $\arg\max$, is not a continuous function of its inputs. To construct an end-to-end differentiable model, we bypass this by propagating the probability estimates of the Extractor directly through the Reasoner.

The Reasoner begins by inserting the answer candidates, which are single words or phrases, into the question sequence $\mathcal{Q}$ at the placeholder location. This forms K hypotheses $\{\mathcal{H}_1, ..., \mathcal{H}_K\}$. At this

point, we consider each hypothesis to have probability $p(\mathcal{H}_k) \approx p_k$, as estimated by the Extractor. The Reasoner updates and refines this estimate.

The hypotheses represent new information in some sense—they are statements we have constructed, albeit from words already present in the question and text passage. The Reasoner estimates entailment between the statements $\mathcal{H}_k$ and the passage $\mathcal{T}$. We denote these estimates using $e_k = F(\mathcal{H}_k, \mathcal{T})$, with F to be defined. We start by reorganizing $\mathcal{T}$ into a sequence of N_s sentences: $\mathcal{T} = \{t_1, \ldots, t_N\} \rightarrow \{\mathcal{S}_1, \ldots, \mathcal{S}_{N_s}\}$, where $\mathcal{S}_i$ is a sequence of words.

For each hypothesis and each sentence of the text, Reasoner input consists of two matrices: $\mathbf{S}_i \in \mathbb{R}^{D \times |\mathcal{S}_i|}$, whose columns are the embedding vectors for each word of sentence $\mathcal{S}_i$, and $\mathbf{H}_k \in \mathbb{R}^{D \times |\mathcal{H}_k|}$, whose columns are the embedding vectors for each word in the hypothesis $\mathcal{H}_k$. The embedding vectors themselves come from matrix $\mathbf{W}$, as before.

These matrices feed into a convolutional architecture based on that of Severyn and Moschitti (2016). The architecture first augments $\mathbf{S}_i$ with matrix $\mathbf{M} \in \mathbb{R}^{2 \times |\mathcal{S}_i|}$. The first row of $\mathbf{M}$ contains the inner product of each word embedding in the sentence with the candidate answer embedding, and the second row contains the maximum inner product of each sentence word embedding with any word embedding in the question. These word-matching features were inspired by similar approaches in Wang and Jiang (2016) and Trischler et al. (2016), where they were shown to improve entailment estimates.

The augmented $\mathbf{S}_i$ is then convolved with a bank of filters $\mathbf{F}^S \in \mathbb{R}^{(D+2) \times m}$, while $\mathbf{H}_k$ is convolved with filters $\mathbf{F}^H \in \mathbb{R}^{D \times m}$, where m is the convolutional filter width. We add a bias term and apply a nonlinearity (we use a ReLU) following the convolution. Maxpooling over the sequences then yields two vectors: the representation of the text sentence, $\mathbf{r}_{\mathcal{S}_i} \in \mathbb{R}^{N_F}$, and the representation of the hypothesis, $\mathbf{r}_{\mathcal{H}_k} \in \mathbb{R}^{N_F}$, where N_F is the number of filters.

We then compute a scalar similarity score between these vector representations using the bilinear form

$$\varsigma = \mathbf{r}_{\mathcal{S}_i}^T \mathbf{R} \mathbf{r}_{\mathcal{H}_k}, \tag{3}$$

where $\mathbf{R} \in \mathbb{R}^{N_F \times N_F}$ is a matrix of trainable parameters. We then concatenate the similarity score with the sentence and hypothesis representations to get a vector, $\mathbf{x}_{ik} = [\varsigma; \mathbf{r}_{\mathcal{S}_i}; \mathbf{r}_{\mathcal{H}_k}]^T$. There are more powerful models of textual entailment that could have been used in place of this convolutional architecture. We adopted the approach of Severyn and Moschitti (2016) for computational efficiency.

The resulting sequence of N_s vectors feeds into yet another GRU for synthesis, of hidden dimension d_S. Intuitively, it is often the case that evidence for a particular hypothesis is distributed over several sentences. For instance, if we hypothesize that *the football is in the park*, perhaps it is because one sentence tells us that *Sam picked up the football* and a later one tells us that *Sam ran to the park*.[3] The Reasoner synthesizes distributed information by running a GRU network over $\mathbf{x}_{ik}$, where i indexes sentences and represents the step dimension.[4] The final hidden state of the GRU is fed through a fully-connected layer, yielding a single scalar y_k. This value represents the collected evidence for $\mathcal{H}_k$ based on the text. In practice, the Reasoner processes all K hypotheses in parallel and the estimated entailment of each is normalized by a softmax, $e_k \propto \exp(y_k)$.

As pointed out in Kadlec et al. (2016), it is a strength of the pointer framework that it does not blend the representations that are being attended. Contrast this with typical attention mechanisms where such a blended representation is used downstream to make similarity comparisons with, *e.g.*, output vectors.

Differentiable attention mechanisms (as in Bahdanau et al. (2015), for example) typically blend internal representations together through a weighted sum, then use this 'blend' downstream for similarity comparisons. The pointer framework does not resort to this blending; Kadlec et al. (2016) explain that this is an advantage, since in comprehension tasks the goal is to select the correct answer among semantically similar candidates and more exact matching is necessary. The reranking function performed by the Reasoner entails this advantage, by examining the separate hypotheses individually without blending.

[3] This example is characteristic of the *bAbI* dataset (Weston et al., 2015a).

[4] Note a benefit of forming the hypothesis: it renders bidirectional aggregation unnecessary, since knowing both the question and the putative answer "closes the loop" the same way that a bidirectional encoding would.

3.4 Combining components

Finally, we combine the evidence from the Reasoner with the probability from the Extractor. We compute the output probability of each hypothesis, π_k, according to the product

$$\pi_k \propto e_k p_k, \tag{4}$$

whereby the evidence of the Reasoner can be interpreted as a correction to the Extractor probabilities, applied as an additive shift in log-space. We experimented with other combinations of the Extractor and Reasoner, but we found the multiplicative approach to yield the best performance.

After combining results from the Extractor and Reasoner to get the probabilities π_k described in Eq. 4, we optimize the parameters of the full EpiReader to minimize a cost comprising two terms, $\mathcal{L}_E$ and $\mathcal{L}_R$. The first term is a standard negative log-likelihood objective, which encourages the Extractor to rate the correct answer above other answers. This is the same loss term used in Kadlec et al. (2016). It is given by:

$$\mathcal{L}_E = \mathop{\mathbb{E}}_{(\mathcal{Q},\mathcal{T},a^*,A)} \left[-\log P(a^* \,|\, \mathcal{T}, \mathcal{Q}) \right], \tag{5}$$

where $P(a^* \,|\, \mathcal{T}, \mathcal{Q})$ is as defined in Eq. 2, and a^* denotes the true answer. The second term is a margin-based loss on the end-to-end probabilities π_k. We define π^* as the probability π_k corresponding to the true answer word a^*. This term is given by:

$$\mathcal{L}_R = \mathop{\mathbb{E}}_{(\mathcal{Q},\mathcal{T},a^*,A)} \left[\sum_{\hat{a}_i \in \{\hat{a}_1,\ldots,\hat{a}_K\} \setminus a^*} [\gamma - \pi^* + \pi_{\hat{a}_i}]_+ \right], \tag{6}$$

where γ is a margin hyperparameter, $\{\hat{a}_1, ..., \hat{a}_K\}$ is the set of K answers proposed by the Extractor, and $[x]_+$ indicates truncating x to be non-negative. Intuitively, this loss says that we want the end-to-end probability π^* for the correct answer to be at least γ larger than the probability $\pi_{\hat{a}_i}$ for any other answer proposed by the Extractor. During training, the correct answer is occasionally missed by the Extractor, especially in early epochs. We counter this issue by forcing the correct answer into the top K set while training. When evaluating the model on validation and test examples we rely fully on the top K answers proposed by the Extractor.

To get the final loss term $\mathcal{L}_{ER}$, minus ℓ_2 regularization terms on the model parameters, we take a weighted combination of $\mathcal{L}_E$ and $\mathcal{L}_R$:

$$\mathcal{L}_{ER} = \mathcal{L}_E + \lambda \mathcal{L}_R, \tag{7}$$

where λ is a hyperparameter for weighting the relative contribution of the Extractor and Reasoner losses. In practice, we found that λ should be fairly large (*e.g.*, $10 < \lambda < 100$). Empirically, we observed that the output probabilities from the Extractor often peak and saturate the first softmax; hence, the Extractor term can come to dominate the Reasoner term without the weight λ (we discuss the Extractor's propensity to overfit in Section 5).

4 Related Work

The Impatient and Attentive Reader models were proposed by Hermann et al. (2015). The Attentive Reader applies bidirectional recurrent encoders to the question and supporting text. It then uses the attention mechanism described in Bahdanau et al. (2015) to compute a fixed-length representation of the text based on a weighted sum of the text encoder's output, guided by comparing the question representation to each location in the text. Finally, a joint representation of the question and supporting text is formed by passing their separate representations through a feed-forward MLP and an answer is selected by comparing the MLP output to a representation of each possible answer. The Impatient Reader operates similarly, but computes attention over the text after processing each consecutive word of the question. The two models achieved similar performance on the CNN and Daily Mail datasets.

Memory Networks were first proposed by Weston et al. (2015b) and later applied to machine comprehension by Hill et al. (2016). This model builds fixed-length representations of the question and of windows of text surrounding each candidate answer, then uses a weighted-sum attention mechanism to combine the window representations. As in the previous Readers, the combined window representation is then compared with each possible answer to form a prediction about the best answer. What distinguishes Memory Networks is how they construct the question and text window representations. Rather than a recurrent network, they use a specially-designed, trainable transformation of the word embeddings.

Most of the details for the very recent AS Reader are provided in the description of our Extractor module in Section 3.2, so we do not summarize it further here. This model (Kadlec et al., 2016) set the previous state-of-the-art on the CBT dataset.

During the write-up of this paper, another very recent model came to our attention. Chen et al. (2016) propose using a bilinear term instead of a $\tanh$ layer to compute the attention between question and passage words, and also uses the attended word encodings for direct, pointer-style prediction as in Kadlec et al. (2016). This model set the previous state-of-the-art on the CNN dataset. However, this model used embedding vectors pretrained on a large external corpus (Pennington et al., 2014).

EpiReader borrows ideas from other models as well. The Reasoner's convolutional architecture is based on Severyn and Moschitti (2016) and Blunsom et al. (2014). Our use of word-level matching was inspired by the Parallel-Hierarchical model of Trischler et al. (2016) and the natural language inference model of Wang and Jiang (2016). Finally, the idea of formulating and testing hypotheses for question-answering was used to great effect in IBM's DeepQA system for *Jeopardy!* (Ferrucci et al., 2010) (although that was a more traditional information retrieval pipeline rather than an end-to-end neural model), and also resembles the framework of structured prediction cascades (Weiss and Taskar, 2010).

5 Evaluation

5.1 Implementation and training details

To train our model we used stochastic gradient descent with the ADAM optimizer (Kingma and Ba, 2015), with an initial learning rate of 0.001. The word embeddings were initialized randomly, drawing from the uniform distribution over $[-0.05, 0.05)$. We used batches of 32 examples, and early stopping with a patience of 2 epochs. Our model was implemented in Theano (Bergstra et al., 2010) using the Keras framework (Chollet, 2015).

The results presented below for EpiReader were obtained by searching over a small grid of hyperparameter settings. We selected the model that, on each dataset, maximized accuracy on the validation set, then evaluated it on the test set. We record the best settings for each dataset in Table 1. As has been done previously, we train separate models on CBT's named entity (CBT-NE) and common noun (CBT-CN) splits. All our models used ℓ_2-regularization at 0.001, $\lambda = 50$, and $\gamma = 0.04$. We did not use dropout but plan to investigate its effect in the future. Hill et al. (2016) and Kadlec et al. (2016) also present results for ensembles of their models. Time did not permit us to generate an ensemble of EpiReaders on the CNN dataset so we omit those measures; however, EpiReader ensembles (of seven models) demonstrated improved performance on the CBT dataset.

Table 1: Hyperparameter settings for best EpiReaders. D is the embedding dimension, d is the hidden dimension in the Extractor GRUs, K is the number of candidates to consider, m is the filter width, N_F is the number of filters, and d_S is the hidden dimension in the Reasoner GRU.

	Hyperparameters					
Dataset	D	d	K	m	N_F	d_S
CBT-NE	300	128	5	3	16	32
CBT-CN	300	128	5	3	32	32
CNN	384	256	10	3	32	32

5.2 Results

In Table 5.2, we compare the performance of EpiReader against that of several baselines, on the validation and test sets of the CBT and CNN corpora. We measure EpiReader performance at the output of both the Extractor and the Reasoner. EpiReader achieves state-of-the-art performance across the board for both datasets. On CNN, we score 2.2% higher on test than the best previous model of Chen et al. (2016). Interestingly, an analysis of the CNN dataset by Chen et al. (2016) suggests that approximately 25% of the test examples contain coreference errors or questions which are "ambiguous/hard" even for a human analyst. If this estimate is accurate, then EpiReader, achieving an absolute test accuracy of 74.0%, is operating close to expected human performance. On the other hand, ambiguity is unlikely to be distributed evenly over entities, so a good model should be able to perform at better-than-chance levels even on questions where the correct answer is uncertain. If, on the 25% of "noisy" questions, the model can shift its hit rate from, *e.g.*, 1/10 to 1/3, then there is still a fair amount of performance to gain.

Model	CBT-NE valid	CBT-NE test	CBT-CN valid	CBT-CN test
Humans (context + query) [1]	-	81.6	-	81.6
LSTMs (context + query) [1]	51.2	41.8	62.6	56.0
MemNNs [1]	70.4	66.6	64.2	63.0
AS Reader [2]	73.8	68.6	68.8	63.4
EpiReader Extractor	73.2	69.4	69.9	66.7
EpiReader	**75.3**	**69.7**	**71.5**	**67.4**
AS Reader (ensemble) [2]	74.5	70.6	71.1	68.9

Table 2: Model comparison on the CBT and CNN datasets. Results marked with [1] are from Hill et al. (2016), with [2] are from Kadlec et al. (2016), with [3] are from Hermann et al. (2015), and with [4] are from Chen et al. (2016).

Ablated component	Validation accuracy (%)
-	**71.5**
Word-match scores	70.3
Bilinear similarity	70.0
Reasoner	68.7
Convolutional encoders	71.0

Table 3: Ablation study on CBT-CN validation set.

On CBT-CN our single model scores 4.0% higher than the previous best of the AS Reader. The improvement on CBT-NE is more modest at 1.1%. Looking more closely at our CBT-NE results, we found that the validation and test accuracies had relatively high variance even in late epochs of training. We discovered that many of the validation and test questions were asked about the same named entity, which may explain this issue.

5.3 Analysis

We measure the contribution of several components of the Reasoner by ablating them. Results on the validation set of CBT-CN are presented in Table 3. The word-match scores (cosine similarities stored in the first two rows of matrix $\mathbf{M}$, see Section 3.3) make a contribution of 1.2% to the validation performance, indicating that they are useful. Similarly, the bilinear similarity score ς, which is passed to the final GRU network, contributes 1.5%.

Removing the Reasoner altogether reduces our model to the AS Reader, whose results we have reproduced to within negligible difference. Aside from achieving state-of-the-art results at its final output, the EpiReader framework gives a boost to its Extractor component through the joint training process. This can be seen by referring back to Table 5.2, wherein we also provide accuracy scores evaluated at the output of the Extractor. These are all higher than the analogous scores reported for the AS Reader. Based on our own work with that model, we found it to overfit the training set rapidly and significantly, achieving training accuracy scores upwards of 98% after only 2 epochs. We suspect that the Reasoner module had a regularizing effect on the Extractor, but leave the confirmation for future work.

Although not exactly an ablation, we also tried bypassing the Reasoner's convolutional encoders altogether, along with the word-match scores and the bilinear similarity. This was done as follows: from the Extractor, we pass to the Reasoner's final GRU (i) the bidirectional hidden representation of the question; (ii) the bidirectional hidden representations of the *end* of each story sentence (recall that the Reasoner operates on sentence representations). Thus, we reuse (parts of) the original biGRU encodings. This cuts down on the number of model parameters and on the length of the graph through which gradients must flow, potentially providing a stronger learning signal to the initial encoders. We found that this change yielded a relatively small reduction in performance on CBT-CN, perhaps for the reasons just discussed—only 0.5%, as given in the final line of

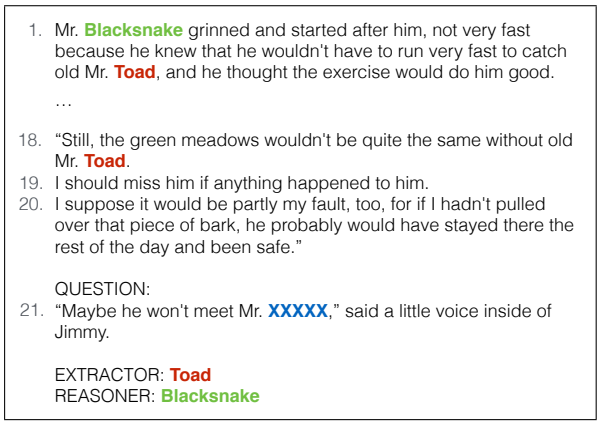

Figure 2: An abridged example from CBT-NE demonstrating corrective reranking by the Reasoner.

Table 3. This suggests that competitive performance may be achieved with other, simpler architectures for the Reasoner's entailment system and this will be the subject of future research.

An analysis by Kadlec et al. (2016) indicates that the trained AS Reader includes the correct answer among its five most probable candidates on approximately 95% of test examples for both datasets. We verified that our Extractor achieved a similar rate, and of course this is vital for performance of the full system, since the Reasoner cannot recover when the correct answer is not among its inputs.

Our results show that the Reasoner often corrects erroneous answers from the Extractor. Figure 2 gives an example of this correction. In the text passage, from CBT-NE, Mr. Blacksnake is pursuing Mr. Toad, presumably to eat him. The dialogue in the question sentence refers to both: Mr. Toad is its subject, referred to by the pronoun "he", and Mr. Blacksnake is its object. In the preceding sentences, it is clear (to a human) that Jimmy is worried about Mr. Toad and his potential encounter with Mr. Blacksnake. The Extractor, however, points most strongly to "Toad", possibly because he has been referred to most recently. The Reasoner corrects this error and selects "Blacksnake" as the answer. This relies on a deeper understanding of the text. The named entity can, in this case, be inferred through an alternation of the entities most recently referred to. This kind alternation is typical of dialogues, when two actors interact in turns. The Reasoner can capture this behavior because it examines sentences in sequence.

6 Conclusion

We presented the novel EpiReader framework for machine comprehension and evaluated it on two large, complex datasets: CNN and CBT. Our model achieves state-of-the-art results on these corpora, outperforming all previous approaches. In future work, we plan to test our framework with alternative models for natural language inference (*e.g.*, Wang and Jiang (2016)), and explore the effect of pretraining such a model specifically on an inference task.

As a general framework that consists in a two-stage cascade, EpiReader can be implemented using a variety of mechanisms in the Extractor and Reasoner stages. We have demonstrated that this cascade-like framework is applicable to machine comprehension and can be trained end-to-end. As more powerful machine comprehension models inevitably emerge, it may be straightforward to boost their performance using EpiReader's structure.

Creating Causal Embeddings for Question Answering with Minimal Supervision

Rebecca Sharp, Mihai Surdeanu, Peter Jansen, Peter Clark, and **Michael Hammond**
University of Arizona, Allen Institute for Artificial Intelligence
{bsharp, msurdeanu, pajansen, hammond}@email.arizona.edu, PeterC@allenai.org

Abstract

A common model for question answering (QA) is that a good answer is one that is closely related to the question, where relatedness is often determined using general-purpose lexical models such as word embeddings. We argue that a better approach is to look for answers that are related to the question in a *relevant way*, according to the information need of the question, which may be determined through task-specific embeddings. With causality as a use case, we implement this insight in three steps. First, we generate causal embeddings cost-effectively by bootstrapping cause-effect pairs extracted from free text using a small set of seed patterns. Second, we train dedicated embeddings over this data, by using task-specific contexts, i.e., the context of a cause is its effect. Finally, we extend a state-of-the-art reranking approach for QA to incorporate these causal embeddings. We evaluate the causal embedding models both *directly* with a casual implication task, and *indirectly*, in a downstream causal QA task using data from Yahoo! Answers. We show that explicitly modeling causality improves performance in both tasks. In the QA task our best model achieves 37.3% P@1, significantly outperforming a strong baseline by 7.7% (relative).

1 Introduction

Question answering (QA), i.e., finding short answers to natural language questions, is one of the most important but challenging tasks on the road towards natural language understanding (Etzioni, 2011). A common approach for QA is to prefer answers that are closely related to the question, where relatedness is often determined using lexical semantic models such as word embeddings (Yih et al., 2013; Jansen et al., 2014; Fried et al., 2015). While appealing for its robustness to natural language variation, this one-size-fits-all approach does not take into account the wide range of distinct question types that can appear in any given question set, and that are best addressed individually (Chu-Carroll et al., 2004; Ferrucci et al., 2010; Clark et al., 2013).

Given the variety of question types, we suggest that a better approach is to look for answers that are related to the question *through the appropriate relation*, e.g., a causal question should have a cause-effect relation with its answer. If we adopt this view, and continue to work with embeddings as a mechanism for assessing relationship, this raises a key question: how do we train and use task-specific embeddings cost-effectively? Using causality as a use case, we answer this question with a framework for producing causal word embeddings with minimal supervision, and a demonstration that such task-specific embeddings significantly benefit causal QA.

In particular, the contributions of this work are:

(1) A methodology for generating causal embeddings cost-effectively by bootstrapping cause-effect pairs extracted from free text using a small set of seed patterns, e.g., *X causes Y*. We then train dedicated embedding (as well as two other distributional similarity) models over this data. Levy and Goldberg (2014) have modified the algorithm of Mikolov et al. (2013) to use an arbitrary, rather than linear, context. Here we make this context task-specific,

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 138–148,
Austin, Texas, November 1-5, 2016.

i.e., the context of a cause is its effect. Further, to mitigate sparsity and noise, our models are bidirectional, and noise aware (by incorporating the likelihood of noise in the training process).

(2) The insight that QA benefits from task-specific embeddings. We implement a QA system that uses the above causal embeddings to answer questions and demonstrate that they significantly improve performance over a strong baseline. Further, we show that causal embeddings encode complementary information to vanilla embeddings, even when trained from the same knowledge resources.

(3) An analysis of direct vs. indirect evaluations for task-specific word embeddings. We evaluate our causal models both *directly*, in terms of measuring their capacity to rank causally-related word pairs over word pairs of other relations, as well as *indirectly* in the downstream causal QA task. In both tasks, our analysis indicates that including causal models significantly improves performance. However, from the direct evaluation, it is difficult to estimate which models will perform best in real-world tasks. Our analysis re-enforces recent observations about the limitations of word similarity evaluations (Faruqui et al., 2016): we show that they have limited coverage and may align poorly with real-world tasks.

2 Related Work

Addressing the need for specialized solving methods in QA, Oh et. al (2013) incorporate a dedicated causal component into their system, and note that it improves the overall performance. However, their model is limited by the need for lexical overlap between a causal construction found in their knowledge base and the question itself. Here, we develop a causal QA component that exploits specialized word embeddings to gain robustness to lexical variation.

There has been a vast body of work which demonstrates that word embeddings derived from distributional similarity are useful in many tasks, including question answering – see *inter alia* (Fried et al., 2015; Yih et al., 2013). However, Levy and Goldberg (2015) note that there are limitations on the type of semantic knowledge which is encoded in these general-purpose similarity embeddings. Therefore, here we build customized task-specific embeddings for causal QA.

Customized embeddings have been created for a variety of tasks, including semantic role labeling (FitzGerald et al., 2015; Woodsend and Lapata, 2015), and binary relation extraction (Riedel et al., 2013). Similar to Riedel et al., we train embeddings customized for specific relations, but we bootstrap training data using minimal supervision (i.e., a small set of patterns) rather than relying on distant supervision and large existing knowledge bases. Additionally, while Riedel et al. represent all relations in a general embedding space, here we train a dedicated embedding space for just the causal relations.

In QA, embeddings have been customized to have question words that are close to either their answer words (Bordes et al., 2014), or to structured knowledge base entries (Yang et al., 2014). While these methods are useful for QA, they do not distinguish between different types of questions, and as such their embeddings are not specific to a given question type.

Additionally, embeddings have been customized to distinguish functional similarity from relatedness (Levy and Goldberg, 2014; Kiela et al., 2015). In particular, Levy and Goldberg train their embeddings by replacing the standard linear context of the target word with context derived from the syntactic dependency graph of the sentence. In this work, we make use of this extension to arbitrary context in order to train our embeddings with contexts derived from binary causal relations. We extract cause-effect text pairs such that the cause text becomes the *target* text and the effect text serves as the *context*.

Recently, Faruqui et al.(2016) discussed issues surrounding the evaluation of similarity word embeddings, including the lack of correlation between their performance on word-similarity tasks and "downstream" or real-world tasks like QA, text classification, etc. As they advocate, in addition to a direct evaluation of our causal embeddings, we also evaluate them independently in a downstream QA task. We provide the same comparison for two alternative approaches (an alignment model and a convolutional neural network model), confirming that the direct evaluation performance can be misleading without the task-specific, downstream evaluation.

With respect to extracting causal relations from text, Girju et al. (2002) use modified Hearst patterns (Hearst, 1992) to extract a large number of potential cause-effect tuples, where both causes and effects must be nouns. However, Cole et al. (2005) show that these nominal-based causal relations account for a relatively small percentage of all causal relations, and for this reason, (Yang and Mao, 2014) allow for more elaborate argument structures in their causal extraction by identifying verbs, and then following the syntactic subtree of the verbal arguments to construct their candidate causes and effects. Additionally, Do et al. (2011) observe that nouns as well as verbs can signal causality. We follow these intuitions in developing our causal patterns by using both nouns and verbs to signal potential participants in causal relations, and then allowing for the entire dominated structures to serve as the cause and/or effect arguments.

3 Approach

Our focus is on reranking answers to causal questions using using task-specific distributional similarity methods. Our approach operates in three steps:

(1) We start by bootstrapping a large number of cause-effect pairs from free text using a small number of syntactic and surface patterns (Section 4).

(2) We then use these bootstrapped pairs to build several task-specific embedding (and other distributional similarity) models (Section 5). We evaluate these models directly on a causal-relation identification task (Section 6).

(3) Finally, we incorporate these models into a reranking framework for causal QA and demonstrate that the resulting approach performs better than the reranker without these task-specific models, even if trained on the same data (Section 7).

4 Extracting Cause-Effect Tuples

Because the success of embedding models depends on large training datasets (Sharp et al., 2015), and such datasets do not exist for open-domain causality, we opted to bootstrap a large number of cause-effect pairs from a small set of patterns. We wrote these patterns using Odin (Valenzuela-Escárcega et al., 2016), a rule-based information extraction framework which has the distinct advantage of being able to operate over multiple representations of content (i.e., surface and syntax). For this work, we make use of rules that operate over both surface sequences as well as dependency syntax in the grammars introduced in steps (2) and (3) below.

Odin operates as a cascade, allowing us to implement a two-stage approach. First, we identify potential participants in causal relations, i.e., the potential causes and effects, which we term **causal mentions (CM)**. A second grammar then identifies actual causal relations that take these CMs as arguments.

We consider both noun phrases (NP) as well as entire clauses to be potential CMs, since causal patterns form around participants that are syntactically more complex than flat NPs. For example, in the sentence *The collapse of the housing bubble caused stock prices to fall*, both the cause (*the collapse of the housing bubble*) and effect (*stock prices to fall*) are more complicated nested structures. Reducing these arguments to non-recursive NPs (e.g., *The collapse* and *stock prices*) is clearly insufficient to capture the relevant context.

Formally, we extract our causal relations using the following algorithm:

(1) Pre-processing: Much of the text we use to extract causal relation tuples comes from the Annotated Gigaword (Napoles et al., 2012). This text is already fully annotated and no further processing is necessary. We additionally use text from the Simple English Wikipedia[1], which we processed using the Stanford CoreNLP toolkit (Manning et al., 2014) and the dependency parser of Chen and Manning (2014).

(2) CM identification: We extract causal mentions (which are able to serve as arguments in our causal patterns) using a set of rules designed to be robust to the variety that exists in natural language. Namely, to find CMs that are noun phrases, we first find words that are tagged as nouns, then follow outgoing dependency links for modifiers and attached prepo-

[1] https://simple.wikipedia.org/wiki/Main_Page. The Simple English version was preferred over the full version due to its simpler sentence structures, which make extracting cause-effect tuples more straightforward.

Corpus	Extracted Tuples
Annotated Gigaword	798,808
Simple English Wikipedia	16,425
Total	815,233

Table 1: Number of causal tuples extracted from each corpus.

sitional phrases[2], to a maximum depth of two links. To find CMs that are clauses, we first find words that are tagged as verbs (excluding verbs which themselves were considered to signal causation[3]), then again follow outgoing dependency links for modifiers and arguments. We used a total of four rules to label CMs.

(3) Causal tuple extraction: After CMs are identified, a grammar scans the text for causal relations that have CMs as arguments. Different patterns have varying probabilities of signaling causation (Khoo et al., 1998). To minimize the noise in the extracted pairs, we restrict ourselves to a set of 13 rules designed to find unambiguously causal patterns, such as *CAUSE led to EFFECT*, where *CAUSE* and *EFFECT* are CMs. The rules operate by looking for a *trigger* phrase, e.g., *led*, and then following the dependency paths to and/or from the trigger phrase to see if all required CM arguments exist.

Applying this causal grammar over Gigaword and Simple English Wikipedia produced 815,233 causal tuples, as summarized in Table 1. As bootstrapping methods are typically noisy, we manually evaluated the quality of approximately 250 of these pairs selected at random. Of the tuples evaluated, approximately 44% contained some amount of noise. For example, from the sentence *Except for Springer's show, which still relies heavily on confrontational topics that lead to fistfights virtually every day...*, while ideally we would only extract (*confrontational topics* $\rightarrow$ *fistfights*), instead we extract the tuple (*show which still relies heavily on confrontational topics* $\rightarrow$ *fistfights virtually every day*), which contains a large amount of noise: *show, relies, heavily*, etc. This finding prompted our noise-aware model described at the end of Section 5.

[2]The outgoing dependency links from the nouns which we followed were: `nn`, `amod`, `advmod`, `ccmod`, `dobj`, `prep_of`, `prep_with`, `prep_for`, `prep_into`, `prep_on`, `prep_to`, and `prep_in`.

[3]The verbs we excluded were: *cause, result, lead, create*.

5 Models

We use the extracted causal tuples to train three distinct distributional similarity models that explicitly capture causality.

Causal Embedding Model (cEmbed): The first distributional similarity model we use is based on the skip-gram word-embedding algorithm of Mikolov et al. (2013), which has been shown to improve a variety of language processing tasks including QA (Yih et al., 2013; Fried et al., 2015). In particular, we use the variant implemented by Levy and Goldberg (2014) which modifies the original algorithm to use an arbitrary, rather than linear, context. Our novel contribution is to make this context task-specific: intuitively, the context of a cause is its effect. Further, these contexts are generated from tuples that are themselves bootstrapped, which minimizes the amount of supervision necessary.

The Levy and Goldberg model trains using single-word pairs, while our CMs could be composed of multiple words. For this reason, we decompose each cause–effect tuple, (CM_c, CM_e), such that each word $w_c \in CM_c$ is paired with each word $w_e \in CM_e$.

After filtering the extracted cause-effect tuples for stop words and retaining only nouns, verbs, and adjectives, we generated over 3.6M (w_c, w_e) word-pairs[4] from the approximately 800K causal tuples.

The model learns two embedding vectors for each word, one for when the word serves as a target word and another for when the word serves as a context word. Here, since the relation of interest is inherently directional, both sets of embeddings are meaningful, and so we make use of both – the target vectors encode the effects of given causes, whereas the context vectors capture the causes of the corresponding effects.

Causal Alignment Model (cAlign): Monolingual alignment (or translation) models have been shown to be successful in QA (Berger et al., 2000; Echihabi and Marcu, 2003; Soricut and Brill, 2006; Riezler et al., 2007; Surdeanu et al., 2011; Yao et al., 2013), and recent work has shown that they can be successfully trained with less data than embedding models (Sharp et al., 2015).

[4]For all models proposed in this section we used lemmas rather than words.

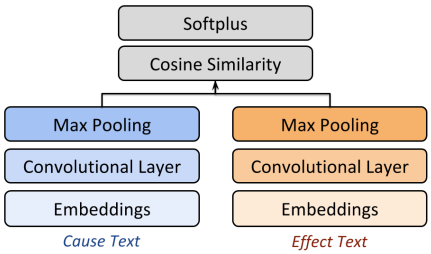

Figure 1: Architecture of the causal convolutional network.

To verify these observations in our context, we train an alignment model that "translates" causes (i.e., the "source language") into effects (i.e., the "destination language"), using our cause–effect tuples. This is done using IBM Model 1 (Brown et al., 1993) and GIZA++ (Och and Ney, 2003).

Causal Convolutional Neural Network Model (cCNN): Each of the previous models have at their root a bag-of-words representation, which is a simplification of the causality task. To address this potential limitation, we additionally trained a convolutional neural network (CNN) which operates over variable-length texts, and maintains distinct embeddings for causes and effects. The architecture of this approach is shown in Figure 1, and consists of two sub-networks (one for cause text and one for effect text), each of which begins by converting the corresponding text into 50-dimensional embeddings. These are then fed to a convolutional layer,[5] which is followed by a max-pooling layer of equal length. Then, these top sub-network layers, which can be thought of as a type of phrasal embedding, are merged by taking their cosine similarity. Finally, this cosine similarity is normalized by feeding it into a dense layer with a single node which has a softplus activation. In designing our CNN, we attempted to minimize architectural and hyperparameter tuning by taking inspiration from Iyyer et al. (2015), preferring simpler architectures. We train the network using a binary cross entropy objective function and the Adam optimizer (Kingma and Ba, 2014), using the Keras library (Chollet, 2015) operating over Theano (Theano Development Team, 2016), a popular deep-learning framework.[6]

[5]The convolutional layer contained 100 filters, had a filter length of 2 (i.e., capturing bigram information), and an inner ReLU activation.

[6]We also experimented with an equivalent architecture where the sub-networks are implemented using long short-term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997), and found that they consistently under-perform this CNN architecture. Our conjecture is that CNNs perform better because LSTMs are more sensitive to overall word order than CNNs, which capture only local contexts, and we have relatively little training data, which prevents the LSTMs from generalizing well.

Noise-aware Causal Embedding Model (cEmbedNoise): We designed a variant of our cEmbed approach to address the potential impact of the noise introduced by our bootstrapping method. While training, we weigh the causal tuples by the likelihood that they are truly causal, which we approximate with pointwise mutual information (PMI). For this, we first score the tuples by their causal PMI and then scale these scores by the overall frequency of the tuple (Riloff, 1996), to account for the PMI bias toward low-frequency items. That is, the score S of a tuple, t, is computed as:

$$S(t) = \log \frac{p(t|causal)}{p(t)} * \log(freq(t)) \qquad (1)$$

We then discretize these scores into five quantiles, ascribing a linearly decreasing weight during training to datums in lower scoring quantiles.

6 Direct Evaluation: Ranking Word Pairs

We begin the assessment of our models with a *direct* evaluation to determine whether or not the proposed approaches capture causality better than general-purpose word embeddings and whether their robustness improves upon a simple database look-up. For this evaluation, we follow the protocol of Levy and Goldberg (2014). In particular, we create a collection of word pairs, half of which are causally related, with the other half consisting of other relations. These pairs are then ranked by our models and several baselines, with the goal of ranking the causal pairs above the others. The embedding models rank the pairs using the cosine similarity between the target vector for the causal word and the context vector of the effect word. The alignment model ranks pairs using the probability $P(\text{Effect}|\text{Cause})$ given by IBM Model 1, and the CNN ranks pairs by the value of the output returned by the network.

6.1 Data

In order to avoid bias towards our extraction methods, we evaluate our models on an external set of

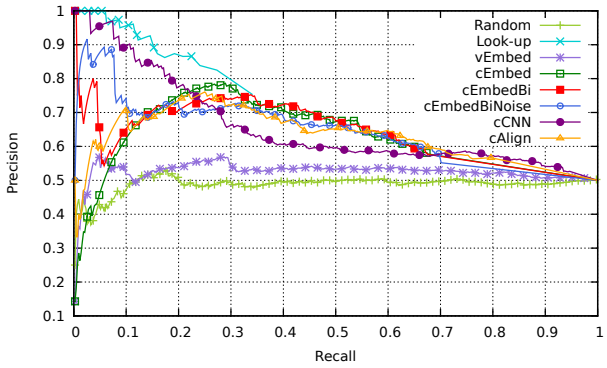

Figure 2: Precision-recall curve showing the ability of each model to rank causal pairs above non-causal pairs. For clarity, we do not plot cEmbedNoise, which performs worse than cEmbedBiNoise. The Look-up model has no data points beyond the 35% recall point.

word pairs drawn from the SemEval 2010 Task 8 (Hendrickx et al., 2009), originally a multi-way classification of semantic relations between nominals. We used a total of 1730 nominal pairs, 865 of which were from the Cause-Effect relation (e.g., (*dancing* → *happiness*)) and an equal number which were randomly selected from the other eight relations (e.g., (*juice* → *grapefruit*), from the Entity-Origin relation). This set was then randomly divided into equally-sized development and test partitions.

6.2 Baselines

We compared our distributional similarity models against three baselines:

Vanilla Embeddings Model (vEmbed): a standard `word2vec` model trained with the skip-gram algorithm and a sliding window of 5, using the original texts from which our causal pairs were extracted.[7] As with the cEmbed model, SemEval pairs were ranked using the cosine similarity between the vector representations of their arguments.

Look-up Baseline: a given SemEval pair was ranked by the number of times it appeared in our extracted cause-effect tuples.

Random: pairs were randomly shuffled.

6.3 Results

Figure 2 shows the precision-recall (PR) curve for each of the models and baselines. As expected, the causal models are better able to rank causal pairs than the vanilla embedding baseline (vEmbed), which, in turn, outperforms the random baseline. Our look-up baseline, which ranks pairs by their frequency in our causal database, shows a high precision for this task, but has coverage for only 35% of the causal SemEval pairs.

Some models perform better on the low-recall portion of the curve (e.g., the look-up baseline and cCNN), while the embedding and alignment models have a higher and more consistent performance across the PR curve. We hypothesize that models that better *balance* precision and recall will perform better in a real-world QA task, which may need to access a given causal relation through a variety of lexical patterns or variations. We empirically validate this observation in Section 7.

The PR curve for the causal embeddings shows an atypical dip at low-recall. To examine this, we analyzed its top-ranked 15% of SemEval pairs, and found that incorrectly ranked pairs were not found in the database of causal tuples. Instead, these incorrect rankings were largely driven by low frequency words whose embeddings could not be robustly estimated due to lack of direct evidence. Because this sparsity is partially driven by directionality, we implemented a bidirectional embedding model (cEmbedBi) that (a) trains a second embedding model by reversing the input (effects as targets, causes as contexts), and (b) ranks pairs by the *average* of the scores returned by these two unidirectional causal embedding models. Specifically, the final bidirectional score of the pair, (e_1, e_2), where e_1 is the can-

[7] All embedding models analyzed here, including this baseline and our causal variants, produced embedding vectors of 200 dimensions.

didate cause and e_2 is the candidate effect, is:

$$s_{bi}(e_1, e_2) = \frac{1}{2}(s_{c\to e}(e_1, e_2) + s_{e\to c}(e_2, e_1)) \quad (2)$$

where $s_{c\to e}$ is the score given by the original causal embeddings, i.e., from cause to effect, and $s_{e\to c}$ is the score given by the reversed-input causal embeddings, i.e., from effect to cause.

As Figure 2 shows, the bidirectional embedding variants consistently outperform their unidirectional counterparts. All in all, the best overall model is cEmbedBiNoise, which is both bidirectional and incorporates the noise handling approach from Section 5. This model substantially improves performance in the low-recall portion of the curve, while also showing strong performance across the curve.

7 Indirect Evaluation: QA Task

The main objective of our work is to investigate the impact of a customized causal embedding model for QA. Following our direct evaluation, which solely evaluated the degree to which our models directly encode causality, here we evaluate each of our proposed causal models in terms of their contribution to a downstream real-world QA task.

Our QA system uses a standard reranking approach (Jansen et al., 2014). In this architecture, the candidate answers are initially extracted and ranked using a shallow candidate retrieval (CR) component that uses solely information retrieval techniques, then they are re-ranked using a "learning to rank" approach. In particular, we used SVM rank[8], a Support Vector Machines classifier adapted for ranking, and re-ranked the candidate answers with a set of features derived from both the initial CR score and the models we have introduced. For our model combinations (see Table 2), the feature set includes the CR score and the features from each of the models in the combination.

7.1 Data

We evaluate on a set of causal questions extracted from the Yahoo! Answers corpus[9] with simple surface patterns such as *What causes ...* and *What is the result of ...*[10]. We extracted a total of 3031 questions, each with at least four candidate answers, and we evaluated performance using five-fold cross-validation, with three folds for training, one for development, and one for testing.

7.2 Models and Features

We evaluate the contribution of the bidirectional and noise-aware causal embedding models (cEmbedBi, and cEmbedBiNoise) as well as the causal alignment model (cAlign) and the causal CNN (cCNN). These models are compared against three baselines: the vanilla embeddings (vEmbed), the lookup baseline (LU), and additionally a vanilla alignment model (vAlign) which is trained over 65k question-answer pairs from Yahoo! Answers.

The features[11] we use for the various models are:

Embedding model features: For both our vanilla and causal embedding models, we use the same set of features as Fried et al. (2015): the maximum, minimum, and average pairwise cosine similarity between question and answer words, as well as the overall similarity between the composite question and answer vectors. When using the causal embeddings, since the relation is directed, we first determine whether the question text is the cause or the effect[12], which in turn determines which embeddings to use for the question text and which to use for the candidate answer texts. For example, in a question such as "*What causes X?*", since *X* is the effect, all cosine similarities would be found using the effect vectors for the question words and the cause vectors for the answer candidate words.

Alignment model features: We use the same global alignment probability, $p(Q|A)$ of Surdeanu et al. (2011). In our causal alignment model, we adapt this to causality as $p(\text{Effect}|\text{Cause})$, and again we first determine the direction of the causal relation implied in the question. We include the additional undirected alignment features based on

[8] http://www.cs.cornell.edu/people/tj/svm_light/svm_rank.html

[9] Freely available through Yahoo!'s Webscope program (research-data-requests@yahoo-inc.com)

[10] We lightly filtered these with stop words to remove non-causal questions, such as those based on math problems and the results of sporting events. Our dataset will be freely available, conditioned on users having obtained the Webscope license.

[11] Due to the variety of features used, each feature described here is independently normalized to lie between 0.0 and 1.0.

[12] We do this through the use of simple regular expressions, e.g., "^ [Ww]hat ([a-z]+){0,3}cause.+"

#	Model	P@1
	Baselines	
1	Random	16.43
2	CR	24.31
3	CR + vEmbed	34.61
4	CR + vAlign	19.24
5	CR + Look-up (LU)	29.56
	Single Causal Models	
6	CR + cEmbedBi	31.32
7	CR + cEmbedBiNoise	30.15
8	CR + cAlign	23.49
9	CR + cCNN	24.66
	Model Combinations	
10	CR + vEmbed + cEmbedBi	37.08*
11	CR + vEmbed + cEmbedBiNoise	35.50*
12	CR + vEmbed + cEmbedBi + LU	36.75*
13	CR + vEmbed + cAlign	34.31
14	CR + vEmbed + cCNN	33.45
	Model Stacking	
15	CR + vEmbed + cEmbedBi + cEmbedBiNoise	**37.28***

Table 2: Performance in the QA evaluation, measured by precision-at-one (P@1). The "Bi" suffix indicates a bidirectional model; the "Noise" suffix indicates a model that is noise aware. * indicates that the difference between the corresponding model and the CR + vEmbed baseline is statistically significant ($p < 0.05$), determined through a one-tailed bootstrap resampling test with 10,000 iterations.

Jensen-Shannon distance, proposed more recently by Fried et al. (2015), in our vanilla alignment model. However, due to the directionality inherent in causality, they do not apply to our causal model so there we omit them.

Look-up feature: For the look-up baseline we count the number of times words from the question and answer appear together in our database of extracted causal pairs, once again after determining the directionality of the questions. If the total number of matches is over a threshold[13], we consider the causal relation to be established and give the candidate answer a score of 1; or a score of 0, otherwise.

7.3 Results

The overall results are summarized in Table 2. Lines 1–5 in the table show that each of our baselines performed better than CR by itself, except for vAlign, suggesting that the vanilla alignment model does not generate accurate predictions for causal questions. The strongest baseline was CR + vEmbed (line 3), the vanilla embeddings trained over Gigaword, at 34.6% P@1. For this reason, we consider this to be the baseline to "beat", and perform statistical significance of all proposed models with respect to it.

Individually, the cEmbedBi model is the best performing of the causal models. While the performance of cAlign in the direct evaluation was comparable to that of cEmbedBi, here it performs far worse (line 6 vs 8), suggesting that the robustness of embeddings is helpful in QA. Notably, despite the strong performance of the cCNN in the low-recall portion of the PR curve in the direct evaluation, here the model performs poorly (line 9).

No individual causal model outperforms the strong vanilla embedding baseline (line 3), likely owing to the reduction in generality inherent to building task-specific QA models. However, comparing lines 6–9 vs. 10–14 shows that the vanilla and causal models are capturing different and complementary kinds of knowledge (i.e., causality vs. association through distributional similarity), and are able to be combined to increase overall task performance (lines 10–12). These results highlight that QA is a complex task, where solving methods need to address the many distinct information needs in question sets, including both causal and direct association relations. This contrasts with the direct evaluation, which focuses strictly on causality, and where the vanilla embedding baseline performs near chance. This observation highlights one weakness of word similarity tasks: their narrow focus may not directly translate to estimating their utility in real-world NLP applications.

Adding in the lookup baseline (LU) to the best-performing causal model does not improve performance (compare lines 10 and 12), suggesting that the bidirectional causal embeddings subsume the contribution of the LU model. cEmbedBi (line 10) also performs better than cEmbedBiNoise (line 11). We conjecture that the "noise" filtered out by cEmbedBiNoise contains distributional similarity information, which is useful for the QA task. cEmbedBi vastly outperforms cCNN (line 14), suggesting that strong overall performance across the precision-recall curve better translates to the QA task. We hypothesize that the low cCNN performance is caused by insufficient training data, preventing the CNN ar-

[13]Empirically determined to be 100 matches. Note that using this threshold performed better than simply using the total number of matches.

Error/observation	% Q
Both chosen and gold are equally good answers	45%
Causal max similarity of chosen is higher	35%
Vanilla overall similarity of chosen is higher	35%
Chosen answer is better than the gold answer	25%
The question is very short / lacks content words	15%
Other	10%

Table 3: Results of an error analysis performed on a random sample of 20 incorrectly answered questions showing the source of the error and the percentage of questions that were affected. Note that questions can belong to multiple categories.

chitecture from generalizing well.

Our best performing overall model combines both variants of the causal embedding model (cEmbedBi and cEmbedBiNoise), reaching a P@1 of 37.3%, which shows a 7.7% relative improvement over the strong CR + vEmbed baseline.

7.4 Error Analysis

We performed an error analysis to gain more insight into our model as well as the source of the remaining errors. For simplicity, we used the combination model CR + vEmbed + cEmbedBi. Examining the model's learned feature weights, we found that the vanilla overall similarity feature had the highest weight, followed by the causal overall similarity and causal maximum similarity features. This indicates that even in causal question answering, the overall *topical* similarity between question and answer is still useful and complementary to the causal similarity features.

To determine sources of error, we randomly selected 20 questions that were incorrectly answered and analyzed them according to the categories shown in Table 3. We found that for 70% of the questions, the answer chosen by our system was as good as or better than the gold answer, often the case with community question answering datasets.

Additionally, while the maximum causal similarity feature is useful, it can be misleading due to embedding noise, low-frequency words, and even the bag-of-words nature of the model (35% of the incorrect questions). For example, in the question *What are the effects of growing up with an older sibling who is better than you at everything?*, the model chose the answer *...You are you and they are them - you will be better and different at other things...* largely because of the high causal similarity between (*grow* $\rightarrow$ *better*). While this could arguably be helpful in another context, here it is irrelevant, suggesting that in the future improvement could come from models that better incorporate textual dependencies.

8 Conclusion

We presented a framework for creating customized embeddings tailored to the information need of causal questions. We trained three popular models (embedding, alignment, and CNN) using causal tuples extracted with minimal supervision by bootstrapping cause-effect pairs from free text, and evaluated their performance both directly (i.e., the degree to which they capture causality), and indirectly (i.e., their real-world utility on a high-level question answering task).

We showed that models that incorporate a knowledge of causality perform best for both tasks. Our analysis suggests that the models that perform best in the real-world QA task are those that have consistent performance across the precision-recall curve in the direct evaluation. In QA, where the vocabulary is much larger, precision must be balanced with high-recall, and this is best achieved by our causal embedding model. Additionally, we showed that vanilla and causal embedding models address different information needs of questions, and can be combined to improve performance.

Extending this work beyond causality, we hypothesize that additional embedding spaces customized to the different information needs of questions would allow for robust performance over a larger variety of questions, and that these customized embedding models should be evaluated both directly and indirectly to accurately characterize their performance.

Abstract

In this work, we show the possibility of inferring the answer type before solving a factoid question and leveraging the type information to improve semantic parsing. By replacing the topic entity in a question with its type, we are able to generate an abstract form of the question, whose answer corresponds to the answer type of the original question. A bidirectional LSTM model is built to train over the abstract form of questions and infer their answer types. It is also observed that if we convert a question into a statement form, our LSTM model achieves better accuracy. Using the predicted type information to rerank the logical forms returned by AgendaIL, one of the leading semantic parsers, we are able to improve the F1-score from 49.7% to 52.6% on the WEBQUESTIONS data.

1 Introduction

Large scale knowledge bases (KB) like Freebase (Bollacker et al., 2008), DBpedia (Auer et al., 2007), and YAGO (Suchanek et al., 2007) that store the world's factual information in a structured fashion have become substantial resources for people to solve questions. KB-based factoid question answering (KB-QA) that attempts to find exact answers to natural language questions has gained much attention recently. KB-QA is a challenging task due to the representation variety between natural language and structural knowledge in KBs.

As one of the promising KB-QA techniques, semantic parsing maps a natural language question into its semantic representation (e.g., logical forms).

Ranking	$F1$	# Improved Qs
AgendaIL	49.7	-
w/ Oracle Types@10	57.3	+234
w/ Oracle Types@20	58.7	+282
w/ Oracle Types@50	60.1	+331
w/ Oracle Types@All	60.5	+345

Table 1: What if the correct answer type is enforced? On WebQuestions, we remove those with incorrect answer types in the top-k logical forms returned by AgendaIL (Berant and Liang, 2015), a leading semantic parsing system, and report the new average F1 score as well as the number of questions with an improved F1 score.

It uses a logical language with predicates closely related to KB schema, and constructs a dictionary that maps relations to KB predicates. The problem then reduces to generating candidate logical forms, ranking them, and selecting one to derive the final answer.

In this work, we propose an answer type prediction model that can improve the ranking of the candidate logical forms generated by semantic parsing. The type of an entity, e.g., `person`, `organization`, `location`, carries very useful information for various down-stream natural language processing tasks such as co-reference resolution (Recasens et al., 2013), knowledge base population (Carlson et al., 2010), relation extraction (Yao et al., 2012), and question answering (Lin et al., 2012). Although the potential clues for answer type from the question has been employed in the recent work AgendaIL (Berant and Liang, 2015) at the lexical level, Table 1 suggests that there is yet a large room for further improvement by explicitly enforc-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 149–159,
Austin, Texas, November 1-5, 2016.

ing answer type. Inspired by this observation, we aim to directly predict the KB type of the answer from the question. In contrast to a small set of predefined types as used in previous answer type prediction methods (e.g., (Li and Roth, 2002)), KBs could have thousands of fine-grained types. Take "When did Shaq come into the NBA?" as a running example. We aim to predict the KB type of its answer as `SportsLeagueDraft`.[1]

The value of typing answers in a fine granularity can be appreciated from two perspectives: (1) Since each entity in a KB like Freebase has a few types, answer type could help prune answer candidates, (2) since each predicate in the KB has a unique type schema, answer type can help rank logical forms.

The key challenge of using answer types to rerank logic forms and hence their corresponding answers, is that it shall be done before the answer is found. Otherwise, there is no need to further infer its type. Inspired by the observation that the answer type of a question is invariant as long as the type of the topic entity (`Shaq`) remains the same (`DraftedAthlete`), we define **abstract question** as the question where the topic entity mention is replaced by its corresponding KB type. For the aforementioned example, the best candidate abstract question is "When did `DraftedAthlete` come into the NBA?" and the answer to this question is `SportsLeagueDraft`. Hence, we can reduce the answer type prediction task to abstract question answering.

The first step in our method is question abstraction, in which we generate candidate abstract questions based on the context of question and its candidate topic entities. We build a bidirectional LSTM network over the question that recursively computes vector representations for the past and future contexts of an entity mention. Based on these context representations, we predict the right type of the entity mention. Next, in order to better utilize the syntactic features of the question, we convert the question form into a normal statement form by using dependency tree of the question. For the running example, after performing the conversion, the abstract question becomes "`DraftedAthlete` come when into the NBA?" We then construct a bidirectional LSTM neural network over this final representation of the question and predict the type of the answer. Using the inferred answer type, we are able to improve the result of AgendaIL (Berant and Liang, 2015) on WebQuestions (Berant et al., 2013) from 49.7% to 52.6%.

[1] KB type of answer ("1992 NBA Draft") in the context.

2 Background

The knowledge base we work with consists of triples in subject-predicate-object form. It can be represented as $\mathcal{K} = \{(e_1, p, e_2) : e_1, e_2 \in \mathcal{E},\ p \in \mathcal{P}\}$, where $\mathcal{E}$ denotes the set of entities (e.g., `ShaquilleOneal`), and $\mathcal{P}$ denotes the set of binary predicates (e.g., `Drafted`). A knowledge base in this format can be visualized as a graph where entities are nodes, and predicates are directed edges between entities. Freebase is used in this work as the knowledge base. It has more than 41M entities, 596M facts, and 24K types.

Types are an integral part of the Freebase schema. Each entity e in Freebase has a set of categories (types) it belongs to, and this information can be obtained by checking the out-going predicates (`Type.Object.Type`) from e. For example, `ShaquilleOneal` has 20 Freebase types including `Person`, `BasketballPlayer`, `DraftedAthlete`, `Celebrity`, and `FilmActor`. For a specific question involving `ShaquilleOneal`, among these types, only a few will be relevant.

Each predicate in Freebase is from a subject entity to an object entity, and has a type signature. It has a unique expected types for its subject and object, independent of the individual subject and object entities themselves. For example, the predicate `People.Person.Profession` expects its subject to be of `Person` type and its object to be of `Profession` type.

3 Question Abstraction

The type of the topic entity rather than the entity itself is essential for inferring the answer type, which is invariant as the topic entity changes within the same class. For example, independent of which NBA player (with `DraftedAthlete` type) is the topic entity of this question "When did Shaq come into the NBA", the type of the answer is always go-

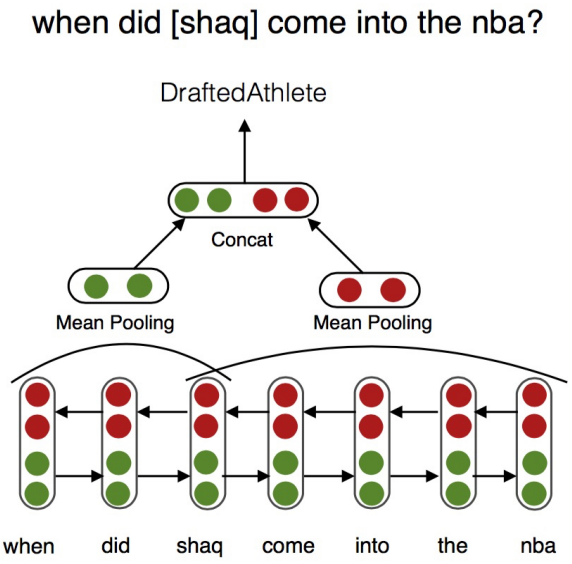

Figure 1: Bi-directional LSTM model for question abstraction. Green circles represent the forward sequence's hidden vectors, while the red circles denote the backward sequence's. `shaq` (the topic entity mention) is the single output node of the network.

ing to be `SportsLeagueDraft` in Freebase. Predicting this distinct type among the large number of candidate types in Freebase is a challenging task. We propose a two-step solution for this problem. In the first step, we compute a confidence score for each possible KB type for a given topic entity using a bidirectional LSTM network. The second step prunes candidate types using the entity type information in Freebase.

3.1 Formulation

Given a natural language question and its topic entity mention, question abstraction is to predict types of the mention in the question context. Formally, let $q = (x_1, x_2, \ldots, x_L)$ denote the question, m be the topic entity mention in q, and $T = \{t_1, t_2, \ldots, t_K\}$ the set of all types in KB. Given q and m, we compute a probability distribution $o \in \mathbb{R}^{K\times 1}$ over T, where o_k denotes the likelihood of t_k being the correct type of m in q.

3.2 Scoring Topic Entity Types with LSTM

Model. We formulate question abstraction as a classification problem. A bidirectional LSTM network is built over q whose output is computed from the nodes that correspond to the words of m. Fig. 1 illustrates the model for the question "When did Shaq come into the NBA?"

Let $u(x) \in \mathbb{R}^{D\times 1}$ denote the vector space embedding of word x. Forward and backward outputs $\overrightarrow{h}_l, \overleftarrow{h}_l \in \mathbb{R}^{D_h\times 1}$ of bidirectional LSTM are recursively computed by

$$\overrightarrow{h}_l, \overrightarrow{c}_l = LSTM(u(x_l), \overrightarrow{h}_{l-1}, \overrightarrow{c}_{l-1}) \quad (1)$$

$$\overleftarrow{h}_l, \overleftarrow{c}_l = LSTM(u(x_l), \overleftarrow{h}_{l+1}, \overleftarrow{c}_{l+1}) \quad (2)$$

as described in Graves (2012), where $\overrightarrow{c_l}, \overleftarrow{c_l} \in \mathbb{R}^{D_h\times 1}$ stand for LSTM cell states.

To encode the context of m to the final output, we apply an AVERAGE pooling layer when computing the output. For each output node $r \in [i, j]$ (i and j correspond to the starting and ending indices of m in q), we compute final forward and backward outputs by

$$\overrightarrow{v_r} = AVG(\overrightarrow{h_1}, \ldots, \overrightarrow{h_r}) \quad (3)$$

$$\overleftarrow{v_r} = AVG(\overleftarrow{h_r}, \ldots, \overleftarrow{h_n}), \quad (4)$$

where AVG stands for average pooling.

We take the average of outputs at each output node

$$\overrightarrow{v} = AVG(\overrightarrow{v_i}, \ldots, \overrightarrow{v_j}) \quad (5)$$

$$\overleftarrow{v} = AVG(\overleftarrow{v_i}, \ldots, \overleftarrow{v_j}) \quad (6)$$

as the forward and backward outputs of the whole network. The final representation v of the network is obtained by concatenating $\overrightarrow{v}$ and $\overleftarrow{v}$.

For question q, the probability distribution o over types is computed by

$$s(q) = W_{hy} v \quad (7)$$

$$o(q) = softmax(s(q)), \quad (8)$$

where $W_{hy} \in \mathbb{R}^{K\times(2D_h)}$ since v is the concatenation of two vectors of dimension D_h, where D_h is the hidden vector dimension.

Objective Function and Learning. Given an input question q with a topic entity mention m, LSTM network computes the probability distribution $o(q) \in \mathbb{R}^{K\times 1}$ as in (8). Let $y(q) \in \mathbb{R}^{K\times 1}$ denote the true target distribution over T for q, where

$y_k(q) = 1/n$ if t_k is a correct type, $y_k(q) = 0$ otherwise, and n is the number of correct types. We use the cross-entropy loss function between $y(q)$ and $o(q)$, and define the objective function over all training data as

$$J(\theta) = -\sum_{q}\sum_{k=1}^{K} y_k(q)\log o_k(q) + \frac{\lambda}{2}\|\theta\|^2,$$

where λ denotes the regularization parameter, and θ represents the set of all model parameters to be learned. We use stochastic gradient descent with RMSProp (Tieleman and Hinton, 2012) for minimizing the objective function.

3.3 Pruning

Let T_e represent the set of KB types for entity e. We define the set of candidate types for entity mention m as

$$C_m = \bigcup_e T_e,$$

where e is a possible match of m in KB. We only need to score the types in C_m. Once the hidden representation v is computed by LSTM, we use submatrix $W_{hy}[C_m]$ that consists of rows of W_{hy} corresponding to the types in C_m as the scoring matrix in (7). This returns the final scores for candidate types in C_m.

4 Conversion to Statement Form

The objective of the conversion is to canonicalize question form into declarative statement (subject-relation-object) form. We use a simple pattern-based method that relies on dependency tree[2] (Manning et al., 2014). It decides whether the sub-trees of the root need reordering based on their dependency relations[3].

Before obtaining the dependency tree, we retrieve named entity (NER) tags of the question tokens. We replace a group of question tokens corresponding a named entity with a special token, ENTITY, to simplify the parse tree. In Figure 2, the question is first transformed to "what boarding school did ENTITY go to?" Each question is represented by the root's

[2]We use Stanford CoreNLP dependency parser

Table 2: Top-5 most common patterns with mappings.

dependency relations to its sub-trees in the original order, e.g., (dep, aux, nsubj, nmod). We cluster all these sequences and detect the patterns that appear at least 5 times in the training data. These patterns are then manually mapped to their corresponding conversion (pattern vs. mapping in Figure 2).

Once the recomposition order of the sub-trees is determined by the conversion mapping, we finalize the reordering of the question tokens by keeping the order of words within the sub-trees same as the original order in the question. The example in Figure 2 becomes "ENTITY go to what boarding school" with its corresponding sub-tree conversion mapping (nsubj, root, nmod, dep). If no mapping is created for a pattern, we keep the order of the words exactly as they occur in the original question form.

The motivation behind conversion is to overcome the potential semantic confusion stemming from varities in syntactic structures. To exemplify, consider two hypothetical questions "who plays X in

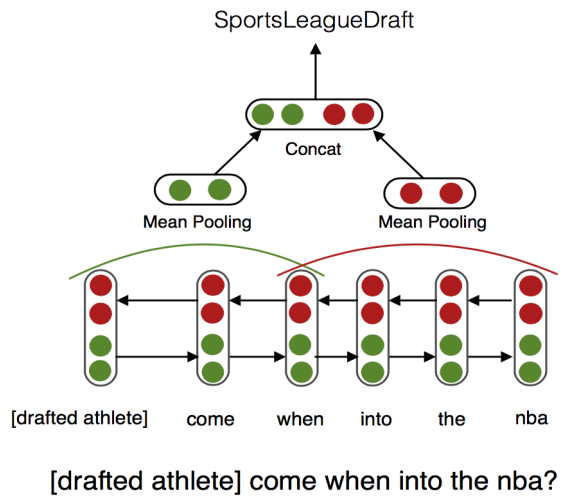

Figure 3: Bi-directional LSTM model over the final representation of the question. Green and red circles are corresponding to forward and backward hidden vectors, respectively. The output node is `when`.

Y?" and "who does Z play in Y?", where X is a `FilmCharacter`, Y is a `Film`, and Z is a `FilmActor`, with answer types `FilmActor` and `FilmCharacter`, respectively. With conversion, we aim to transform second question into "Z play who in Y", while leaving the first one as it is. Noting that the order of words affects the output of our answer type inference network, our intuition is to let the model distinguish better between such questions using their syntactic structure in this way.

5 Answer Type Prediction

Given a reordered question with topic entity mention m, and a topic entity type $t_e \in T$, our task is to predict a probability distribution $o \in \mathbb{R}^{K\times 1}$ over the answer types.

A topic entity type $t_e \in T$ is described as a set of words, $\{x_i\}$. Let $u(x_i) \in \mathbb{R}^{D\times 1}$ represent the vector space embedding of x_i, the representation of t_e is computed by the average encoding,

$$u(t_e) = \frac{1}{|\{x_i\}|}\sum_{x_i} u(x_i). \quad (9)$$

As the first step, we replace the words of entity mention m with topic entity type t_e, and obtain a new input word sequence r. t_e is treated as one word and encoded by Eq. 9. We construct a bidirectional LSTM network over this input sequence r, whose output node corresponds to the question word. The output of the network is a probability distribution over types denoting the likelihood of being the answer type. Figure 3 shows how the network is constructed for the running example. The same average pooling described in Section 3.2 is applied to obtain the final forward and backward output vectors $\overrightarrow{v}$ and $\overleftarrow{v}$ from the output node (this time, single output node) of network. The final output vector v for prediction is obtained by concatenating $\overrightarrow{v}$, and $\overleftarrow{v}$. The distribution o is computed by a standard softmax layer. The learning is performed by the same cross-entropy loss and objective function described in Section 3.2.

6 Reranking by Answer Type

In this section, we describe how to rerank logical forms based on our answer type prediction model.

Reranking Model. Let $l_1, l_2, \ldots, l_N$ be the logical forms generated for question q by a semantic parser, e.g., AgendaIL. Each logical form has a score from the semantic parser. Meanwhile, our answer type prediction model generates a score for the answer type of each logical form. Therefore, we can represent each logical form l_i using a pair of scores: the score from semantic parser and the score from our type prediction model. Suppose we know which logical forms are "correct", using the two scores as input, we train a logistic regression model with cross-entropy loss to learn a binary classifier for predicting the correct logical forms. We rerank the top-k logical forms using their probability computed by the trained logistic regression model, and select the one with the highest probability. Finally, we run the selected logical form against KB to retrieve the answer. We select the optimal value of k from $[1, N]$ using the training data. For AgendaIL on WebQuestions, we find that $k = 80$ gives the best result.

Training Data Selection. We now discuss which logical forms are "correct", i.e., how to select the positive examples to train the logistic regression model. Because a question can have more than one answer, we use the $F1$ score, the harmonic mean of *precision* and *recall*, to evaluate logical forms. We select all the logical forms with $F1 > 0$ as the set of positive examples. However, taking all the logical forms with $F1 = 0$ as negative examples will

not work well. Even though the $F1$ score of a logical form is 0, its answer type could still be correct. Therefore, we use the following trick: If there is a positive example with answer type t, we do not treat any other logical form with answer type t as negative example. The logical forms having $F1 = 0$, with the aforementioned exception, are then selected as the final set of negative examples. Our empirical study shows this trick works well.

7 Experiments

In this section, we describe the datasets, model training, and experimental results.

7.1 Dataset and Evaluation Metrics

Datasets. To evaluate our method, we use the WebQuestions dataset (Berant et al., 2013), which contains 5,810 questions crawled via Google Suggest API. The answers to these questions are annotated from Freebase using Amazon Mechanical Turk. The data is split into training and test sets of size 3,778 and 2,032 questions, respectively. This dataset has been popularly used in question answering and semantic parsing.

The SimpleQuestions (Bordes et al., 2015) contains 108,442 questions written in natural language by English-speaking human annotators. This dataset is a collection of question/Freebase-fact pairs rather than question/answer pairs. The data[4] is split and provided as training(75,910), test(21,687), and validation(10,845) sets. Each question is mapped to the subject, relation, and object of the corresponding Freebase fact. This dataset is only used for training the question abstraction model.

Training Data Preparation. Since WebQuestions only provides question-answer pairs along with annotated topic entities, we need to figure out the type information, which can be used as training data. We obtain *simulated* types as follows: We retrieve 1-hop and 2-hop predicates r from/to annotated topic entity e in Freebase. For each relation r, we query $(e, r, ?)$ and $(?, r, e)$ against Freebase and retrieve the candidate answers r_a. The $F1$ value of each candidate answer r_a is computed with respect to the annotated answer. The subject and object types of the relation r with the highest $F1$ value is selected as the *simulated* type for the topic entity and the answer. When there are multiple such relations, we obtain multiple *simulated* types for topic entity and answer, one from each relation. We treat each of them as correct with equal probability.

Candidate Logical Forms for Evaluation. To obtain candidate logical forms, we train AgendaIL (Berant and Liang, 2015) on WebQuestions with beam size 200 using the publicly available code[5] by the authors.

Evaluation Metric. We report average $F1$ score of the reranked logical forms using the predicted answer types as the main evaluation metric. It is a common performance measure in question answering as questions might have multiple answers.

7.2 Experimental Setup

We use 50 dimensional word embeddings, which are initialized by the 50 dimensional pre-trained word vectors[6] from GloVe (Pennington et al., 2014), and updated in the training process. Hyperparameters are tuned on the development set. The size of the LSTM hidden layer is set at 50. We use RMSProp (Tieleman and Hinton, 2012) with a learning rate of 0.005 and mini-batch size of 32 for the optimization. We use a dropout layer with probability 0.5 for regularization. We implemented the LSTM networks using *Theano* (Theano Development Team, 2016).

Identifying Topic Entity. We use Stanford NER tagger (Manning et al., 2014) to identify topic entity span for both training and test data. For entity linking, annotated mention span is mapped to a ranked list of candidate Freebase entities using Freebase Search API for the test data. For the training data, we use the gold Freebase topic entity linkings of each question provided by WebQuestions, coming from its question generation process.

Question Abstraction. We first pre-train the LSTM model described in Section 3.2 on the SimpleQuestions dataset. Then, we update the pre-trained model on the training portion of WebQuestions data where the *simulated* topic entity types are used as true labels. We use the detected topic entity mentions to obtain candidate matching entities in the KB using Freebase Search API. We use top-

Answer Type Prediction. We train *Answer Type Prediction* model using the *simulated* topic entity and answer types for each question. We perform the answer type prediction on test data using the predicted topic entity type.

7.3 Results

Our main result is presented in Table 3. Our system adds 2.9% absolute improvement over AgendaIL, and achieves 52.6% in $F1$ measure. Yih et al. (2015) achieve 52.5% by leveraging ClueWeb and S-MART (Yang and Chang, 2015), an advanced entity linking system. Xu et al. (2016) achieve 53.3% by leveraging Wikipedia and S-MART. If tested without Clueweb/Wikipedia/S-MART, their F1 scores are 48.4% and 47.1%, respectively. When our method is tested without using SimpleQuestions data for pretraining question abstraction module, it attains F1 score of 51.6%.

In Table 4, we present some question examples where our method can select a better logical form. Take the question "who did [australia] fight in the first world war?" as an example. Our topic entity type prediction module returns `MilitaryCombatant`, `StatisticalRegion`, and `Kingdom` as the top-3 results for the type of "australia" in this question, which indicates that it exploits the context of this short question successfully. The abstract question is "[military combatant] fight who in the first world war?" for which our system returns `MilitaryCombatant`, `MilitaryConflict`, and `MilitaryCommander` as answer types with probabilities 0.73, 0.25, and 0.005, respectively, `MilitaryCombatant` is indeed the right answer type. This example shows the effect of abstraction in channeling the context in the most relevant direction to find the right answer type. In Table 5, we provide a comparison of the selected logical forms based on AgendaIL rankings and our rankings.

Method	F1	Gain	Loss
Base	50.3	69	47
Base + Conv	50.5	96	56
Base + Abs	52.2	184	87
Base + Abs + Conv	52.6	203	93
AgendaIL	49.7	-	-

Table 6: Ablation analysis of modules of our method. Gain/Loss columns denote the number of questions where the F1 score of our selected logical form is greater/less than that of the top ranked logical forms from AgendaIL.

7.4 Ablation Analysis

In this section, we evaluate the effect of individual components of our model. Note that the answer type prediction model described in Section 5 can work independently from question abstraction and form conversion. We develop the following variants i) Base, ii) Base + Conversion, iii) Base + Abstraction, iv) Base + Abstraction + Conversion, where Base corresponds to a model that infers answer types without employing abstraction or form conversion. We train/test each variant separately. Table 6 shows each component contributes and question abstraction does help boost the performance.

Suppose we perform answer type prediction without question abstraction, and feed "[australia] fight who in the first world war?" into the answer type prediction model (Base + Conversion). The predicted answer type is `Location`. Unfortunately, there is neither a 1-hop or 2-hop correct relation from/to `Australia` with the expected type `Location` nor a correct (with positive $F1$) candi-

Question	Topic Entity Type Prediction	Answer Type Prediction	AgendaIL Answer Type	F1 Gain
who inspired **obama**?	InfluenceNode	InfluenceNode	UsVicePresident	1.0
what are some books that **mark twain** wrote?	Author	WrittenWork	InfluenceNode	0.3
who won the **league cup** in 2002?	SportsAwardType	SportsAwardWinner	SportsLeagueSeason	1.0
what type of government does **france** use?	Country	FormOfGovernment	Government	1.0
where are the **new orleans hornets** moving to?	SportsTeam	SportsFacility	Location	1.0
who did **australia** fight in the first world war?	MilitaryCombatant	MilitaryCombatant	MilitaryCommander	0.4

what country does **rafael nadal** play for?	Athlete	Country	OlympicDiscipline	1.0

Table 4: Example questions where our type prediction helps select a better logical form. The F1 gain shows the difference between the F1 score of the logical form we select and the top ranked logical form from AgendaIL.

Questions and Selected Logical Forms
1. what are some books that **mark twain** wrote? AgendaIL: (MarkTwain - Influence.InfluenceNode.InfluencedBy - ?) Ours: (MarkTwain - Book.Author.WorksWritten - ?)
2. what guitar does **corey taylor** play? AgendaIL: (? - Organization.Organization.Founders - CoreyTaylor) Ours: (CoreyTaylor - Music.GroupMember.InstrumentsPlayed - ?)
3. what type of government does **france** use? AgendaIL: (France - Government.GovernmentalJurisdiction.Government - ?) Ours: (France - Location.Country.FormOfGovernment - ?)

Table 5: Comparison of selected logical forms for some examples. Logical forms are simplified and canonicalized into (subject - predicate - object) format for better readability, where ? corresponds to answer nodes.

date logical form with the answer type Location. This shows that through question abstraction, a better logical form is selected for this question.

To exemplify another benefit of question abstraction, consider the question "where does [marta] play soccer?" The top 3 entity linkings via Freebase Search API for "marta" are MetropolitanAtlantaRapidTransitAuthority, Marta, and SantaMarta, where the correct entity is the second one. Our question abstraction system returns FootballPlayer as the top topic entity type prediction that is indeed corresponding to the correct entity. Utilizing the context via question abstraction we are able to recover useful information when the entity linking is uncertain.

Table 6 also shows that the conversion to statement form also helps, especially together with *Abstraction*. In the above example, the model without *Conversion* (Base + Abs) predicts the answer type for "where does [football player] play soccer" as SportsFacility, whereas the full model, considering Conversion as well, finds the answer type for "[football player] play soccer where" as SportsTeam which is the better type in this case.

7.5 Error Analysis

We present a further analysis of our approach by classifying the type inference errors made on randomly sampled 100 questions. 9% of the errors are due to inference at incorrect granularity (e.g., City instead of Location). 12% of the errors are the result of incorrect answer labels (hence incorrect answer types) or question ambiguity (e.g., "where is dwight howard now?"). 11% of them are incorrect, but acceptable inferences, e.g., BookWrittenWork instead of BookEdition for question "what dawkins book to read first?" 39% of the errors are due to the sparsity problem: They are made on questions whose answer type appears less than 5 times in the training data (e.g., DayOfYear). The remaining 29% of them are due to incorrect question abstraction. In most of the question abstraction errors, the predicted topic entity type is semantically close to the correct type. In other cases such as "what did joey jordison play in slipknot?" where we predict FilmActor as the topic entity type while Musician is the correct one. In these cases, the answer type inference is not able to correct the abstraction error. These 29% of errors also contain the entity linking errors.

8 Related Work

Freebase QA has been studied from two different perspectives: grounded QA systems that work directly on KBs and general purpose ungrounded QA systems. Kwiatkowski et al. (2013) generates KB agnostic intermediary CCG parses of questions which are grounded afterwards given a KB. Bordes et al. (2014) uses a vector space embedding approach to measure the semantic similarity between question and answers. Yao and Van Durme (2014), Bast and Haussmann (2015) and Yih et al. (2015) exploit a graph centric approach where a grounded subgraph query is generated from question and then executed against a KB. In this work, we propose a neural answer type inference method that can be incorporated in existing grounded semantic parsers as a complementary feature to improve ranking of the candidate logical forms.

Berant and Liang (2015) uses lambda DCS logical language with predicates from Freebase. In their approach, types are included as a part of unary lexicon for building the logical forms from natural language questions. However, no explicit type inference is exploited. We show that such information could indeed be useful for selecting logical forms.

There have been a series of studies investigating the expected answer type of a question in different contexts such as Li and Roth (2002), Lally et al. (2012), and Balog and Neumayer (2012). Most of these approaches classify the questions into a small set of types. Even when the set of classes is more fine-grained, e.g., 50 classes in Li and Roth (2002), they cannot be used for our purpose as it would require nontrivial mapping between these categories and a much larger number of KB types. Furthermore, these methods often rely on a rich set of hand crafted features and external resources.

Sun et al. (2015) uses Freebase types to learn the relevance of candidate answers to a given question via an association model. Their model directly ranks the answer candidates by utilizing types, whereas ours ranks the logical forms via predicting answer type. In this sense, we are able to take advantage of both logical form and type inference. Su et al. (2015) exploits answer typing to facilitate knowledge graph search, but their input is graph query instead of natural language question. They predict answer types using additional relevance feedback for graph queries, while our algorithm directly infers answer types from input questions. On the question abstraction side, our work is related to a recent study (Dong et al., 2015a) which classifies entity mentions into 22 types derived from DBpedia. They use a multilayer perceptron over a fixed size window and a recurrent neural network for the representations of context and entity mention, respectively. Instead, we use a bidirectional LSTM network to exploit the full context more flexibly.

9 Conclusion

In this paper, we present a question answer type inference framework and leverage it to improve semantic parsing. We define the notion of abstract question as the class of questions that can be answered by type instead of entity. Question answer type inference is then reduced to "question abstraction" and "abstract question answering", both of which are formulated as classification problems. Question abstraction is performed by exploiting the topic entity and its context in question via an LSTM network . A separate neural network is trained to exploit the abstraction to make the final question answer type inference. Our method improves the ranking of logical forms returned by AgendaIL on the WEBQUESTIONS dataset. In the future, we would like to investigate how the abstraction and explicit type inference can be incorporated in the early stage of semantic parsing for generating better candidate logical forms.

Semantic Parsing to Probabilistic Programs for Situated Question Answering

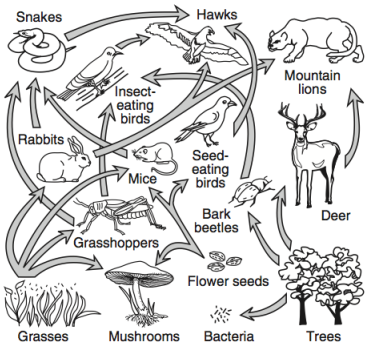
Abstract

Situated question answering is the problem of answering questions about an environment such as an image or diagram. This problem requires jointly interpreting a question and an environment using background knowledge to select the correct answer. We present Parsing to Probabilistic Programs (P^3), a novel situated question answering model that can use background knowledge and global features of the question/environment interpretation while retaining efficient approximate inference. Our key insight is to treat semantic parses as probabilistic programs that execute nondeterministically and whose possible executions represent environmental uncertainty. We evaluate our approach on a new, publicly-released data set of 5000 science diagram questions, outperforming several competitive classical and neural baselines.

1 Introduction

Situated question answering is a challenging problem that requires reasoning about uncertain interpretations of both a question and an environment together with background knowledge to determine the answer. To illustrate these challenges, consider the 8th grade science diagram questions in Figure 1, which are motivated by the Aristo project (Clark and Etzioni, 2016). These questions require both computer vision to interpret the diagram and compositional question understanding. These components, being imperfect, introduce uncertainty that must be jointly reasoned about to avoid implausible interpretations. These uncertain interpretations must further be combined with background knowledge, such as the definition of a "predator," to determine the correct answer.



1. According to the given food chain, what is the number of organisms that eat deer? (A) 3 (B) 2 (C) 4 **(D) 1**

2. Which organism is both predator and prey? (A) Bark Beetles **(B) Insect-eating birds** (C) Deer (D) Hawks

3. Based on the given food web, what would happen if there were no insect-eating birds? **(A) The grasshopper population would increase.** (B) The grasshopper population would decrease. (C) There would be no change in grasshopper number.

Figure 1: Example food web questions. A food web depicts a collection of organisms in an ecosystem with an arrow from organism x to y indicating that y eats x. Questions may require counting (1), knowing animal roles (2) and reasoning about population changes (3).

The challenges of situated question answering have not been completely addressed by prior work. Early "possible worlds" models (Matuszek et al., 2012; Krishnamurthy and Kollar, 2013; Malinowski and Fritz, 2014) were capable of compositional question understanding and using background knowledge, but did not jointly reason about environ-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 160–170,
Austin, Texas, November 1-5, 2016.

ment/question uncertainty. These models also used unscalable inference algorithms for reasoning about the environment, despite the lack of joint reasoning. More recent neural models (Antol et al., 2015; Malinowski et al., 2015; Yang et al., 2015) are incapable of using background knowledge and it remains unclear to what extent these models can represent compositionality in language.

We present Parsing to Probabilistic Programs (P^3), a novel approach to situated question answering that addresses these challenges. It is motivated by two observations: (1) situated question answering can be formulated as semantic parsing with an execution model that is a *learned function of the environment*, and (2) *probabilistic programming* is a natural and powerful method for specifying the space of permissible execution models and learning over it. In P^3, we define a domain theory for the task as a probabilistic program, then train a joint loglinear model to semantically parse questions to logical forms in this theory and execute them in an environment. Importantly, the model includes global features over parsing and execution that enable it to avoid unlikely joint configurations. P^3 leverages semantic parsing to represent compositionality in language and probabilistic programming to specify background knowledge and perform linear-time approximate inference over the environment.

We present an experimental evaluation of P^3 on a new data set of 5000 food web diagram questions (Figure 1). We compare our approach to several baselines, including possible worlds and neural network approaches, finding that P^3 outperforms both. An ablation study demonstrates that global features help the model achieve high accuracy. We also demonstrate that P^3 improves accuracy on a previously published data set. Finally, we have released our data and code to facilitate further research.

2 Prior Work

Situated question answering is often formulated in terms of parsing both the question and environment into a common meaning representation where they can be combined to select the answer. This general approach has been implemented using different meaning representations:

Possible world models use a logical meaning representation defined by a knowledge base schema. These models train a semantic parser to map questions to queries and an environment model to map environments to knowledge bases in this schema. Executing the queries against the knowledge bases produces answers. These models assume that the parser and environment model are independent and furthermore that the knowledge base consists of independent predicate instances (Matuszek et al., 2012; Krishnamurthy and Kollar, 2013; Malinowski and Fritz, 2014). Despite these strong independence assumptions, these models have intractable inference. An exception is Seo et al., (2015) who incorporate hard constraints on the joint question/environment interpretation; however, this approach does not generalize to soft constraints or arbitrary logical forms. In some work only the environment model is learned (Kollar et al., 2010; Tellex et al., 2011; Howard et al., 2014b; Howard et al., 2014a; Berant et al., 2014; Krishnamurthy and Mitchell, 2015).

Neural networks use a vector meaning representation that encodes both the question and environment as vectors. These networks have mostly been applied to visual question answering (Antol et al., 2015), where many architectures have been proposed (Malinowski et al., 2015; Yang et al., 2015; Fukui et al., 2016). It is unclear to what extent these networks can represent compositionality in language using their vector encodings. Dynamic Neural Module Networks (Andreas et al., 2016a; Andreas et al., 2016b) are the exception to the above generalization. This approach constructs a neural network to represent the meaning of the question via semantic parsing, then executes this network against the image to produce an answer. Our approach is similar except that we construct and execute a probabilistic program. Advantages of our approach are that it naturally represents the discrete structure of food webs and can use background knowledge.

Preliminaries for our work are semantic parsing and probabilistic programming. Semantic parsing translates natural language questions into executable logical forms and has been used in applications such as question answering against a knowledge base (Zelle and Mooney, 1993; Zettlemoyer and Collins, 2005; Liang et al., 2011; Kwiatkowski et al., 2013; Berant et al., 2013; Reddy et al., 2014; Yih et al., 2015; Xu et al., 2016), direction following

(Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013), and information extraction (Krishnamurthy and Mitchell, 2012; Choi et al., 2015). Semantic parsing alone is insufficient for situated question answering because it does not interpret the environment; many of the above approaches use semantic parsing as a component in a larger model.

Probabilistic programming languages extend programming languages with primitives for nondeterministic choice (McCarthy, 1963; Goodman and Stuhlmüller, 2014). We express logical forms in a probabilistic variant of Scheme similar to Church (Goodman et al., 2008); however, this paper uses Python-like pseudocode for clarity. The language has a single choice primitive called `choose` that nondeterministically returns one of its arguments. For example `choose(1,2,3)` can execute three ways, returning either 1, 2, or 3. Multiple calls to `choose` can be combined. For example, `choose(1,2)+choose(1,2)` adds two nondeterministically chosen values, and therefore has four executions that return 2, 3, 3 and 4. Each execution also has a probability; in our case, these probabilities are assigned by a trained model given the environment and not explicitly specified in the program.

3 Parsing to Probabilistic Programs (P^3)

The P^3 model is motivated by two observations. The first is that situated question answering can be formulated as semantic parsing with an execution model that is a learned function of the environment. Consider the first question in Figure 1. The meaning of this question could be represented by a logical form such as $\text{COUNT}(\lambda x.\text{EATS}(x, \text{DEER}))$, which we could train a semantic parser to predict given a suitable *domain theory* of functions such as COUNT and EATS. However, the information required to execute this logical form and answer the question must be extracted from the diagram. Specifically, $\text{EATS}(x, y)$ depends on whether an arrow is present between x and y, which we must train a vision model to determine. Thus, EATS should be a *learned function of the environment*.

This first observation suggests a need for a formalism for representing uncertainty and performing learning over the domain theory's functions. Our second observation is that probabilistic programming is a natural fit for this task. In this paradigm, the domain theory is a probabilistic program that defines the information to be extracted from the environment by using `choose`. To a first approximation, the diagram question theory includes:

```
def eats(x, y)
  choose(true, false)
```

Logical forms are then probabilistic programs, each of whose possible executions represents a different interpretation of the environment. For example, executing $\text{EATS}(\text{LION}, \text{DEER})$ hits the `choose` in the above definition, resulting in two executions where the lion either eats or does not eat the deer. In the COUNT example above, each execution represents a different set of animals that eat the deer. To learn the correct environment interpretation, we train an execution model to assign a probability to each execution given features of the environment. Using probabilistic programming enables us to combine learned functions, such as EATS, with background knowledge functions, such as COUNT, and also facilitates inference.

According to these observations, applying P^3 has two steps. The first step is to define an appropriate domain theory. This theory is the main design decision in instantiating P^3 and provides a powerful way to encode domain knowledge. The second step is to train a loglinear model consisting of a semantic parser and an execution model. This model learns to semantically parse questions into logical forms in the theory and execute them in the environment to answer questions correctly. We defer discussion of the diagram question domain theory to Section 4 and focus on the loglinear model in this section.

3.1 Model Overview

The input to the P^3 model is a question and an environment and its output is a denotation, which is a formal answer to the question. P^3 is a loglinear model with two factors: a semantic parser and an execution model. The semantic parser scores syntactic parses and logical forms for the question. These logical forms are probabilistic programs with multiple possible executions (specified by the domain theory), each of which may return a different denotation. The execution model assigns a score to each of these executions given the environment. Formally,

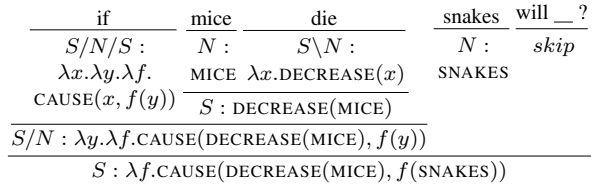


Figure 2: Example CCG parse of a question as predicted by the semantic parser f_{p}. The logical form ℓ for the question is shown on the bottom line.

the model predicts a denotation γ for a question q in an environment v using three latent variables:

$$P(\gamma|v,q;\theta) = \sum_{e,\ell,t} P(e,\ell,t|v,q;\theta)\mathbf{1}(\text{ret}(e)=\gamma)$$

$$P(e,\ell,t|v,q;\theta) = \frac{1}{Z_{q,v}} f_{\text{ex}}(e,\ell,v;\theta_{\text{ex}}) f_{\text{p}}(\ell,t,q;\theta_{\text{p}})$$

The model is composed of two factors. f_{p} represents the semantic parser that scores logical forms ℓ and syntactic parse trees t given question q and parameters θ_{p}. f_{ex} represents the execution model. Given parameters θ_{ex}, this factor assigns a score to a logical form ℓ and its execution e in environment v. The denotation γ, i.e., the formal answer to the question, is simply the value returned by e. $Z_{q,v}$ represents the model's partition function. The following sections describe these factors in more detail.

3.2 Semantic Parser

The factor f_{p} represents a Combinatory Categorial Grammar (CCG) semantic parser (Zettlemoyer and Collins, 2005) that scores logical forms for a question. Given a lexicon[1] mapping words to syntactic categories and logical forms, CCG defines a set of possible syntactic parses t and logical forms ℓ for a question q. Figure 3.2 shows an example CCG parse. f_{p} is a loglinear model over parses (ℓ, t):

$$f_{\text{p}}(\ell,t,q;\theta_{\text{p}}) = \exp\{\theta_{\text{p}}^T \phi(\ell,t,q)\}$$

The function ϕ maps parses to feature vectors. We use a rich set of features similar to those for syntactic CCG parsing (Clark and Curran, 2007); a full description is provided in an online appendix.

3.3 Execution Model

The factor f_{ex} is a loglinear model over the executions of a logical form given an environment. Logical forms in P^3 are probabilistic programs with a *set* of possible executions, where each execution e is a sequence, $e = [e_0, e_1, e_2, ..., e_n]$. e_0 is the program's starting state, e_i represents the state immediately after the ith call to `choose`, and e_n is the state at termination. The score of an execution is:

$$f_{\text{ex}}(e,\ell,v;\theta_{\text{ex}}) = \prod_{i=1}^{n} \exp\{\theta_{\text{ex}}^T \phi(e_{i-1}, e_i, \ell, v)\}$$

In the above equation, θ_{ex} represents the model's parameters and ϕ represents a feature function that produces a feature vector for the difference between sequential program states e_{i-1} and e_i given environment v and logical form ℓ. ϕ can include arbitrary features of the execution, logical form and environment, which is important, for example, to detect cycles in a food web (Section 4.3).

3.4 Inference

P^3 is designed to rely on approximate inference: our goal is to use rich features to accurately make local decisions, as in linear-time parsers (Nivre et al., 2006). We perform approximate inference using a two-stage beam search. Given a question q, the first stage performs a beam search over CCG parses to produce a list of logical forms scored by f_{p}. This step is performed by using a CKY-style chart parsing algorithm then marginalizing out the syntactic parses. The second stage performs a beam search over executions of each logical form. The space of possible executions of a logical form is a tree (Figure 4.2) where each internal node represents a partial execution up to a `choose` call. The search maintains a beam of partial executions at the same depth, and each iteration advances the beam to the next depth, discarding the lowest-scoring executions according to f_{ex} to maintain a fixed size beam. This procedure runs in time linear to the number of `choose` calls. We implement the search by rewriting the probabilistic program into continuation-passing style, which allows `choose` to be implemented as a function that adds multiple continuations to the search queue; we refer the reader to Goodman and Stuhlmüller (2014) for details. Our experiments use a beam size of 100 in the semantic parser, executing each of the 10 highest-scoring logical forms with a beam of 100 executions.

[1] In our experiments, we automatically learn the lexicon in a preprocessing step. See Section 5.2 for details.

3.5 Training

P^3 is trained by maximizing loglikelihood with stochastic gradient ascent. The training data $\{(q^i, v^i, c^i)\}_{i=1}^n$ is a collection of questions q^i and environments v^i paired with *supervision oracles* c^i. $c^i(e) = 1$ for a correct execution e and $c^i(e) = 0$ otherwise. The oracle c^i can implement various kinds of supervision, including: (1) labeled denotations, by verifying the value returned by e and (2) labeled environments, by verifying each choice made by e. The oracle for diagram question answering combines both forms of supervision (Section 4.5).

The objective function O is the loglikelihood of predicting a correct execution:

$$O(\theta) = \sum_{i=1}^{n} \log \sum_{e,l,t} c^i(e) P(e, \ell, t | q^i, v^i; \theta)$$

We optimize this objective function using stochastic gradient ascent, using the approximate inference algorithm from Section 3.4 to estimate the necessary marginals. When computing the marginal distribution over correct executions, we filter each step of the beam search using the supervision oracle c^i to improve the approximation.

4 Diagram Question Answering with P^3

As a case study, we apply P^3 to the task of answering food web diagram questions from an 8th grade science domain. A few steps are required to apply P^3. First, we create a domain theory of food webs that represents extracted information from the diagram and background knowledge for the domain. Second, we define the features of the execution model that are used to learn how programs in the domain theory execute given a diagram. Third, we define a component to select a multiple-choice answer given a denotation. Finally, we define the supervision oracle used for training.

4.1 Food Web Diagram Questions

We consider the task of answering food web diagram questions. The input consists of a diagram depicting a food web, a natural language question and a list of natural language answer options (Figure 1). The goal is to select the correct answer option. This task has many regularities that require global features: for example, food webs are usually acyclic and certain animals usually have certain roles (e.g., mice are herbivores). We have collected and released a data set for this task (Section 5.1).

We preprocess the diagrams in the data set using a computer vision system that identifies candidate diagram elements (Kembhavi et al., 2016). This system extracts a collection of text labels (via OCR), arrows, arrowheads and objects, each with corresponding scores. It also extracts a collection of scored linkages between these elements. These extractions are noisy and contain many discrepancies such as overlapping text labels and spurious linkages. We use these extractions to define a set of candidate organisms (using the text labels), and also to define features of the execution model.

4.2 Domain Theory

The domain theory is a probabilistic program encoding the information to extract from the environment as well as background knowledge about food webs. It represents the structure of a food web using two functions. These functions are predicates that invoke `choose` to return either true or false. The execution model learns to predict which of these values is correct for each set of arguments given the diagram. It furthermore has a collection of deterministic functions that encode domain knowledge, including definitions of animal roles such as HERBIVORE and a model of population change causation.

Figure 4.2 shows pseudocode for a portion of the domain theory. Food webs are represented using two functions over the extracted text labels: ORGANISM(x) indicates whether the label x is an organism (as opposed to, e.g., the diagram title); and EATS(x, y). The definitions of these functions invoke `choose` while remembering previously chosen values to avoid double counting probabilities when executing logical forms such as ORGANISM(DEER) $\wedge$ ORGANISM(DEER). The remembered values are stored in a global variable that is also used to implement the supervision oracle. Deterministic functions such as CAUSE are defined in terms of these learned functions.

The uses of `choose` in the domain theory create a tree of possible executions for every logical form. Figure 4.2 illustrates this tree for the logical form λf.CAUSE(DECREASE(MICE), f(SNAKES)), which

```
# initialize predicate instance variables
# from text labels in environment
world = {"mice": undef,
         ("mice", "snakes"): undef, ...}
def organism(name)
  if (world[name] == undef)
    world[name] = choose(true, false)
  return world[name]

def eats(x, y)
  # same as organism but with pairs.

# entities referenced in the logical form
# must be organisms. choose() represents
# failure; it returns no values.
def getOrganism(x)
  if (organism(x)) return x else choose()

# change events are direction/
# text label tuples
def decrease(x)
  return ("decrease", x)

def cause(e1, e2)
  e12 = eats(e1[1], e2[1])
  e21 = eats(e2[1], e1[1])
  # deterministic model with cases. e.g.
  # if eats(y, x) then (cause (decrease x)
  # (decrease y)) -> true
  return doCause(e1[0], e2[0], e12, e21)
```

Figure 3: Domain theory pseudocode for diagram question answering.

corresponds to the question "what happens to the snakes when the mice decrease?" This logical form is shorthand for the following program:

```
filter(lambda f.cause(
    decrease(getOrganism("mice")),
    f(getOrganism("snakes"))),
  set(decrease, increase, unchanged))
```

Specifically, entities such as MICE are created by calling `getOrganism` and logical forms with functional types implicitly represent filters over the appropriate argument type. Executing this program first applies the filter predicate to `decrease`. Next, it evaluates `getOrganism("mice")`, which calls `organism` and encounters the first call to `choose`. This call is shown as the first branch of the tree in Figure 4.2. The successful branch proceeds to evaluate `getOrganism("snakes")`, shown as the second branch. Finally, the successful branch evaluates `cause`, which calls `eats` twice, resulting in the final two branches. The value returned by each branch is determined by the causation model which performs

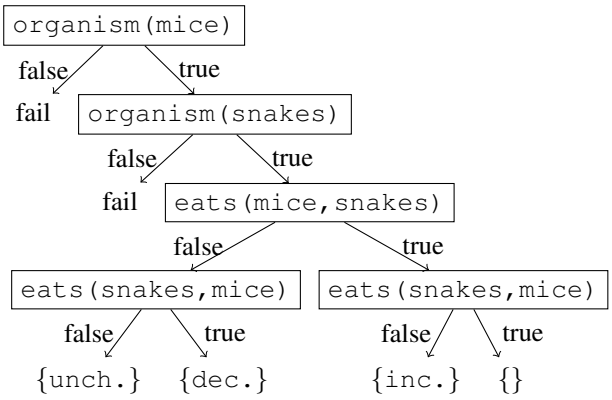

Figure 4: Tree of possible executions for the logical form $\lambda f.\text{CAUSE}(\text{DECREASE}(\text{MICE}), f(\text{SNAKES}))$. Each path from root to leaf represents a single execution that returns the indicated denotation or fails, and each internal node represents a nondeterministic choice made with `choose`.

some deterministic logic on the truth values of the two eats relations.

4.3 Execution Features

The execution model uses three sets of features: instance features, predicate features, and denotation features. Instance features treat each predicate instance independently, while the remainder are global features of multiple predicate instances and the logical form. We provide a complete listing of features in an online appendix.

Instance features fire whenever an execution chooses a truth value for a predicate instance. These features are similar to the per-predicate-instance features used in prior work to produce a distribution over possible worlds. For $\text{ORGANISM}(x)$, our features are the vision model's extraction score for x and indicator features for the number of tokens in x. For $\text{EATS}(x, y)$, our features are various combinations of the vision model's scores for arrows that may connect the text labels x and y.

Predicate features fire based on the global assignment of truth values to all instances of a single predicate. The features for ORGANISM count occurrences of overlapping text labels among true instances. The features for EATS include cycle count features for various cycle lengths and arrow reuse features. The cycle count features help the model learn that food webs are typically, but not always, acyclic and the arrow reuse features aim to prevent the model from predicting two different EATS instances on the basis of a single arrow.

Denotation features fire on the return value of an execution. There are two kinds of denotation features: size features that count the number of entities in denotations of various types and denotation element features for specific logical forms. The second kind of feature can be used to learn that the denotation of $\lambda x.\text{HERBIVORE}(x)$ is likely to contain MOUSE, but unlikely to contain WOLF.

4.4 Answer Selection

P^3 predicts a distribution over denotations for each question, which for our problem must be mapped to a distribution over multiple choice answers. Answer selection performs this task using string match heuristics and an LSTM (Hochreiter and Schmidhuber, 1997). The string match heuristics score each answer option given a denotation then select the highest scoring answer, abstaining in the case of a tie. The score computation depends on the denotation's type. If the denotation is a set of entities, the score is an approximate count of the number of entities in the denotation mentioned in the answer using a fuzzy string match. If the denotation is a set of change events, the score is a fuzzy match of both the change direction and the animal name. If the denotation is a number, string matching is straightforward. Applying these heuristics and marginalizing out denotations yields a distribution over answer options.

A limitation of the above approach is that it does not directly incorporate linguistic prior knowledge about likely answers. For example, "snake" is usually a good answer to "what eats mice?" regardless of the diagram. Such knowledge is known to be essential for visual question answering (Antol et al., 2015; Andreas et al., 2016b) and important in our task as well. We incorporate this knowledge in a standard way, by training a neural network on question/answer pairs (without the diagram) and combining its predictions with the string match heuristics above. The network is a sequence LSTM that is applied to the question concatenated with each answer option a to produce a 50-dimensional vector v_a for each answer. The distribution over answers is the softmax of the inner product of these vectors with a learned parameter vector w. For simplicity, we combine these two components using a 50/50 mix of their answer distributions.

4.5 Supervision Oracle

The supervision oracle for diagram question answering combines supervision of both answers and environment interpretations. We assume that each diagram has been labeled with a food web. An execution is correct if and only if (1) all of the chosen values in the global variable encoding the food web are consistent with the labeled food web, and (2) string match answer selection applied to its denotation chooses the correct answer. The first constraint guarantees that every logical form has at most one correct execution for any given diagram.

5 Evaluation

Our evaluation compares P^3 to both possible worlds and neural network approaches on our data set of food web diagram questions. An ablation study demonstrates that both sets of global features improve accuracy. Finally, we demonstrate P^3's generality by applying it to a previously-published data set, obtaining state-of-the-art results.

Code, data and supplementary material for this paper are available at: `http://www.allenai.org/paper-appendix/emnlp2016-p3`

5.1 FOODWEBS Data Set

FOODWEBS consists of ∼500 food web diagrams and ∼5000 questions designed to imitate actual questions encountered on 8th grade science exams. The train/validation/test sets contain ∼300/100/100 diagrams and their corresponding questions. The data set has three kinds of annotations in addition to the correct answer for each question. First, each diagram is annotated with the food web that it depicts using ORGANISM and EATS. Second, each diagram has predictions from a vision system for various diagram elements such as arrows and text labels (Kembhavi et al., 2016). These are noisy predictions, not ground truth. Finally, each question is annotated by the authors with a logical form (or null if its meaning is not representable in the domain theory). These logical forms are not used to train P^3 but are useful to measure per-component error.

We collected FOODWEBS by using a crowdsourcing process to expand a collection of real exam questions. First, we collected 89 questions from 4th and 8th grade exams and 500 food web diagrams us-

ing an image search engine. Second, we generated questions for these diagrams using Mechanical Turk. Workers were shown a diagram and a real question for inspiration and asked to write a new question and its answer options. We validated each generated question by asking 3 workers to answer it, discarding questions where at least 2 did not choose the correct answer. We also manually corrected any ambiguous (e.g., two answer options are correct) and poorly-formatted (e.g., two answer options have the same letter) questions. The final data set has high quality: a human domain expert correctly answered 95 out of 100 randomly-sampled questions.

5.2 Baseline Comparison

Our first experiment compares P^3 with several baselines for situated question answering. The first baseline, WORLDS, is a possible worlds model based on Malinowski and Fritz (2014). This baseline learns a semantic parser $P(\ell, t|q)$ and a distribution over food webs $P(w|v)$, then evaluates ℓ on w to produce a distribution over denotations. This model is implemented by independently training P^3's CCG parser (on question/answer pairs and labeled food webs) and a possible-worlds execution model (on labeled food webs). The CCG lexicon for both P^3 and WORLDS was generated by applying PAL (Krishnamurthy, 2016) to the same data. Both models select answers as described in Section 4.4.

We also compared P^3 to several neural network baselines. The first baseline, LSTM, is the text-only answer selection model described in Section 4.4. The second baseline, VQA, is a neural network for visual question answering. This model represents each image as a vector by using the final layer of a pre-trained VGG19 model (Simonyan and Zisserman, 2014) and applying a single fully-connected layer. It scores answer options by using the answer selection LSTM to encode question/answer pairs, then computing a dot product between the text and image vectors. This model is somewhat limited because VGG features are unlikely to encode important diagram structure, such as the content of text labels. Our third baseline, DQA, is a neural network that rectifies this limitation (Kembhavi et al., 2016). It encodes the diagram predictions from the vision system as vectors and attends to them using the LSTM-encoded question vector to select an answer. This model is trained with question/answer pairs and diagram parses, which is roughly comparable to the supervision used to train P^3.

Model	Accuracy	Accuracy (Unseen Organisms)
P^3	**69.1**	**57.7**
WORLDS	63.6	50.8
LSTM	60.3	34.7
VQA	56.5	36.8
DQA	59.3	33.0
Random	25.2	25.2

Table 1: Accuracy of P^3 and several baselines on the FOODWEBS test set and a modified test set with unseen organisms.

Model	Accuracy	Δ
P^3	69.1	
-LSTM	59.8	-9.3
-LSTM -denotation	55.8	-13.3
-LSTM -denotation -predicate	52.4	-16.7

Table 2: Test set accuracy of P^3 removing LSTM answer selection (Section 4.4), denotation features and predicate features (Section 4.3).

Table 5.2 compares the accuracy of P^3 to these baselines. Accuracy is the fraction of questions answered correctly. LSTM performs well on this data set, suggesting that many questions can be answered without using the image. This result is consistent with results on visual question answering (Antol et al., 2015). The other neural network models have similar performance to LSTM, whereas both WORLDS and P^3 outperform it. We also find that P^3 outperforms WORLDS likely due to its global features, which we investigate in the next section.

Given these results, we hypothesized that the neural models were largely memorizing common patterns in the text and were not able to interpret the diagram. We tested this hypothesis by running each model on a test set with unseen organisms created by reversing the organism names in every question and diagram (Table 5.2, right column). As expected, the accuracy of LSTM is considerably reduced on this data set. VQA and DQA again perform similarly to LSTM, which is consistent with our hypothesis. In contrast, we find that the accuracies of WORLDS and P^3 are only slightly reduced, which is consistent with superior diagram interpretation abilities but ineffective LSTM answer selection.

5.3 Ablation Study

We performed an ablation study to further understand the impact of LSTM answer selection and global features. Table 5.2 shows the accuracy of P^3 trained without these components. We find that LSTM answer selection improves accuracy by 9 points, as expected due to the importance of linguistic prior knowledge. Global features improve accuracy by 7 points, which is roughly comparable to the delta between P^3 and WORLDS in Table 5.2.

5.4 Component Error Analysis

Our third experiment analyses sources of error by training and evaluating P^3 while providing the gold logical form, food web, or both as input. Table 5.5 shows the accuracy of these three models. The final entry shows the maximum accuracy possible given our domain theory and answer selection. The larger accuracy improvement with gold food webs suggests that the execution model is responsible for more error than semantic parsing, though both components contribute.

5.5 SCENE Experiments

Our final experiment applies P^3 to the SCENE data set of Krishnamurthy and Kollar (2013). In this data set, the input is a natural language expression, such as "blue mug to the left of the monitor," and the output is the set of objects in an image that the expression denotes. The images are annotated with a bounding box for each candidate object. The data set includes a domain theory that was automatically generated by creating a category and/or relation per word based on its part of speech. It also includes a CCG lexicon and image features. We use these resources, adding predicate and denotation features.

Table 5.5 compares P^3 to prior work on SCENE. The evaluation metric is exact match accuracy between the predicted and labeled sets of objects. We consider three supervision conditions: QA trains with question/answer pairs, QA+E further includes labeled environments, and QA+E+LF further includes labeled logical forms. We trained P^3 in the first two conditions, while prior work trained in the first and third conditions. KK2013 is a possible worlds model with a max-margin training objective. P^3 slightly outperforms in the QA condition and P^3 trained with labeled environments outperforms prior work trained with additional logical form labels.

Model	Accuracy	Δ
P^3	69.1	
+ gold logical form	75.1	+6.0
+ gold food web	82.3	+13.2
+ both	91.6	+22.5

Table 3: Accuracy of P^3 when trained and evaluated with labeled logical forms, food webs, or both.

	Supervision		
Model	QA	QA+E	QA+E+LF
P^3	68	75	–
KK2013	67	–	70

Table 4: Accuracy on the SCENE data set. KK2013 results are from Krishnamurthy and Kollar (2013).

6 Conclusion

Parsing to Probabilistic Programs (P^3) is a novel model for situated question answering that jointly reasons about question and environment interpretations using background knowledge to produce answers. P^3 uses a domain theory – a probabilistic program – to define the information to be extracted from the environment and background knowledge. A semantic parser maps questions to logical forms in this theory, which are probabilistic programs whose possible executions represent possible interpretations of the environment. An execution model scores these executions given features of the environment. Both the semantic parser and execution model are jointly trained in a loglinear model, which thereby learns to both parse questions and interpret environments. Importantly, the model includes global features of the logical form and executions, which help the model avoid implausible interpretations. We demonstrate P^3 on a challenging new data set of 5000 science diagram questions, where it outperforms several competitive baselines.

Abstract

A common problem in cognitive modelling is lack of access to accurate broad-coverage models of event-level surprisal. As shown in, e.g., Bicknell et al. (2010), event-level knowledge does affect human expectations for verbal arguments. For example, the model should be able to predict that *mechanics* are likely to check *tires*, while *journalists* are more likely to check *typos*. Similarly, we would like to predict what locations are likely for *playing football* or *playing flute* in order to estimate the surprisal of actually-encountered locations. Furthermore, such a model can be used to provide a probability distribution over fillers for a thematic role which is not mentioned in the text at all.

To this end, we train two neural network models (an incremental one and a non-incremental one) on large amounts of automatically role-labelled text. Our models are probabilistic and can handle several roles at once, which also enables them to learn interactions between different role fillers. Evaluation shows a drastic improvement over current state-of-the-art systems on modelling human thematic fit judgements, and we demonstrate via a sentence similarity task that the system learns highly useful embeddings.

1 Introduction

Our goals in this paper are to learn a representation of events and their thematic roles based on large quantities of automatically role-labelled text and to be able to calculate probability distributions over the possible role fillers of specific missing roles. In this sense, the task is closely related to work on selectional preference acquisition (Van de Cruys, 2014). We focus here on the roles *agent*, *patient*, *location*, *time*, *manner* and the *predicate* itself. The model we develop is trained to represent the event-relevant context and hence systematically captures long-range dependencies. This has been previously shown to be beneficial also for more general language modelling tasks (e.g., Chelba and Jelinek, 1998; Tan et al., 2012).

This type of modelling is potentially relevant to a wide range of tasks, for instance for performing thematic fit judgment tasks, detecting anomalous events (Dasigi and Hovy, 2014), or predicting event structure that is not explicitly present in the text. The latter could be useful for inferring missing information in entailment tasks or improving identification of thematic roles outside the sentence containing the predicate. Potential applications also include predicate prediction based on arguments and roles, which has been noted to be relevant for simultaneous machine translation for a verb-final to a verb-medial source language (Grissom II et al., 2014). Within cognitive modelling, our model could help to more accurately estimate *semantic surprisal* for broad-coverage texts, when used in combination with an incremental role labeller (e.g., Konstas and Keller, 2015), or to provide surprisal estimates for content words as a control variable for psycholinguistic experimental materials.

In this work, we focus on the predictability of verbs and nouns, and we suggest that the predictability of these words depends to a large extent on the relationship of these words to other nouns and

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 171–182,
Austin, Texas, November 1-5, 2016.

verbs, especially those connected via the same event. We choose a neural network (NN) model because we found that results from existing related models, e.g. Baroni and Lenci's Distributional Memory, depend heavily on how exactly the distributional space is defined, while having no principled way of optimizing the space. A crucial advantage of a neural network-based approach is thus that the model can be trained to optimize the distributional representation for the task.

Our model is trained specifically to predict missing semantic role-fillers based on the predicate and other available role-fillers of that predicate. The model can also predict the predicate based on the semantic roles and their fillers. In our model, there is no difference in how the semantic roles or the predicate are treated. Thus, when we refer here to *roles*, we usually mean both semantic roles and the predicate, unless otherwise explicitly stated.

Our model is compositional in that it has access to several role-fillers (including the verb) at the same time, and can thus represent interdependencies between participants of an event and predict from a combined representation. Consider, for example, the predicate *serve*, whose likely patients include e.g., *drinks*. If we had the agent *robber*, we would like to be able to predict a patient like *sentence*, in the sense of "the robber will serve his sentence..." This task is related to modelling thematic fit. In this paper, we evaluate our model on a variety of thematic fit rating datasets as well as on a sentence similarity dataset that tests for successful compositionality in our model's representations.

This paper makes the following contributions:

- We compare two novel NN models for generating a probability distribution over selectional preferences given one or more roles and fillers.
- We show that our technique outperforms state of the art thematic fit models on many datasets.
- We show that the embeddings thus obtained are effective in measuring sentence similarity.

1.1 Neural networks

Neural networks have proven themselves to be very well suited for language modeling. By learning distributed representations of words (Bengio et al., 2003), they are able to generalize to new contexts that were not observed word-by-word in the training corpus. They can also use a relatively large number of context words in order to make predictions about the upcoming word. In fact, the recurrent neural network (RNN) LM (Mikolov et al., 2010) does not explicitly fix the context size at all but is potentially able to compress the relevant information about the entire context in its recurrent layer. These are the properties that we would like to see in our role-filler prediction model as well.

Neural networks have also been used for selectional preference acquisition, as in Van de Cruys (2014). His selectional preference model differs from our model in several aspects. First, unlike our model it is limited to a fixed number of inputs. Another difference is that his model uses separate embeddings for all input words, while ours enables partial parameter sharing. Finally and crucially for role-filler prediction, selectional preference models score the inputs, while our model gives a probability distribution over all words for the queried target role.

We discuss the components necessary for our model in more detail in section 3.

2 Data source

Our source of training data is the ukWaC corpus, which is part of the WaCky project, as well as the British National Corpus. The corpus consists of web pages crawled from the `.uk` web domain, containing approximately 138 million sentences.

These sentences were run through a semantic role labeller and head words were extracted as described in Sayeed et al. (2015). The semantic role labeller used, SENNA (Collobert and Weston, 2007), generates PropBank-style role labels. While PropBank argument positions (ARG0, ARG1, etc.) are primarily designed to be verb-specific, rather than directly representing "classical" thematic roles (agent, patient, etc.), in the majority of cases, ARG0 lines up with agent roles and ARG1 lines up with patient roles. PropBank-style roles have been used in other recent efforts in thematic fit modelling (e.g., Baroni et al., 2014; Vandekerckhove et al., 2009),

For processing purposes, the corpus was divided into 3500 segments. Fourteen segments (approx 500 thousand sentences) each were used for development and testing, and the rest were used for training.

In order to construct our incremental model and compare it to n-gram language models, we needed a precise mapping between the lemmatized argument words and their positions in the original sentence. This required aligning the SENNA tokenization and the original ukWaC tokenization used for MaltParser. Because of the heterogeneous nature of web data, this alignment was not always achievable—we skipped a small number of sentences in this case. In the development and testing portions of the data set, we filtered sentences containing predicates where there were multiple role-assignees with the same role for the same predicate.

3 Model design and implementation

Our model is a neural network with a single nonlinear hidden layer and a *Softmax* output layer. All inputs are one-hot encoded—i.e., represented as a binary vector with size equal to the number of possible input values, where all entries are zero except the entry at the index corresponding to the current input value.

3.1 Two-part view of the model

The parameters of a neural network classifier with a single hidden layer and one-hot encoded inputs can be viewed as serving two distinct purposes: moving from inputs towards outputs, the first weight matrix that we encounter is responsible for learning distributed representations (or embeddings) of the inputs; the second weight matrix represents the parameters of a maximum entropy classifier that uses the learned embeddings as inputs.

Considering the task of role-filler prediction, we would want these two sets of parameters to have the following properties:

- The **classifier layer** should be different for each target role, because the suitable filler given the context can clearly be very different depending on the role (e.g., verb vs. agent).
- The **embedding layer** should also be different depending on the role of context word. Otherwise, the network would not have any information about the role of the context word. For example, the suitable verb filler for context word *dog* in an agent role is probably very different from what it would be, were it in a patient role (e.g. *bark* vs. *feed*).

We now briefly describe some incrementally improved intermediate approaches that we also considered as they help to understand the steps that led to our final solution for achieving the desired properties of the embedding and classifier layer.

A naive way to accomplish the aspired properties would be to have a separate model for each input role and target role pair. This approach has several drawbacks. For a start, there is no obvious way to model interactions of different input roles and fillers in order to make predictions based on multiple input role-word pairs simultaneously. Another problem is that the parameters are trained only on a fraction of available training data—e.g., verb embedding weights are trained independently for each target role classifier. Finally, given that we have chosen to distinguish between n different roles, it would require us to train and tune hyper-parameters for n^2 models.

One of these problems (data under-utilization) can be alleviated by sharing role-specific embedding and classifier weights across different models. For example, the verb embedding matrix would be shared across all models that predict different role fillers based on input verbs. Other problems remain, and training the large number of models becomes even more difficult because of parameter synchronization, but this is a step towards the next improvement.

Shared role-specific embedding and classifier weights enable us to combine all input-target role pair models into a single model. This can be done by stacking role-specific embedding matrices to form a 3-way embedding tensor and building a classifier parameter tensor analogously. Having a single model saves us from tuning multiple models and makes modelling interactions between inputs possible.

Despite these advantages, having two tensors in our model has a drawback of rapidly growing the number of parameters as vocabulary size, number of roles, and hidden layer size increase. This may lead to over-fitting and increases training time.

A more subtle weakness is the fact that this kind of model lacks parameter sharing across role-specific embedding weight matrices. It is clear that some characteristics of words (e.g., semantics) usu-

ally remain the same across different roles. Thus it is practical to share some information across role-specific weights so that the embeddings can benefit from more data and learn better semantic representations while leaving room for role-specific traits.

For these reasons we replace the tensors with their factored form in our models.

3.2 Factored parameter tensors

Factoring classifier and embedding tensors helps to alleviate both the efficiency and parameter sharing problems brought out in Section 3.1.

Given vocabulary size $|V|$, number of roles $|R|$ and hidden layer size H, each tensor T would require $|V| \times |R| \times H$ parameters. The number of parameters can be reduced by expressing the tensor as a sum of F rank-one tensors (Hitchcock, 1927). This technique enables us to replace the tensor T with three factor matrices A, B and C. Each tensor element $T[i, j, k]$ can then be written as:

$$T[i, j, k] = \sum_{f=1}^{F} A[i, f]B[j, f]C[f, k] \quad (1)$$

Assuming lateral slices of T represent role-specific weight matrices (index j denotes roles), we write each role specific weight matrix W as:

$$W = A \,\mathrm{diag}(rB)C \quad (2)$$

where r is a one-hot encoded role vector and $diag$ is a function that returns a square matrix with the argument vector on the main diagonal and zeros elsewhere. For example, with a vocabulary of 50000 words, 7 roles and number of factors and hidden units equal to 512, the factorization reduces the number of parameters from 179M to 26M and greatly improves training speed. Factorization also enables parameter sharing, since factor matrices A and C are shared across all roles.

Factored tensors have been used in different neural network models before. Starting with restricted Boltzmann machines, Memisevic and Hinton (2010) used a factored 3-way interaction tensor in their image transformation model. Sutskever et al. (2011) created a character level RNN LM that was efficiently able to use input character specific recurrent weights by using a factored tensor. Alumäe (2013) used a factored tensor in a multi-domain LM to be able to use a domain-specific hidden layer weight matrix that would take into account the differences while exploiting similarities between domains. A multi-modal LM by Kiros et al. (2014) uses a factored tensor to change the effective output layer weights based on image features.

It has been noticed before, that training models with factored tensors as parameters using gradient descent is difficult (Sutskever et al., 2011; Kiros et al., 2014). As explained by Sutskever et al. (2011), this is caused by the fact that each tensor element is represented as a product of three parameters, which may cause disproportionate updates if these three factors have magnitudes that are too different. Another problem is that if the factor matrix B happens to have too small or too large values, then this might also cause instabilities in the lower layers as the back-propagated gradients are scaled by role-specific row of B in our model. This situation is magnified in our models, since we have not one, but two factored layers.

To solve this problem, Sutskever et al. (2011) suggest using 2nd order methods instead of gradient descent. Alumäe (2013) has alleviated the problem of shrinking back-propagated gradients by adding a bias (initialized with ones) to the domain-specific factor vector. We found that using AdaGrad (Duchi et al., 2011) to update the parameters is very effective. The method provides parameter-specific learning rates that depend on the historic magnitudes of the gradients of these parameters. This seems to neutralize the effect of vanishing or exploding gradients by reducing the step size for parameters that tend to have large gradients and allow a bigger learning rate for parameters with smaller gradients.

3.3 General structure of the model

Our general approach, common to both role-filler models, is shown in Figure 1. First, role-specific word embedding vector e is computed by implicitly taking a fiber (word indexed row of a role indexed slice) from the factored embedding tensor:

$$e = wA_e \,\mathrm{diag}(rB_e)C_e \quad (3)$$

$$h = \mathrm{PReLU}(e + b_h) \quad (4)$$

where w and r are one-hot encoded word and role vectors respectively, b_h is hidden layer bias, and A_e,

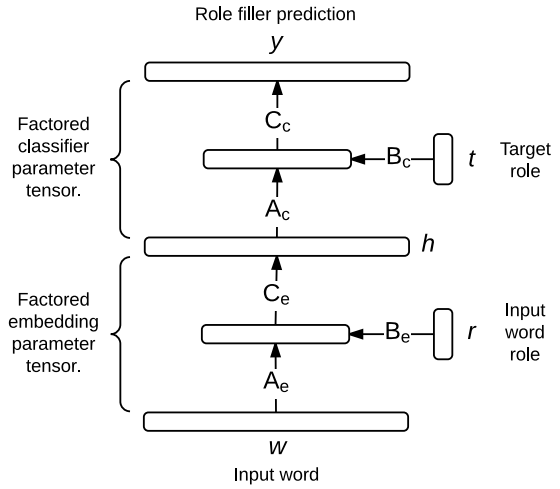

Figure 1: General structure of role-filler models.

B_e and C_e represent the factor matrices that the embedding tensor is factored into. Next, we apply a parametric rectifier (PReLU; He et al., 2015) nonlinearity to the role-specific word embedding to obtain the hidden activation vector h.

The hidden layer activation vector h is fed to the *Softmax* output layer through a target role specific classifier weight matrix (a target role-indexed slice of the classifier parameter tensor):

$$c = hA_c \,\text{diag}(tB_c)C_c \quad (5)$$

$$y = \text{Softmax}(c + b_y) \quad (6)$$

where t is a one-hot encoded target role vector, b_y is output layer bias, and y is the output of the model representing the probability distribution over the output vocabulary.

3.4 Modeling input interactions

The general approach described in Section 3.3 also allows us to model interactions between different input role-word pairs. If we know the order in which the inputs were introduced, then we can add a recurrent connection to the hidden layer to implement an incremental role filler predictor. When word order is unknown, then input role-word pair representations can be added together to compose the representation of the entire predicate context[1]. We chose addition over concatenation (often preferred in language models) because the non-incremental model does not need to preserve information about word order, and addition also enables using a variable number of inputs.

The incremental model adds information about the previous hidden state h_{t-1} to the current input word role-specific embedding e_t through recurrent weights W_r. So, Equation 4 is replaced with:

$$h_t = \text{PReLU}(e_t + h_{t-1}W_r + p_tW_p + b_h) \quad (7)$$

where p_t is a binary predicate boundary indicator that informs the model about the start of a new predicate and equals 1 when the target word belongs to a new predicate and 0 otherwise. The predicate boundary input p_t is connected to the network through parameter vector W_p. The hidden state h_0 is initialized to zeros.

The non-incremental model adds role-specific embedding vectors of all input words together to form the representation of the entire predicate context and replaces Equation 4 with:

$$h = \text{PReLU}(\sum_{i=1}^{N} e_i + b_h) \quad (8)$$

where N is the number of input role-word pairs.

3.5 Training details

First, we give details that are common to both the RNN and NN models. The models are trained with mini-batches of 128 samples. The hidden layer consists of 256 PReLU units; embedding and classifier tensor factorization layer sizes are 256 and 512 respectively. The input and output vocabularies are the same, consisting of 50,000 most frequent lemmatized words in the training corpus. The role vocabulary consists of 5 argument roles (ARG0, ARG1, ARGM-LOC, ARGM-TMP and ARGM-MNR), the verb is treated as the sixth role, and all the other roles are mapped to a shared OTHER label. Parameters are updated using AdaGrad (Duchi et al., 2011) with a learning rate of 0.1. All models are implemented using Theano (Bastien et al., 2012; Bergstra et al., 2010) and trained on GPUs for 8 days.

RNN model gradients are computed using backpropagation through time (Rumelhart et al., 1986)

[1] In applications like natural language generation, for example, where role-fillers need to be predicted, it is not necessarily always the case that the order will be known in advance or that the thematic fit model will be used to generate the full sentence in correct word order.

Model Name	Dev	Test
3-gram LM	450.1 ± 2.6	438.9 ± 2.6
3-gram CWM	859.6 ± 4.6	834.9 ± 4.5
RNN CWM	485.8 ± 2.7	473.2 ± 2.6
RNN RF	244.6 ± 1.4	237.8 ± 1.4
NN RF	248.2 ± 1.4	241.9 ± 1.4

Table 1: Perplexities on dev/test dataset.

over 3 time steps. The NN model is trained on mini-batches of 128 samples that are randomly drawn with replacement from the training set.

3.6 Model comparison

Perplexity allows us to compare all our models in similar terms, and evaluate the extent to which access to thematic roles helps the model to predict missing role fillers. For comparability, the perplexities of all models are computed only on content word probabilities (i.e., predicates and their arguments). We also report the 95% confidence interval for perplexity, which is computed according to Klakow and Peters (2002). All models are trained on exactly the same sentences of lemmatized words. Probability mass is distributed across the vocabulary of the 50,000 most frequent content words in the training corpus.

3.6.1 Models

First, we compare our model to a conventional 3-gram language model **3-gram LM**, conditioning on the previous context containing the immediately preceding context of content and function words. All n-grams are discounted with Kneser-Ney smoothing, and n-gram probability estimates are interpolated with lower order estimates. Sentence onset in all models is padded with a special sentence onset tag. The vocabulary of context words for this model consists of all words from the training corpus.

As a second model, we train a 3-gram content word model **3-gram CWM**, which is an N-gram LM that is trained only on content words.

Next, we have **RNN CWM**—an RNN LM (Mikolov et al., 2010) trained on content words only. The context size of this model is not explicitly defined and the model can potentially utilize more context words than 3-gram CWM (even from outside the sentence boundary).

Our incremental role-filler **RNN RF** is similar to RNN CWM, except for using role-specific embedding and classifier weights (slices of factored tensor). It thus has additional information about the content word roles[2].

Finally, the non-incremental role-filler **NN RF** loses the information about word order and the ability to use information outside predicate boundaries and trades it for the ability to see the future (i.e., the context includes both the preceding and the following content words and their roles).

3.6.2 Results

The results of content word perplexity evaluation are summarized in Table 1. The thematic-role informed models outperform all other models by a very large margin, cutting perplexity almost in half. The incremental model achieves a slightly lower perplexity than the non-incremental one (237.8 vs. 241.9), hinting that the content word order and out-of-predicate role-word pairs can be even more informative than a preview of upcoming role-word pairs.

The difference between normal LM and the CWM can be explained by the loss of information from function words, combined with additional sparsity in the model because content word sequences are much sparser than sequences of content and function words.

This also explains why using a neural network-based RNN CWM model improves the performance so much (perplexity drops from 834.9 to 473.2), as neural network based language models are well known for their ability to generalize well to unseen contexts by learning distributed representations of words (Bengio et al., 2003).

4 Evaluation on thematic fit ratings

In order to see whether our model accurately represents events and their typical thematic role fillers, we evaluate our model on a range of existing datasets containing human thematic fit ratings. This evaluation also allows us to compare our model to existing models that have been used on this task.

[2] A reviewer kindly points out, as a matter of historical interest, that the high-level architecture of the RNN RF model bears some resemblance to the parallel distributed processing model in McClelland et al. (1989) and St. John and McClelland (1990).

Data source	# ratings	Roles	NN RF	BL2010	GSD2015	BDK2014
Pado (agent, patient)	414	ARG0, ARG1, ARG2	0.52 (8)	**0.53** (0)	**0.53** (0)	0.41
McRae (agent, patient)	1444	ARG0, ARG1	**0.38** (20)	0.32 (70)	0.36 (70)	0.28
Ferretti (location)	274	ARGM-LOC	**0.44** (3)	0.23 (3)	0.29 (3)	-
Ferretti (instrument)	248	ARGM-MNR	**0.45** (6)	0.36 (17)	0.42 (17)	-
Greenberg (patient)	720	ARG1	**0.61** (8)	0.46 (18)	0.48 (18)	-
Pado+McRae+Ferretti	2380		**0.41** (37)	0.35 (90)	0.38 (90)	-

Table 2: Thematic fit evaluation scores, consisting of Spearman's ρ correlations between average human judgements and model output, with numbers of missing values (due to missing vocabulary entries) in brackets. The baseline scores come from the TypeDM (Baroni and Lenci, 2010) model, further developed and evaluated in Greenberg et al. (2015a,b) and the neural network *predict* model described in Baroni et al. (2014). NN RF is the non-incremental model presented in this article. Our model maps ARG2 in Pado to OTHER role. Significances were calculated using paired two-tailed significance tests for correlations (Steiger, 1980). NN RF was significantly better than both of the other models on the Greenberg and Ferretti location datasets and significantly better than BL2010 but not GSD2015 on McRae and Pado+McRae+Ferretti; differences were not statistically significant for Pado and Ferretti instruments.

4.1 Related work

State-of-the-art computational models of thematic fit quantify the similarity between a role filler of a verb and the proto-typical filler for that role for the verb based on distributional vector space models. For example, the thematic fit of *grass* as a patient for the verb *eat* would be determined by the cosine of a distributional vector representation of *grass* and a prototypical patient of *eat*. The proto-typical patient is in turn obtained from averaging representations of words that typically occur as a patient of *eat* (e.g., Erk, 2007; Baroni and Lenci, 2010; Sayeed and Demberg, 2014; Greenberg et al., 2015b). For more than one role, information from both the agent and the predicate can be used to jointly to predict a patient (e.g., Lenci, 2011).

4.2 Data

Previous studies obtained thematic fit ratings from humans by asking experimental participants to rate how common, plausible, typical, or appropriate some test role-fillers are for given verbs on a scale from 1 (least plausible) to 7 (most plausible) (McRae et al., 1998; Ferretti et al., 2001; Binder et al., 2001; Padó, 2007; Padó et al., 2009; Vandekerckhove et al., 2009; Greenberg et al., 2015a). The datasets include agent, patient, location and instrument roles. For example, in the Padó et al. (2009) dataset, the noun *sound* has a very low rating of 1.1 as the subject of *hear* and a very high rating of 6.8 as the object of *hear*. Each of the verb-role-noun triples was rated by several humans, and our evaluations are done against the average human score. The datasets differ from one another in size (as shown in Table 2), choice of verb-noun pairs, and in how exactly the question was asked of human raters.

4.3 Methods

A major difference between what the state-of-the-art models do and what our model does is that our model distributes a probability mass of one across the vocabulary, while the thematic fit models have no such overall constraint; they will assign a high number to all words that are similar to the prototypical vector, without having to distribute probability mass. Specifically, this implies that two synonymous fillers, one of which is a frequent word like *fire*, and the other of which is an infrequent word, e.g., *blaze*, will get similar ratings by the distributional similarity models, but quite different ratings by the neural network model, as the more frequent word will have higher probability. Greenberg et al. (2015a) showed that human ratings are insensitive to noun frequency. Hence, we report results that adjust for frequency effects by setting the output layer bias of the neural network model to zero. Since the output unit biases of the neural network model are independent from the inputs, they correlate strongly ($r_s = 0.74, p = 0.0$) with training corpus word frequencies after being trained. Therefore, setting the learned output layer bias vector to a zero-vector is a simple way to reduce the effect of word frequencies on the model's output probability distribution.

Role	# ratings	ρ (# NaN)
ARG0	924	0.38 (14)
ARG1	1615	0.51 (22)
ARG2	39	0.59 (0)
ARGM-MNR	248	0.45 (6)
ARGM-LOC	274	0.44 (3)
ALL	3100	0.45 (45)

Table 3: Per role thematic-fit evaluation scores in terms of Spearmans ρ correlations between average human judgements and model output.

4.4 Results

We can see that the neural network model outperforms the baselines on all the datasets except the Pado dataset. An error analysis on the role filler probabilities generated by the neural net points to the effect of level of constraint of the verb on the estimates. For a relatively non-constraining verb, the neural net model will have to distribute the probability mass across many different suitable fillers, while the semantic similarity models do not suffer from this. This implies that filler fit is not directly comparable across verbs in the NN model (only filler predictability is comparable).

Per role results are shown in Table 3. Surprisingly, the model output has the highest correlation with the averaged human judgements for the target role ARG2, despite the fact that ARG2 is mapped to OTHER along with several other roles. The model struggles the most when it comes to predicting fillers for ARG0. There is no noticeable correlation between the role-specific performance and the role occurrence frequency in the samples of our training set. This implies that parameter sharing between roles does indeed help when it comes to balancing the performance between rare and ubiquitous roles as discussed in section 3.1.

4.5 Compositionality

The above thematic role fit data sets only assess the fit between two words. Our model can however also model the interaction between different roles; see Figure 2 for an example of model predictions. We are only aware of one small dataset that can be used to systematically test the effectiveness of the compositionality for this task. The Bicknell et al. (2010) dataset contains triples like *journalist check spelling* vs. *mechanic check spelling* and *journalist check tires* vs. *mechanic check tires* together with human congruity judgments.

Model	NN RF	Lenci 2011
Accuracy 1	**0.687**	0.671
Accuracy 2	0.828	**0.844**

Table 4: Accuracies on the Bicknell evaluation task.

The goal in this task is for the model to reproduce the human judgments on the 64 sentence pairs. Lenci (2011), which we compare against in Table 4, proposed a first compositional model based on TypeDM to evaluate on this task.

We use two accuracy scores for the evaluation, which we call "Accuracy 1" and "Accuracy 2". "Accuracy 1" counts a hit iff the model assigns the composed subject-verb combination a higher score when we test a human-rated better-fitting object in contrast with when we test a worse-fitting one; in other words, a hit is achieved when *journalist check spelling* should be better than *journalist check tires*, if we give the model *journalist check* as the predicate to test against different objects. (The result from Lenci for this task was transmitted by private communication.)

"Accuracy 2" counts a hit iff, given an object, the composed subject-verb combination gives a higher score when the subject is better fitting. That is, a hit is achieved when *journalist check spelling* has a higher score than *mechanic check spelling*, setting the query to the model as *journalist check* and *mechanic check* and finding a score for *spelling* in that context. This accuracy metric is proposed and evaluated in Lenci (2011).

Evaluation shows that our model performs similarly to that of Lenci, although only limited conclusions can be drawn due to the small data set size.

5 Evaluation of event representations: sentence similarity

To show that our model learns to represent input words and their roles in a useful way that reflects the meaning and interactions between inputs, we evaluate our non-incremental model on a sentence similarity task from Grefenstette and Sadrzadeh (2015).

We assign similarity scores to sentence pairs by computing representations for each sentence by tak-

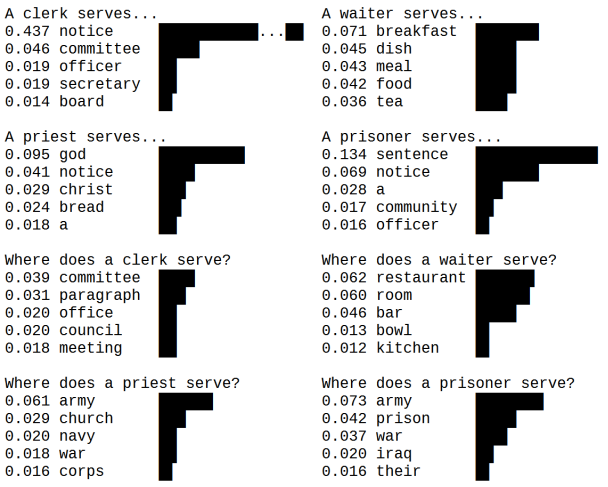

Figure 2: Examples of model predictions for the verb *serve* with different agents and target roles *patient* and *location*.

ing the hidden layer state (Equation 8) of the non-incremental model given the words in the sentence and their corresponding roles. Sentence similarity is then rated with the cosine similarity between the representations of the two sentences.

Spearman's rank correlation between the cosine similarities produced by our model and human ratings are shown in Table 5. Our model achieves much higher correlation with human ratings than the best result reported by Grefenstette and Sadrzadeh (2015), showing our model's ability to compose meaningful representations of multiple input words and their roles.

We also compare our model with another NN word representation model baseline that does not embed role information; by this comparison, we can determine the size of the improvement brought by our role-specific embeddings. The baseline sentence representations are constructed by element-wise addition of pre-trained word2vec (Mikolov et al., 2013) word embeddings[3]. Scores are again computed by using cosine similarity. The large gap between our model's and word2vec baseline's performance illustrates the importance of embedding role information in word representations.

6 Conclusions

In this paper we proposed two neural network architectures for learning proto-typical event representations. These models were trained to generate probability distributions over role fillers for a given semantic role. In our perplexity evaluation, we demonstrated that giving the model access to thematic role information substantially improved prediction performance. We also compared the performance of our model to the performance of current state-of-the-art models in predicting human thematic fit ratings and showed that our model outperforms the existing models by a large margin. Finally, we also showed that the event representations from the hidden layer of our model are highly effective in a sentence similarity task. In future work, we intend to test the potential contribution of this model when applied to larger tasks such as entailment and inference tasks as well as semantic surprisal-based prediction tasks.

Abstract

Word embedding has been widely studied and proven helpful in solving many natural language processing tasks. However, the ambiguity of natural language is always a problem on learning high quality word embeddings. A possible solution is sense embedding which trains embedding for each sense of words instead of each word. Some recent work on sense embedding uses context clustering methods to determine the senses of words, which is heuristic in nature. Other work creates a probabilistic model and performs word sense disambiguation and sense embedding iteratively. However, most of the previous work has the problems of learning sense embeddings based on imperfect word embeddings as well as ignoring the dependency between sense choices of neighboring words. In this paper, we propose a novel probabilistic model for sense embedding that is not based on problematic word embedding of polysemous words and takes into account the dependency between sense choices. Based on our model, we derive a dynamic programming inference algorithm and an Expectation-Maximization style unsupervised learning algorithm. The empirical studies show that our model outperforms the state-of-the-art model on a word sense induction task by a 13% relative gain.

1 Introduction

Distributed representation of words (aka word embedding) aims to learn continuous-valued vectors to represent words based on their context in a large corpus. They can serve as input features for algorithms of natural language processing (NLP) tasks. High quality word embeddings have been proven helpful in many NLP tasks (Collobert and Weston, 2008; Turian et al., 2010; Collobert et al., 2011; Maas et al., 2011; Chen and Manning, 2014). Recently, with the development of deep learning, many novel neural network architectures are proposed for training high quality word embeddings (Mikolov et al., 2013a; Mikolov et al., 2013b).

However, since natural language is intrinsically ambiguous, learning one vector for each word may not cover all the senses of the word. In the case of a multi-sense word, the learned vector will be around the average of all the senses of the word in the embedding space, and therefore may not be a good representation of any of the senses. A possible solution is sense embedding which trains a vector for each sense of a word. There are two key steps in training sense embeddings. First, we need to perform word sense disambiguation (WSD) or word sense induction (WSI) to determine the senses of words in the training corpus. Then, we need to train embedding vectors for word senses according to their contexts.

Early work on sense embedding (Reisinger and Mooney, 2010; Huang et al., 2012; Chen et al., 2014; Neelakantan et al., 2014; Kageback et al., 2015; Li and Jurafsky, 2015) proposes context clustering methods which determine the sense of a word by clustering aggregated embeddings of words in its context. This kind of methods is heuristic in nature and relies on external knowledge from lexicon like WordNet (Miller, 1995).

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 183–191,
Austin, Texas, November 1-5, 2016.

Recently, sense embedding methods based on complete probabilistic models and well-defined learning objective functions (Tian et al., 2014; Bartunov et al., 2016; Jauhar et al., 2015) become more popular. These methods regard the choice of senses of the words in a sentence as hidden variables. Learning is therefore done with expectation-maximization style algorithms, which alternate between inferring word sense choices in the training corpus and learning sense embeddings.

A common problem with these methods is that they model the sense embedding of each center word dependent on the word embeddings of its context words. As we previously explained, word embedding of a polysemous word is not a good representation and may negatively influence the quality of inference and learning. Furthermore, these methods choose the sense of each word in a sentence independently, ignoring the dependency that may exist between the sense choices of neighboring words. We argue that such dependency is important in word sense disambiguation and therefore helpful in learning sense embeddings. For example, consider the sentence "He cashed a check at the bank". Both "check" and "bank" are ambiguous here. Although the two words hint at banking related senses, the hint is not decisive (as an alternative interpretation, they may represent a check mark at a river bank). Fortunately, "cashed" is not ambiguous and it can help disambiguate "check". However, if we consider a small context window in sense embedding, then "cashed" cannot directly help disambiguate "bank". We need to rely on the dependency between the sense choices of "check" and "bank" to disambiguate "bank".

In this paper, we propose a novel probabilistic model for sense embedding that takes into account the dependency between sense choices of neighboring words. We do not learn any word embeddings in our model and hence avoid the problem with embedding polysemous words discussed above. Our model has a similar structure to a high-order hidden Markov model. It contains a sequence of observable words and latent senses and models the dependency between each word-sense pair and between neighboring senses in the sequence. The energy of neighboring senses can be modeled using existing word embedding approaches such as CBOW and Skip-gram (Mikolov et al., 2013a; Mikolov et al., 2013b). Given the model and a sentence, we can perform exact inference using dynamic programming and get the optimal sense sequence of the sentence. Our model can be learned from an unannotated corpus by optimizing a max-margin objective using an algorithm similar to hard-EM.

Our main contributions are the following:

1. We propose a complete probabilistic model for sense embedding. Unlike previous work, we model the dependency between sense choices of neighboring words and do not learn sense embeddings dependent on problematic word embeddings of polysemous words.

2. Based on our proposed model, we derive an exact inference algorithm and a max-margin learning algorithm which do not rely on external knowledge from any knowledge base or lexicon (except that we determine the numbers of senses of polysemous words according to an existing sense inventory).

3. The performance of our model on contextual word similarity task is competitive with previous work and we obtain a 13% relative gain compared with previous state-of-the-art methods on the word sense induction task of SemEval-2013.

The rest of this paper is organized as follows. We introduce related work in section 2. Section 3 describes our models and algorithms in detail. We present our experiments and results in section 4. In section 5, a conclusion is given.

2 Related Work

Distributed representation of words (aka word embedding) was proposed in 1986 (Hinton, 1986; Rumelhart et al., 1986). In 2003, Bengio et al. (2003) proposed a neural network architecture to train language models which produced word embeddings in the neural network. Mnih and Hinton (2007) replaced the global normalization layer of Bengio's model with a tree-structure to accelerate the training process. Collobert and Weston (2008) introduced a max-margin objective function

to replace the most computationally expensive max-likelihood objective function. Recently proposed Skip-gram model, CBOW model and GloVe model (Mikolov et al., 2013a; Mikolov et al., 2013b; Pennington et al., 2014) were more efficient than traditional models by introducing a log-linear layer and making it possible to train word embeddings with a large scale corpus. With the development of neural network and deep learning techniques, there have been a lot of work based on neural network models to obtain word embedding (Turian et al., 2010; Collobert et al., 2011; Maas et al., 2011; Chen and Manning, 2014). All of them have proven that word embedding is helpful in NLP tasks.

However, the models above assumed that one word has only one vector as its representation which is problematic for polysemous words. Reisinger and Mooney (2010) proposed a method for constructing multiple sense-specific representation vectors for one word by performing word sense disambiguation with context clustering. Huang et al. (2012) further extended this context clustering method and incorporated global context to learn multi-prototype representation vectors. Chen et al. (2014) extended the context clustering method and performed word sense disambiguation according to sense glosses from WordNet (Miller, 1995). Neelakantan et al. (2014) proposed an extension of the Skip-gram model combined with context clustering to estimate the number of senses for each word as well as learn sense embedding vectors. Instead of performing word sense disambiguation tasks, Kageback et al. (2015) proposed the instance-context embedding method based on context clustering to perform word sense induction tasks. Li and Jurafsky (2015) introduced a multi-sense embedding model based on the Chinese Restaurant Process and applied it to several natural language understanding tasks.

Since the context clustering based models are heuristic in nature and rely on external knowledge, recent work tends to create probabilistic models for learning sense embeddings. Tian et al. (2014) proposed a multi-prototype Skip-gram model and designed an Expectation-Maximization (EM) algorithm to do word sense disambiguation and learn sense embedding vectors iteratively. Jauhar et al. (2015) extended the EM training framework and retrofitted embedding vectors to the ontology of WordNet. Bartunov et al. (2016) proposed a non-parametric Bayesian extension of Skip-gram to automatically learn the required numbers of representations for all words and perform word sense induction tasks.

3 Context-Dependent Sense Embedding Model

We propose the context-dependent sense embedding model for training high quality sense embeddings which takes into account the dependency between sense choices of neighboring words. Unlike pervious work, we do not learn any word embeddings in our model and hence avoid the problem with embedding polysemous words discussed previously. In this section, we will introduce our model and describe our inference and learning algorithms.

3.1 Model

We begin with the notation in our model. In a sentence, let w_i be the i^{th} word of the sentence and s_i be the sense of the i^{th} word. $S(w)$ denotes the set of all the senses of word w. We assume that the sets of senses of different words do not overlap. Therefore, in this paper a word sense can be seen as a lexeme of the word (Rothe and Schutze, 2015).

Our model can be represented as a Markov network shown in Figure 1. It is similar to a high-order hidden Markov model. The model contains a sequence of observable words $(w_1, w_2, \ldots)$ and latent senses $(s_1, s_2, \ldots)$. It models the dependency between each word-sense pair and between neighboring senses in the sequence. The energy function is formulated as follows:

$$E(\mathbf{w}, \mathbf{s}) = \sum_i \Big(E_1(w_i, s_i) + E_2(s_{i-k}, \ldots, s_{i+k}) \Big) \tag{1}$$

Here $\mathbf{w} = \{w_i | 1 \leq i \leq l\}$ is the set of words in a sentence with length l and $\mathbf{s} = \{s_i | 1 \leq i \leq l\}$ is the set of senses. The function E_1 models the dependency between a word-sense pair. As we assume that the sets of senses of different words do not overlap, we can formulate E_1 as follows:

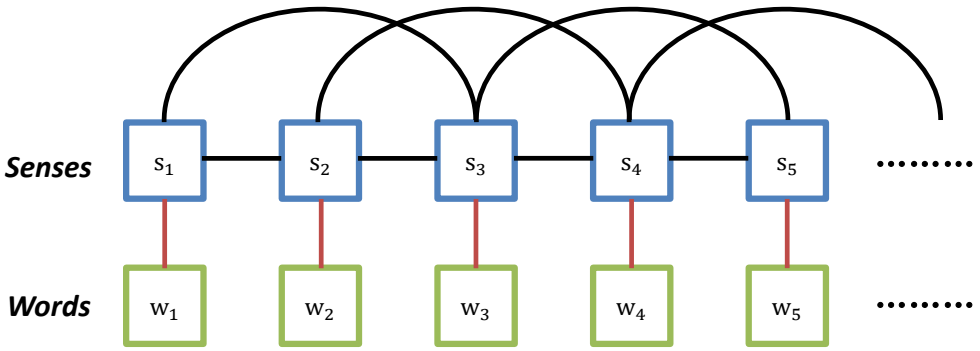

Figure 1: Context-Dependent Sense Embedding Model with window size $k = 1$

$$E_1(w_i, s_i) = \begin{cases} 0 & s_i \in S(w_i) \\ +\infty & s_i \notin S(w_i) \end{cases} \quad (2)$$

Here we assume that all the matched word-sense pairs have the same energy, but it would also be interesting to model the degrees of matching with different energy values in E_1. In Equation 1, the function E_2 models the compatibility of neighboring senses in a context window with fixed size k. Existing embedding approaches like CBOW and Skip-gram (Mikolov et al., 2013a; Mikolov et al., 2013b) can be used here to define E_2. The formulation using CBOW is as follows:

$$E_2(s_{i-k}, \ldots, s_{i+k}) = -\sigma\left(\sum_{i-k \le j \le i+k, j \neq i} V^T(s_j) V'(s_i)\right) \quad (3)$$

Here $V(s)$ and $V'(s)$ are the input and output embedding vectors of sense s. The function σ is an activation function and we use the sigmoid function here in our model. The formulation using Skip-gram can be defined in a similar way:

$$E_2(s_{i-k}, \ldots, s_{i+k}) = -\sum_{i-k \le j \le i+k, j \neq i} \sigma\left(V^T(s_j) V'(s_i)\right) \quad (4)$$

3.2 Inference

In this section, we introduce our inference algorithm. Given the model and a sentence **w**, we want to infer the most likely values of the hidden variables (i.e. the optimal sense sequence of the sentence) that minimize the energy function in Equation 1:

$$\mathbf{s}^* = \arg\min_{\mathbf{s}} E(\mathbf{w}, \mathbf{s}) \quad (5)$$

We use dynamic programming to do inference which is similar to the Viterbi algorithm of the hidden Markov model. Specifically, for every valid assignment $A_{i-2k}, \ldots, A_{i-1}$ of every subsequence of senses $s_{i-2k}, \ldots, s_{i-1}$, we define $m(A_{i-2k}, \ldots, A_{i-1})$ as the energy of the best sense sequence up to position $i-1$ that is consistent with the assignment $A_{i-2k}, \ldots, A_{i-1}$. We start with $m(A_1, \ldots, A_{2k}) = 0$ and then recursively compute m in a left-to-right forward process based on the update formula:

$$m(A_{i-2k+1}, \ldots, A_i) = \min_{A_{i-2k}} \Big(m(A_{i-2k}, \ldots, A_{i-1}) + E_1(w_i, A_i) + E_2(A_{i-2k}, \ldots, A_i) \Big) \quad (6)$$

Once we finish the forward process, we can retrieve the best sense sequence with a backward process. The time complexity of the algorithm is $O(n^{4k}l)$ where n is the maximal number of senses of a word. Because most words in a typical sentence have either a single sense or far less than n senses, the actual running time of the algorithm is very fast.

3.3 Learning

In this section, we introduce our unsupervised learning algorithm. In learning, we want to learn all the

input and output sense embedding vectors that optimize the following max-margin objective function:

$$\Theta^* = \arg\min_{\Theta} \sum_{\mathbf{w}\in C} \min_{\mathbf{s}} \sum_{i=1}^{\|\mathbf{w}\|} \sum_{s_{neg}\in S_{neg}(w_i)} \max\Big(1 + E_1(w_i, s_i) + E_2(s_{i-k}, \ldots, s_{i+k}) - E_2(s_{i-k}, \ldots, s_{i-1}, s_{neg}, s_{i+1}, \ldots, s_{i+k}), 0\Big) \quad (7)$$

Here Θ is the set of all the parameters including V and V' for all the senses. C is the set of training sentences. Our learning objective is similar to the negative sampling and max-margin objective proposed for word embedding (Collobert and Weston, 2008). $S_{neg}(w_i)$ denotes the set of negative samples of senses of word w_i which is defined with the following strategy. For a polysemous word w_i, $S_{neg}(w_i) = S(w_i)\backslash\{s_i\}$. For the other words with a single sense, $S_{neg}(w_i)$ is a set of randomly selected senses of a fixed size.

The objective in Equation 7 can be optimized by coordinate descent which in our case is equivalent to the hard Expectation-Maximization algorithm. In the hard E step, we run the inference algorithm using the current model parameters to get the optimal sense sequences of the training sentences. In the M step, with the sense sequences **s** of all the sentences fixed, we learn sense embedding vectors. Assume we use the CBOW model for E_2 (Equation 3), then the M-step objective function is as follows:

$$\Theta^* = \arg\min_{\Theta} \sum_{\mathbf{w}\in C} \sum_{i=1}^{\|\mathbf{w}\|} \sum_{s_{neg}\in S_{neg}(w_i)} \max\Big(1 - \sigma(\sum_{i-k\le j\le i+k, j\neq i} V(s_j)^T V'(s_i)) + \sigma(\sum_{i-k\le j\le i+k, j\neq i} V(s_j)^T V'(s_{neg})), 0\Big) \quad (8)$$

Here E_1 is omitted because the sense sequences produced from the E-step always have zero E_1 value. Similarly, if we use the Skip-gram model for E_2 (Equation 4), then the M-step objective function is:

$$\Theta^* = \arg\min_{\Theta} \sum_{\mathbf{w}\in C} \sum_{i=1}^{\|\mathbf{w}\|} \sum_{i-k\le j\le i+k, j\neq i} \sum_{s_{neg}\in S_{neg}(w_i)} \max\Big(1 - \sigma(V(s_j)^T V'(s_i)) + \sigma(V(s_j)^T V'(s_{neg})), 0\Big) \quad (9)$$

We optimize the M-step objective function using stochastic gradient descent.

We use a mini batch version of the hard EM algorithm. For each sentence in the training corpus, we run E-step to infer its sense sequence and then immediately run M-step (for 1 iteration of stochastic gradient descent) to update the model parameters based on the senses in the sentence. Therefore, the batch size of our algorithm depends on the length of each sentence.

The advantage of using mini batch is twofold. First, while our learning objective is highly non-convex (Tian et al., 2014), the randomness in mini batch hard EM may help us avoid trapping into local optima. Second, the model parameters are updated more frequently in mini batch hard EM, resulting in faster convergence.

Note that before running hard-EM, we need to determine, for each word w, the size of $S(w)$. In our experiments, we used the sense inventory provided by Coarse-Grained English All-Words Task of SemEval-2007 Task 07 (Navigli et al., 2007) to determine the number of senses for each word. The sense inventory is a coarse version of WordNet sense inventory. We do not use the WordNet sense inventory because the senses in WordNet are too fine-grained and are difficult to recognize even for human annotators (Edmonds and Kilgarriff, 2002). Since we do not link our learned senses with external sense inventories, our approach can be seen as performing WSI instead of WSD.

4 Experiments

This section presents our experiments and results. First, we describe our experimental setup including the training corpus and the model configuration.

Word	Nearest Neigbors
bank_1	banking, lender, loan
bank_2	river, canal, basin
bank_3	slope, tilted, slant
apple_1	macintosh, imac, blackberry
apple_2	peach, cherry, pie
date_1	birthdate, birth, day
date_2	appointment, meet, dinner
fox_1	cbs, abc, nbc
fox_2	wolf, deer, rabbit

Table 1: The nearest neighbors of senses of polysemous words

Then, we perform a qualitative evaluation on our model by presenting the nearest neighbors of senses of some polysemous words. Finally, we introduce two different tasks and show the experimental results on these tasks respectively.

4.1 Experimental Setup

4.1.1 Training Corpus

Our training corpus is the commonly used Wikipedia corpus. We dumped the October 2015 snapshot of the Wikipedia corpus which contains 3.6 million articles. In our experiments, we removed the infrequent words with less than 20 occurrences and the training corpus contains 1.3 billion tokens.

4.1.2 Configuration

In our experiments, we set the context window size to 5 (5 words before and after the center word). The embedding vector size is set to 300. The size of negative sample sets of single-sense words is set to 5. We trained our model using AdaGrad stochastic gradient decent (Duchi et al., 2010) with initial learning rate set to 0.025. Our configuration is similar to that of previous work.

Similar to Word2vec, we initialized our model by randomizing the sense embedding vectors. The number of senses of all the words is determined with the sense inventory provided by Coarse-Grained English All-Words Task of SemEval-2007 Task 07 (Navigli et al., 2007) as we explained in section 3.3.

4.2 Case Study

In this section, we give a qualitative evaluation of our model by presenting the nearest neighbors of the senses of some polysemous words. Table 1 shows the results of our qualitative evaluation. We list several polysemous words in the table, and for each word, some typical senses of the word are picked. The nearest neighbors of each sense are listed aside. We used the cosine distance to calculate the distance between sense embedding vectors and find the nearest neighbors.

In Table 1, we can observe that our model produces good senses for polysemous words. For example, the word "bank" can be seen to have three different sense embedding vectors. The first one means the financial institution. The second one means the sloping land beside water. The third one means the action of tipping laterally.

4.3 Word Similarity in Context

This section gives a quantitative evaluation of our model on word similarity tasks. Word similarity tasks evaluate a model's performance with the Spearman's rank correlation between the similarity scores of pairs of words given by the model and the manual labels. However, traditional word similarity tasks like Wordsim-353 (Finkelstein et al., 2001) are not suitable for evaluating sense embedding models because these datasets do not include enough ambiguous words and there is no context information for the models to infer and disambiguate the senses of the words. To overcome this issue, Huang et al. (2012) released a new dataset named Stanford's Contextual Word Similarities (SCWS) dataset. The dataset consists of 2003 pairs of words along with human labelled similarity scores and the sentences containing these words.

Given a pair of words and their contexts, we can perform inference using our model to disambiguate the questioned words. A similarity score can be calculated with the cosine distance between the two embedding vectors of the inferred senses of the questioned words. We also propose another method for calculating similarity scores. In the inference process, we compute the energy of each sense choice of the questioned word and consider the negative energy as the confidence of the sense choice. Then we calculate the cosine similarity between all pairs of senses of the questioned words and compute the average of similarity weighted by the confidence of the senses. The first method is named HardSim and the

Model	Similarity Metrics	$\rho \times 100$
Huang	AvgSim	62.8
Huang	AvgSimC	65.7
Chen	AvgSim	66.2
Chen	AvgSimC	68.9
Neelakantan	AvgSim	67.2
Neelakantan	AvgSimC	69.2

Tian	Model_M	63.6
Tian	Model_W	65.4
Bartunov	AvgSimC	61.2
Ours + CBOW	HardSim	64.3
Ours + CBOW	SoftSim	65.6
Ours + Skip-gram	HardSim	64.9
Ours + Skip-gram	SoftSim	**66.1**

Table 2: Spearman's rank correlation results on the SCWS dataset

second method is named SoftSim.

Table 2 shows the results of our context-dependent sense embedding models on the SCWS dataset. In this table, ρ refers to the Spearman's rank correlation and a higher value of ρ indicates better performance. The baseline performances are from Huang et al. (2012), Chen et al. (2014), Neelakantan et al. (2014), Li and Jurafsky (2015), Tian et al. (2014) and Bartunov et al. (2016). Here Ours + CBOW denotes our model with a CBOW based energy function and Ours + Skip-gram denotes our model with a Skip-gram based energy function. The results above the thick line are the models based on context clustering methods and the results below the thick line are the probabilistic models including ours. The similarity metrics of context clustering based models are AvgSim and AvgSimC proposed by Reisinger and Mooney (2010). Tian et al. (2014) propose two metrics Model_M and Model_W which are similar to our HardSim and SoftSim metrics.

From Table 2, we can observe that our model outperforms the other probabilistic models and is not as good as the best context clustering based model. The context clustering based models are overall better than the probabilistic models on this task. A possible reason is that most context clustering based methods make use of more external knowledge than probabilistic models. However, note that Faruqui et al. (2016) presented several problems associated with the evaluation of word vectors on word similarity datasets and pointed out that the use of word similarity tasks for evaluation of word vectors is not sustainable. Bartunov et al. (2016) also suggest that SCWS should be of limited use for evaluating word representation models. Therefore, the results on this task shall be taken with caution. We consider that more realistic natural language processing tasks like word sense induction are better for evaluating sense embedding models.

4.4 Word Sense Induction

In this section, we present an evaluation of our model on the word sense induction (WSI) tasks. The WSI task aims to discover the different meanings for words used in sentences. Unlike a word sense disambiguation (WSD) system, a WSI system does not link the sense annotation results to an existing sense inventory. Instead, it produces its own sense inventory and links the sense annotation results to this sense inventory. Our model can be seen as a WSI system, so we can evaluate our model with WSI tasks.

We used the dataset from task 13 of SemEval-2013 as our evaluation set (Jurgens and Klapaftis, 2013). The dataset contains 4664 instances inflected from one of the 50 lemmas. Both single-sense instances and instances with a graded mixture of senses are included in the dataset. In this paper, we only consider the single sense instances. Jurgens and Klapaftis (2013) propose two fuzzy measures named Fuzzy B-Cubed (FBC) and Fuzzy Normalized Mutual Information (FNMI) for comparing fuzzy sense assignments from WSI systems. the FBC measure summarizes the performance per instance while the FNMI measure is based on sense clusters rather than instances.

Table 3 shows the results of our context-dependent sense embedding models on this dataset. Here HM is the harmonic mean of FBC and FNMI. The result of AI-KU is from Baskaya et al. (2013), MSSG is from Neelakantan et al. (2014), ICE-online and ICE-kmeans are from Kageback et al. (2015). Our models are denoted in the same way as in the previous section.

From Table 3, we can observe that our models

Model	FBC(%)	FNMI(%)	HM
AI-KU	35.1	4.5	8.0
MSSG	45.9	3.7	6.8
ICE-online	48.7	5.5	9.9
ICE-kmeans	51.1	5.9	10.6
Ours + CBOW	53.8	6.3	11.3
Ours + Skip-gram	56.9	6.7	**12.0**

Table 3: Results of single-sense instances on task 13 of SemEval-2013

outperform the previous state-of-the-art models and achieve a 13% relative gain. It shows that our models can beat context clustering based models on realistic natural language processing tasks.

5 Conclusion

In this paper we propose a novel probabilistic model for learning sense embeddings. Unlike previous work, we do not learn sense embeddings dependent on word embeddings and hence avoid the problem with inaccurate embeddings of polysemous words. Furthermore, we model the dependency between sense choices of neighboring words which can help us disambiguate multiple ambiguous words in a sentence. Based on our model, we derive a dynamic programming inference algorithm and an EM-style unsupervised learning algorithm which do not rely on external knowledge from any knowledge base or lexicon except that we determine the number of senses of polysemous words according to an existing sense inventory. We evaluate our model both qualitatively by case studying and quantitatively with the word similarity task and the word sense induction task. Our model is competitive with previous work on the word similarity task. On the word sense induction task, our model outperforms the state-of-the-art model and achieves a 13% relative gain.

For the future work, we plan to try learning our model with soft EM. Besides, we plan to use shared senses instead of lexemes in our model to improve the generality of our model. Also, we will study unsupervised methods to link the learned senses to existing inventories and to automatically determine the numbers of senses. Finally, we plan to evaluate our model with more NLP tasks.

Abstract

Embedding knowledge graphs into continuous vector spaces has recently attracted increasing interest. Most existing methods perform the embedding task using only fact triples. Logical rules, although containing rich background information, have not been well studied in this task. This paper proposes a novel method of jointly embedding knowledge graphs and logical rules. The key idea is to represent and model triples and rules in a unified framework. Specifically, triples are represented as atomic formulae and modeled by the translation assumption, while rules represented as complex formulae and modeled by t-norm fuzzy logics. Embedding then amounts to minimizing a global loss over both atomic and complex formulae. In this manner, we learn embeddings compatible not only with triples but also with rules, which will certainly be more predictive for knowledge acquisition and inference. We evaluate our method with link prediction and triple classification tasks. Experimental results show that joint embedding brings significant and consistent improvements over state-of-the-art methods. Particularly, it enhances the prediction of new facts which cannot even be directly inferred by pure logical inference, demonstrating the capability of our method to learn more predictive embeddings.

1 Introduction

Knowledge graphs (KGs) provide rich structured information and have become extremely useful resources for many NLP related applications like word sense disambiguation (Wasserman-Pritsker et al., 2015) and information extraction (Hoffmann et al., 2011). A typical KG represents knowledge as multi-relational data, stored in triples of the form (*head entity*, *relation*, *tail entity*), e.g., (`Paris`, `Capital-Of`, `France`). Although powerful in representing structured data, the symbolic nature of such triples makes KGs, especially large-scale KGs, hard to manipulate.

Recently, a promising approach, namely knowledge graph embedding, has been proposed and successfully applied to various KGs (Nickel et al., 2012; Socher et al., 2013; Bordes et al., 2014). The key idea is to embed components of a KG including entities and relations into a continuous vector space, so as to simplify the manipulation while preserving the inherent structure of the KG. The embeddings contain rich semantic information about entities and relations, and can significantly enhance knowledge acquisition and inference (Weston et al., 2013).

Most existing methods perform the embedding task based solely on fact triples (Bordes et al., 2013; Wang et al., 2014; Nickel et al., 2016). The only requirement is that the learned embeddings should be compatible with those facts. While logical rules contain rich background information and are extremely useful for knowledge acquisition and inference (Jiang et al., 2012; Pujara et al., 2013), they have not been well studied in this task. Wang et al. (2015) and Wei et al. (2015) tried to leverage both embedding methods and logical rules for KG completion. In their work, however, rules are modeled separately from embedding methods, serving as post-processing steps, and thus will not help to obtain

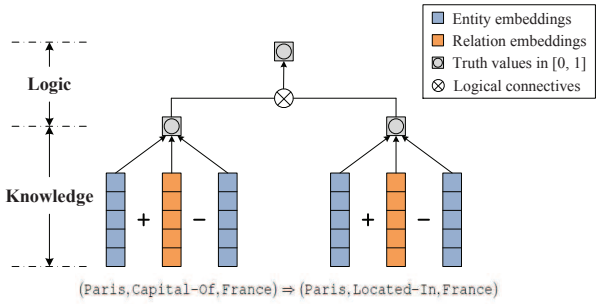

Figure 1: Simple illustration of KALE.

better embeddings. Rocktäschel et al. (2015) recently proposed a joint model which injects first-order logic into embeddings. But it focuses on the relation extraction task, and creates vector embeddings for entity pairs rather than individual entities. Since entities do not have their own embeddings, relations between unpaired entities cannot be effectively discovered (Chang et al., 2014).

In this paper we introduce KALE, a new approach that learns entity and relation Embeddings by jointly modeling Knowledge And Logic. Knowledge triples are taken as atoms and modeled by the translation assumption, i.e., relations act as translations between head and tail entities (Bordes et al., 2013). A triple (e_i, r_k, e_j) is scored by $\|\mathbf{e}_i + \mathbf{r}_k - \mathbf{e}_j\|_1$, where $\mathbf{e}_i$, $\mathbf{r}_k$, and $\mathbf{e}_j$ are the vector embeddings for entities and relations. The score is then mapped to the unit interval $[0, 1]$ to indicate the truth value of that triple. Logical rules are taken as complex formulae constructed by combining atoms with logical connectives (e.g., $\wedge$ and $\Rightarrow$), and modeled by t-norm fuzzy logics (Hájek, 1998). The truth value of a rule is a composition of the truth values of the constituent atoms, defined by specific logical connectives. In this way, KALE represents triples and rules in a unified framework, as atomic and complex formulae respectively. Figure 1 gives a simple illustration of the framework. After unifying triples and rules, KALE minimizes a global loss involving both of them to obtain entity and relation embeddings. The learned embeddings are therefore compatible not only with triples but also with rules, which will definitely be more predictive for knowledge acquisition and inference.

The main contributions of this paper are summarized as follows. (i) We devise a unified framework that jointly models triples and rules to obtain more predictive entity and relation embeddings. The new framework KALE is general enough to handle any type of rules that can be represented as first-order logic formulae. (ii) We evaluate KALE with link prediction and triple classification tasks on WordNet (Miller, 1995) and Freebase (Bollacker et al., 2008). Experimental results show significant and consistent improvements over state-of-the-art methods. Particularly, joint embedding enhances the prediction of new facts which cannot even be directly inferred by pure logical inference, demonstrating the capability of KALE to learn more predictive embeddings.

2 Related Work

Recent years have seen rapid growth in KG embedding methods. Given a KG, such methods aim to encode its entities and relations into a continuous vector space, by using neural network architectures (Socher et al., 2013; Bordes et al., 2013; Bordes et al., 2014), matrix/tensor factorization techniques (Nickel et al., 2011; Riedel et al., 2013; Chang et al., 2014), or Bayesian clustering strategies (Kemp et al., 2006; Xu et al., 2006; Sutskever et al., 2009). Among these methods, TransE (Bordes et al., 2013), which models relations as translating operations, achieves a good trade-off between prediction accuracy and computational efficiency. Various extensions like TransH (Wang et al., 2014) and TransR (Lin et al., 2015b) are later proposed to further enhance the prediction accuracy of TransE. Most existing methods perform the embedding task based solely on triples contained in a KG. Some recent work tries to further incorporate other types of information available, e.g., relation paths (Neelakantan et al., 2015; Lin et al., 2015a; Luo et al., 2015), relation type-constraints (Krompaßet al., 2015), entity types (Guo et al., 2015), and entity descriptions (Zhong et al., 2015), to learn better embeddings.

Logical rules have been widely studied in knowledge acquisition and inference, usually on the basis of Markov logic networks (Richardson and Domingos, 2006; Bröcheler et al., 2010; Pujara et al., 2013; Beltagy and Mooney, 2014). Recently, there has been growing interest in combining logical rules and embedding models. Wang et al. (2015) and Wei et al. (2015) tried to utilize rules to refine predictions

made by embedding models, via integer linear programming or Markov logic networks. In their work, however, rules are modeled separately from embedding models, and will not help obtain better embeddings. Rocktäschel et al. (2015) proposed a joint model that injects first-order logic into embeddings. But their work focuses on relation extraction, creating vector embeddings for entity pairs, and hence fails to discover relations between unpaired entities. This paper, in contrast, aims at learning more predictive embeddings by jointly modeling knowledge and logic. Since each entity has its own embedding, our approach can successfully make predictions between unpaired entities, providing greater flexibility for knowledge acquisition and inference.

3 Jointly Embedding Knowledge and Logic

We first describe the formulation of joint embedding. We are given a KG containing a set of triples $\mathcal{K} = \{(e_i, r_k, e_j)\}$, with each triple composed of two entities $e_i, e_j \in \mathcal{E}$ and their relation $r_k \in \mathcal{R}$. Here $\mathcal{E}$ is the entity vocabulary and $\mathcal{R}$ the relation set. Besides the triples, we are given a set of logical rules $\mathcal{L}$, either specified manually or extracted automatically. A logical rule is encoded, for example, in the form of $\forall x, y : (x, r_s, y) \Rightarrow (x, r_t, y)$, stating that any two entities linked by relation r_s should also be linked by relation r_t. Entities and relations are associated with vector embeddings, denoted by $\mathbf{e}, \mathbf{r} \in \mathbb{R}^d$, representing their latent semantics. The proposed method, KALE, aims to learn these embeddings by jointly modeling knowledge triples $\mathcal{K}$ and logical rules $\mathcal{L}$.

3.1 Overview

To enable joint embedding, a key ingredient of KALE is to unify triples and rules, in terms of first-order logic (Rocktäschel et al., 2014; Rocktäschel et al., 2015). A triple (e_i, r_k, e_j) is taken as a ground atom which applies a relation r_k to a pair of entities e_i and e_j. Given a logical rule, it is first instantiated with concrete entities in the vocabulary $\mathcal{E}$, resulting in a set of ground rules. For example, a universally quantified rule $\forall x, y : (x, \texttt{Capital-Of}, y) \Rightarrow (x, \texttt{Located-In}, y)$ might be instantiated with the concrete entities of `Paris` and `France`, giving the ground rule $(\texttt{Paris}, \texttt{Capital-Of}, \texttt{France}) \Rightarrow (\texttt{Paris}, \texttt{Located-In}, \texttt{France})$.[1] A ground rule can then be interpreted as a complex formula, constructed by combining ground atoms with logical connectives (e.g. $\wedge$ and $\Rightarrow$).

Let $\mathcal{F}$ denote the set of training formulae, both atomic (triples) and complex (ground rules). KALE further employs a truth function $I : \mathcal{F} \rightarrow [0, 1]$ to assign a soft truth value to each formula, indicating how likely a triple holds or to what degree a ground rule is satisfied. The truth value of a triple is determined by the corresponding entity and relation embeddings. The truth value of a ground rule is determined by the truth values of the constituent triples, via specific logical connectives. In this way, KALE models triples and rules in a unified framework. See Figure 1 for an overview. Finally, KALE minimizes a global loss over the training formulae $\mathcal{F}$ to learn entity and relation embeddings compatible with both triples and rules. In what follows, we describe the key components of KALE, including triple modeling, rule modeling, and joint learning.

3.2 Triple Modeling

To model triples we follow TransE (Bordes et al., 2013), as it is simple and efficient while achieving state-of-the-art predictive performance. Specifically, given a triple (e_i, r_k, e_j), we model the relation embedding $\mathbf{r}_k$ as a translation between the entity embeddings $\mathbf{e}_i$ and $\mathbf{e}_j$, i.e., we want $\mathbf{e}_i + \mathbf{r}_k \approx \mathbf{e}_j$ when the triple holds. The intuition here originates from linguistic regularities such as $\texttt{France} - \texttt{Paris} = \texttt{Germany} - \texttt{Berlin}$ (Mikolov et al., 2013). In relational data, such analogy holds because of the certain relation `Capital-Of`, through which we will get $\texttt{Paris} + \texttt{Capital-Of} = \texttt{France}$ and $\texttt{Berlin} + \texttt{Capital-Of} = \texttt{Germany}$. Then, we score each triple on the basis of $\|\mathbf{e}_i + \mathbf{r}_k - \mathbf{e}_j\|_1$, and define its soft truth value as

$$I(e_i, r_k, e_j) = 1 - \frac{1}{3\sqrt{d}} \|\mathbf{e}_i + \mathbf{r}_k - \mathbf{e}_j\|_1, \quad (1)$$

where d is the dimension of the embedding space. It is easy to see that $I(e_i, r_k, e_j) \in [0, 1]$ with the constraints $\|\mathbf{e}_i\|_2 \leq 1$, $\|\mathbf{e}_j\|_2 \leq 1$, and $\|\mathbf{r}_k\|_2 \leq$

[1] Our approach actually takes as input rules represented in first-order logic, i.e., those with quantifiers such as $\forall$. But it could be hard to deal with quantifiers, so we use ground rules, i.e., propositional statements during learning.

1.[2] $I(e_i, r_k, e_j)$ is expected to be large if the triple holds, and small otherwise.

3.3 Rule Modeling

To model rules we use t-norm fuzzy logics (Hájek, 1998), which define the truth value of a complex formula as a composition of the truth values of its constituents, through specific t-norm based logical connectives. We follow Rocktäschel et al. (2015) and use the product t-norm. The compositions associated with logical conjunction ($\wedge$), disjunction ($\vee$), and negation ($\neg$) are defined as follow:

$$\begin{aligned} I(f_1 \wedge f_2) &= I(f_1) \cdot I(f_2), \\ I(f_1 \vee f_2) &= I(f_1) + I(f_2) - I(f_1) \cdot I(f_2), \\ I(\neg f_1) &= 1 - I(f_1), \end{aligned}$$

where f_1 and f_2 are two constituent formulae, either atomic or complex. Given these compositions, the truth value of any complex formula can be calculated recursively, e.g.,

$$\begin{aligned} I(\neg f_1 \wedge f_2) &= I(f_2) - I(f_1) \cdot I(f_2), \\ I(f_1 \Rightarrow f_2) &= I(f_1) \cdot I(f_2) - I(f_1) + 1. \end{aligned}$$

This paper considers two types of rules. The first type is $\forall x, y : (x, r_s, y) \Rightarrow (x, r_t, y)$. Given a ground rule $f \triangleq (e_m, r_s, e_n) \Rightarrow (e_m, r_t, e_n)$, the truth value is calculated as:

$$\begin{aligned} I(f) = & I(e_m, r_s, e_n) \cdot I(e_m, r_t, e_n) \\ & - I(e_m, r_s, e_n) + 1, \end{aligned} \tag{2}$$

where $I(\cdot,\cdot,\cdot)$ is the truth value of a constituent triple, defined by Eq. (1). The second type is $\forall x, y, z : (x, r_{s_1}, y) \wedge (y, r_{s_2}, z) \Rightarrow (x, r_t, z)$. Given a ground rule $f \triangleq (e_\ell, r_{s_1}, e_m) \wedge (e_m, r_{s_2}, e_n) \Rightarrow (e_\ell, r_t, e_n)$, the truth value is:

$$\begin{aligned} I(f) = & I(e_\ell, r_{s_1}, e_m) \cdot I(e_m, r_{s_2}, e_n) \cdot I(e_\ell, r_t, e_n) \\ & - I(e_\ell, r_{s_1}, e_m) \cdot I(e_m, r_{s_2}, e_n) + 1. \end{aligned} \tag{3}$$

The larger the truth values are, the better the ground rules are satisfied. It is easy to see that besides these two types of rules, the KALE framework is general enough to handle any rules that can be represented as first-order logic formulae. The investigation of other types of rules will be left for future work.

[2]Note that $0 \leq \|\mathbf{e}_i + \mathbf{r}_k - \mathbf{e}_j\|_1 \leq \|\mathbf{e}_i\|_1 + \|\mathbf{r}_k\|_1 + \|\mathbf{e}_j\|_1 \leq 3\sqrt{d}$, where the last inequality holds because $\|\mathbf{x}\|_1 = \sum_i |x_i| \leq \sqrt{d \sum_i x_i^2} = \sqrt{d}\,\|\mathbf{x}\|_2$ for any $\mathbf{x} \in \mathbb{R}^d$, according to the Cauchy-Schwarz inequality.

3.4 Joint Learning

After unifying triples and rules as atomic and complex formulae, we minimize a global loss over this general representation to learn entity and relation embeddings. We first construct a training set $\mathcal{F}$ containing all positive formulae, including (i) observed triples, and (ii) ground rules in which at least one constituent triple is observed. Then we minimize a margin-based ranking loss, enforcing positive formulae to have larger truth values than negative ones:

$$\begin{aligned} \min_{\{\mathbf{e}\},\{\mathbf{r}\}} & \sum_{f^+ \in \mathcal{F}} \sum_{f^- \in \mathcal{N}_{f^+}} \left[\gamma - I(f^+) + I(f^-)\right]_+, \\ \text{s.t.} \quad & \|\mathbf{e}\|_2 \leq 1, \forall e \in \mathcal{E}; \quad \|\mathbf{r}\|_2 \leq 1, \forall r \in \mathcal{R}. \end{aligned} \tag{4}$$

Here $f^+ \in \mathcal{F}$ is a positive formula, $f^- \in \mathcal{N}_{f^+}$ a negative one constructed for f^+, γ a margin separating positive and negative formulae, and $[x]_+ \triangleq \max\{0, x\}$. If $f^+ \triangleq (e_i, r_k, e_j)$ is a triple, we construct f^- by replacing either e_i or e_j with a random entity $e \in \mathcal{E}$, and calculate its truth value according to Eq. (1). For example, we might generate a negative instance $(\texttt{Paris}, \texttt{Capital-Of}, \texttt{Germany})$ for the triple $(\texttt{Paris}, \texttt{Capital-Of}, \texttt{France})$. If $f^+ \triangleq (e_m, r_s, e_n) \Rightarrow (e_m, r_t, e_n)$ or $(e_\ell, r_{s_1}, e_m) \wedge (e_m, r_{s_2}, e_n) \Rightarrow (e_\ell, r_t, e_n)$ is a ground rule, we construct f^- by replacing r_t in the consequent with a random relation $r \in \mathcal{R}$, and calculate its truth value according to Eq. (2) or Eq. (3). For example, given a ground rule $(\texttt{Paris}, \texttt{Capital-Of}, \texttt{France}) \Rightarrow (\texttt{Paris}, \texttt{Located-In}, \texttt{France})$, a possible negative instance $(\texttt{Paris}, \texttt{Capital-Of}, \texttt{France}) \Rightarrow (\texttt{Paris}, \texttt{Has-Spouse}, \texttt{France})$ could be generated. We believe that most instances (both triples and ground rules) generated in this way are truly negative. Stochastic gradient descent in mini-batch mode is used to carry out the minimization. To satisfy the ℓ_2-constraints, $\mathbf{e}$ and $\mathbf{r}$ are projected to the unit ℓ_2-ball before each mini-batch. Embeddings learned in this way are required to be compatible with not only triples but also rules.

3.5 Discussions

Complexity. We compare KALE with several state-of-the-art embedding methods in space complexity and time complexity (per iteration) during learning. Table 1 shows the results, where d is the dimension

Method	Complexity (Space/Time)	
SE (Bordes et al., 2011)	$n_e d+2n_r d^2$	$O(n_t d^2)$
LFM (Jenatton et al., 2012)	$n_e d+n_r d^2$	$O(n_t d^2)$
TransE (Bordes et al., 2013)	$n_e d+n_r d$	$O(n_t d)$
TransH (Wang et al., 2014)	$n_e d+2n_r d$	$O(n_t d)$
TransR (Lin et al., 2015b)	$n_e d+n_r(d^2+d)$	$O(n_t d^2)$
KALE (this paper)	$n_e d+n_r d$	$O(n_t d+n_g d)$

Table 1: Complexity of different embedding methods.

of the embedding space, and $n_e/n_r/n_t/n_g$ is the number of entities/relations/triples/ground rules. The results indicate that incorporating additional rules will not significantly increase the space or time complexity of KALE, keeping the model complexity almost the same as that of TransE (optimal among the methods listed in the table). But please note that KALE needs to ground universally quantified rules before learning, which further requires $O(n_u n_t/n_r)$ in time complexity. Here, n_u is the number of universally quantified rules, and n_t/n_r is the averaged number of observed triples per relation. During grounding, we select those ground rules with at least one triple observed. Grounding is required only once before learning, and is not included during the iterations.

Extensions. Actually, our approach is quite general. (i) Besides TransE, a variety of embedding methods, e.g., those listed in Table 1, can be used for triple modeling (Section 3.2), as long as we further define a mapping $f : \mathbb{R} \to [0, 1]$ to map original scores to soft truth values. (ii) Besides the two types of rules introduced in Section 3.3, other types of rules can also be handled as long as they can be represented as first-order logic formulae. (iii) Besides the product t-norm, other types of t-norm based fuzzy logics can be used for rule modeling (Section 3.3), e.g., the Łukasiewicz t-norm used in probabilistic soft logic (Bröcheler et al., 2010) and the minimum t-norm used in fuzzy description logic (Stoilos et al., 2007). (iv) Besides the pairwise ranking loss, other types of loss functions can be designed for joint learning (Section 3.4), e.g., the pointwise squared loss or the logarithmic loss (Rocktäschel et al., 2014; Rocktäschel et al., 2015).

4 Experiments

We empirically evaluate KALE with two tasks: (i) link prediction and (ii) triple classification.

Dataset	# Ent	# Rel	# Train/Valid/Test-I/Test-II				# Rule
FB122	9,738	122	91,638	9,595	5,057	6,186	78,488
WN18	40,943	18	141,442	5,000	1,394	3,606	119,222

Table 3: Statistics of datasets.

4.1 Experimental Setup

Datasets. We use two datasets: WN18 and FB122. WN18 is a subgraph of WordNet containing 18 relations. FB122 is composed of 122 Freebase relations regarding the topics of "people", "location", and "sports", extracted from FB15K. Both WN18 and FB15K are released by Bordes et al. (2013)[3]. Triples on each dataset are split into training/validation/test sets, used for model training, parameter tuning, and evaluation respectively. For WN18 we use the original data split, and for FB122 we extract triples associated with the 122 relations from the training, validation, and test sets of FB15K.

We further create logical rules for each dataset, in the form of $\forall x, y : (x, r_s, y) \Rightarrow (x, r_t, y)$ or $\forall x, y, z : (x, r_{s_1}, y) \wedge (y, r_{s_2}, z) \Rightarrow (x, r_t, z)$. To do so, we first run TransE to get entity and relation embeddings, and calculate the truth value for each of such rules according to Eq. (2) or Eq. (3). Then we rank all such rules by their truth values and manually filter those ranked at the top. We finally create 47 rules on FB122, and 14 on WN18 (see Table 2 for examples). The rules are then instantiated with concrete entities (grounding). Ground rules in which at least one constituent triple is observed in the *training* set are used in joint learning.

Note that some of the test triples can be inferred by directly applying these rules on the training set (pure logical inference). On each dataset, we further split the test set into two parts, test-I and test-II. The former contains triples that *cannot* be directly inferred by pure logical inference, and the latter the remaining test triples. Table 3 gives some statistics of the datasets, including the number of entities, relations, triples in training/validation/test-I/test-II set, and ground rules.

Comparison settings. As baselines we take the embedding techniques of TransE, TransH, and TransR. TransE models relation embeddings as translation operations between entity embeddings. TransH

[3] https://everest.hds.utc.fr/doku.php?id=en:smemlj12

$\forall x, y$: /sports/athlete/team$(x, y) \Rightarrow$ /sports/sports_team/player(y, x)
$\forall x, y$: /location/country/capital$(x, y) \Rightarrow$ /location/location/contains(x, y)
$\forall x, y, z$: /people/person/nationality$(x, y) \wedge$ /location/country/official_language$(y, z) \Rightarrow$ /people/person/languages(x, z)
$\forall x, y, z$: /country/administrative_divisions$(x, y) \wedge$ /administrative_division/capital$(y, z) \Rightarrow$ /country/second_level_divisions(x, z)
$\forall x, y$: _hypernym$(x, y) \Rightarrow$ _hyponym(y, x)
$\forall x, y$: _instance_hypernym$(x, y) \Rightarrow$ _instance_hyponym(y, x)
$\forall x, y$: _synset_domain_topic_of$(x, y) \Rightarrow$ _member_of_domain_topic(y, x)

Table 2: Examples of rules created.

and TransR are extensions of TransE. They further allow entities to have distinct embeddings when involved in different relations, by introducing relation-specific hyperplanes and projection matrices respectively. All the three methods have been demonstrated to perform well on WordNet and Freebase data.

We further test our approach in three different scenarios. (i) KALE-Trip uses triples alone to perform the embedding task, i.e., only the training triples are included in the optimization Eq. (4). It is a linearly transformed version of TransE. The only difference is that relation embeddings are normalized in KALE-Trip, but not in TransE. (ii) KALE-Pre first repeats pure logical inference on the training set and adds inferred triples as additional training data, until no further triples can be inferred. Both original and inferred triples are then included in the optimization. For example, given a logical rule $\forall x, y : (x, r_s, y) \Rightarrow (x, r_t, y)$, a new triple (e_i, r_t, e_j) can be inferred if (e_i, r_s, e_j) is observed in the training set, and both triples will be used as training instances for embedding. (iii) KALE-Joint is the joint learning scenario, which considers both training triples and ground rules in the optimization. In the aforementioned example, training triple (e_i, r_s, e_j) and ground rule $(e_i, r_s, e_j) \Rightarrow (e_i, r_t, e_j)$ will be used in the training process of KALE-Joint, *without* explicitly incorporating triple (e_i, r_t, e_j). Among the methods, TransE/TransH/TransR and KALE-Trip use only triples, while KALE-Pre/KALE-Joint further incorporates rules, before or during embedding.

Implementation details. We use the code provided by Bordes et al. (2013) for TransE[4], and the code provided by Lin et al. (2015b) for TransH and TransR[5]. KALE is implemented in Java. Note that Lin et al. (2015b) initialized TransR with the results of TransE. However, to ensure fair comparison, we randomly initialize all the methods in our experiments. For all the methods, we create 100 mini-batches on each dataset, and tune the embedding dimension d in $\{20, 50, 100\}$. For TransE, TransH, and TransR which score a triple by a distance in $\mathbb{R}^+$, we tune the learning rate η in $\{0.001, 0.01, 0.1\}$, and the margin γ in $\{1, 2, 3, 4\}$. For KALE which scores a triple (as well as a ground rule) by a soft truth value in the unit interval $[0, 1]$, we set the learning rate η in $\{0.01, 0.02, 0.05, 0.1\}$, and the margin γ in $\{0.1, 0.12, 0.15, 0.2\}$. KALE allows triples and rules to have different weights, with the former fixed to 1, and the latter (denoted by λ) selected in $\{0.001, 0.01, 0.1, 1\}$.

4.2 Link Prediction

This task is to complete a triple (e_i, r_k, e_j) with e_i or e_j missing, i.e., predict e_i given (r_k, e_j) or predict e_j given (e_i, r_k).

Evaluation protocol. We follow the same evaluation protocol used in TransE (Bordes et al., 2013). For each test triple (e_i, r_k, e_j), we replace the head entity e_i by every entity e'_i in the dictionary, and calculate the truth value (or distance) for the corrupted triple (e'_i, r_k, e_j). Ranking the truth values in descending order (or the distances in ascending order), we get the rank of the correct entity e_i. Similarly, we can get another rank by corrupting the tail entity e_j. Aggregated over all the test triples, we report three metrics: (i) the mean reciprocal rank (MRR), (ii) the median of the ranks (MED), and (iii) the proportion of ranks no larger than n (HITS@N). We do not report the averaged rank (i.e., the "Mean Rank" metric used by Bordes et al. (2013)), since it is usually sensitive to outliers (Nickel et al., 2016).

Note that a corrupted triple may exist in KGs, which should also be taken as a valid triple. Consider a test triple (`Paris`, `Located-In`, `France`)

and a possible corruption (`Lyon`, `Located-In`, `France`). Both triples are valid. In this case, ranking `Lyon` before the correct answer `Paris` should not be counted as an error. To avoid such phenomena, we follow Bordes et al. (2013) and remove those corrupted triples which exist in either the training, validation, or test set before getting the ranks. That means, we remove `Lyon` from the candidate list before getting the rank of `Paris` in the aforementioned example. We call the original setting "raw" and the new setting "filtered".

Optimal configurations. For each of the methods to be compared, we tune its hyperparameters in the ranges specified in Section 4.1, and select a best model that leads to the highest filtered MRR score on the validation set (with a total of 500 epochs over the training data). The optimal configurations for KALE are: $d = 100$, $\eta = 0.05$, $\gamma = 0.12$, and $\lambda = 1$ on FB122; $d = 50$, $\eta = 0.05$, $\gamma = 0.2$, and $\lambda = 0.1$ on WN18. To better see and understand the effects of rules, we use the same configuration for KALE-Trip, KALE-Pre, and KALE-Joint on each dataset.

Results. Table 4 and Table 5 show the results in the raw setting and filtered setting respectively. On each dataset we report the metrics on three sets: test-I, test-II, and the whole test set (denoted by test-all). Test-I contains test triples that cannot be directly inferred by performing pure logical inference on the training set, and hence might be intrinsically more difficult for the rules. The remaining test triples (i.e., the directly inferable ones) are included in Test-II. These triples have either been used directly as train-

ing instances in KALE-Pre, or encoded explicitly in training ground rules in KALE-Joint, making this set trivial for the rules to some extent. From the results, we can see that in both settings: (i) KALE-Pre and KALE-Joint outperform (or at least perform as well as) the other methods which use triples alone on almost all the test sets, demonstrating the superiority of incorporating logical rules. (ii) On the test-I sets which contain triples beyond the scope of pure logical inference, KALE-Joint performs significantly better than KALE-Pre. On these sets KALE-Joint can still beat all the baselines by a significant margin in most cases, while KALE-Pre can hardly outperform KALE-Trip. It demonstrates the capability of the joint embedding scenario to learn more predictive embeddings, through which we can make better predictions even beyond the scope of pure logical inference. (iii) On the test-II sets which contain directly inferable triples, KALE-Pre can easily beat all the baselines (even KALE-Joint). That means, for triples covered by pure logical inference, it is trivial to improve the performance by directly incorporating them as training instances.

To better understand how the joint embedding scenario can learn more predictive embeddings, on each dataset we further split the test-I set into two parts. Given a triple (e_i, r_k, e_j) in the test-I set, we assign it to the first part if relation r_k is covered by the rules, and the second part otherwise. We call the two parts Test-Incl and Test-Excl respectively. Table 6 compares the performance of KALE-Trip and KALE-Joint on the two parts. The results show that KALE-Joint outperforms KALE-Trip on both parts, but the improvements on Test-Incl are much more significant than those on Test-Excl. Take the filtered setting on WN18 as an example. On Test-Incl, KALE-Joint increases the metric MRR by 55.7%, decreases the metric MED by 26.9%, and increases the metric HITS@10 by 38.2%. On Test-Excl, however, MRR rises by 3.1%, MED remains the same, and HITS@10 rises by only 0.3%. This observation indicates that jointly embedding triples and rules helps to learn more predictive embeddings, especially for those relations that are used to construct the rules. This might be the main reason that KALE-Joint can make better predictions even beyond the scope of pure logical inference.

4.3 Triple Classification

This task is to verify whether an unobserved triple (e_i, r_k, e_j) is correct or not.

Evaluation protocol. We take the following evaluation protocol similar to that used in TransH (Wang et al., 2014). We first create labeled data for evaluation. For each triple in the test or validation set (i.e., a positive triple), we construct 10 negative triples for it by randomly corrupting the entities, 5 at the head position and the other 5 at the tail position.[6] To make the negative triples as difficult as possible, we corrupt a position using only entities that have appeared in that position, and further ensure that the corrupted triples do not exist in either the training, validation, or test set. We simply use the truth values (or distances) to classify triples. Triples with large truth values (or small distances) tend to be predicted as positive. To evaluate, we first rank the triples associated with each specific relation (in descending order according to their truth values, or in ascending order according to the distances), and calculate the average precision for that relation. We then report on the test sets the mean average precision (MAP)

[6] Previous work typically constructs only a single negative case for each positive one. We empirically found such a balanced classification task too simple for our datasets. So we consider a highly unbalanced setting, with a positive-to-negative ratio of 1:10, for which the previously used metric accuracy is no longer suitable.

	FB122			WN18		
	MAP (Test-I/II/ALL)			MAP (Test-I/II/ALL)		
TransE	0.552	0.852	0.634	0.592	0.993	0.958
TransH	0.576	0.758	0.641	0.604	0.978	0.947
TransR	0.572	0.699	0.619	0.412	0.854	0.836
KALE-Trip	0.578	0.829	0.652	0.618	0.995	0.953
KALE-Pre	0.575	**0.916**	0.668	0.620	**0.997**	**0.964**
KALE-Joint	**0.599**	0.870	**0.677**	**0.627**	**0.997**	0.961

Table 7: Triple classification results on the test-I, test-II, and test-all sets of FB122 and WN18.

aggregated over different relations.

Optimal configurations. The hyperparameters of each method are again tuned in the ranges specified in Section 4.1, and the best models are selected by maximizing MAP on the validation set. The optimal configurations for KALE are: $d = 100$, $\eta = 0.1$, $\gamma = 0.2$, and $\lambda = 0.1$ on FB122; $d = 100$, $\eta = 0.1$, $\gamma = 0.2$, and $\lambda = 0.001$ on WN18. Again, we use the same configuration for KALE-Trip, KALE-Pre, and KALE-Joint on each dataset.

Results. Table 7 shows the results on the test-I, test-II, and test-all sets of our datasets. From the results, we can see that: (i) KALE-Pre and KALE-Joint outperform the other methods which use triples alone on almost all the test sets, demonstrating the superiority of incorporating logical rules. (ii) KALE-Joint performs better than KALE-Pre on the test-I sets, i.e., triples that cannot be directly inferred by performing pure logical inference on the training set. This observation is similar to that observed in the link prediction task, demonstrating that the joint embedding scenario can learn more predictive embeddings and make predictions beyond the capability of pure logical inference.

5 Conclusion and Future Work

In this paper, we propose a new method for jointly embedding knowledge graphs and logical rules, referred to as KALE. The key idea is to represent and model triples and rules in a unified framework. Specifically, triples are represented as atomic formulae and modeled by the translation assumption, while rules as complex formulae and by the t-norm fuzzy logics. A global loss on both atomic and complex formulae is then minimized to perform the embedding task. Embeddings learned in this way are compatible not only with triples but also with rules, which are certainly more useful for knowledge acquisition and inference. We evaluate KALE with the link prediction and triple classification tasks on WordNet and Freebase data. Experimental results show that joint embedding brings significant and consistent improvements over state-of-the-art methods. More importantly, it can obtain more predictive embeddings and make better predictions even beyond the scope of pure logical inference.

For future work, we would like to (i) Investigate the efficacy of incorporating other types of logical rules such as $\forall x, y, z : (x, \texttt{Capital-Of}, y) \Rightarrow \neg(x, \texttt{Capital-Of}, z)$. (ii) Investigate the possibility of modeling logical rules using only relation embeddings as suggested by Demeester et al. (2016), e.g., modeling the above rule using only the embedding associated with `Capital-Of`. This avoids grounding, which might be time and space inefficient especially for complicated rules. (iii) Investigate the use of automatically extracted rules which are no longer hard rules and tolerant of uncertainty.

Abstract

We introduce a simple semi-supervised approach to improve implicit discourse relation identification. This approach harnesses large amounts of automatically extracted discourse connectives along with their arguments to construct new distributional word representations. Specifically, we represent words in the space of discourse connectives as a way to directly encode their rhetorical function. Experiments on the Penn Discourse Treebank demonstrate the effectiveness of these task-tailored representations in predicting implicit discourse relations. Our results indeed show that, despite their simplicity, these connective-based representations outperform various off-the-shelf word embeddings, and achieve state-of-the-art performance on this problem.

1 Introduction

A natural distinction is often made between explicit and implicit discourse relations depending on whether they are lexicalized by a connective or not, respectively. To illustrate, the *Contrast* relation in example (1a) is triggered by the connective *but*, while it is not overtly marked in example (1b).[1] Given the lack of strong explicit cues, the identification of implicit relations is a much more challenging and still open problem. The typically low performance scores for this task also hinder the development of text-level discourse parsers (Lin et al., 2010; Xue et al., 2015): implicit discourse relations account for around half of the data for different genres and languages (Prasad et al., 2008; Sporleder and Lascarides, 2008; Taboada, 2006; Subba and Di Eugenio, 2009; Soria and Ferrari, 1998; Versley and Gastel, 2013).

(1) a. The house has voted to raise the ceiling to $3.1 trillion, *but* the Senate isn't expected to act until next week at the earliest.

b. That's not to say that the nutty plot of "A Wild Sheep Chase" is rooted in reality. It's imaginative and often funny.

The difficulty of this task lies in its dependence on a wide variety of linguistic factors, ranging from syntax, lexical semantics and also world knowledge (Asher and Lascarides, 2003). In order to deal with this issue, a common approach is to exploit hand-crafted resources to design features capturing lexical, temporal, modal, or syntactic information (Pitler et al., 2009; Park and Cardie, 2012). By contrast, more recent work show that using simple low-dimensional word-based representations, either cluster-based or distributed (aka word embeddings), yield comparable or better performance (Rutherford and Xue, 2014; Braud and Denis, 2015), while dispensing with feature engineering.

While standard low-dimensional word representations appear to encode relevant linguistic information, they have not been built with the specific rhetorical task in mind. A natural question is therefore whether one could improve implicit discourse relation identification by using word representations that are more directly related to the task. The

problem of learning good representation for discourse has been recently tackled by Ji and Eisenstein (2014) on the problem of text-level discourse parsing. Their approach uses two recursive neural networks to jointly learn the task and a transformation of the discourse segments to be attached. While this type of joint learning yields encouraging results, it is also computationally intensive, requiring long training times, and could be limited by the relatively small amount of manually annotated data available.

In this paper, we explore the possibility of learning a distributional word representation adapted to the task by selecting relevant rhetorical contexts, in this case discourse connectives, extracted from large amounts of automatically detected connectives along with their arguments. Informally, the assumption is that the estimated word-connective co-occurrence statistics will in effect give us an important insight to the rhetorical function of different words. The learning phase in this case is extremely simple, as it amounts to merely estimating co-occurrence frequencies, potentially combined with a reweighting scheme, between each word appearing in a discourse segment and its co-occurring connective. To assess the usefulness of these connective-based representations,[2] we compare them with pre-trained word representations, like Brown clusters and other word embeddings, on the task of implicit discourse relation identification. Our experiments on the Penn Discourse Treebank (PDTB) (Prasad et al., 2008) show that these new representations deliver improvements over systems using these generic representations and yield state-of-the-art results, and this without the use of other hand-crafted features, thus also alleviating the need for external linguistic resources (like lexical databases). Thus, our approach could be easily extended to resource-poor languages as long as connectives can be reliably identified on raw texts.

Section 2 summarizes related work. In Section 3, we detail our connective-based distributional word representation approach. Section 4 presents the automatic annotation of the explicit examples used to build the word representation. In Section 5, we describe our comparative experiments on the PDTB.

2 Related Work

Implicit discourse relation identification has attracted growing attention since the release of the PDTB, the first discourse corpus to make the distinction between explicit and implicit examples. Within the large body of research on this problem, we identify two main strands directly relevant to our work.

2.1 Finding the Right Input Representation

The first work on this task (Marcu and Echihabi, 2002), which pre-dates the release of the PDTB, proposed a simple word-based representation: they use the Cartesian product of words appearing in the two segments. Given the knowledge-rich nature of the task, following studies attempted to exploit various hand-crafted resources and pre-processing systems to enrich their model with information on modality, polarity, tense, lexical semantics, and syntax, possibly combined with feature selection methods (Pitler et al., 2009; Lin et al., 2009; Park and Cardie, 2012; Biran and McKeown, 2013; Li and Nenkova, 2014). Interestingly, Park and Cardie (2012) concluded on the worthlessness of word-based features, as long as hand-crafted linguistic features were used. More recent studies however reversed this conclusion (Rutherford and Xue, 2014; Braud and Denis, 2015), demonstrating that word-based features can be effective provided they were not encoded using the sparse one-hot representation, but instead with a denser one (cluster based or distributed). This paper takes one step further by testing whether learning a simple task-specific, distributional word representation could lead to further improvements.

As noted, some previous work have also attempted to learn discourse-specific representation for the related problem of discourse parsing. Thus, Ji and Eisenstein (2014) reports improvements on the RST Discourse Treebank (Carlson et al., 2001), by jointly learning a combination of the discourse units, represented by bag-of-words in a one-hot encoding, along with the sequence of actions of their shift-reduce parser. Our approach is attractively simpler, since training reduces to collecting frequency counts, and it can easily generate representations for unseen words without having to retrain the whole system.

2.2 Leveraging Explicit Discourse Data

Another line of work, also initiated in (Marcu and Echihabi, 2002), propose to deal with the sparseness of the word pair representation by using additional data automatically annotated using discourse connectives. An appeal of this strategy is that one can easily identify explicit relations in raw data, as performance are high on this task (Pitler et al., 2009) and it is even possible to rely on simple heuristics (Marcu and Echihabi, 2002; Sporleder and Lascarides, 2005; Lan et al., 2013). It has been shown, however, that using explicit examples as additional data for training an implicit relation classifier degrades performance, due to important distribution differences (Sporleder and Lascarides, 2008).

Recent attempts to overcome this issue involve domain adaptation strategies (Braud and Denis, 2014; Ji et al., 2015), sample selection (Rutherford and Xue, 2015; Wang et al., 2012), or multi-task algorithms (Lan et al., 2013). However, it generally involves longer training time since models are built on a massive amount of data, the strategy requiring a large corpus of explicit examples to overcome the noise induced by the automatic annotation strategy. In this paper, we circumvent this problem by using explicit data only for learning our word representations and not for estimating the parameters of our implicit classification model. Some aspects of the present work are similar to Biran and McKeown (2013) in that they also exploit explicit data to compute co-occurrence statistics between word pairs and connectives. But the perspective is reversed, as they represent connectives in the contexts of co-occurring word pairs, with the aim of deriving similarity features between each implicit example and each connective. Furthermore, their approach did not outperform state-of-the-art systems.

3 The Connective Vector Space Model

Our discourse-based word representation model is a simple variant of the standard vector space model (Turney and Pantel, 2010): that is, it represents individual words in specific co-occurring contexts (in this case, discourse connectives) that define the dimensions of the underlying vector space. Our specific choice of contexts was guided by two main considerations. On the one hand, we aim at learning word representations that live in a relatively low-dimensional space, so as to make learning a classification function over that space feasible. The number of parameters of that function grows proportionally with that of the input size. Although there is often a lack of consensus among linguists as to the exact definition of discourse connectives, they nevertheless form a closed class. For English, the PDTB recognizes 100 distinct connectives. On the other hand, we want to learn a vectorial representation that captures relevant aspects of the problem, in this case the rhetorical contribution of words. Adapting Harris (1954)'s famous quote, we make the assumption that words occurring in similar *rhetorical* contexts tend to have similar *rhetorical* meanings. Discourse connectives are by definition strong rhetorical cues. As an illustration, Pitler et al. (2009) found that connectives alone unambiguously predict a single relation in 94% of the PDTB level 1 data. By using connectives as contexts, we are thus linking each word to a relation (or a small set of relations), namely those that can be triggered by this connective. Note that for level 2 relations in the PDTB, the connectives are much more ambiguous (86.77% reported in (Lin et al., 2010)), and it could be also the case if we expand the list of forms considered as connectives for English, or if we try to deal with other languages and domains. We however believe that the set of relations that can be triggered by a connective is limited (not all relations can be expressed by the same connective), and that one attractive feature of our strategy is precisely to keep this ambiguity.

Before turning to the details of how we construct our distributional connective-based model, note that we decided to learn a unique representation for any individual word, irrespective of its position (with)in a particular segment. That is, we represent both arguments of a connective as a single bag of words. Other designs are of course possible: we could directly learn distinct word representation for left and right segment words, or even the pair of words (Conrath et al., 2014), to take into account the fact that some relations are oriented (e.g. *Reason* contains the cause in the first argument and *Result* in the second one). An obvious drawback of these more expressive representations is that they would need much more data to compute a robust estimate of the frequency counts.

	but			*while*			*before*		
Word	Freq.	TF-IDF	PPMI-IDF	Freq.	TF-IDF	PPMI-IDF	Freq.	TF-IDF	PPMI-IDF
reality	12	0.0	0.0	13	0.0	0.0	10	0.0	0.0

week	0	0.0	0.0	110	0.10	0.04	90	0.12	0.12

Table 1: Illustrative example of association measures between connectives and words.

3.1 Building the Distributional Representation

Our discourse-based representations of words are obtained by computing a matrix of co-occurrence between the words and the chosen contexts. The frequency counts are then weighted in order to highlight relevant associations. More formally, we note $\mathcal{V}$ the set of the n words appearing in the arguments, and $\mathcal{C}$ the set of the m connective contexts. We build the matrix $\mathbf{F}$, of size $n \times m$, by computing the frequency of each element of $\mathcal{V}$ with each element of $\mathcal{C}$. We note $f_{i,j}$ the frequency of the word $w_i \in \mathcal{V}$ appearing in one argument of the connective $c_j \in \mathcal{C}$. We use two standard weighting functions on these raw frequencies: the normalized Term Frequency (TF), eq. (1), and the Positive Pointwise Mutual Information (PPMI), eq. (2), which is a version of the PMI where negative values are ignored (with $p_{i,j}$ the joint probability that the word w_i appears with connective c_j, and $p_{i,*}$ and $p_{*,j}$, relative frequency of resp. w_i and c_j). These two measures are then normalized by multiplying the value by the Inverse Document Frequency (IDF) for a word w_i, eq. (3), as in (Biran and McKeown, 2013). In the final matrices, the i^{th} row corresponds to the m-dimensional vector for the i^{th} word of $\mathcal{V}$. The j^{th} column is a vector corresponding to the j^{th} connective.

$$\text{TF}_{i,j} = \frac{f_{i,j}}{\sum_{k=1}^{n} f_{k,j}} \quad (1)$$

$$\text{PPMI}_{i,j} = \max(0, \log\left(\frac{p_{i,j}}{p_{i,*}\, p_{*,j}}\right)) \quad (2)$$

$$\text{IDF}_i = \log\left(\frac{m}{\sum_{k=1}^{m} f_{i,k}}\right) \quad (3)$$

Table 1 illustrates the weighting of the words using the TF and the PPMI normalized with IDF. For instance, the presence of the negation "not" is positively linked to *Contrast* through *but* and *while* whereas it receives a null or a very small weight with the temporal connective *before*. The final vector for this word, $< 0.37, 0.18, 0.0 >$ with TF-IDF or $< 0.36, 0.06, 0.0 >$ with PPMI-IDF, is intended to guide the implicit model toward a contrastive relation, thus potentially helping in identifying the relation in example (1b). In contrast, the word "week" is more likely to be found in the arguments of temporal relations that can be triggered by *before* but also *while*, an ambiguity kept in our representation whereas approaches based on using explicit examples as new training data generally choose to annotate them using the most frequent sense associated with the connective, often limiting themselves to the less ambiguous ones (Marcu and Echihabi, 2002; Sporleder and Lascarides, 2008; Lan et al., 2013; Braud and Denis, 2014; Rutherford and Xue, 2015). Finally, a word occuring with all connectives, not discriminant, such as "reality" is associated with a null weight for all dimensions: it thus has no impact on the model.

Since we have 100 connectives for the PDTB, the representation is already of quite low dimensionality. However, it has been shown (Turney and Pantel, 2010) that using a dimensionality reduction algorithm could help capturing the latent dimensions between the words and their contexts and reducing the noise. We thus also test versions with a reduction Components Analysis (PCA) (Jolliffe, 2002).

3.2 Using the Word-based Representation

So far, our distributional framework associates a word with a d-dimensional vector (where $d \leq m$). We now need to represent a pair of arguments (i.e., the spans of text linked by a relation), modeled here as a pair of bags of words. Following (Braud and Denis, 2015), we first sum all word vectors contained in each segment, thus obtaining a d-dimensional vector for each segment. We then combine the two segment vectors to build a composite vector representing the pair of arguments, by ei-

ther concatenating the two segment vectors (leading to a $2d$-dimensional vector) or by computing the Kronecker product between them (leading to a d^2-dimensional vector). Finally, these segment-pair representations will be normalized using the L_2 norm to avoid segment size effects. These will then be used as the input of a classification model, as described in Section 5. Given these combination schemes, it should be clear that despite the fact that each individual word receives a unique vectorial representation irrespective of its position, the parameters of the classification model associated with a given word are likely to be different depending of whether it appears in the left or right segment.

4 Automatic Annotation of Explicit Examples

In order to collect reliable word-connective co-occurrence frequencies, we need a large corpus where the connectives and their arguments have been identified. We therefore rely on automatic annotation of raw data, instead of using the relatively small amount of explicit examples manually annotated in the PDTB (roughly $18,000$ examples). Specifically, we used the *Bllip* corpus[3] composed of news articles from the *LA Times*, the *Washington Post*, the *New York Times* and *Reuters* and containing 310 millions of words automatically POS-tagged.

Identifying the Connectives and their Arguments We have two tasks to perform: identifying the connectives and extracting their arguments.[4] Rather than relying on manually defined patterns to annotate explicit examples (Marcu and Echihabi, 2002; Sporleder and Lascarides, 2008; Rutherford and Xue, 2015), we use two binary classification models inspired by previous works on the PDTB (Pitler and Nenkova, 2009; Lin et al., 2010): the first one identifies the connectives and the second one localizes the arguments between inter- and intra-sentential, an heuristic being then used to decide on the exact boundaries of the arguments.

Discourse connectives are words (e.g., *but*, *since*) or grammaticalized multi-word expressions (e.g., *as soon as*, *on the other hand*) that may trigger a discourse relation. However, these forms can also appear without any discourse reading, such as *because* in: *He can't sleep because of the deadline*. We thus need to disambiguate these forms between discourse and non discourse readings, a task that has proven to be quite easy on the PDTB (Pitler and Nenkova, 2009). This is the task performed by our first binary classifier: a pattern-matching is used to identify all potential connectives, and the model predicts if they have discourse reading in context.

We then need to extract the arguments of the identified connectives, that is the two spans of text linked by the connective. This latter task has proven to be extremely hard on the PDTB (Lin et al., 2010; Xue et al., 2015) because of some annotation principles that make the possible types of argument very diverse. As first proposed in (Lin et al., 2010), we thus split this task into two subtasks: identifying the relative positions of the arguments and delimiting their exact boundaries.

For an explicit example in the PDTB, one argument, called *Arg2*, is linked to the connective, and thus considered as easy to extract (Lin et al., 2010). The other argument, called *Arg1*, may be located at different places relative to *Arg2* (Prasad et al., 2008): we call intra-sentential the examples where *Arg1* is a clause within the same sentence as *Arg2* (60.9% of the explicit examples in the PDTB), and inter-sentential the other examples, that is *Arg1* is found in the previous sentence, in a non-adjacent previous sentence (9%) or in a following sentence (less than 0.1%). In this work, we build a localization model by only considering these two coarse cases – the example is either intra- or inter-sentential. Note that this distinction is similar to what has been done in (Lin et al., 2010): more precisely, these authors distinguish between "same-sentence" and "previous sentence" and ignore the cases where the *Arg1* is in a following sentence. We rather choose to include them as being also inter-sentential. When the position of *Arg1* has been predicted, an heuristic is in charge of finding the exact boundaries of the arguments.

Here, the problem is that in addition to the variety of locations, the annotators were almost free to choose any boundary for an argument in the PDTB:

[3] https://catalog.ldc.upenn.edu/LDC2008T13

[4] Note that contrary to studies using automatically annotated explicit examples as new training data, we do not need to annotate the relation triggered by the connective.

an argument can cover only a part of a sentence, an entire sentence or several sentences. Statistical approaches intended to solve this task lead for now to low performance even when complex sequential models are used, and they often rely on the syntactic configurations (Lin et al., 2010; Xue et al., 2015). We thus decided to define an heuristic to perform this task, following the simplifying assumptions also used in previous work since (Marcu and Echihabi, 2002). We assume that: (1) *Arg1* is either in the same sentence as *Arg2* or in the previous one, (2) an argument covers at most one sentence and (3) a sentence contains at most two arguments. As it can be deduced from (1), our final model ignores the finer distinctions one can make for the position of inter-sentential examples (i.e. we never extract *Arg1* from a non-adjacent previous sentence or a following one).

According to these assumptions, once a connective is identified, knowing its localization is almost enough to identify the boundaries of its arguments. More precisely, if a connective is predicted as inter-sentential, then our heuristic picks the entire preceding sentence as *Arg1*, *Arg2* being the sentence containing the connective, according to assumptions (1) and (2). If a connective is predicted as intra-sentential, then the sentence containing the connective is split into two segments – according to (3) –, more precisely, the sentence is split around the connective using the punctuation and making it necessary to have a verb in each argument.

Settings We thus built two models using the PDTB: one to identify the discourse markers (connective *vs* not connective), and one to identify the position of the arguments with respect to the connective (inter- *vs* intra-sentential). The PDTB contains $18,459$ explicit examples for 100 connectives. For both models, we use the same split of the data as in (Lin et al., 2014). The test set contains 923 positive instances of connectives and $2,075$ negative instances, and 546 inter-sentential and 377 intra-sentential examples. Both models are built using a logistic regression model optimized on the development set (see Section 5), and the same simple feature set (Lin et al., 2014; Johannsen and Sgaard, 2013) without syntactic information. With C the connective, F the following word and P the previous one, our features are: C, P+C, C+F, C-POS[5], P-POS, F-POS, P-POS+C-POS and C-POS+F-POS.

Results Our model identifies discourse connective with a micro-accuracy of 92.9% (macro-F_1 91.5%). These scores are slightly lower than the state-of-the-art in micro-accuracy, but high enough to rely on this annotation. When applying our model to the *Bllip* data, we found 4 connectives that correspond to no examples. We thus have examples for only 96 connectives. For distinguishing between inter- and intra-sentential examples, we get a micro-accuracy of 96.1% (macro-F_1 96.0), with an F_1 of 96.7 for the intra- and 95.3 for the inter-sentential class, again close enough to the state-of-the-art (Lin et al., 2014).

Coverage Using these models on *Bllip*, we are able to extract around 3 million connectives, along with their arguments. Our word representation has a large vocabulary (see Table 2) compared to existing off-the-shelf word vectors, with only $2,902$ out of vocabulary (OOV) tokens in set of implicit relations.[6]

	# words	# OOV
HLBL	$246,122$	$5,439$
CnW	$268,810$	$5,638$
Brown	$247,339$	$5,413$
H-PCA	$178,080$	$7,042$
Bllip	$\mathbf{422,199}$	$\mathbf{2,902}$

Table 2: Lexicon coverage for *Brown* clusters (Brown et al., 1992), Collobert and Weston (*CnW*) (Collobert and Weston, 2008) and hierarchical log-bilinear embeddings (*HLBL*) (Mnih and Hinton, 2007) using the implementation in (Turian et al., 2010), Hellinger PCA (*H-PCA*) (Lebret and Collobert, 2014) and our connective-based representation (*Bllip*).

5 Experiments

Our experiments investigate the relevance of our connective-based representations for implicit discourse relation identification, recast here as multi-class classification problem. That is, we aim at evaluating the usefulness of having a word representation linked to the task, compared to using generic

[5]The connective POS is either the node covering the connective, or the POS of its first word if no such node exists.

[6]Training and development sets, only.

Table 3: Number of examples in train, dev, test.

word representations (either one-hot, cluster-based or distributed), and whether they encode all the information relevant to the task, thus comparing systems with or without additional hand-crafted features.

5.1 Data

The PDTB (Prasad et al., 2008) is the largest corpus annotated for discourse relations, formed by newspaper articles from the Wall Street Journal. It contains 16,053 pairs of spans of text annotated with one or more implicit relations. The relation set is organized in a three-level hierarchy. We focus on the level 1 coarse-grained relations and keep only the first relation annotated. We use the most spread split of the data, used in (Rutherford and Xue, 2014; Rutherford and Xue, 2015; Braud and Denis, 2015) among others, that is sections 2-20 for training and 21-22 for testing. The other sections are used for development. The number of examples per relation is reported in Table 3. It can be seen that the dataset is highly imbalanced, with the relation *Expansion* accounting for more than 50% of the examples.

5.2 Settings

Feature Set Our main features are based on the words occurring in the arguments. We test simple baselines using raw tokens. The first one uses the Cartesian product of the tokens, a feature template, generally called "Word pairs", used in most of the previous study for this task as in (Marcu and Echihabi, 2002; Pitler et al., 2009; Lin et al., 2011; Braud and Denis, 2015; Ji et al., 2015). It is the sparsest representation one can build from words, and it corresponds to using the combination scheme based on the Kronecker product to combine the one-hot vectors representing each word. We also report results with a less sparse version where the vectors are combined using concatenation.

We also compare our systems to previous approaches that make use of word based representations but not linked to the task. We implement the systems proposed in (Braud and Denis, 2015) in multiclass, that is using the *Brown* clusters (Brown et al., 1992), the Collobert and Weston (Collobert and Weston, 2008) and the hierarchical log-bilinear embeddings (Mnih and Hinton, 2007) using the implementation in (Turian et al., 2010)[7], and the *HPCA* (Lebret and Collobert, 2014)[8]. We use the combination schemes described in Section 3 to build vector representations for pairs of segments. For these systems and ours, using the connective-based representations, the dimensionality of the final model depends on the number of dimensions d of the representation used and on the combination scheme – the concatenation leading to $2d$ dimensions and the Kronecker product to d^2.

All the word representations used – the off-the-shelf representations as well as our connective-based representation (see Section 4) – are solely or mainly trained on newswire data, thus on the same domain as our evaluation data. The *CnW* embeddings we use in this paper, with the implementation in (Turian et al., 2010), as well as the *HLBL* embeddings have been obtained using the RCV1 corpus, that is one year of Reuters English newswire. The *H-PCA* have been built on the Wikipedia, the Reuters corpus and the Wall street Journal. We thus do not expect any out-of-domain issue when using these representations.

Finally, we experiment with additional features proposed in previous studies and well described in (Pitler et al., 2009; Park and Cardie, 2012): production rules[9], information on verbs (average verb phrases length and Levin classes), polarity (Wilson et al., 2005), General Inquirer tags (Stone and Kirsh, 1966), information about the presence of numbers and modals, and first, last and first three words. We concatenate these features to the ones built using word representations.

[7] http://metaoptimize.com/projects/wordreprs/

[8] http://lebret.ch/words/

[9] We use the gold standard parses provided in the Penn Treebank (Marcus et al., 1993).

Model We train a multinomial multiclass logistic regression model.[10] In order to deal with the class imbalance issue, we use a sample weighting scheme where each instance has a weight inversely proportional to the frequency of the class it belongs to.

Parameters We optimize the hyper-parameters of the algorithm, that is the regularization norm (L1 or L2), and the strength of the regularization $C \in \{0.001, 0.005, 0.01, 0.1, 0.5, 1, 5, 10, 100\}$. When using additional features or one-hot sparse encodings over the pairs of raw tokens, we also optimize a filter on the features by defining a frequency cutoff $t \in \{1, 2, 5, 10, 15, 20\}$. We evaluate the unsupervised representations with different number of dimensions. We test versions of the *Brown* clusters with 100, 320, 1,000 and 3,200 clusters, of the Collobert and Weston embeddings with 25, 50, 100 and 200 dimensions, of the hierarchical log-bilinear embeddings with 50 and 100 dimensions, and of the Hellinger PCA with 50, 100 and 200 dimensions. Finally, the distributional representations of words based on the connective are built using either no PCA – thus corresponding to 96 dimensions– , or a PCA[11] keeping the first k dimensions with $k \in \{2, 5, 10, 50\}$.[12] We optimize both the hyper-parameters of the algorithm and the number of dimensions of the unsupervised representation on the development set based on the macro-F_1 score, the most relevant measure to track when dealing with imbalanced data.

5.3 Results

Our results are summarized in Table 4. Using our connective-based word representation allows improvements of above 2% in macro-F_1 over the baseline systems based on raw tokens (*One-hot*), the competitive systems using pre-trained representations (*Brown* and *Embed.*) and the state-of-the-art results in terms of macro-F_1 (R&X 15). These improvements demonstrate the efficiency of the representation for this task.

We found that using an unsupervised word representation generally leads to improvements over the use of raw tokens (*One-hot*), a conclusion in line with the results reported in (Braud and Denis, 2015) for binary systems. However, contrary to their findings, in multiclass, the best results are not obtained using the *Brown* clusters, but rather the dense, real valued representations (*Embed.* and *Bllip*). Furthermore, concerning the combination schemes, the concatenation ($\oplus$) generally outperforms the Kronecker product ($\otimes$), in effect favoring lower dimensional models.

Representation	Macro-F_1	Acc.
One-hot $\otimes$	39.0	48.6
One-hot $\oplus$	40.2	50.2
Best *Brown* $\otimes$	37.5	50.6
Best *Brown* $\oplus$	40.6	51.2
Best *Embed.* $\otimes$	41.0	51.7
Best *Embed.* $\oplus$	41.6	50.1
Best dense + add feat.	40.8	51.2
Bllip TF-IDF $\otimes$	41.4	51.0
Bllip TF-IDF $\oplus$	40.1	50.0
Bllip PPMI-IDF $\otimes$	38.9	48.2
Bllip PPMI-IDF $\oplus$	**42.2***	52.5
Best *Bllip* + add feat.	**42.8***	51.7
R&X 15	40.5	57.1

Table 4: Results for multiclass experiments. R&X 15 are the scores reported in (Rutherford and Xue, 2015) ; *One-hot*: one-hot encoding of raw tokens ; *Brown* and *Embed.*: pre-trained representations ; *Bllip*: connective based representation. * $p \leq 0.1$ compared to *One-hot* $\otimes$ with t-test and Wilcoxon.

More importantly, the distributional representations based on connectives (*Bllip*) allows performance at least similar or even better than those obtained with the other dense representations unconnected to the task (*Embed.*). While simply based on weighted co-occurrence counts, thus really easy and fast to build, these representations generally outperform the ones learned using neural networks (see CnW and HLBL in Figure 1). Besides, our second best representation is also distributional, namely HPCA (see Figure 1). These result are thus in line with the conclusions in (Lebret and Collobert, 2014) for other NLP tasks: distributional representations, while simpler to obtain, may allow similar results than distributed ones.

[11] Implemented in scikit-learn, applied with default settings.

[12] Keeping resp. 11.3%, 36.6%, 56.2% or 95.3% of the variance of the data.

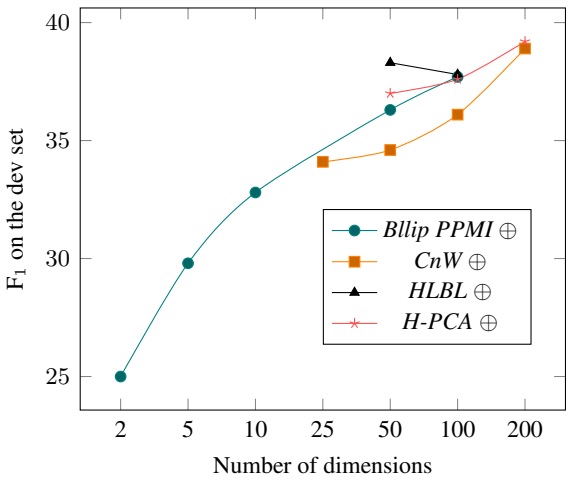

Figure 1: F_1 scores on dev against the number of dimensions.

Our best results with *Bllip* are obtained without the use of a dimensionality reduction method, thus keeping the 96 dimensions corresponding to the connectives identified in the raw data. Our new word representation like the other low-dimensional ones yield higher scores as one increases the number of dimensions (see Figure 1). This could be a limitation of our strategy, since the number of connectives in the PDTB is fixed. However, one could easily expand our model to include additional lexical elements that might have a rhetorical function such as modals or specific expressions such as *one reason is*.

We also tested the addition of hand-crafted features traditionally used for the task. We found that, either using a pre-trained word representation or our representation based on connectives, adding these features leads to small or even no improvements and suggest that these representations already encode the information provided by these features. This conclusion has however to be nuanced: when looking at the scores per relation reported in Table 5, the use of the connective based word representation alone allows the best performance for *Temporal* and *Contingency*, but the addition of new features dramatically increase the scores for *Comparison* showing that some information are missing for this relation. Moreover, this relation is the one taking the most advantage of the addition of explicit data in (Rutherford and Xue, 2015), demonstrating that these data could probably provide even more information than the ones we leverage through our representations.

Finally, our results are similar or even better than those reported in (Rutherford and Xue, 2015) in terms of macro-F_1. Our systems correspond however to a lower micro-accuracy. Looking at the scores per relation in Table 5, we found that we obtain better results for all the relations except *Expansion*, the most represented, which could explain the loss in accuracy. It is noteworthy that we generally obtain better results even without the additional features used in this work. Moreover, our systems requires lower training time (since we only train on implicit examples) and alleviate the need for the sample selection strategy used to deal with the distribution differences between the two types of data.

	Bllip PPMI-IDF ⊕		*Bllip* + *add feat*		R&X 15	
Rel	Prec	F_1	Prec	F_1	Prec	F_1
Temp	23.0	**29.9**	23.7	27.9	38.5	14.7
Cont	49.6	**47.1**	46.7	46.3	49.3	43.9
Comp	35.9	27.7	35.0	**34.3**	44.9	34.2
Exp	62.8	64.0	63.7	62.6	61.4	**69.1**

Table 5: Scores per relation for multiclass experiments, "R&X 15" are the scores reported in (Rutherford and Xue, 2015).

6 Conclusion

We presented a new approach to leverage information from explicit examples for implicit relation identification. We showed that building distributional representations linked to the task through connectives allows state-of-the-art performance and alleviates the need for additional features. Future work includes extending the representations to new contexts – such as the Alternative Lexicalization annotated in the PDTB, the modals or some adverbs – using more sophisticated weighting schemes (Lebret and Collobert, 2014) and testing this strategy for other languages and domains.

Aspect Level Sentiment Classification with Deep Memory Network

Duyu Tang, Bing Qin*, Ting Liu
Harbin Institute of Technology, Harbin, China
{dytang, qinb, tliu}@ir.hit.edu.cn

Abstract

We introduce a deep memory network for aspect level sentiment classification. Unlike feature-based SVM and sequential neural models such as LSTM, this approach explicitly captures the importance of each context word when inferring the sentiment polarity of an aspect. Such importance degree and text representation are calculated with multiple computational layers, each of which is a neural attention model over an external memory. Experiments on laptop and restaurant datasets demonstrate that our approach performs comparable to state-of-art feature based SVM system, and substantially better than LSTM and attention-based LSTM architectures. On both datasets we show that multiple computational layers could improve the performance. Moreover, our approach is also fast. The deep memory network with 9 layers is 15 times faster than LSTM with a CPU implementation.

1 Introduction

Aspect level sentiment classification is a fundamental task in the field of sentiment analysis (Pang and Lee, 2008; Liu, 2012; Pontiki et al., 2014). Given a sentence and an aspect occurring in the sentence, this task aims at inferring the sentiment polarity (e.g. positive, negative, neutral) of the aspect. For example, in sentence "*great food but the service was dreadful!*", the sentiment polarity of aspect "*food*" is positive while the polarity of aspect "*service*" is negative. Researchers typically use machine learning algorithms and build sentiment classifier in a supervised manner. Representative approaches in literature include feature based Support Vector Machine (Kiritchenko et al., 2014; Wagner et al., 2014) and neural network models (Dong et al., 2014; Lakkaraju et al., 2014; Vo and Zhang, 2015; Nguyen and Shirai, 2015; Tang et al., 2015a). Neural models are of growing interest for their capacity to learn text representation from data without careful engineering of features, and to capture semantic relations between aspect and context words in a more scalable way than feature based SVM.

Despite these advantages, conventional neural models like long short-term memory (LSTM) (Tang et al., 2015a) capture context information in an implicit way, and are incapable of explicitly exhibiting important context clues of an aspect. We believe that only some subset of context words are needed to infer the sentiment towards an aspect. For example, in sentence "*great food but the service was dreadful!*", "*dreadful*" is an important clue for the aspect "*service*" but "*great*" is not needed. Standard LSTM works in a sequential way and manipulates each context word with the same operation, so that it cannot explicitly reveal the importance of each context word. A desirable solution should be capable of explicitly capturing the importance of context words and using that information to build up features for the sentence after given an aspect word. Furthermore, a human asked to do this task will selectively focus on parts of the contexts, and acquire information where it is needed to build up an internal representation towards an aspect in his/her mind.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 214–224,
Austin, Texas, November 1-5, 2016.

In pursuit of this goal, we develop deep memory network for aspect level sentiment classification, which is inspired by the recent success of computational models with attention mechanism and explicit memory (Graves et al., 2014; Bahdanau et al., 2015; Sukhbaatar et al., 2015). Our approach is data-driven, computationally efficient and does not rely on syntactic parser or sentiment lexicon. The approach consists of multiple computational layers with shared parameters. Each layer is a content- and location- based attention model, which first learns the importance/weight of each context word and then utilizes this information to calculate continuous text representation. The text representation in the last layer is regarded as the feature for sentiment classification. As every component is differentiable, the entire model could be efficiently trained end-to-end with gradient descent, where the loss function is the cross-entropy error of sentiment classification.

We apply the proposed approach to laptop and restaurant datasets from SemEval 2014 (Pontiki et al., 2014). Experimental results show that our approach performs comparable to a top system using feature-based SVM (Kiritchenko et al., 2014). On both datasets, our approach outperforms both LSTM and attention-based LSTM models (Tang et al., 2015a) in terms of classification accuracy and running speed. Lastly, we show that using multiple computational layers over external memory could achieve improved performance.

2 Background: Memory Network

Our approach is inspired by the recent success of memory network in question answering (Weston et al., 2014; Sukhbaatar et al., 2015). We describe the background on memory network in this part.

Memory network is a general machine learning framework introduced by Weston et al. (2014). Its central idea is inference with a long-term memory component, which could be read, written to, and jointly learned with the goal of using it for prediction. Formally, a memory network consists of a memory m and four components I, G, O and R, where m is an array of objects such as an array of vectors. Among these four components, I converts input to internal feature representation, G updates old memories with new input, O generates an output representation given a new input and the current memory state, R outputs a response based on the output representation.

Let us take question answering as an example to explain the work flow of memory network. Given a list of sentences and a question, the task aims to find evidences from these sentences and generate an answer, e.g. a word. During inference, I component reads one sentence s_i at a time and encodes it into a vector representation. Then G component updates a piece of memory m_i based on current sentence representation. After all sentences are processed, we get a memory matrix m which stores the semantics of these sentences, each row representing a sentence. Given a question q, memory network encodes it into vector representation e_q, and then O component uses e_q to select question related evidences from memory m and generates an output vector o. Finally, R component takes o as the input and outputs the final response. It is worth noting that O component could consist of one or more computational layers (hops). The intuition of utilizing multiple hops is that more abstractive evidences could be found based on previously extracted evidences. Sukhbaatar et al. (2015) demonstrate that multiple hops could uncover more abstractive evidences than single hop, and could yield improved results on question answering and language modeling.

3 Deep Memory Network for Aspect Level Sentiment Classification

In this section, we describe the deep memory network approach for aspect level sentiment classification. We first give the task definition. Afterwards, we describe an overview of the approach before presenting the content- and location- based attention models in each computational layer. Lastly, we describe the use of this approach for aspect level sentiment classification.

3.1 Task Definition and Notation

Given a sentence $s = \{w_1, w_2, ..., w_i, ...w_n\}$ consisting of n words and an aspect word w_i [1] occurring in sentence s, aspect level sentiment classification aims at determining the sentiment polarity of

[1] In practice, an aspect might be a multi word expression such as "*battery life*". For simplicity we still consider aspect as a single word in this definition.

sentence s towards the aspect w_i. For example, the sentiment polarity of sentence "*great food but the service was dreadful!*" towards aspect "*food*" is positive, while the polarity towards aspect "*service*" is negative. When dealing with a text corpus, we map each word into a low dimensional, continuous and real-valued vector, also known as word embedding (Mikolov et al., 2013; Pennington et al., 2014). All the word vectors are stacked in a word embedding matrix $L \in \mathbb{R}^{d \times |V|}$, where d is the dimension of word vector and $|V|$ is vocabulary size. The word embedding of w_i is notated as $e_i \in \mathbb{R}^{d \times 1}$, which is a column in the embedding matrix L.

3.2 An Overview of the Approach

We present an overview of the deep memory network for aspect level sentiment classification.

Given a sentence $s = \{w_1, w_2, ..., w_i, ...w_n\}$ and the aspect word w_i, we map each word into its embedding vector. These word vectors are separated into two parts, aspect representation and context representation. If aspect is a single word like "*food*" or "*service*", aspect representation is the embedding of aspect word. For the case where aspect is multi word expression like "*battery life*", aspect representation is an average of its constituting word vectors (Sun et al., 2015). To simplify the interpretation, we consider aspect as a single word w_i. Context word vectors $\{e_1, e_2 ... e_{i-1}, e_{i+1} ... e_n\}$ are stacked and regarded as the external memory $m \in \mathbb{R}^{d \times (n-1)}$, where n is the sentence length.

An illustration of our approach is given in Figure 1, which is inspired by the use of memory network in question answering (Sukhbaatar et al., 2015). Our approach consists of multiple computational layers (hops), each of which contains an attention layer and a linear layer. In the first computational layer (hop 1), we regard aspect vector as the input to adaptively select important evidences from memory m through attention layer. The output of attention layer and the linear transformation of aspect vector[2] are summed and the result is considered as the input of next layer (hop 2). In a similar way, we stack multiple hops and run these steps multiple times, so that more abstractive evidences could be selected from the external memory m. The output vector in last hop is considered as the representation of sentence with regard to the aspect, and is further used as the feature for aspect level sentiment classification.

[2]In preliminary experiments, we tried directly using aspect vector without a linear transformation, and found that adding a linear layer works slightly better.

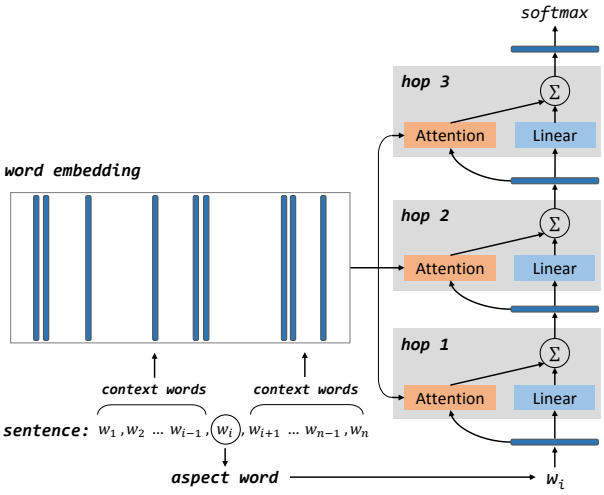

Figure 1: An illustration of our deep memory network with three computational layers (hops) for aspect level sentiment classification.

It is helpful to note that the parameters of attention and linear layers are shared in different hops. Therefore, the model with one layer and the model with nine layers have the same number of parameters.

3.3 Content Attention

We describe our attention model in this part. The basic idea of attention mechanism is that it assigns a weight/importance to each lower position when computing an upper level representation (Bahdanau et al., 2015). In this work, we use attention model to compute the representation of a sentence with regard to an aspect. The intuition is that context words do not contribute equally to the semantic meaning of a sentence. Furthermore, the importance of a word should be different if we focus on different aspect. Let us again take the example of "*great food but the service was dreadful!*". The context word "*great*" is more important than "*dreadful*" for aspect "*food*". On the contrary, "*dreadful*" is more important than "*great*" for aspect "*service*".

Taking an external memory $m \in \mathbb{R}^{d \times k}$ and an aspect vector $v_{aspect} \in \mathbb{R}^{d \times 1}$ as input, the attention model outputs a continuous vector $vec \in \mathbb{R}^{d \times 1}$. The output vector is computed as a weighted sum of each

piece of memory in m, namely

$$vec = \sum_{i=1}^{k} \alpha_i m_i \quad (1)$$

where k is the memory size, $\alpha_i \in [0, 1]$ is the weight of m_i and $\sum_i \alpha_i = 1$. We implement a neural network based attention model. For each piece of memory m_i, we use a feed forward neural network to compute its semantic relatedness with the aspect. The scoring function is calculated as follows, where $W_{att} \in \mathbb{R}^{1\times 2d}$ and $b_{att} \in \mathbb{R}^{1\times 1}$.

$$g_i = tanh(W_{att}[m_i; v_{aspect}] + b_{att}) \quad (2)$$

After obtaining $\{g_1, g_2, ... g_k\}$, we feed them to a $softmax$ function to calculate the final importance scores $\{\alpha_1, \alpha_2, ... \alpha_k\}$.

$$\alpha_i = \frac{exp(g_i)}{\sum_{j=1}^{k} exp(g_j)} \quad (3)$$

We believe that such an attention model has two advantages. One advantage is that this model could adaptively assign an importance score to each piece of memory m_i according to its semantic relatedness with the aspect. Another advantage is that this attention model is differentiable, so that it could be easily trained together with other components in an end-to-end fashion.

3.4 Location Attention

We have described our neural attention framework and a content-based model in previous subsection. However, the model mentioned above ignores the location information between context word and aspect. Such location information is helpful for an attention model because intuitively a context word closer to the aspect should be more important than a farther one. In this work, we define the location of a context word as its absolute distance with the aspect in the original sentence sequence[3]. On this basis, we study four strategies to encode the location information in the attention model. The details are described below.

[3]The location of a context word could also be measured by its distance to the aspect along a syntactic path. We leave this as a future work as we prefer to developing a purely data-driven approach without using external parsing results.

• Model 1. Following Sukhbaatar et al. (2015), we calculate the memory vector m_i with

$$m_i = e_i \odot v_i \quad (4)$$

where $\odot$ means element-wise multiplication and $v_i \in \mathbb{R}^{d\times 1}$ is a location vector for word w_i. Every element in v_i is calculated as follows,

$$v_i^k = (1 - l_i/n) - (k/d)(1 - 2 \times l_i/n) \quad (5)$$

where n is sentence length, k is the hop number and l_i is the location of w_i.

• Model 2. This is a simplified version of Model 1, using the same location vector v_i for w_i in different hops. Location vector v_i is calculated as follows.

$$v_i = 1 - l_i/n \quad (6)$$

• Model 3. We regard location vector v_i as a parameter and compute a piece of memory with vector addition, namely

$$m_i = e_i + v_i \quad (7)$$

All the position vectors are stacked in a position embedding matrix, which is jointly learned with gradient descent.

• Model 4. Location vectors are also regarded as parameters. Different from Model 3, location representations are regarded as neural gates to control how many percent of word semantics is written into the memory. We feed location vector v_i to a sigmoid function σ, and calculate m_i with element-wise multiplication:

$$m_i = e_i \odot \sigma(v_i) \quad (8)$$

3.5 The Need for Multiple Hops

It is widely accepted that computational models that are composed of multiple processing layers have the ability to learn representations of data with multiple levels of abstraction (LeCun et al., 2015). In this work, the attention layer in one layer is essentially a weighted average compositional function, which is not powerful enough to handle the sophisticated computationality like negation, intensification and contrary in language. Multiple computational layers allow the deep memory network to learn representations of text with multiple levels of abstraction. Each layer/hop retrieves important context words,

and transforms the representation at previous level into a representation at a higher, slightly more abstract level. With the composition of enough such transformations, very complex functions of sentence representation towards an aspect can be learned.

3.6 Aspect Level Sentiment Classification

We regard the output vector in last hop as the feature, and feed it to a $softmax$ layer for aspect level sentiment classification. The model is trained in a supervised manner by minimizing the cross entropy error of sentiment classification, whose loss function is given below, where T means all training instances, C is the collection of sentiment categories, (s, a) means a sentence-aspect pair.

$$loss = -\sum_{(s,a)\in T}\sum_{c\in C} P_c^g(s,a)\cdot log(P_c(s,a)) \quad (9)$$

$P_c(s,a)$ is the probability of predicting (s,a) as category c produced by our system. $P_c^g(s,a)$ is 1 or 0, indicating whether the correct answer is c. We use back propagation to calculate the gradients of all the parameters, and update them with stochastic gradient descent. We clamp the word embeddings with 300-dimensional Glove vectors (Pennington et al., 2014), which is trained from web data and the vocabulary size is 1.9M[4]. We randomize other parameters with uniform distribution $U(-0.01, 0.01)$, and set the learning rate as 0.01.

4 Experiment

We describe experimental settings and report empirical results in this section.

4.1 Experimental Setting

We conduct experiments on two datasets from SemEval 2014 (Pontiki et al., 2014), one from laptop domain and another from restaurant domain. Statistics of the datasets are given in Table 1. It is worth noting that the original dataset contains the fourth category - conflict, which means that a sentence expresses both positive and negative opinion towards an aspect. We remove conflict category as the number of instances is very tiny, incorporating which will make the dataset extremely unbalanced. Evaluation metric is classification accuracy.

Dataset	Pos.	Neg.	Neu.
Laptop-Train	994	870	464
Laptop-Test	341	128	169
Restaurant-Train	2164	807	637
Restaurant-Test	728	196	196

Table 1: Statistics of the datasets.

4.2 Comparison to Other Methods

We compare with the following baseline methods on both datasets.

(1) **Majority** is a basic baseline method, which assigns the majority sentiment label in training set to each instance in the test set.

(2) **Feature-based SVM** performs state-of-the-art on aspect level sentiment classification. We compare with a top system using ngram features, parse features and lexicon features (Kiritchenko et al., 2014).

(3) We compare with three LSTM models (Tang et al., 2015a)). In **LSTM**, a LSTM based recurrent model is applied from the start to the end of a sentence, and the last hidden vector is used as the sentence representation. **TDLSTM** extends LSTM by taking into account of the aspect, and uses two LSTM networks, a forward one and a backward one, towards the aspect. **TDLSTM+ATT** extends TDLSTM by incorporating an attention mechanism (Bahdanau et al., 2015) over the hidden vectors. We use the same Glove word vectors for fair comparison.

(4) We also implement **ContextAVG**, a simplistic version of our approach. Context word vectors are averaged and the result is added to the aspect vector. The output is fed to a $softmax$ function.

Experimental results are given in Table 2. Our approach using only content attention is abbreviated to MemNet (k), where k is the number of hops. We can find that feature-based SVM is an extremely strong performer and substantially outperforms other baseline methods, which demonstrates the importance of a powerful feature representation for aspect level sentiment classification. Among three recurrent models, TDLSTM performs better than LSTM, which indicates that taking into account of the aspect information is helpful. This is reasonable as the sentiment polarity of a sentence towards different as-

ContextAVG	61.22	71.33
MemNet (1)	67.66	76.10
MemNet (2)	71.14	78.61
MemNet (3)	71.74	79.06
MemNet (4)	72.21	79.87
MemNet (5)	71.89	80.14
MemNet (6)	72.21	80.05
MemNet (7)	**72.37**	80.32
MemNet (8)	72.05	80.14
MemNet (9)	72.21	**80.95**

Table 2: Classification accuracy of different methods on laptop and restaurant datasets. Best scores in each group are in bold.

pects (e.g. "*food*" and "*service*") might be different. It is somewhat disappointing that incorporating attention model over TDLSTM does not bring any improvement. We consider that each hidden vector of TDLSTM encodes the semantics of word sequence until the current position. Therefore, the model of TDLSTM+ATT actually selects such mixed semantics of word sequence, which is weird and not an intuitive way to selectively focus on parts of contexts. Different from TDLSTM+ATT, the proposed memory network approach removes the recurrent calculator over word sequence and directly apply attention mechanism on context word representations.

We can also find that the performance of ContextAVG is very poor, which means that assigning the same weight/importance to all the context words is not an effective way. Among all our models from single hop to nine hops, we can observe that using more computational layers could generally lead to better performance, especially when the number of hops is less than six. The best performances are achieved when the model contains seven and nine hops, respectively. On both datasets, the proposed approach could obtain comparable accuracy compared to the state-of-art feature-based SVM system.

4.3 Runtime Analysis

We study the runtime of recurrent neural models and the proposed deep memory network approach with different hops. We implement all these approaches based on the same neural network infrastructure, use the same 300-dimensional Glove word vectors, and run them on the same CPU server.

Method	Time cost
LSTM	417
TDLSTM	490
TDLSTM + ATT	520
MemNet (1)	3
MemNet (2)	7
MemNet (3)	9
MemNet (4)	15
MemNet (5)	20
MemNet (6)	24
MemNet (7)	26
MemNet (8)	27
MemNet (9)	29

Table 3: Runtime (seconds) of each training epoch on the restaurant dataset.

The training time of each iteration on the restaurant dataset is given in Table 3. We can find that LSTM based recurrent models are indeed computationally expensive, which is caused by the complex operations in each LSTM unit along the word sequence. Instead, the memory network approach is simpler and evidently faster because it does not need recurrent calculators of sequence length. Our approach with nine hops is almost 15 times faster than the basic LSTM model.

4.4 Effects of Location Attention

As described in Section 3.4, we explore four strategies to integrate location information into the attention model. We incorporate each of them separately into the basic content-based attention model. It is helpful to restate that the difference between four location-based attention models lies in the usage of location vectors for context words. In Model 1 and Model 2, the values of location vectors are fixed and calculated in a heuristic way. In Model 3 and Model 4, location vectors are also regarded as the parameters and jointly learned along with other parameters in the deep memory network.

(a) Aspect: *service*, Answer: -1, Prediction: -1

Table 5: Examples of attention weights in different hops for aspect level sentiment classification. The model also takes into account of the location information (Model 2). This example is as same as the one we use in Table 4.

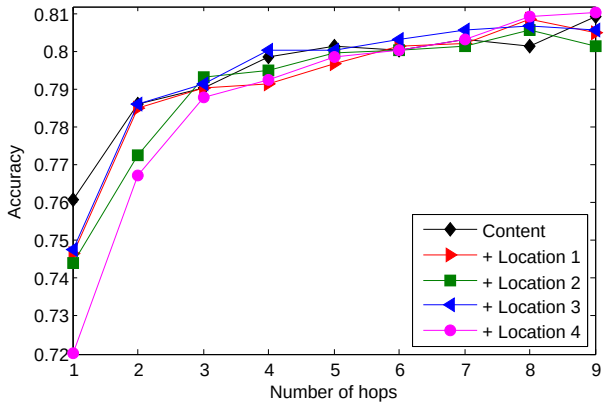

Figure 2: Classification accuracy of different attention models on the restaurant dataset.

Figure 2 shows the classification accuracy of each attention model on the restaurant dataset. We can find that using multiple computational layers could consistently improve the classification accuracy in all these models. All these models perform comparably when the number of hops is larger than five. Among these four location-based models, we prefer Model 2 as it is intuitive and has less computation cost without loss of accuracy. We also find that Model 4 is very sensitive to the choice of neural gate. Its classification accuracy decreases by almost 5 percentage when the $sigmoid$ operation over location vector is removed.

4.5 Visualize Attention Models

We visualize the attention weight of each context word to get a better understanding of the deep memory network approach. The results of context-based model and location-based model (Model 2) are given in Table 4 and Table 5, respectively.

From Table 4(a), we can find that in the first hop the context words "*great*", "*but*" and "*dreadful*" contribute equally to the aspect "*service*". While after the second hop, the weight of "*dreadful*" increases and finally the model correctly predict the polarity towards "*service*" as negative. This case shows the effects of multiple hops. However, in Table 4(b), the content-based model also gives a larger weight to "*dreadful*" when the target we focus on is "*food*". As a result, the model incorrectly predicts the polarity towards "*food*" as negative. This phenomenon might be caused by the neglect of location information. From Table 5(b), we can find that the weight of "*great*" is increased when the location of context word is considered. Accordingly, Model 2 predict-

s the correct sentiment label towards "*food*". We believe that location-enhanced model captures both content and location information. For instance, in Table 5(a) the closest context words of the aspect "*service*" are "*the*" and "*was*", while "*dreadful*" has the largest weight.

4.6 Error Analysis

We carry out an error analysis of our location enhanced model (Model 2) on the restaurant dataset, and find that most of the errors could be summarized as follows. The first factor is non-compositional sentiment expression. This model regards single context word as the basic computational unit and cannot handle this situation. An example is "*dessert was also to die for!*", where the aspect is underlined. The sentiment expression is "*die for*", whose meaning could not be composed from its constituents "*die*" and "*for*". The second factor is complex aspect expression consisting of many words, such as "*ask for the round corner table next to the large window.*" This model represents an aspect expression by averaging its constituting word vectors, which could not well handle this situation. The third factor is sentimental relation between context words such as negation, comparison and condition. An example is "*but dinner here is never disappointing, even if the prices are a bit over the top*". We believe that this is caused by the weakness of weighted average compositional function in each hop. There are also cases when comparative opinions are expressed such as "*i 've had better japanese food at a mall food court*".

5 Related Work

This work is connected to three research areas in natural language processing. We briefly describe related studies in each area.

5.1 Aspect Level Sentiment Classification

Aspect level sentiment classification is a fine-grained classification task in sentiment analysis, which aims at identifying the sentiment polarity of a sentence expressed towards an aspect (Pontiki et al., 2014). Most existing works use machine learning algorithms, and build sentiment classifier from sentences with manually annotated polarity labels. One of the most successful approaches in literature is feature based SVM. Experts could design effective feature templates and make use of external resources like parser and sentiment lexicons (Kiritchenko et al., 2014; Wagner et al., 2014). In recent years, neural network approaches (Dong et al., 2014; Lakkaraju et al., 2014; Nguyen and Shirai, 2015; Tang et al., 2015a) are of growing attention for their capacity to learn powerful text representation from data. However, these neural models (e.g. LSTM) are computationally expensive, and could not explicitly reveal the importance of context evidences with regard to an aspect. Instead, we develop simple and fast approach that explicitly encodes the context importance towards a given aspect. It is worth noting that the task we focus on differs from fine-grained opinion extraction, which assigns each word a tag (e.g. B,I,O) to indicate whether it is an aspect/sentiment word (Choi and Cardie, 2010; Irsoy and Cardie, 2014; Liu et al., 2015). The aspect word in this work is given as a part of the input.

5.2 Compositionality in Vector Space

In NLP community, compositionality means that the meaning of a composed expression (e.g. a phrase/sentence/document) comes from the meanings of its constituents (Frege, 1892). Mitchell and Lapata (2010) exploits a variety of addition and multiplication functions to calculate phrase vector. Yessenalina and Cardie (2011) use matrix multiplication as compositional function to compute vectors for longer phrases. To compute sentence representation, researchers develop denoising autoencoder (Glorot et al., 2011), convolutional neural network (Kalchbrenner et al., 2014; Kim, 2014; Yin and Schütze, 2015), sequence based recurrent neural models (Sutskever et al., 2014; Kiros et al., 2015; Li et al., 2015b) and tree-structured neural networks (Socher et al., 2013; Tai et al., 2015; Zhu et al., 2015). Several recent studies calculate continuous representation for documents with neural networks (Le and Mikolov, 2014; Bhatia et al., 2015; Li et al., 2015a; Tang et al., 2015b; Yang et al., 2016).

5.3 Attention and Memory Networks

Recently, there is a resurgence in computational models with attention mechanism and explicit memory to learn representations of texts (Graves et al., 2014; Weston et al., 2014; Sukhbaatar et al., 2015;

Bahdanau et al., 2015). In this line of research, memory is encoded as a continuous representation and operations on memory (e.g. reading and writing) are typically implemented with neural networks. Attention mechanism could be viewed as a compositional function, where lower level representations are regarded as the memory, and the function is to choose "where to look" by assigning a weight/importance to each lower position when computing an upper level representation. Such attention based approaches have achieved promising performances on a variety of NLP tasks (Luong et al., 2015; Kumar et al., 2015; Rush et al., 2015).

6 Conclusion

We develop deep memory networks that capture importances of context words for aspect level sentiment classification. Compared with recurrent neural models like LSTM, this approach is simpler and faster. Empirical results on two datasets verify that the proposed approach performs comparable to state-of-the-art feature based SVM system, and substantively better than LSTM architectures. We implement different attention strategies and show that leveraging both content and location information could learn better context weight and text representation. We also demonstrate that using multiple computational layers in memory network could obtain improved performance. Our potential future plans are incorporating sentence structure like parsing results into the deep memory network.

Lifelong-RL: Lifelong Relaxation Labeling for Separating Entities and Aspects in Opinion Targets

Abstract

It is well-known that opinions have targets. Extracting such targets is an important problem of opinion mining because without knowing the target of an opinion, the opinion is of limited use. So far many algorithms have been proposed to extract opinion targets. However, an opinion target can be an entity or an aspect (part or attribute) of an entity. An opinion about an entity is an opinion about the entity as a whole, while an opinion about an aspect is just an opinion about that specific attribute or aspect of an entity. Thus, opinion targets should be separated into entities and aspects before use because they represent very different things about opinions. This paper proposes a novel algorithm, called *Lifelong-RL*, to solve the problem based on *lifelong machine learning* and *relaxation labeling*. Extensive experiments show that the proposed algorithm Lifelong-RL outperforms baseline methods markedly.

1 Introduction

A core problem of opinion mining or sentiment analysis is to identify each opinion/sentiment target and to classify the opinion/sentiment polarity on the target (Liu, 2012). For example, in a review sentence for a car, one wrote "Although the engine is slightly weak, this car is great." The person is positive (opinion polarity) about the car (opinion target) as a whole, but slightly negative (opinion polarity) about the car's engine (opinion target).

Past research has proposed many techniques to extract *opinion targets* (we will just call them *targets* hereafter for simplicity) and also to classify sentiment polarities on the targets. However, a target can be an entity or an aspect (part or attribute) of an entity. "Engine" in the above sentence is just one aspect of the car, while "this car" refers to the whole car. Note that in (Liu, 2012), an entity is called a *general aspect*. For effective opinion mining, we need to classify whether a target is an entity or an aspect because they refer to very different things. One can be positive about the whole entity (car) but negative about some aspects of it (e.g., engine) and vice versa. This paper aims to perform the target classification task, which, to our knowledge, has not been attempted before. Although in supervised extraction one can annotate entities and aspects with separate labels in the training data to build a model to extract them separately, in this paper our goal is to help unsupervised target extraction methods to classify targets. Unsupervised target extraction methods are often preferred because they save the time-consuming data labeling or annotation step for each domain.

Problem Statement: Given a set of opinion targets $T = \{t_1, \ldots, t_n\}$ extracted from an opinion corpus d, we want to classify each target $t_i \in T$ into one of the three classes, *entity*, *aspect*, or *NIL*, which are called class labels. NIL means that the target is neither an entity nor an aspect and is used because target extraction algorithms can make mistakes.

This paper does not propose a new target extraction algorithm. We use an existing unsupervised method, called *Double Propagation* (DP) (Qiu et al., 2011), for extraction. We only focus on target classification after the targets have been extracted. Note that an entity here can be a named entity, a prod-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 225–235,
Austin, Texas, November 1-5, 2016.

uct category, or an abstract product (e.g., "this machine" and "this product"). An named entity can be the name of a brand, a model, or a manufacturer. An aspect is a part or attribute of an entity, e.g., "battery" and "price" of the entity "camera".

Since our entities not just include the traditional named entities (e.g., "Microsoft" and "Google") but also other expressions that refer to such entities, traditional named entity recognition algorithms are not sufficient. Pronouns such as "it," "they," etc., are not considered in this paper as co-reference resolution is out of the scope of this work.

We solve this problem in an unsupervised manner so that there is no need for labor-intensive manual labeling of the training data. One key observation of the problem is that although entities and aspects are different, they are closely related because aspects are parts or attributes of entities and they often have syntactic relationships in a sentence, e.g., "This phone's screen is super." Thus it is natural to solve the problem using a relational learning method. We employ the graph labeling algorithm, *Relaxation Labeling* (RL) (Hummel and Zucker, 1983), which performs unsupervised belief propagation on a graph. In our case, each target extracted from the given corpus d forms a graph node and each relation identified in d between two targets forms an edge. With some initial probability assignments, RL can assign each target node the most probable class label. Although some other graph labeling methods can be applied as well, the key issue here is that just using a propagation method in isolation is far from sufficient due to lack of information from the given corpus, which we detail in Section 5. We then employ *Lifelong Machine Learning* (LML) (Thrun, 1998; Chen and Liu, 2014b) to make a major improvement.

LML works as follows: The learner has performed a number learning tasks in the past and has retained the knowledge gained so far. In the new/current task, it makes use of the past knowledge to help current learning and problem solving. Since RL is unsupervised, we can assume that the system has performed the same task on reviews of a large number of products/domains (or corpora). It has also saved all the graphs and classification results from those past domains in a *Knowledge Base* (KB). It then exploits this past knowledge to help classification in the current task/domain. We call this combined approach of relaxation labeling and LML *Lifelong-RL*. The approach is effective because there is a significant amount of sharing of targets and target relations across domains.

LML is different from the classic learning paradigm (supervised or unsupervised) because classic learning has no memory. It basically runs a learning algorithm on a given data in isolation without considering any past learned knowledge (Silver et al., 2013). LML aims to mimic human learning, which always retains the learned knowledge from the past and uses it to help future learning.

Our experimental results show that the proposed Lifelong-RL system is highly promising. The paradigm of LML helps improve the classification results greatly.

2 Related Work

Although many target extraction methods exist (Hu and Liu, 2004; Zhuang et al., 2006; Ku et al., 2006; Wang and Wang, 2008; Wu et al., 2009; Lin and He, 2009; Zhang et al., 2010; Mei et al., 2007; Li et al., 2010; Brody and Elhadad, 2010; Wang et al., 2010; Mukherjee and Liu, 2012; Fang and Huang, 2012; Zhou et al., 2013; Liu et al., 2013; Poria et al., 2014), we are not aware of any attempt to solve the proposed problem. As mentioned in the introduction, although in supervised target extraction, one can annotate entities and aspects with different labels, supervised methods need manually labeled training data, which is time-consuming and labor-intensive to produce (Jakob and Gurevych, 2010; Choi and Cardie, 2010; Mitchell et al., 2013). Note that relaxation labeling was used for sentiment classification in (Popescu and Etzioni, 2007), but not for target classification. More details of opinion mining can be found in (Liu, 2012; Pang and Lee, 2008).

Our work is related to transfer learning (Pan and Yang, 2010), which uses the source domain labeled data to help target domain learning, which has little or no labeled data. Our work is not just using a source domain to help a target domain. It is a continuous and cumulative learning process. Each new task can make use of the knowledge learned from all past tasks. Knowledge learned from the new task can also help improve learning of any past task. Transfer learning is not continuous, does not

accumulate knowledge over time and cannot improve learning in the source domain. Our work is also related to multi-task learning (Caruana, 1997), which jointly optimizes a set of related learning tasks. Clearly, multi-task learning is different as we learn and save information which is more realistic when a large number of tasks are involved.

Our work is most related to Lifelong Machine Learning (LML). Traditional LML focuses on supervised learning (Thrun, 1998; Ruvolo and Eaton, 2013; Chen et al., 2015). Recent work used LML in topic modeling (Chen and Liu, 2014a), which is unsupervised. Basically, they used topics generated from past domains to help current domain model inference. However, they are just for aspect extraction. So is the method in (Liu et al., 2016). They do not solve our problem. Their LML methods are also different from ours as we use a graph and results obtained in the past domains to augment the current task/domain graph to solve the problem.

3 Lifelong-RL: The General Framework

In this section, we present the proposed general framework of lifelong relaxation labeling (Lifelong-RL). We first give an overview of the relaxation labeling algorithm, which forms the base. We then incorporate it with the LML capability. The next two sections detail how this general framework is applied to our proposed task of separating entities and aspects in opinion targets.

3.1 Relaxation Labeling

Relaxation Labeling (RL) is an unsupervised graph-based label propagation algorithm that works iteratively. The graph consists of nodes and edges. Each edge represents a binary relationship between two nodes. Each node t_i in the graph is associated with a multinomial distribution $P(L(t_i))$ ($L(t_i)$ being the label of t_i) on a label set Y. Each edge is associated with two conditional probability distributions $P(L(t_i)|L(t_j))$ and $P(L(t_j)|L(t_i))$, where $P(L(t_i)|L(t_j))$ represents how the label $L(t_j)$ influences the label $L(t_i)$ and vice versa. The neighbors $Ne(t_i)$ of a node t_i are associated with a weight distribution $w(t_j|t_i)$ with $\sum_{t_j \in Ne(t_i)} w(t_j|t_i) = 1$.

Given the initial values of these quantities as inputs, RL iteratively updates the label distribution of each node until convergence. Initially, we have $P^0(L(t_i))$. Let $\Delta P^{r+1}(L(t_i))$ be the change of $P(L(t_i))$ at iteration $r+1$. Given $P^r(L(t_i))$ at iteration r, $\Delta P^{r+1}(L(t_i))$ is computed by:

$$\Delta P^{r+1}(L(t_i)) = \sum_{t_j \in Ne(t_i)} (w(t_j|t_i) \cdot \sum_{y \in Y} (P(L(t_i)|L(t_j) = y) P^r(L(t_j) = y))) \quad (1)$$

Then, the updated label distribution for iteration $r+1$, $P^{r+1}(L(t_i))$, is computed as follows:

$$P^{r+1}(L(t_i)) = \frac{P^r(L(t_i))(1+\Delta P^{r+1}(L(t_i)))}{\sum_{y \in Y} P^r(L(t_i)=y)(1+\Delta P^{r+1}(L(t_i)=y))} \quad (2)$$

Once RL ends, the final label of node t_i is its highest probable label: $L(t_i) = \underset{y \in Y}{\operatorname{argmax}}(P(L(t_i) = y))$.

Note that $P(L(t_i)|L(t_j))$ and $w(t_j|t_i)$ are not updated in each RL iteration but only $P(L(t_i))$ is. $P(L(t_i)|L(t_j))$, $w(t_j|t_i)$ and $P^0(L(t_i))$ are provided by the user or computed based on the application context. RL uses these values as input and iteratively updates $P(L(t_i))$ based on Equations (1) and (2) until convergence. Next we discuss how to incorporate LML in RL.

3.2 Lifelong Relaxation Labeling

For LML, it is assumed that at any time step, the system has worked on u past domain corpora $D = \{d_1, \ldots, d_u\}$. For each past domain corpus $d \in D$, the same Lifelong-RL algorithm was applied and its results were saved in the Knowledge Base (KB). Then the algorithm can borrow some useful prior/past knowledge in the KB to help RL in the new/current domain d_{u+1}. Once the results of the current domain are produced, they are also added to the KB for future use.

We now detail the specific types of information or knowledge that can be obtained from the past domains to help RL in the future, which should thus be stored in the KB.

1. *Prior edges*: In many applications, the graph is not given. Instead, it has to be constructed based on the data from the new task/domain data d_{u+1}. However, due to the limited data in d_{u+1}, some edges between nodes that should be present are not extracted from the data. But such edges between the nodes may exist in

some past domains. Then, those edges and their associated probabilities can be borrowed.

2. *Prior labels*: Some nodes in the current new domain may also exist in some past domains. Their labels in the past domains are very likely to be the same as those in the current domain. Then, those prior labels can give us a better idea about the initial label probability distributions of the nodes in the current domain d_{u+1}.

To leverage those edges and labels from the past domains, the system needs to ensure that they are likely to be correct and applicable to the current task domain. This is a challenge problem. In the next two sections, we detail how to ensure these to a large extent in our application context along with how to compute those initial probabilities.

4 Initialization of Relaxation Labeling

We now discuss how the proposed Lifelong-RL general framework is applied to solve our problem. In our case, each node in the graph is an extracted target $t_i \in T$, and each edge represents a binary relationship between two targets. T is the given set of all opinion targets extracted by an extraction algorithm from a review dataset/corpus d. The label set for each target is $Y = \{\text{entity}, \text{aspect}, \text{NIL}\}$. In this section, we describe how to use text clues in the corpus d to compute $P(L(t_i)|L(t_j))$, $w(t_j|t_i)$ and $P^0(L(t_i))$. In the next section, we present how these quantities are improved using prior knowledge from the past domains in the LML fashion.

4.1 Text Clues for Initialization

We use two kinds of text clues, called *type modifiers* $M(t)$ and *relation modifiers* M_R to compute the initial label distribution $P(L(t_i))$ and conditional label distribution $P(L(t_i)|L(t_j))$ respectively.

Type Modifier: This has two kinds $M_T = \{m_E, m_A\}$, where m_E and m_A represent entity modifier and aspect modifier respectively. For example, the word "this" as in "this camera is great" indicates that "camera" is probably an entity. Thus, "this" is a type modifier indicating $M(camera) = m_E$. "These" is also a type modifier. Aspect modifier is implicitly assumed when the number of appearances of entity modifiers is less than or equal to a threshold (see Section 4.2).

Relation Modifier: Given two targets, t_i and t_j, we use $M_{t_j}(t_i)$ to denote the relation modifier that the label of target t_i is influenced by the label of target t_j. Relation modifiers are further divided into 3 kinds: $M_R = \{m_c, m_{A|E}, m_{E|A}\}$.

Conjunction modifier m_c: Conjoined items are usually of the same type. For example, in "price and service", "and service" indicates a conjunction modifier for "price" and vice versa.

Entity-aspect modifier $m_{A|E}$: A possessive expression indicates an entity and an aspect relation. For example, in "the camera's battery", "camera" indicates an *entity-aspect modifier* for "battery".

Aspect-entity modifier $m_{E|A}$: Same as above except that "battery" indicates an *aspect-entity modifier* for "camera".

Modifier Extraction: These modifiers are identified from the corpus d using three syntactic rules. "This" and "these" are used to extract type modifier $M(t) = m_E$. $C_{m_E}(t)$ is the occurrence count of that modifier on target t, which is used in determining the initial label distribution in Section 4.2.

Relation modifiers are identified by dependency relations $conj(t_i, t_j)$ and $poss(t_i, t_j)$ using the Stanford Parser (Klein and Manning, 2003). Each occurrence of a relation rule contributes one count of $M_{t_j}(t_i)$ for t_i and one count of $M_{t_i}(t_j)$ for t_j. We use $C_{m_c,t_j}(t_i)$, $C_{m_{A|E},t_j}(t_i)$ and $C_{m_{E|A},t_j}(t_i)$ to denote the count of t_j modifying t_i with conjunction, entity-aspect and aspect-entity modifiers respectively. For example, "price and service" will contribute one count to $C_{m_c,\text{price}}(\text{service})$ and one count to $C_{m_c,\text{service}}(\text{price})$. Similarly, "camera's battery" will contribute one count to $C_{m_{A|E},\text{camera}}(\text{battery})$ and one count to $C_{m_{E|A},\text{battery}}(\text{camera})$.

4.2 Computing Initial Probabilities

The initial label probability distribution of target t is computed based on $C_{m_E}(t)$, i.e.,

$$P^0(L(t)) = \begin{cases} P_{m_E}(L(t)) & \text{if} \quad C_{m_E}(t) > \alpha \\ P_{m_A}(L(t)) & \text{if} \quad C_{m_E}(t) \leq \alpha \end{cases} \tag{3}$$

Here, we have two pre-defined distributions: P_{m_E} and P_{m_A}, which have a higher probability on entity and aspect respectively. The parameter α is a threshold indicating that if the entity modifier rarely occurs, the target is more likely to be an aspect. These

values are set empirically (see Section 6).

Let term $q(M_{t_j}(t_i) = m)$ be the normalized weight on the count for each kind of relation modifier $m \in M_R$:

$$q(M_{t_j}(t_i) = m) = \frac{C_{m,t_j}(t_i)}{C_{t_j}(t_i)} \quad (4)$$

where $C_{t_j}(t_i) = \sum_{m \in M_R} C_{m,t_j}(t_i)$.

The conditional label distribution $P(L(t_i)|L(t_j))$ of t_i given the label of t_j is the weighted sum over the three kinds of relation modifiers:

$$\begin{aligned} &P(L(t_i)|L(t_j)) = \\ &q(M_{t_j}(t_i) = m_c) \cdot P_{m_c}(L(t_i)|L(t_j)) \\ &+q(M_{t_j}(t_i) = m_{A|E}) \cdot P_{m_{A|E}}(L(t_i)|L(t_j)) \\ &+q(M_{t_j}(t_i) = m_{E|A}) \cdot P_{m_{E|A}}(L(t_i)|L(t_j)) \end{aligned} \quad (5)$$

where P_{m_c}, $P_{m_{A|E}}$, and $P_{m_{E|A}}$ are pre-defined conditional distributions. They are filled with values to model the label influence from neighbors and can be found in Section 6.

Finally, target t_i's neighbor weight for target t_j, i.e., $w(t_j|t_i)$, is the ratio of the count of relation modifiers $C_{t_j}(t_i)$ over the total of all t_i's neighbors:

$$w(t_j|t_i) = \frac{C_{t_j}(t_i)}{\sum_{t_{j'} \in Ne(t_i)} C_{t_{j'}}(t_i)} \quad (6)$$

If $C_{t_j}(t_i) = 0$, t_i and t_j has no edge between them.

5 Using Past Knowledge in Lifelong-RL

Due to the fact that the review corpus d_{u+1} in the current task domain may not be very large and that we use high quality syntactic rules to extract relations to build the graph to ensure precision, the number of relations extracted can be small and insufficient to produce a graph that is information rich with accurate initial probabilities. We thus apply LML to help using knowledge learned in the past. The proposed LML process in Lifelong-RL for our task is shown in Figure 1.

Our prior knowledge includes type modifiers, relation modifiers and labels of targets obtained from past domains in D. Each record in the KB is stored as a 9-tuple: $(d, t_i, t_j, M^d(t_i), M^d(t_j), C^d_{m,t_j}(t_i), C^d_{m,t_i}(t_j), L^d(t_i), L^d(t_j))$ where $d \in D$ is a past domain; t_i and t_j are two targets; $M^d(t_i)$, $M^d(t_j)$ are their type

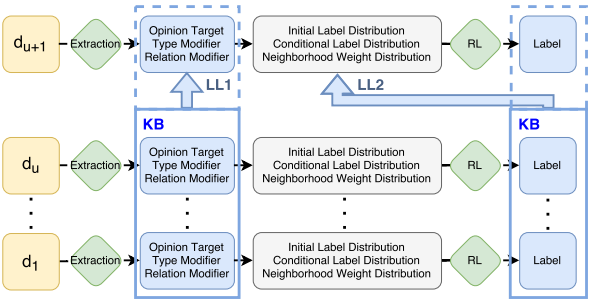

Figure 1: The proposed LML process.

modifiers, $C^d_{m,t_j}(t_i)$ and $C^d_{m,t_i}(t_j)$ are counts for relation modifiers; $L^d(t_i)$ and $L^d(t_j)$ are labels decided by RL. For example, the sentence "This camera's battery is good" forms: $(d, \text{camera}, \text{battery}, m_E, m_A, C_{m_{E|A},battery}(camera) = 1, C_{m_{A|E},camera}(battery) = 1, \text{entity}, \text{aspect})$. It means that in the past domain d, "camera" and "battery" are extracted targets. Since "camera" is followed by "this", its type modifier is m_E. Since "battery" is not identified by an entity modifier, it is m_A. The pattern "camera's battery" contributes one count for both relation modifiers $C_{m_{E|A},battery}(camera)$ and $C_{m_{A|E},camera}(battery)$. RL has labeled "camera" as entity and "battery" as aspect in d.

The next two subsections present how to use the knowledge in the KB to improve the initial assignments for the label distributions, conditional label distributions and neighborhood weight distributions in order to achieve better final labeling/classification results for the current/new domain d_{u+1}.

5.1 Exploiting Relation Modifiers in the KB

If two targets in the current domain corpus have no edge, we can check whether relation modifiers of the same two targets exist in some past domains. If so, we may be able to borrow them. But to ensure suitability, two consistency checks are performed.

Label Consistency Check: Since RL makes mistakes, we need to ensure that relation modifiers in a record in the KB are consistent with target labels in that past domain. For example, "camera's battery" is confirmed by "camera" being labeled as entity and "battery" being labeled as aspect in a past domain $d \in D$. Without this consistency, the record may not be reliable and should be discarded from the KB.

We define an indicator variable $\mathbb{I}^d_{m,t_j}(t_i)$ to ensure that the record r's relation modifier is *consistent*

with the labels of its two targets:

$$\mathbb{I}^d_{m_{A|E},t_j}(t_i) = \begin{cases} 1 & \text{if } C^d_{m_{A|E},t_j}(t_i) > 0 \\ & \text{and } L^d(t_i) = \text{aspect} \\ & \text{and } L^d(t_j) = \text{entity} \\ 0 & \text{otherwise} \end{cases} \quad (7)$$

For example, if "camera" is labeled as entity and "battery" is labeled as aspect in the past domain d, we have $\mathbb{I}^d_{m_{A|E},\text{camera}}(\text{battery}) = 1$ and $\mathbb{I}^d_{m_{E|A},\text{battery}}(\text{camera}) = 1$.

Type Consistency Check: Here we ensure the type modifiers for two targets in the current domain d_{u+1} are consistent with these type modifiers in the past domain $d \in D$. This is because an item can be an aspect in one domain but an entity in another. For example, if the current domain is "Cellphone", borrowing the relation "camera's battery" from domain "Camera" can introduce an error because "camera" is an aspect in domain "Cellphone".

Syntactic pattern "this" is a good indicator for this checking. In the "Cellphone" domain, "its camera" or "the camera" are often mentioned but not "this camera". In the "Camera" domain, "this camera" is often mentioned. The type modifier of "camera" in "Cellphone" is m_A, but in "Camera" it is m_E.

Updating Probabilities in Current Domain d_{u+1}: Edges for RL are in the forms of conditional label distribution $P(L(t_i)|L(t_j))$ and neighborhood weight distribution $w(t_j|t_i)$. We now discuss how to use the KB to estimate them more accurately.

Updating Conditional Label Distribution: Equation (5) tells that conditional label distribution $P(L(t_i)|L(t_j))$ is the weighted sum of relation modifiers' label distributions P_{m_c}, $P_{m_{A|E}}$, and $P_{m_{E|A}}$. These 3 label distributions are pre-defined and given in Table 2. They are not changed. Thus, we update conditional label distribution through updating the three relation modifiers' weights $q(M_{t_j}(t_i))$ with the knowledge in the KB. Recall the three relation modifiers are $M_R = \{m_c, m_{A|E}, m_{E|A}\}$.

After consistency check, there can be multiple relation modifiers between two targets in similar past domains $D^s \subset D$. The number of domains supporting a relation modifier $m \in M_R$ can tell which kind of relation modifiers is common and likely to be correct. For example, given many past domains like "Laptop", "Tablet", "Cellphone", etc., "camera and battery" appears more than "camera's battery", "camera" should be modified by "battery" more with $m_{E|A}$ rather than m_c (likely to be an aspect).

Let $C^{d_{u+1}}_{m,t_j}(t_i)$ be the count that target t_i modified by target t_j on relation m in the current domain d_{u+1} (not in KB). The count $C^{(\text{CL})}$ is for updating the Conditional Label (CL) distributions considering the information in both the current domain d_{u+1} and the KB. It is calculated as:

$$C^{(\text{CL})}_{m,t_j}(t_i) = \begin{cases} C^{d_{u+1}}_{m,t_j}(t_i) & \text{if } C^{d_{u+1}}_{m,t_j}(t_i) > 0 \\ \sum_{d \in D^s} \mathbb{I}^d_{m,t_j}(t_i) & \text{if } \sum_{m \in M_R} C^{d_{u+1}}_{m,t_j}(t_i)) = 0 \end{cases}$$

This equation says that if there is any relation modifier existing between the two targets in the new domain d_{u+1}, we do not borrow edges from the KB; Otherwise, the number of similar past domains supporting the relation modifier m is used. Recall that $\mathbb{I}^d_{m,t_j}(t_i)$ is the result calculated by Equation (7) after label consistency check.

We use count $C^{(\text{CL})}_{m,t_j}(t_i)$ to update $q^{d_{u+1}}(M_{t_j}(t_i))$ using Equation (4) in Section 4.2. Then the conditional label distribution accommodating relation modifiers in the KB, $P^{(\text{LL1})}(L(t_i)|L(t_j))$, is calculated by Equation, (5) using $q^{d_{u+1}}(M_{t_j}(t_i))$. LL1 denotes *Lifelong Learning* 1.

Updating Neighbor Weight Distribution: Equation (6) says that $w(t_j|t_i)$ is the importance of target t_i's neighbor t_j to t_i among all t_i's neighbors. When updating conditional label distribution using the KB, the number of domains can decide which kind of relation modifiers m is more common between the two targets t_i and t_j. But we cannot tell that neighbor t_j is more important than another neighbor $t_{j'}$ to t_i.

For example, given the past domains such as "Laptop", "Tablet", "Cellphone", etc., no matter how many domains believe "camera" is an aspect given "battery" is also an aspect, if the current domain is "All-in-one desktop computer", we should not consider the strong influences from "battery" in the past domains. We should rely more on the weights of "camera"'s neighbors provided by "All-in-one desktop computer". That means "mouse", "keyboard", "screen" etc., should have strong influences on "camera" than "battery" because most All-in-one desktops (e.g. iMac) do not have battery.

We introduce another indicator variable $\mathbb{I}^D_{m,t_j}(t_i) = \bigcup_{d \in D^s} \mathbb{I}^d_{m,t_j}(t_i)$, to indicate whether target t_j modified t_i on relation m in past similar domains D^s. It only considers the existence of a

relation modifier m among domains D^s.

The count $C_{t_j}^{(w)}(t_i)$ for updating the neighbor weight (w) distribution considers both the KB and the current domain d_{u+1}. It is as follows: $C_{t_j}^{(w)}(t_i) = \begin{cases} \sum_{m \in M_R} C_{m,t_j}^{d_{u+1}}(t_i) & \text{if } \sum_{m \in M_R} C_{m,t_j}^{d_{u+1}}(t_i) > 0 \\ \sum_{m \in M_R} \mathbb{I}_{m,t_j}^{D_u}(t_i) & \text{if } \sum_{m \in M_R} C_{m,t_j}^{d_{u+1}}(t_i) = 0 \end{cases}$ This equation tells that if there are relation modifiers existing between the two targets in the new domain d_{u+1}, we count the total times that t_j modifies t_i in the new domain; Otherwise, we count the total kinds of relation modifiers in M_R if a relation modifier $m \in M_R$ existed in past domains. Let $w^{(\text{LL1})}(t_j|t_i)$ be the neighbor weight distribution considering knowledge from the KB and d_{u+1}. It is calculated by Equation (6) using $C_{t_j}^{(w)}(t_i)$.

The initial label distribution $P^{d_{u+1},0}$ is calculated by Equation (3) only using type modifiers found in the new domain d_{u+1}. We use Lifelong-RL-1 to denote the method that employs $P^{(\text{LL1})}(L(t_i)|L(t_j))$, $w^{(\text{LL1})}(t_j|t_i)$ and $P^{d_{u+1},0}$ as inputs for RL.

5.2 Exploiting Target Labels in the KB

Since we have target labels from past domains, we may have a better idea about the initial label probabilities of targets in the current domain d_{u+1}. For example, after labeling domains like "Cellphone", "Laptop", "Tablet," and "E-reader", we may have a good sense that "camera" is likely to be an aspect. To use such knowledge, we need to check if the type modifier of target t in the current domain matches those in past domains and only keep those domains that have such a matching type modifier.

Let $D^s \subset D$ be the past domains consistent with target t's type modifier in the current domain d_{u+1}. Let $C^{D^s}(L(t))$ be the number of domains in D^s that target t is labeled as $L(t)$. Let λ be the ratio that controls how much we trust knowledge from the KB. Then the initial label probability distribution $P^{d_{u+1},0}$ calculated by Equation (3) only using type modifier found in d_{u+1} is replaced by :

$$P^{(\text{LL2}),0}(L(t)) = \frac{|D| \times P^{d_{u+1},0}(L(t)) + \lambda C^{D^s}(L(t))}{|D| + \lambda |D|} \tag{8}$$

Similarly, let $D^s \subset D$ be the past domains consistent with both targets t_i's and t_j's type modifiers in d_{u+1}. Let $C^{D^s}(L(t_i), L(t_j))$ be the number of domains in D^s that t_i and t_j are labeled as $L(t_i)$ and $L(t_j)$ respectively. The conditional label probability distribution accommodating relation modifiers in the KB, $P^{(\text{LL1})}(L(t_i)|L(t_j))$, is further updated to $P^{(\text{LL2})}(L(t_i)|L(t_j))$ by exploiting the target labels in KB (LL2 denotes *Lifelong Learning* 2):

$$P^{(\text{LL2})}(L(t_i)|L(t_j)) = \frac{|D| \times P^{(\text{LL1})}(L(t_i)|L(t_j)) + \lambda C^{D^s}(L(t_i), L(t_j))}{|D| + \lambda |D|} \tag{9}$$

For example, given "this camera", "battery" in the current domain, we are more likely to consider domains (e.g. "Film Camera", "DSLR", but not "Cellphone") that have entity modifiers on "camera" and aspect modifiers on "battery". Then we count the number of those domains that label "camera" as entity and "battery" as aspect: $C^{D^s}(L(\text{camera}) = \text{entity}, L(\text{battery}) = \text{aspect})$. Similarly, we count domains having other types of target labels on "camera" and "battery". These counts form an updated conditional label distribution that estimates "camera" as an entity and "battery" as an aspect.

Note that $|D - D^s|$, the number of past domains not consistent with targets' type modifiers, is added to $C^{D^s}(L(t_i) = \text{NIL})$ and $C^{D^s}(L(t_i) = \text{NIL}, L(t_j))$ for Equations (8) and (9) respectively to make the sum over $L(t_i)$ equal to 1. We use Lifelong-RL to denote this method which uses $P^{(\text{LL2}),0}(L(t))$, $P^{(\text{LL2})}(L(t_i)|L(t_j))$ and $w^{(\text{LL1})}(t_j|t_i)$ as input for RL.

6 Experiments

We now evaluate the proposed method and compare with baselines. We use the DP method for target extraction (Qiu et al., 2011). This method uses dependency relations between opinion words and targets to extract targets using seed opinion words. Since our paper does not focus on extraction, interested readers can refer to (Qiu et al., 2011) for details.

6.1 Experiment Settings

Evaluation Datasets: We use two sets of datasets. The first set consists of eight (8) annotated review datasets. We use each of them as the new domain data in LML to compute precision, recall, F1 scores. Five of them are from (Hu and Liu, 2004), and the remaining three are from (Liu et al., 2016). They have been used for target extraction, and thus have annotated targets, but no annotation on whether a

target is an entity or aspect. We made this annotation, which is straightforward. We used two annotators to annotate the datasets. The Cohen's kappa is 0.84. Through discussion, the annotators got complete agreement. Details of the datasets are listed in Table 1. Each cell is the number of distinct terms. These datasets are not very large but they are realistic because many products do not have a large number of reviews.

The second set consists of unlabeled review datasets from 100 diverse products or domains (Chen and Liu 2014). Each domain has 1000 reviews. They are treated as past domain data in LML since they are not annotated and thus cannot be used for computing evaluation measures.

Evaluating Measures: We mainly use precision $\mathcal{P}$, recall $\mathcal{R}$, and F_1-score $\mathcal{F}_1$ as evaluation measures. We take multiple occurrences of the same target as one count, and only evaluate entities and aspects. We will also give the accuracy results.

Compared Methods: We compare the following methods, including our proposed method, *Lifelong-RL*.

NER+TM: NER is Named Entity Recognition. We can regard the extracted terms from a NER system as entities and the rest of the targets as aspects. However, a NER system cannot identify entities such as "this car" from "this car is great." Its result is rather poor. But our type modifier (TM) does that, i.e., if an opinion target appears after "this" or "these" in at least two sentences, TM labels the target as an entity; otherwise an aspect. However, TM cannot extract named entities. Its result is also rather poor. We thus combine the two methods to give NER+TM as they complement each other very well. To make NER more powerful, we use two NER systems: Stanford-NER [1](Manning et al., 2014) and UIUC-NER[2] (Ratinov and Roth, 2009). NER+TM treats the extracted entities by the three systems as entities and the rest of the targets as aspects.

NER+TM+DICT: We run NER+TM on the 100 datasets for LML to get a list of entities, which we call the $dictionary$ (DICT). For a new task, if any target word is in the list, it is treated as an entity; otherwise an aspect.

RL: This is the base method described in Section 3. It performs relaxation labeling (RL) without the help of LML.

Lifelong-RL-1: This performs LML with RL but the current task only uses the relations in the KB from previous tasks (Section 5.1).

Lifelong-RL: This is our proposed final method. It improves Lifelong-RL-1 by further incorporating target labels in the KB from previous tasks (Section 5.2).

Parameter Settings: RL has 2 initial label distributions P_{m_E} and P_{m_A} and 3 conditional label distributions P_{m_c}, $P_{m_{E|A}}$ and $P_{m_{A|E}}$. Like other belief propagation algorithms, these probabilities need to be set empirically, as shown in Table 2. The parameter α is set to 1. Our LML method has one parameter λ for Lifelong-RL. We set it to 0.1.

6.2 Results Analysis

Table 3 shows the test results of all systems in precision, recall and F_1-score except NER+TM+DICT. NER+TM+DICT is not included due to space limitations and because it performed very poorly. The reason is that a target can be an entity in one domain

Table 3: Comparative results on Entity and Aspect in precision, recall and F_1 score: NER+TM+DICT's results are very poor and not included (see Section 6.2) for the average results.

but an aspect in another. Its average F_1-score for entity is only 49.2, and for aspect is only 50.2.

Entity Results Comparison: We observe from the table that although NER+TM combines NER and TM, its result for entities is still rather poor. We notice that phrases like "this price" causes low precision. Since it does not use many other relations and NER does not recognize many named entities that are written in lower case letters (e.g., "apple is good"), its recall is also low.

RL has a higher precision as it considers relation modifiers. However, its recall is low because it lacks information in its graph, which causes RL to make many wrong decisions. Lifelong-RL-1 introduces relation modifiers in KB from past domains into the current task. Both precision and recall increase markedly.

Lifelong-RL improves Lifelong-RL-1 further by considering target labels of past domains. Their counts improve the initial label probability distributions and conditional label probability distributions. For example, "this price" may appear in some domains but "price"'s target label is mostly aspect. We consider their counts in initial label distributions and thus rectify the initial distribution of "price". This makes "price" easier to be classified as aspect and thus improves the precision for entity.

Aspect Results Comparison: For aspects, the trend is the same but the improvements are not as dramatic as for entity. This is because the distribution of entity and aspect in the data is highly skewed. There are many more aspects than entities as we can see from the Table 1. When an entity term is wrongly classified as an aspect, it has much less impact on the aspect result than on the entity result.

Accuracy Results Comparison: Table 4 gives the classification accuracy results considering all three classes. We can see the similar trend. NER+TM+DICT's average accuracy is only 45.89 and is not included in the table.

Dataset	NER+TM	RL	Lifelong-RL-1	Lifelong-RL

Average	73.55	75.07	78.24	79.59

Table 4: Results in accuracy: NER+TM+DICT's results are again very poor and thus not included.

7 Conclusion

This paper studied the problem of classifying opinion targets into entities and aspects. To the best of our knowledge, this problem has not been attempted in the unsupervised opinion target extraction setting. But this is an important problem because without separating or classifying them one will not know whether an opinion is about an entity as a whole or about a specific aspect of an entity. This paper proposed a novel method based on relaxation labeling and the paradigm of lifelong machine learning to solve the problem. Experimental results showed the effectiveness of the proposed method.

Abstract

In this paper, we study cross-domain sentiment classification with neural network architectures. We borrow the idea from Structural Correspondence Learning and use two auxiliary tasks to help induce a sentence embedding that supposedly works well across domains for sentiment classification. We also propose to jointly learn this sentence embedding together with the sentiment classifier itself. Experiment results demonstrate that our proposed joint model outperforms several state-of-the-art methods on five benchmark datasets.

1 Introduction

With the growing need of correctly identifying the sentiments expressed in subjective texts such as product reviews, sentiment classification has received continuous attention in the NLP community for over a decade (Pang et al., 2002; Pang and Lee, 2004; Hu and Liu, 2004; Choi and Cardie, 2008; Nakagawa et al., 2010). One of the big challenges of sentiment classification is how to adapt a sentiment classifier trained on one domain to a different new domain. This is because sentiments are often expressed with domain-specific words and expressions. For example, in the **Movie** domain, words such as *moving* and *engaging* are usually positive, but they may not be relevant in the **Restaurant** domain. Since labeled data is expensive to obtain, it would be very useful if we could adapt a model trained on a *source domain* to a *target domain*.

Much work has been done in sentiment analysis to address this *domain adaptation* problem (Blitzer et al., 2007; Pan et al., 2010; Bollegala et al., 2011; Ponomareva and Thelwall, 2012; Bollegala et al., 2016). Among them, an appealing method is the Structural Correspondence Learning (SCL) method (Blitzer et al., 2007), which uses pivot feature prediction tasks to induce a projected feature space that works well for both the source and the target domains. The intuition behind is that these pivot prediction tasks are highly correlated with the original task. For sentiment classification, Blitzer et al. (2007) first chose pivot words which have high mutual information with the sentiment labels, and then set up the pivot prediction tasks to be the predictions of each of these pivot words using the other words.

However, the original SCL method is based on traditional discrete feature representations and linear classifiers. In recent years, with the advances of deep learning in NLP, multi-layer neural network models such as RNNs and CNNs have been widely used in sentiment classification and achieved good performance (Socher et al., 2013; Dong et al., 2014a; Dong et al., 2014b; Kim, 2014; Tang et al., 2015). In these models, dense, real-valued feature vectors and non-linear classification functions are used. By using real-valued word embeddings pre-trained from a large corpus, these models can take advantage of the embedding space that presumably better captures the syntactic and semantic similarities between words. And by using non-linear functions through multi-layer neural networks, these models represent a more expressive hypothesis space. Therefore, it would be interesting to explore how these neural network models could be extended for cross-domain sentiment classification.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 236–246,
Austin, Texas, November 1-5, 2016.

There has been some recent studies on neural network-based domain adaptation (Glorot et al., 2011; Chen et al., 2012; Yang and Eisenstein, 2014). They use Stacked Denoising Auto-encoders (SDA) to induce a hidden representation that presumably works well across domains. However, SDA is fully unsupervised and does not consider the end task we need to solve, i.e., the sentiment classification task. In contrast, the idea behind SCL is to use carefully-chosen auxiliary tasks that correlate with the end task to induce a hidden representation. Another line of work aims to learn a low dimensional representation for each feature in both domains based on predicting its neighboring features (Yang and Eisenstein, 2015; Bollegala et al., 2015). Different from these methods, we aim to directly learn sentence embeddings that work well across domains.

In this paper, we aim to extend the main idea behind SCL to neural network-based solutions to sentiment classification to address the domain adaptation problem. Specifically, we borrow the idea of using pivot prediction tasks from SCL. But instead of learning thousands of pivot predictors and performing singular value decomposition on the learned weights, which all relies on *linear* transformations, we introduce only two auxiliary binary prediction tasks and directly learn a *non-linear* transformation that maps an input to a dense embedding vector. Moreover, different from SCL and the auto-encoder-based methods, in which the hidden feature representation and the final classifier are learned sequentially, we propose to jointly learn the hidden feature representation together with the sentiment classification model itself, and we show that joint learning works better than sequential learning.

We conduct experiments on a number of different source and target domains for sentence-level sentiment classification. We show that our proposed method is able to achieve the best performance compared with a number of baselines for most of these domain pairs.

2 Related Work

Domain Adaptation: Domain adaptation is a general problem in NLP and has been well studied in recent years (Blitzer et al., 2006; Daumé III, 2007; Jiang and Zhai, 2007; Dredze and Crammer, 2008; Titov, 2011; Yu and Jiang, 2015). For sentiment classification, most existing domain adaptation methods are based on traditional discrete feature representations and linear classifiers. One line of work focuses on inducing a general low-dimensional cross-domain representation based on the co-occurrences of domain-specific and domain-independent features (Blitzer et al., 2007; Pan et al., 2010; Pan et al., 2011). Another line of work tries to derive domain-specific sentiment words (Bollegala et al., 2011; Li et al., 2012). Our proposed method is similar to the first line of work in that we also aim to learn a general, cross-domain representation (sentence embeddings in our case).

Neural Networks for Sentiment Classification: A recent trend of deep learning enhances various kinds of neural network models for sentiment classification, including Convolutional Neural Networks (CNNs), Recursive Neural Network (ReNNs) and Recurrent Neural Network (RNNs), which have been shown to achieve competitive results across different benchmarks (Socher et al., 2013; Dong et al., 2014a; Dong et al., 2014b; Kim, 2014; Tang et al., 2015). Inspired by their success in standard in-domain settings, it is intuitive for us to apply these neural network models to domain adaptation settings.

Denoising Auto-encoders for Domain Adaptation: Denoising Auto-encoders have been extensively studied in cross-domain sentiment classification, since the representations learned through multi-layer neural networks are robust against noise during domain adaptation. The initial application of this idea is to directly employ stacked denoising auto-encoders (SDA) by reconstructing the original features from data that are corrupted with noise (Glorot et al., 2011), and Chen et al. (2012) proposed to analytically marginalize out the corruption during SDA training. Later Yang and Eisenstein (2014) further showed that their proposed structured dropout noise strategy can dramatically improve the efficiency without sacrificing the accuracy. However, these methods are still based on traditional discrete representation and do not exploit the idea of using auxiliary tasks that are related to the end task. In contrast, the sentence embeddings learned from our method are derived from real-valued feature vectors and rely on related auxiliary tasks.

3 Method

In this section we present our sentence embedding-based domain adaptation method for sentiment classification. We first introduce the necessary notation and an overview of our method. we then delve into the details of the method.

3.1 Notation and Method Overview

We assume that each input is a piece of text consisting of a sequence of words. For the rest of this paper, we assume each input is a sentence, although our method is general enough for longer pieces of text. Let $\boldsymbol{x} = (x_1, x_2, \ldots)$ denote a sentence where each $x_i \in \{1, 2, \ldots, V\}$ is a word in the vocabulary and V is the vocabulary size. Let the sentiment label of $\boldsymbol{x}$ be $y \in \{+, -\}$ where $+$ denotes a positive sentiment and $-$ a negative sentiment. We further assume that we are given a set of labeled training sentences from a source domain, denoted by $\mathcal{D}^s = \{(\boldsymbol{x}_i^s, y_i^s)\}_{i=1}^{N^s}$. Also, we have a set of unlabeled sentences from a target domain, denoted by $\mathcal{D}^t = \{\boldsymbol{x}_i^t\}_{i=1}^{N^t}$. Our goal is to learn a good sentiment classifier from both $\mathcal{D}^s$ and $\mathcal{D}^t$ such that the classifier works well on the target domain.

A baseline solution without considering any domain difference is to simply train a classifier using $\mathcal{D}^s$, and with the recent advances in neural network-based methods to sentence classification, we consider a baseline that uses a multi-layer neural network such as a CNN or an RNN to perform the classification task. To simplify the discussion and focus on the domain adaptation ideas we propose, we will leave the details of the neural network model we use in Section 3.5. For now, we assume that a multi-layer neural network is used to transform each input $\boldsymbol{x}$ into a sentence embedding vector $\boldsymbol{z}$. Let us use f_Θ to denote the transformation function parameterized by Θ, that is, $\boldsymbol{z} = f_\Theta(\boldsymbol{x})$. Next, we assume that a linear classifier such as a softmax classifier is learned to map $\boldsymbol{z}$ to a sentiment label y.

We introduce two auxiliary tasks which presumably are highly correlated with the sentiment classification task itself. Labels for these auxiliary tasks can be automatically derived from unlabeled data in both the source and the target domains. With the help of the two auxiliary tasks, we learn a non-linear transformation function $f_{\Theta'}$ from unlabeled data and use it to derive a sentence embedding vector $\boldsymbol{z}'$ from sentence $\boldsymbol{x}$, which supposedly works better across domains. Finally we use the source domain's training data to learn a linear classifier on the representation $\boldsymbol{z} \oplus \boldsymbol{z}'$, where $\oplus$ is the operator that concatenates two vectors. Figure 1 gives the outline of our method.

3.2 Auxiliary Tasks

Our two auxiliary tasks are about whether an input sentence contains a positive or negative domain-independent sentiment word. The intuition is the following. If we have a list of domain-independent positive sentiment words, then an input sentence that contains one of these words, regardless of the domain the sentence is from, is more likely to contain an overall positive sentiment. For example, a sentence containing the word *good* is likely to be overall positive. Moreover, the rest of the sentence excluding the word *good* may contain domain-specific words or expressions that also convey a positive sentiment. For example, in the sentence "The laptop is good and goes really fast," we can see that the word *fast* is a domain-specific sentiment word, and its sentiment polarity correlates with that of the word *good*, which is domain-independent. Therefore, we can hide the domain-independent positive words in a sentence and try to use the other words in the sentence to predict whether the original sentence contains a domain-independent positive word. There are two things to note about this auxiliary task: (1) The label of the task can be automatically derived provided that we have the domain-independent positive word list. (2) The task is closely related to the original task of sentence-level sentiment classification. Similarly, we can introduce a task to predict the existence of a domain-independent negative sentiment word in a sentence.

Formally, let us assume that we have two domain-independent sentiment word lists, one for the positive sentiment and the other for the negative sentiment. Details of how these lists are obtained will be given in Section 3.5. Borrowing the term from SCL, we refer to these sentiment words as pivot words. For each sentence $\boldsymbol{x}$, we replace all the occurrences of these pivot words with a special token *UNK*. Let $g(\cdot)$ be a function that denotes this procedure, that is, $g(\boldsymbol{x})$ is the resulting sentence with

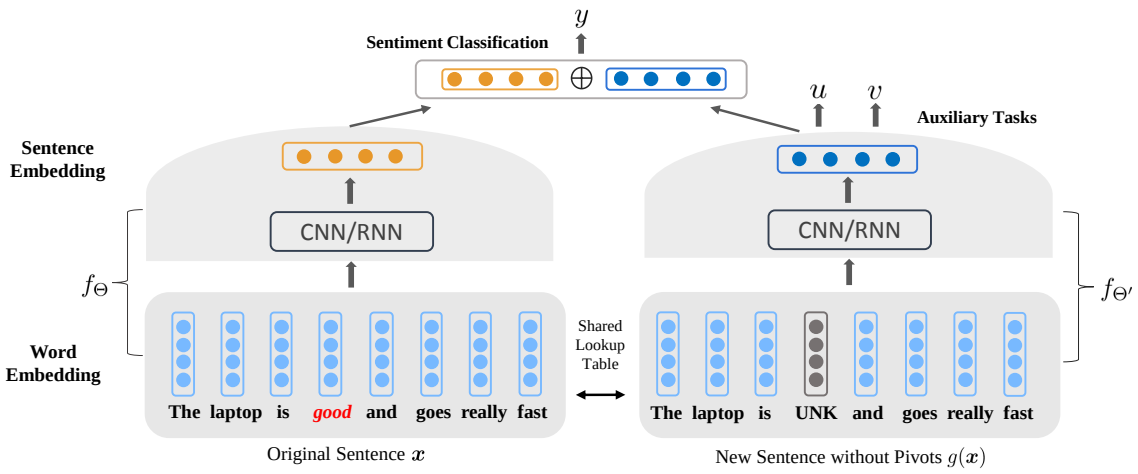

Figure 1: The Outline of our Proposed Method.

UNK tokens. We then introduce two binary labels for $g(\boldsymbol{x})$. The first label u indicates whether the original sentence $\boldsymbol{x}$ contains at least one domain-independent positive sentiment word, and the second label v indicates whether $\boldsymbol{x}$ contains at least one domain-independent negative sentiment word. Figure 1 shows an example sentence $\boldsymbol{x}$, its modified version $g(\boldsymbol{x})$ and the labels u and v for $\boldsymbol{x}$. We further use $\mathcal{D}^a = \{(\boldsymbol{x}_i, u_i, v_i)\}_{i=1}^{N^a}$ to denote a set of training sentences for the auxiliary tasks. Note that the sentences in $\mathcal{D}^a$ can be from the sentences in $\mathcal{D}^s$ and $\mathcal{D}^t$, but they can also be from other unlabeled sentences.

3.3 Sentence Embeddings for Domain Adaptation

With the two auxiliary tasks, we can learn a neural network model in a standard way to produce sentence embeddings that work well for the auxiliary tasks. Specifically, we still use Θ' to denote the parameters of the neural network that produces the sentence embeddings (and $f_{\Theta'}$ the corresponding transformation function), and we use $\boldsymbol{\beta}^+$ and $\boldsymbol{\beta}^-$ to denote the parameters of two softmax classifiers for the two auxiliary tasks, respectively. Using cross-entropy loss, we can learn Θ' by minimizing the following loss function:

$$
\begin{aligned}
& J(\Theta', \boldsymbol{\beta}^+, \boldsymbol{\beta}^-) \\
= & -\sum_{(\boldsymbol{x},u,v)\in\mathcal{D}^a} \Big(\log p(u|f_{\Theta'}(g(\boldsymbol{x})); \boldsymbol{\beta}^+) \\
& + \log p(v|f_{\Theta'}(g(\boldsymbol{x})); \boldsymbol{\beta}^-) \Big),
\end{aligned}
$$

where $p(y|\boldsymbol{z}; \boldsymbol{\beta})$ is the probability of label y given vector $\boldsymbol{z}$ and parameter $\boldsymbol{\beta}$ under softmax regression.

With the learned Θ', we can derive a sentence embedding $\boldsymbol{z}'$ from any sentence. Although we could simply use this embedding $\boldsymbol{z}'$ for sentiment classification through another softmax classifier, this may not be ideal because $\boldsymbol{z}'$ is transformed from $g(\boldsymbol{x})$, which has the domain-independent sentiment words removed. Similar to SCL and some other previous work, we concatenate the embedding vector $\boldsymbol{z}'$ with the standard embedding vector $\boldsymbol{z}$ for the final classification.

3.4 Joint Learning

Although we can learn Θ' using $\mathcal{D}^a$ as a first step, here we also explore a joint learning setting. In this setting, Θ' is learned together with the neural network model used for the end task, i.e., sentiment classification. This way, the learning of Θ' depends not only on $\mathcal{D}^a$ but also on $\mathcal{D}^s$, i.e., the sentiment-labeled training data from the source domain.

Specifically, we use Θ to denote the parameters for a neural network that takes the original sentence $\boldsymbol{x}$ and transforms it to a sentence embedding (and f_Θ the corresponding transformation function). We use $\boldsymbol{\gamma}$ to denote the parameters of a softmax classifier that operates on the concatenated sentence embedding $\boldsymbol{z} \oplus \boldsymbol{z}'$ for sentiment classification. With joint learning, we try to minimize the following loss func-

tion:

$$
\begin{aligned}
& J(\Theta, \Theta', \boldsymbol{\gamma}, \boldsymbol{\beta}^+, \boldsymbol{\beta}^-) \\
= & -\sum_{(\boldsymbol{x},y)\in\mathcal{D}^s} \Big(\log p(y|f_\Theta(\boldsymbol{x}) \oplus f_{\Theta'}(g(\boldsymbol{x})); \boldsymbol{\gamma}) \Big) \\
& -\sum_{(\boldsymbol{x},u,v)\in\mathcal{D}^a} \Big(\log p(u|f_{\Theta'}(g(\boldsymbol{x})); \boldsymbol{\beta}^+) \\
& + \log p(v|f_{\Theta'}(g(\boldsymbol{x})); \boldsymbol{\beta}^-) \Big).
\end{aligned}
$$

We can see that this loss function contains two parts. The first part is the cross-entropy loss based on the true sentiment labels of the sentences in $\mathcal{D}^s$. The second part is the loss based on the auxiliary tasks and the data $\mathcal{D}^a$, which are derived from unlabeled sentences.

Finally, to make a prediction on a sentence, we use the learned Θ and Θ' to derive a sentence embedding $f_\Theta(\boldsymbol{x}) \oplus f_{\Theta'}(g(\boldsymbol{x}))$, and then use the softmax classifier parameterized by the learned $\boldsymbol{\gamma}$ to make the final prediction.

3.5 Implementation Details

In this section we explain some of the model details.

Pivot Word Selection

Recall that the two auxiliary tasks depend on two domain-independent sentiment word lists, i.e., pivot word lists. Different from Blitzer et al. (2007), we employ weighted log-likelihood ratio (WLLR) to select the most positive and negative words in both domains as pivots. The reason is that in our preliminary experiments we observe that mutual information (used by Blitzer et al. (2007)) is biased towards low frequency words. Some high frequency words including *good* and *great* are scored low. In comparison, WLLR does not have this issue. The same observation was also reported previously by Li et al. (2009).

More specifically, we first tokenize the sentences in $\mathcal{D}^s$ and $\mathcal{D}^t$ and perform part-of-speech tagging using the NLTK toolkit. Next, we extract only adjectives, adverbs and verbs with a frequency of at least 3 in the source domain and at least 3 in the target domain. We also remove negation words such as *not* and stop words using a stop word list. We then measure each remaining candidate word's relevance to the positive and the negative classes based on $\mathcal{D}^s$ by computing the following scores:

$$
r(w, y) \;=\; \tilde{p}(w|y) \log \frac{\tilde{p}(w|y)}{\tilde{p}(w|\bar{y})},
$$

where w is a word, $y \in \{+, -\}$ is a sentiment label, $\bar{y}$ is the opposite label of y, and $\tilde{p}(w|y)$ is the empirical probability of observing w in sentences labeled with y. We can then rank the candidate words in decreasing order of $r(w, +)$ and $r(w, -)$. Finally, we select the top 25% from each ranked list as the final lists of pivot words for the positive and the negative sentiments. Some manual inspection shows that most of these words are indeed domain-independent sentiment words.

Neural Network Model

Our framework is general and potentially we can use any neural network model to transform an input sentence to a sentence embedding vector. In this paper, we adopt a CNN-based approach because it has been shown to work well for sentiment classification. Specifically, each word (including the token *UNK*) is represented by a word embedding vector. Let $\mathbf{W} \in \mathbb{R}^{d\times V}$ denote the lookup table for words, where each column is a d-dimensional embedding vector for a word type. Two separate CNNs are used to process $\boldsymbol{x}$ and $g(\boldsymbol{x})$, and their mechanisms are the same. For a word x_i in each CNN, the embedding vectors inside a window of size n centered at i are concatenated into a new vector, which we refer to as $\mathbf{e}_i \in \mathbb{R}^{nd}$. A convolution operation is then performed by applying a filter $\mathbf{F} \in \mathbb{R}^{h\times nd}$ on $\mathbf{e}_i$ to produce a hidden vector $\mathbf{h}_i = m(\mathbf{F}\mathbf{e}_i + \mathbf{b})$, where $\mathbf{b} \in \mathbb{R}^h$ is a bias vector and m is an element-wise non-linear transformation function. Note that we pad the original sequence in front and at the back to ensure that at each position i we have n vectors to be combined into $\mathbf{h}_i$. After the convolution operation is applied to the whole sequence, we obtain $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \ldots]$, and we apply a max-over-time pooling operator to take the maximum value of each row of $\mathbf{H}$ to obtain an overall hidden vector, i.e., $\boldsymbol{z}$ for $\boldsymbol{x}$ and $\boldsymbol{z}'$ for $g(\boldsymbol{x})$.

It is worth noting that the two neural networks corresponding to f_Θ and $f_{\Theta'}$ share the same word embedding lookup table. This lookup table is initialized with word embeddings from *word2vec*[1] and

[1] https://code.google.com/p/word2vec/

is updated during our learning process. Note that the token *UNK* is initialized as a zero vector and never updated.

3.6 Differences from SCL

Although our method is inspired by SCL, there are a number of major differences: (1) Our method is based on neural network models with continuous, dense feature representations and non-linear transformation functions. SCL is based on discrete, sparse feature vectors and linear transformations. (2) Although our pivot word selection is similar to that of SCL, in the end we only use two auxiliary tasks while SCL uses much more pivot prediction tasks. (3) We can directly learn the transformation function f'_Θ that produces the hidden representation, while SCL relies on SVD to learn the projection function. (4) We perform joint learning of the auxiliary tasks and the end task, i.e., sentiment classification, while SCL performs the learning in a sequential manner.

4 Experiments

4.1 Data Sets and Experiment Settings

Data Set	# Sentences	# Words
Movie1(MV1)	10662	18765
Movie2(MV2)	9613	16186
Camera(CR)	3770	5340
Laptop(LT)	1907	2837
Restaurant(RT)	1572	2930

Table 1: Statistics of our data sets.

To evaluate our proposed method, we conduct experiments using five benchmark data sets. The data sets are summarized in Table 1. *Movie1*[2] and *Movie2*[3] are movie reviews labeled by Pang and Lee (2005) and Socher et al. (2013), respectively. *Camera*[4] are reviews of digital products such as MP3 players and cameras (Hu and Liu, 2004). *Laptop* and *Restaurant*[5] are laptop and restaurant reviews taken from SemEval 2015 Task 12.

We consider 18 pairs of data sets where the two data sets come from different domains.[6] For neural network-based methods, we randomly pick 200 sentences from the target domain as the development set for parameter tuning, and the rest of the data from the target domain as the test data.

4.2 Baselines and Hyperparameters

We consider the following baselines:

Naive is a non-domain-adaptive baseline based on bag-of-word representations.

SCL is our implementation of the Structural Correspondence Learning method. We set the number of induced features K to 100 and rescale factor $\alpha = 5$, and we use 1000 pivot words based on our preliminary experiments.

mDA is our implementation of marginalized Denoising Auto-encoders (Chen et al., 2012), one of the state-of-the-art domain adaptation methods, which learns a shared hidden representation by reconstructing pivot features from corrupted inputs. Following Yang and Eisenstein (2014), we employ the efficient and effective structured dropout noise strategy without any parameter. The top 500 features are chosen as pivots based on our preliminary experiments.

NaiveNN is a non-domain-adaptive baseline based on CNN, as described in Section 3.5.

Aux-NN is a simple combination of our auxiliary tasks with NaiveNN, which treats the derived label of two auxiliary tasks as two features and then appends them to the hidden representation learned from CNN, followed by a softmax classifier.

SCL-NN is a naive combination of SCL with NaiveNN, which appends the induced representation from **SCL** to the hidden representation learned from CNN, followed by a softmax classifier.

mDA-NN is similar to **SCL-NN** but uses the hidden representation derived from **mDA**.

Sequential is our proposed method without joint learning, which first learns Θ' based on $\mathcal{D}^a$ and then learns Θ and γ based on $\mathcal{D}^s$ with fixed Θ'.

Joint is our proposed joint learning method, that is, we jointly learn Θ and Θ'.

[2] https://www.cs.cornell.edu/people/pabo/movie-review-data/

[3] http://nlp.stanford.edu/sentiment/

[4] http://www.cs.uic.edu/~liub/FBS/sentiment-analysis.html

[5] Note that the original data set is for aspect-level sentiment analysis. We remove sentences with opposite polarities towards different aspects, and use the consistent polarity as the sentence-level sentiment of each remaining sentence.

[6] Because *Movie1* and *Movie2* come from the same domain, we do not take this pair.

Table 2: Comparison of classification accuracies of different methods. * indicates that our joint method is significantly better than NaiveNN, Aux-NN, SCL-NN and mDA-NN with $p < 0.05$ based on McNemar's paired significance test.

For **Naive**, **SCL** and **mDA**, we use LibLinear[7] to train linear classifiers and use its default hyperparameters. In all the tasks, we use unigrams and bigrams with a frequency of at least 4 as features for classification. For the word embeddings, we set the dimension d to 300. For CNN, we set the window size to 3. Also, the size of the hidden representations $\boldsymbol{z}$ and $\boldsymbol{z}'$ is set to 100. Following Kim (2014), the non-linear activation function in CNN is Relu, the mini-batch size is 50, the dropout rate α equals 0.5, and the hyperparameter for the l_2 norms is set to be 3. For **Naive**, **SCL** and **mDA**, we do not use the 200 sentences in the development set for tuning parameters. Hence, for fair comparison, we also include settings where the 200 sentences are added to the training set. We denote these settings by **++**.

4.3 Results

In Table 2, we report the results of all the methods. It is easy to see that the performance of **Naive** is very limited, and the incorporation of 200 reviews in the development set (**Naive++**) brings in 4.3% of improvement on average. **SCL++** and **mDA++** can further improve the average accuracy respectively by 0.8% and 1.9%, which verifies the usefulness of these two domain adaptation methods. However, we can easily see that the performance of these domain adaptation methods based on discrete, bag-of-word representations is even much lower than the non-domain-adaptive method on continuous representations (**NaiveNN**). This confirms that it is useful to develop domain adaptation methods based on embedding vectors and neural network models.

Moreover, we can find that the performance of simply appending two features from auxiliary tasks to **NaiveNN** (i.e., **Aux-NN**) is quite close to that of **NaiveNN** on most data set pairs, which shows that it is not ideal for domain adaptation. In addition, although the shared hidden representations derived from SCL and mDA are based on traditional bag-of-word representations, **SCL-NN** and **mDA-NN** can still improve the performance of **NaiveNN** on most data set pairs, which indicates that the derived shared hidden representations by SCL and by mDA can generalize better across domains and are generally useful for domain adaptation.

Finally, it is easy to see that our method with joint learning outperforms **SCL-NN** on almost all the data set pairs. And in comparison with **mDA-NN**, our method with joint learning can also outper-

Table 3: Comparison of our method **Joint** with **NaiveNN** and **mDA-NN** in a setting where some labeled target data is used.

form it on most data set pairs, especially when the size of the labeled data in the source domain is relatively large. Furthermore, we can easily observe that for our method, joint learning generally works better than sequential learning. All these observations show the advantage of our joint learning method.

In Table 3, we also show the comparison between **mDA-NN** and our model under a setting some labeled target data is used. Specifically, we randomly select 100 sentences from the development set and mix them with the training set. We can observe that our method **Joint** outperforms **NaiveNN** and **mDA-NN** by 1.2% and 0.6%, respectively, which further confirms the effectiveness of our model. But, in comparison with the setting where no target data is available, the average improvement of our method over **NaiveNN** is relatively small.

Hence, to give a deeper analysis, we further show the comparison of **Joint** and **NaiveNN** with respect to the number of labeled target data in Figure 2. Note that for space limitation, we only present the results on *MV2* $\rightarrow$ *RT* and *MV2* $\rightarrow$ *CR*. Similar trends have been observed on other data set pairs. As we can see from Figure 2, the difference between the performance of **NaiveNN** and that of **Joint** gradually decreases with the increase of the number of labeled

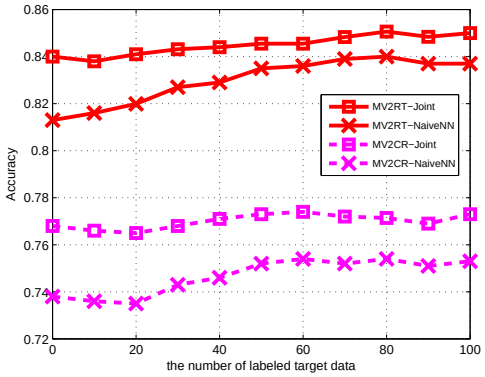

Figure 2: The influence of the number of labeled target data.

target data. This indicates that our joint model is much more effective when no or small number of labeled target data is available.

4.4 Case Study

To obtain a better understanding of our method, we conduct a case study where the source is *CR* and the target is *RT*.

For each sentiment polarity, we try to extract the most useful trigrams for the final predictions. Recall that our CNN models use a window size of 3, which corresponds to trigrams. By tracing the final prediction scores back through the neural network, we are able to locate the trigrams which have contributed the most through max-pooling. In Table 4, we present the most useful trigrams of each polarity extracted by **NaiveNN** and by the two components of our sequential and joint method. **Sequential-original** and **Joint-original** refer to the CNN corresponding to f_Θ while **Sequential-auxiliary** and **Joint-auxiliary** refer to the CNN corresponding to $f_{\Theta'}$, which is related to the auxiliary tasks.

In Table 4, we can easily observe that for **NaiveNN**, the most important trigrams are domain-independent, which contain some general sentiment words like *good*, *great* and *disappointing*. For our sequential model, the most important trigrams captured by **Sequential-original** are similar to **NaiveNN**, but due to the removal of the pivot words in each sentence, the most important trigrams extracted by **Sequential-auxiliary** are domain-specific, including target-specific sentiment words like *oily*, *friendly* and target-specific aspect words like *flavor*, *atmosphere*. But since aspect words are irrelevant to our sentiment classification

Method	Negative Sentiment	Positive Sentiment
NaiveNN	disappointing_*_*, **disgusting_*_***, it_is_not, slow_*_*, *_too_bad, *_*_terrible, **place_is_not**, unpleasant_experience_*, **would_not_go**, *_the_only	*_*_great, good_*_*,*_*_best, *_i_love, was_very_good,*_*_excellent, wonderful_*_*, *_*_amazing, *_*_nice
Sequential-original	**disgusting_*_***, disappointing_*_*, *_*_terrible expensive_*_*, it_is_not, unpleasant_experience_*, slow_*_*, *_too_bad, probably_would_not, awful_*_*	*_*_great, good_*_*, *_*_best, *_i_love, *_highly_recommended, *_*_excellent, wonderful_*_*, is_amazing_*, is_the_perfect
Sequential-auxiliary	**disgusting_*_***, **never_go_back**, money_*_*, **rude_*_***, flavor_*_*, *_this_place, **oily_*_***, prices_*_*, **inedible_!_***, **this_place_survives**	**delicious_*_***, **friendly_*_***, food_*_*, food_is_UNK, *_highly_UNK, **fresh_*_***, atmosphere_*_*, *_i_highly, nyc_*_*
Joint-original	**disgusting_*_***, **soggy_*_***, disappointing_*_*, *_too_bad, *_would_never, it_is_not, **rude_*_***, *_*_terrible, **place_is_not**, disappointment_*_*	*_*_great, good_*_*, *_*_best, *_i_love, *_*_amazing, **delicious_*_***, **back_*_***, *_i_highly, of_my_favorite
Joint-auxiliary	**soggy_*_***, **disgusting_*_***, **rude_*_***, disappointment_*_*, **not_go_back**, **was_not_fresh**, prices_*_*, **inedible_!_***, **oily_*_***, overpriced_*_*	**delicious_*_***, **go_back_***, **is_always_fresh**, **friendly_*_***, **to_die_for**, also_very_UNK, of_my_favorite, food_*_*, *_i_highly, **delicious_!_***

Table 4: Comparison of the most useful trigrams chosen by our method and by NaiveNN on $CR \rightarrow RT$. Here * denotes a "padding", which we added at the beginning and the end of each sentence. The domain-specific sentiment words are in **bold**.

task, it might bring in some noise and affect the performance of our sequential model. In contrast to **Sequential-auxiliary**, **Joint-auxiliary** is jointly learnt with the sentiment classification task, and it is easy to see that most of its extracted trigrams are target-specific sentiment words. Also, for **Joint-original**, since we share the word embeddings of two components and do not remove any pivot, it is intuitive to see that the extracted trigrams contain both domain-independent and domain-specific sentiment words. These observations agree with our motivations behind the model.

Finally, we also sample several sentences from the test dataset, i.e., *RT*, to get a deeper insight of our joint model. Although **NaiveNN** and **Sequential** correctly predict sentiments of the following two sentences:

1. "*I've also been amazed at all the new additions in the past few years: A new Jazz Bar, the most fantastic Dining Garden, the Best Thin Crust Pizzas, and now a Lasagna Menu which is **to die for**!*"

2. "*The have a great cocktail with Citrus Vodka and lemon and lime juice and mint leaves that is **to die for**!*"

Both of them give wrong predictions on another three sentences containing ***to die for***:

3. "*Try their chef's specials– they are **to die for**.*"

4. "*Their tuna tartar appetizer is **to die for**.*"

5. "*It's **to die for**!*".

However, since ***to die for*** co-occurs with some general sentiment words like *fantastic*, *best* and *great* in previous two sentences, our joint model can implicitly learn that ***to die for*** is highly correlated with the positive sentiment via our auxiliary tasks, and ultimately make correct predictions for the latter three sentences. This further indicates that our joint model can identify more domain-specific sentiment words in comparison with **NaiveNN** and **Sequential**, and therefore improve the performance.

5 Conclusions

We presented a domain adaptation method for sentiment classification based on sentence embeddings. Our method induces a sentence embedding that works well across domains, based on two auxiliary tasks. We also jointly learn the cross-domain sentence embedding and the sentiment classifier. Experiment results show that our proposed joint method can outperform several highly competitive domain adaptation methods on 18 source-target pairs using five benchmark data sets. Moreover, further analysis confirmed that our method is able to pick up domain-specific sentiment words.

Abstract

Most of the state-of-the-art sentiment classification methods are based on supervised learning algorithms which require large amounts of manually labeled data. However, the labeled resources are usually imbalanced in different languages. Cross-lingual sentiment classification tackles the problem by adapting the sentiment resources in a resource-rich language to resource-poor languages. In this study, we propose an attention-based bilingual representation learning model which learns the distributed semantics of the documents in both the source and the target languages. In each language, we use Long Short Term Memory (LSTM) network to model the documents, which has been proved to be very effective for word sequences. Meanwhile, we propose a hierarchical attention mechanism for the bilingual LSTM network. The sentence-level attention model learns which sentences of a document are more important for determining the overall sentiment while the word-level attention model learns which words in each sentence are decisive. The proposed model achieves good results on a benchmark dataset using English as the source language and Chinese as the target language.

1 Introduction

Most of the sentiment analysis research focuses on sentiment classification which aims to determine whether the users attitude is positive, neutral or negative. There are two classes of mainstreaming sentiment classification algorithms: unsupervised methods which usually require a sentiment lexicon (Taboada et al., 2011) and supervised methods (Pang et al., 2002) which require manually labeled data. However, both of these sentiment resources are unbalanced in different languages. The sentiment lexicon or labeled data are rich in several languages such as English and are poor in others. Manually building these resources for all the languages will be expensive and time-consuming. Cross-lingual sentiment classification tackles the problem by trying to adapt the resources in one language to other languages. It can also be regarded as a special kind of cross-lingual text classification task.

Recently, there have been several bilingual representation learning methods such as (Hermann and Blunsom, 2014; Gouws et al., 2014) for cross-lingual sentiment or text classification which achieve promising results. They try to learn a joint embedding space for different languages such that the training data in the source language can be directly applied to the test data in the target language. However, most of the studies only use simple functions, e.g. arithmetic average, to synthesize representations for larger text sequences. Some of them use more complicated compositional models such as the bi-gram non-linearity model in (Hermann and Blunsom, 2014) which also fail to capture the long distance dependencies in texts.

In this study, we propose an attention-based bilingual LSTM network for cross-lingual sentiment classification. LSTMs have been proved to be very effective to model word sequences and are powerful to learn on data with long range temporal dependencies. After translating the training data into the target language using machine translation

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 247–256,
Austin, Texas, November 1-5, 2016.

tools, we use the bidirectional LSTM network to model the documents in both of the source and the target languages. The LSTMs show strong ability to capture the compositional semantics for the bilingual texts in our experiments.

For the traditional LSTM network, each word in the input document is treated with equal importance, which is reasonable for traditional text classification tasks. In this paper, we propose a hierarchical attention mechanism which enables our model to focus on certain part of the input document. The motivation mainly comes from the following three observations: 1) the machine translation tool that we use to translate the documents will always introduce much noise for sentiment classification. We hope that the attention mechanism can help to filter out these noises. 2) In each individual language, the sentiment of a document is usually decided by a relative small part of it. In a long review document, the user might discuss both the advantages and disadvantages of a product. The sentiment will be confusing if we consider each sentence of the same contribution. For example, in the first review of Table 1, the first sentence reveals a negative sentiment towards the movie but the second one reveals a positive sentiment. As human readers, we can understand that the review is expressing a positive overall sentiment but it is hard for the sequence modeling algorithms including LSTM to capture. 3) At the sentence level, it is important to focus on the sentiment signals such as the sentiment words. They are usually very decisive to determine the polarity even for a very long sentence, e.g. "easy" and "nice" in the second example of Table 1.

"I felt it could have been a lot better with a little less comedy and a little more drama to get the point across. *However, its still a must see for any Jim Carrey fan.* "
"It is *easy* to read, it is *easy* to look things up in and provides a *nice* section on the treatments."

Table 1: Examples of the sentiment attention

In sum, the main contributions of this study are summarized as follows:

1) We propose a bilingual LSTM network for cross-lingual sentiment classification. Compared to the previous methods which only use weighted or arithmetic average of word embeddings to represent the document, LSTMs have obvious advantage to model the compositional semantics and to capture the long distance dependencies between words for bilingual texts.

2) We propose a hierarchical bilingual attention mechanism for our model. To the best of our knowledge, this is the first attention-based model designed for cross-lingual sentiment analysis.

3) The proposed framework achieves good results on a benchmark dataset from a cross-language sentiment classification evaluation. It outperforms the best team in the evaluation as well as several strong baseline methods.

2 Related Work

Sentiment analysis is the field of studying and analyzing peoples opinions, sentiments, evaluations, appraisals, attitudes, and emotions (Liu, 2012). The most common task of sentiment analysis is polarity classification which arises with the emergence of customer reviews on the Internet. Pang et al. (2002) used supervised learning methods and achieved promising results with simple unigram and bi-gram features. In subsequent research, more features and learning algorithms were tried for sentiment classification by a large number of researchers. Recently, the emerging of deep learning has also shed light on this area. Lots of representation learning methods has been proposed to address the sentiment classification task and many of them achieve the state-of-the-art performance on several benchmark datasets, such as the recursive neural tensor network (Socher et al., 2013), paragraph vector (Le and Mikolov, 2014), multi-channel convolutional neural networks (Kim, 2012), dynamic convolutional neural network (Blunsom et al., 2014) and tree structure LSTM (Tai et al., 2015). Very recently, Yang et al. (2016) proposed a similar hierarchical attention network based on GRU in the monolingual setting. Note that our work is independent with theirs and their study was released online after we submitted this study.

Cross-lingual sentiment classification is also a popular research topic in the sentiment analysis

community which aims to solve the sentiment classification task from a cross-language view. It is of great importance since it can exploit the existing labeled information in a source language to build a sentiment classification system in any other target language. Cross-lingual sentiment classification has been extensively studied in the very recent years. Mihalcea et al. (2007) translated English subjectivity words and phrases into the target language to build a lexicon-based classifier. Wan (2009) translated both the training data (English to Chinese) and the test data (Chinese to English) to train different models in both the source and target languages. Chen et al. (2015) proposed a knowledge validation method and incorporated it into a boosting model to transfer credible information between the two languages during training.

There have also been several studies addressing the task via multi-lingual text representation learning. Xiao and Guo (2013) learned different representations for words in different languages. Part of the word vector is shared among different languages and the rest is language-dependent. Klementiev et al. (2012) treated the task as a multi-task learning problem where each task corresponds to a single word, and the task relatedness is derived from co-occurrence statistics in bilingual parallel corpora. Chandar A P et al. (2014) and Zhou et al. (2015) used the autoencoders to model the connections between bilingual sentences. It aims to minimize the reconstruction error between the bag-of-words representations of two parallel sentences. Pham et al. (2015) extended the paragraph model into bilingual setting. Each pair of parallel sentences shares the same paragraph vector.

Compared to the existing studies, we propose to use the bilingual LSTM network to learn the document representations of reviews in each individual language. It has obvious advantage to model the compositional semantics and to capture the long distance dependencies between words. Besides, we propose a hierarchical neural attention mechanism to capture the sentiment attention in each document. The attention model helps to filter out the noise which is irrelevant to the overall sentiment.

3 Preliminaries

3.1 Problem Definition

Cross-language sentiment classification aims to use the training data in the source language to build a model which is adaptable for the test data in the target language. In our setting, we have labeled training data in English $L_{EN} = \{x_i, y_i\}_{i=1}^{N}$, where x_i is the review text and y_i is the sentiment label vector. $y_i = (1, 0)$ represents the positive sentiment and $y_i = (0, 1)$ represents the negative sentiment. In the target language Chinese, we have the test data $T_{CN} = \{x_i\}_{i=1}^{T}$ and unlabeled data $U_{CN} = \{x_i\}_{i=1}^{M}$. The task is to use L_{EN} and U_{CN} to learn a model and classify the sentiment polarity for the review texts in T_{CN}.

In our method, the labeled, unlabeled and test data are all translated into the other language using an online machine translation tool. In the subsequent part of the paper, we refer to a document and its corresponding translation in the other language as a pair of parallel documents.

3.2 RNN and LSTM

Recurrent neural network (RNN) (Rumelhart et al., 1988) is a special kind of feed-forward neural network which is useful for modeling time-sensitive sequences. At each time *t*, the model receives input from the current example and also from the hidden layer of the network's previous state. The output is calculated given the hidden state at that time stamp. The recurrent connection makes the output at each time associated with all the previous inputs. The vanilla RNN model has been considered to be difficult to train due to the well-known problem of vanishing and exploding gradients. The LSTM (Hochreiter and Schmidhuber, 1997) addresses the problem by re-parameterizing the RNN model. The core idea of LSTM is introducing the "gates" to control the data flow in the recurrent neural unit. The LSTM structure ensures that the gradient of the long-term dependencies cannot vanish. The detailed architecture that we use in shown in Figure 1.

4 Framework

In this study, we try to model the bilingual texts through the attention based LSTM network. We first

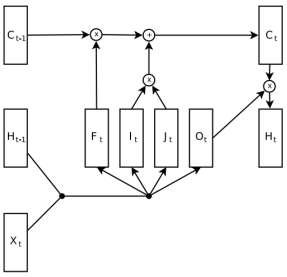

Figure 1: The LSTM architecture. The image is adopted from (Jozefowicz et al., 2015).

describe the general architecture of the model and then describe the attention mechanism used in it.

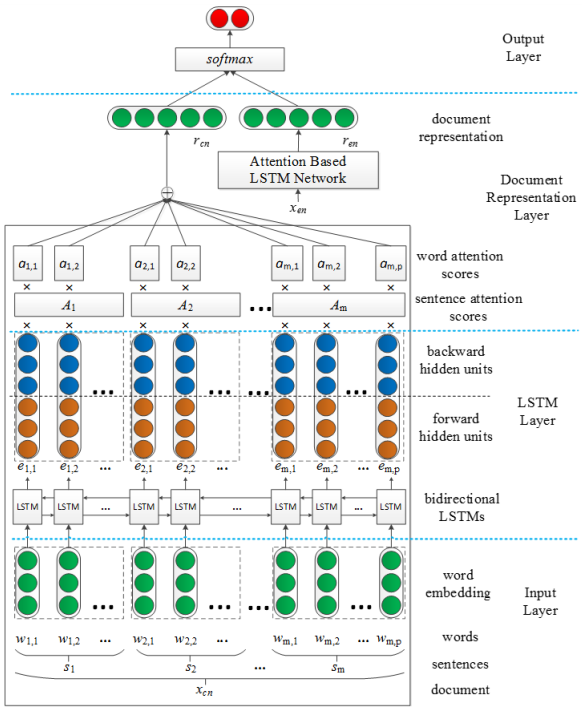

Figure 2: The architecture of the proposed framework. The inputs x_{cn} and x_{en} are parallel documents. Due to space limit, we only illustrate the attention based LSTM network in Chinese language. For the English document x_{en}, the network architecture is the same as the Chinese side but has different model parameters.

4.1 Architecture

The general architecture of our approach is shown in Figure 2. For a pair of parallel documents x_{cn} and x_{en}, each of them is sent into the attention based LSTM network. The English-side and Chinese-side architectures are the same but have different parameters. We only show the Chinese-side network in the figure due to space limit. The whole model is divided into four layers. In the input layer, the documents are represented as a word sequence where each position corresponds to a word vector from pre-trained word embeddings. In the LSTM layer, we get the high-level representation from a bidirectional LSTM network. We use the hidden units from both the forward and backward LSTMs. In the document representation layer, we incorporate the attention model into the network and derive the final document representation. At the output layer, we concatenate the representations of the English and Chinese documents and use the softmax function to predict the sentiment label.

Input Layer: The input layer of the network is the word sequences in a document x which can be either Chinese or English. The document x contains several sentences $\{s_i\}_{i=1}^{|x|}$ and each sentence is composed of several words $s_i = \{w_{i,j}\}_{j=1}^{|s_i|}$. We represent each word in the document as a fixed-size vector from pre-trained word embeddings.

LSTM Layer: In each individual language, we use bi-directional LSTMs to model the input sequences. In the bidirectional architecture, there are two layers of hidden nodes from two separate LSTMs. The two LSTMs capture the dependencies in different directions. The first hidden layers have recurrent connections from the past words while second one's direction of recurrent of connections is flipped, passing activation backwards in the texts. Therefore, in the LSTM layer, we can get the forward hidden state $\overrightarrow{h}_{i,j}$ from the forward LSTM network and the backward hidden state $\overleftarrow{h}_{i,j}$ from the backward LSTM network. We represent the final state at position (i, j), i.e. the j-th word in the i-th sentence of the document, with the concatenation of $\overrightarrow{h}_{i,j}$ and $\overleftarrow{h}_{i,j}$.

$$h_{i,j} = \overrightarrow{h}_{i,j} \parallel \overleftarrow{h}_{i,j}$$

It captures the compositional semantics in both directions of the word sequences.

Document Representation Layer: As described above, different parts of the document usually have different importance for the overall sentiment. Some

sentences or words can be decisive while the others are irrelevant. In this study, we use a hierarchical attention mechanism which assigns a real value score for each word and a real value score for each sentence. The detailed strategy of our attention model will be described in the next subsection.

Suppose we have the sentence attention score A_i for each sentence $s_i \in x$, and the word attention score $a_{i,j}$ for each word $w_{i,j} \in s_i$, both of the scores are normalized which satisfy the following equations,

$$\sum_i A_i = 1 \quad and \quad \sum_j a_{i,j} = 1$$

The sentence attention measures which sentence is more important for the overall sentiment while the word attention captures sentiment signals such as sentiment words in each sentence. Therefore, the document representation r for document x is calculated as follows,

$$r = \sum_i [A_i \cdot \sum_j (a_{i,j} \cdot h_{i,j})]$$

Note that many LSTM based models represent the word sequences only using the hidden layer at the final node. In this study, the hidden states at all the positions are considered with different attention weights. We believe that, for document sentiment classification, focusing on some certain parts of the document will be effective to filter out the sentiment-irrelevant noise.

Output Layer: At the output layer, we need to predict the overall sentiment of the document. For each English document x_{en} and its corresponding translation x_{cn}, suppose the document representations of them are obtained in previous steps as r_{en} and r_{cn}, we simply concatenate them as the feature vector and use the softmax function to predict the final sentiment.

$$\hat{y} = softmax(r_{cn} \parallel r_{en})$$

4.2 Hierarchical Attention Mechanism

For document-level sentiment classification task, we have shown that capturing both the sentence and word level attention is important. The general idea is inspired by previous works such as Bahdanau et al. (2014) and Hermann et al. (2015) which have successfully applied the attention model to machine translation and question answering. Bahdanau et al. (2014) incorporated the attention model into the sequence to sequence learning framework. During the decoding phase of the machine translation task, the attention model helps to find which input word should be "aligned" to the current output. In our case, the output of the model is not a sequence but only one sentiment vector. We hope to find the important units in the input sequence which are influential for the output.

We propose to learn a hierarchical attention model jointly with the bilingual LSTM network. The first level is the sentence attention model which measures which sentences are more important for the overall sentiment of a document. For each sentence $s_i = \{w_{i,j}\}_{j=1}^{|s_i|}$ in the document, we represent the sentence via the final hidden state of the forward LSTM and the backward LSTM, i.e.

$$s_i = \vec{h}_{i,|s_i|} \parallel \overleftarrow{h}_{i,1}$$

We use a two-layer feed-forward neural network to predict the attention score of s_i

$$\hat{A}_i = f(s_i; \theta_s)$$

$$A_i = \frac{\exp(\hat{A}_i)}{\sum_j \exp(\hat{A}_j)}$$

where f denotes the two-layer feed-forward neural network and θ_s denotes the parameters in it.

At the word level, we represent each word $w_{i,j}$ using its word embedding and the hidden state of the bidirectional LSTM layer, i.e. $h_{i,j}$. Similarly, we use a two-layer feed forward neural network to predict the attention score of $w_{i,j}$,

$$e_{i,j} = w_{i,j} \parallel \vec{h}_{i,j} \parallel \overleftarrow{h}_{i,j}$$

$$\hat{a}_{i,j} = f(e_{i,j}; \theta_w)$$

$$a_{i,j} = \frac{\exp(\hat{a}_{i,j})}{\sum_j \exp(\hat{a}_{i,j})}$$

where θ_w denotes the parameters for predicting word attention.

4.3 Training of the Proposed Model

The proposed model is trained in a semi-supervised manner. In the supervised part, we use the cross entropy loss to minimize the sentiment prediction error between the output results and the gold standard labels,

$$L_1 = \sum_{(x_{en}, x_{cn})} \sum_i -y_i \log(\hat{y}_i)$$

where x_{en} and x_{cn} are a pair of parallel documents in the training data, y is the gold-standard sentiment vector and $\hat{y}$ is the predicted vector from our model.

The unsupervised part tries to minimize the document representations between the parallel data. Following previous research, we simply measure the distance of two parallel documents via the Euclidean Distance,

$$L_2 = \sum_{(x_{en}, x_{cn})} \|r_{en} - r_{cn}\|^2$$

where x_{en} and x_{cn} are a pair of parallel documents from both the labeled and unlabeled data.

The final objective function is a weighted sum of L_1 and L_2,

$$L = L_1 + \alpha \cdot L_2$$

where α is the hyper-parameter controlling the weight. We use Adadelta (Zeiler, 2012) to update the parameters during training. It can dynamically adapt over time using only first order information and has minimal computational overhead beyond vanilla stochastic gradient descent.

In the test phase, the test document in T_{CN} is sent into our model along with the corresponding machine translated text in T_{EN}. The final sentiment is predicted via a softmax function over the concatenated representation of the bilingual texts as described above.

5 Experiment

5.1 Dataset

We use the dataset from the cross-language sentiment classification evaluation of NLP&CC 2013.[1] The dataset contains reviews in three domains including book, DVD and music. In each domain, it has 2000 positive reviews and 2000 negative reviews in English for training and 4000 Chinese reviews for test. It also contains 44113, 17815 and 29678 unlabeled reviews for book, DVD and music respectively.

5.2 Implementation Detail

We use Google Translate[2] to translate the labeled data to Chinese and translate the unlabeled data and test data to English. All the texts are tokenized and converted into lower case.

In the proposed framework, the dimensions of the word vectors and the hidden layers of LSTMs are set as 50. The initial word embeddings are trained on both the unlabeled and labeled reviews using `word2vec` in each individual language. The word vectors are fine-tuned during the training procedure. The hyper-parameter a is set to 0.2. The dropout rate is set to 0.5 to prevent overfitting. Ten percent of the training data are randomly selected as validation set. The training procedure is stopped when the prediction accuracy does not improve for 10 iterations. We implement the framework based on theano (Bastien et al., 2012) and use a GTX 980TI graphic card for training.

5.3 Baselines and Results

To evaluate the performance of our model, we compared it with the following baseline methods:

LR and **SVM:** We use logistic regression and SVM to learn different classifiers based on the translated Chinese training data. We simply use unigram features.

MT-PV: Paragraph vector (Le and Mikolov, 2014) is considered as one of the state-of-the-art monolingual document modeling methods. We translate all the training data into Chinese and use paragraph vector to learn a vector representation for the training and test data. A logistic regression classifier is used to predict the sentiment polarity.

Bi-PV: Pham et al. (2015) is one the state-of-the-art bilingual document modeling methods. It extends the paragraph vector into bilingual setting.

[1] The dataset can be found at http://tcci.ccf.org.cn/conference/2013/index.html. NLP&CC is an annual conference specialized in the fields of Natural Language Processing (NLP) and Chinese Computing (CC) organized by Chinese Computer Federation (CCF).

[2] http://translate.google.com/

Each pair of parallel sentences in the training data shares the same vector representation.

BSWE: Zhou et al. (2015) proposed the bilingual sentiment word embedding algorithm based on denoising autoencoders. It learns the vector representations for 2000 sentiment words. Each document is then represented by the sentiment words and the corresponding negation words in it.

H-Eval: Gui et al. (2013) got the highest performance in the NLP&CC 2013 cross-lingual sentiment classification evaluation. It uses a mixed CLSC model by combining co-training and transfer learning strategies.

A-Eval: This is the average performance of all the teams in the NLP&CC 2013 cross-lingual sentiment classification evaluation.

The attention-based models **EN-Attention, CN-Attention** and **BI-Attention**: Bi-Attention is the model described in the above sections which concatenate the document representations of the English side and the Chinese side texts. EN-Attention only translates the Chinese test data into English and uses English-side attention model while CN-Attention only uses the Chinese side attention model.

Method	Domains			Average
	book	DVD	music	
LR	0.765	0.796	0.741	0.767
SVM	0.779	0.814	0.707	0.767
MT-PV	0.753	0.799	0.748	0.766
Bi-PV	0.785	0.820	0.753	0.796
BSWE	0.811	0.816	0.794	0.807
A-Eval	0.662	0.660	0.675	0.666
H-Eval	0.785	0.777	0.751	0.771
EN-Attention	0.798	0.827	0.808	0.811
CN-Attention	0.820	**0.840**	0.809	0.823
BI-Attention	**0.821**	0.837	**0.813**	**0.824**

Table 2: Cross-lingual sentiment prediction accuracy of our methods and the comparison approaches.

Table 2 shows the cross-lingual sentiment classification accuracy of all the approaches. The first kind baseline algorithms are based on traditional bag-of-word features. SVM performs better than LR on book and DVD but gets much worse result on music. The second kind baseline algorithms are based on deep learning methods which learn the vector representations for words or documents. MT-PV achieves similar results with LR. Bi-PV improves the accuracy by about 0.03 using both the bilingual documents. While MT-PV and Bi-PV directly learn document representations, BSWE learns the embedding for the words in a bilingual sentiment lexicon. It gets higher accuracy than both Bi-PV and MT-PV which shows that the sentiment words are very important for this task.

Our attention based models achieve the highest prediction accuracy among all the approaches. The results show that CN-Attention always outperforms EN-Attention. The combination of the English-side and Chinese-side model brings improvement to both the book and music domains and yields the highest average prediction accuracy. The attention-based models outperform the algorithms using traditional features as well as the existing deep learning based methods. Compared to the highest performance in the NLP&CC evaluation, we improve the average accuracy by about 0.05.

5.4 Influence of the Attention Mechanism

In this study, we propose a hierarchical attention mechanism to capture the sentiment-related information of each document. In table 3, we show the results of models with different attention mechanisms. All the models are based on the bilingual bi-directional LSTM network as shown in Figure 2. LSTM is the basic bilingual bi-directional LSTM network. LSTM+SA considers only sentence-level attention while LSTM+WA considers only word-level attention. LSTM+HA combines both word-level and sentence-level attentions. From the results, we can observe that LSTM+HA outperforms the other three methods, which proves the effectiveness of the hierarchical attention mechanism. Besides, the word-level attention shows better performance than the sentence-level attention.

Method	Average Accuracy
LSTM	0.811
LSTM+SA	0.814
LSTM+WA	0.821
LSTM+HA	0.824

Table 3: Comparison of different attention mechanisms

We also conduct a case study using the examples in Table 1. We show the visualized word attention

using a heat map in Figure 3 by drawing the attention of each word in it. The darker color reveals higher attention scores while the lighter part has little importance. We can observe that our model successfully identifies the important units of the sentence. The sentiment word "easy" gets much higher attention score than the other words. The word "nice" gets the third highest score in the sentence right after the two "easy". Note that our attention mechanism considers both the word embedding vector and the hidden state vectors. Therefore, the same word "easy" gets different scores in different positions.

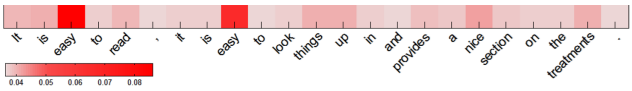

Figure 3: Attention visualization for a review sentence

5.5 Influence of the Word Embeddings

For the deep learning based methods, the initial word embeddings used as the inputs for the network usually play an important role. We study four different settings called *rand*, *static*, *fine-tuned* and *multi-channel*, respectively. In *rand* setting, the word embeddings are randomly initialized. The *static* setting keeps initial embedding fixed while the *fine-tuned* setting learns a refined embedding during the training procedure. *Multi-channel* is the combination of *static* and *fine-tuned*. Two same word vectors are concatenated to represent each word. During the training procedure, half of it is fine-tuned while the rest is fixed. Note that *fine-tuned* is the embedding setting that we use in our model.

Embedding Settings	Domains			Average
	book	DVD	music	
rand	0.789	0.786	0.746	0.774
static	0.804	0.810	0.784	0.799
fine-tuned	0.821	0.837	0.813	0.824
multi-channel	0.822	0.835	0.806	0.821

Table 4: Performance of our model with four different word embedding settings

Table 4 shows the performance of our model in these settings. *Rand* gets the lowest accuracy among them. The *fine-tuned* word embeddings perform better than *static* which fits the results in previous study (Kim, 2012). *Multi-channel* gets similar results with *fine-tuned* on DVD and music but is a bit lower on book. We also find that using pre-trained word embeddings helps the model to converge much faster than random initialization.

5.6 Influence of Vector Sizes

In our experiment, we set the size of the hidden layers in both the forward and backward LSTMs the same as the size of the input word vectors. Therefore, the dimension of the document representation is twice of the word vector size. In Figure 4, we show the performance of our model with different input vector sizes. We use the vector size in the following set $\{10, 25, 50, 100, 150, 200\}$. Note that the dimensions of all the units in the model also change with that.

We can observe from Figure 4 that the prediction accuracy for the book domain keeps steady when the vector size changes. For DVD and music, the performance increases at the beginning and becomes stable after the vector size grows larger than 50. It shows that our model is robust to a wide range of vector sizes.

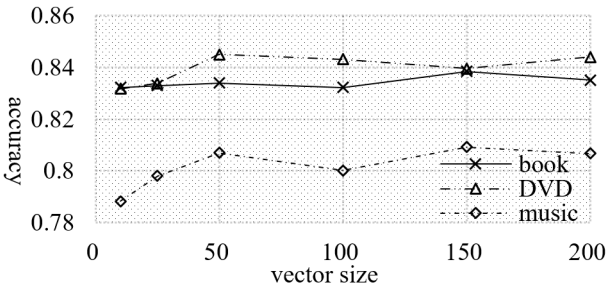

Figure 4: Performance with different vector sizes

6 Conclusion

In this paper, we propose an attention based LSTM network for cross-language sentiment classification. We use the bilingual bi-directional LSTMs to model the word sequences in the source and target languages. Based on the special characteristics of the sentiment classification task, we propose a hierarchical attention model which is jointly trained with the LSTM network. The sentence level attention

enables us to find the key sentences in a document and the word level attention helps to capture the sentiment signals. The proposed model achieves promising results on a benchmark dataset using Chinese as the source language and English as the target language. It outperforms the best results in the NLPC&CC cross-language sentiment classification evaluation as well as several strong baselines. In future work, we will evaluate the performance of our model on more datasets and more language pairs. The sentiment lexicon is also another kind of useful resource for classification. We will explore how to make full usages of these resources in the proposed framework.

Abstract

Within the field of Statistical Machine Translation (SMT), the neural approach (NMT) has recently emerged as the first technology able to challenge the long-standing dominance of phrase-based approaches (PBMT). In particular, at the IWSLT 2015 evaluation campaign, NMT outperformed well established state-of-the-art PBMT systems on English-German, a language pair known to be particularly hard because of morphology and syntactic differences. To understand in what respects NMT provides better translation quality than PBMT, we perform a detailed analysis of neural *vs.* phrase-based SMT outputs, leveraging high quality post-edits performed by professional translators on the IWSLT data. For the first time, our analysis provides useful insights on what linguistic phenomena are best modeled by neural models – such as the reordering of verbs – while pointing out other aspects that remain to be improved.

1 Introduction

The wave of neural models has eventually reached the field of Statistical Machine Translation (SMT). After a period in which Neural MT (NMT) was too computationally costly and resource demanding to compete with state-of-the-art Phrase-Based MT (PBMT)[1], the situation changed in 2015. For the first time, in the latest edition of IWSLT[2] (Cettolo et al., 2015), the system described in (Luong and Manning, 2015) overtook a variety of PBMT approaches with a large margin ($+5.3$ BLEU points) on a difficult language pair like English-German – anticipating what, most likely, will be the new NMT era.

This impressive improvement follows the distance reduction previously observed in the WMT 2015 shared translation task (Bojar et al., 2015). Just few months earlier, the NMT systems described in (Jean et al., 2015b) ranked on par with the best phrase-based models on a couple of language pairs. Such rapid progress stems from the improvement of the recurrent neural network encoder-decoder model, originally proposed in (Sutskever et al., 2014; Cho et al., 2014b), with the use of the attention mechanism (Bahdanau et al., 2015). This evolution has several implications. On one side, NMT represents a simplification with respect to previous paradigms. From a management point of view, similar to PBMT, it allows for a more efficient use of human and data resources with respect to rule-based MT. From the architectural point of view, a large recurrent network trained for end-to-end translation is considerably simpler than traditional MT systems that integrate multiple components and processing steps. On the other side, the NMT process is less transparent than previous paradigms. Indeed, it represents a further step in the evolution from rule-based approaches that explicitly manipulate knowledge, to the statistical/data-driven framework, still comprehensible in its inner workings, to a sub-symbolic framework in which the translation process is totally opaque to the analysis.

What do we know about the strengths of NMT

[1] We use the generic term phrase-based MT to cover standard phrase-based, hierarchical and syntax-based SMT approaches.

and the weaknesses of PBMT? What are the linguistic phenomena that deep learning translation models can handle with such greater effectiveness? To answer these questions and go beyond poorly informative BLEU scores, we perform the very first comparative analysis of the two paradigms in order to shed light on the factors that differentiate them and determine their large quality differences.

We build on evaluation data available for the IWSLT 2015 MT English-German task, and compare the results of the first four top-ranked participants. We choose to focus on one language pair and one task because of the following advantages: *(i)* three state-of-the art PBMT systems compared against the NMT system on the same data and in the very same period (that of the evaluation campaign); *(ii)* a challenging language pair in terms of morphology and word order differences; *(iii)* availability of MT outputs' post-editing done by professional translators, which is very costly and thus rarely available. In general, post-edits have the advantage of allowing for informative and detailed analyses since they directly point to translation errors. In this specific framework, the high quality data created by professional translators guarantees reliable evaluations. For all these reasons we present our study as a solid contribution to the better understanding of this new paradigm shift in MT.

After reviewing previous work (Section 2), we introduce the analyzed data and the systems that produced them (Section 3). We then present three increasingly fine levels of MT quality analysis. We first investigate how MT systems' quality varies with specific characteristics of the input, *i.e.* sentence length and type of content of each talk (Section 4). Then, we focus on differences among MT systems with respect to morphology, lexical, and word order errors (Section 5). Finally, based on the finding that word reordering is the strongest aspect of NMT compared to the other systems, we carry out a fine-grained analysis of word order errors (Section 6).

2 Previous Work

To date, NMT systems have only been evaluated by BLEU in single-reference setups (Bahdanau et al., 2015; Sutskever et al., 2014; Luong et al., 2015; Jean et al., 2015a; Gülçehre et al., 2015). Additionally, the Montreal NMT system submitted to WMT 2015 (Jean et al., 2015b) was part of a manual evaluation experiment where a large number of non-professional annotators were asked to rank the outputs of multiple MT systems (Bojar et al., 2015). Results for the Montreal system were very positive – ranked first in English-German, third in German-English, English-Czech and Czech-English – which confirmed and strengthened the BLEU results published so far. Unfortunately neither BLEU nor manual ranking judgements tell us which translation aspects are better modeled by different MT frameworks. To this end, a detailed and systematic error analysis of NMT *vs.* PBMT output is required.

Translation error analysis, as a way to identify systems' weaknesses and define priorities for their improvement, has received a fair amount of attention in the MT community. In this work we opt for the *automatic* detection and classification of translation errors based on *manual* post-edits of the MT output. We believe this choice provides an optimal trade-off between fully manual error analysis (Farrús Cabeceran et al., 2010; Popović et al., 2013; Daems et al., 2014; Federico et al., 2014; Neubig et al., 2015), which is very costly and complex, and fully automatic error analysis (Popović and Ney, 2011; Irvine et al., 2013), which is noisy and biased towards one or few arbitrary reference translations.

Existing tools for translation error detection are either based on Word Error Rate (WER) and Position-independent word Error Rate (PER) (Popović, 2011) or on output-reference alignment (Zeman et al., 2011). Regarding error classification, Hjerson (Popović, 2011) detects five main types of word-level errors as defined in (Vilar et al., 2006): morphological, reordering, missing words, extra words, and lexical choice errors. We follow a similar but simpler error classification (morphological, lexical, and word order errors), but detect the errors differently using TER as this is the most natural choice in our evaluation framework based on post-edits (see also Section 3.4). Irvine et al. (2013) propose another word-level error analysis technique specifically focused on lexical choice and aimed at understanding the effects of domain differences on MT. Their error classification is strictly related to model coverage and insensitive to word order differences. The technique requires access to the sys-

tem's phrase table and is thus not applicable to NMT, which does not rely on a fixed inventory of translation units extracted from the parallel data.

Previous error analyses based on manually post-edited translations were presented in (Bojar, 2011; Koponen, 2012; Popović et al., 2013). We are the first to conduct this kind of study on the output of a neural MT system.

3 Experimental Setting

We perform a number of analyses on data and results of the IWSLT 2015 MT *En-De* task, which consists in translating manual transcripts of English TED talks into German. Evaluation data are publicly available through the WIT^3 repository (Cettolo et al., 2012).[3]

3.1 Task Data

TED Talks[4] are a collection of rather short speeches (max 18 minutes each, roughly equivalent to 2,500 words) covering a wide variety of topics. All talks have captions, which are translated into many languages by volunteers worldwide. Besides representing a popular benchmark for spoken language technology, TED Talks embed interesting research challenges. Translating TED Talks implies dealing with spoken rather than written language, which is hence expected to be structurally less complex, formal and fluent (Ruiz and Federico, 2014). Moreover, as human translations of the talks are required to follow the structure and rhythm of the English captions, a lower amount of rephrasing and reordering is expected than in the translation of written documents.

As regards the English-German language pair, the two languages are interesting since, while belonging to the same language family, they have marked differences in levels of inflection, morphological variation, and word order, especially long-range reordering of verbs.

3.2 Evaluation Data

Five systems participated in the MT *En-De* task and were manually evaluated on a representative subset of the official 2015 test set. The Human Evaluation (HE) set includes the first half of each of the 12 test talks, for a total of 600 sentences and around 10K words. Five professional translators were asked to post-edit the MT output by applying the minimal edits required to transform it into a fluent sentence with the same meaning as the source sentence. Data were prepared so that all translators equally post-edited the five MT outputs, *i.e.* 120 sentences for each evaluated system.

The resulting evaluation data consist of five new reference translations for each of the sentences in the HE set. Each one of these references represents the *targeted translation* of the system output from which it was derived, but the other four *additional translations* can also be used to evaluate each MT system. We will see in the next sections how we exploited the available post-edits in the more suitable way depending on the kind of analysis carried out.

System	Approach	Data
PBSY (Huck and Birch, 2015)	Combination: Phrase+Syntax-based GHKM string-to-tree; hierarchical + sparse lexicalized reordering models	175M/ 3.1B
HPB (Jehl et al., 2015)	Hierarchical Phrase-based source pre-ordering (dependency tree -based); re-scoring with neural LM	166M/ 854M
SPB (Ha et al., 2015)	Standard Phrase-based source pre-ordering (POS- and tree-based); re-scoring with neural LMs	117M/ 2.4B
NMT (Luong & Manning, 2015)	Recurrent neural network (LSTM) attention-based; source reversing; rare words handling	120M/ –

Table 1: MT systems' overview. Data column: size of parallel/monolingual training data for each system in terms of English and German tokens.

3.3 MT Systems

Our analysis focuses on the first four top-ranking systems, which include NMT (Luong and Manning, 2015) and three different phrase-based approaches: standard phrase-based (Ha et al., 2015), hierarchical (Jehl et al., 2015) and a combination of phrase-based and syntax-based (Huck and Birch, 2015). Table 1 presents an overview of each system, as well as figures about the training data used.[5]

The phrase+syntax-based (PBSY) system combines the outputs of a string-to-tree decoder, trained with the GHKM algorithm, with those of two stan-

[3] wit3.fbk.eu

[4] http://www.ted.com/

[5] Detailed information about training data was kindly made available by participating teams.

dard phrase-based systems featuring, among others, adapted phrase tables and language models enriched with morphological information, hierarchical lexicalized reordering models and different variations of the operational sequence model.

The hierarchical phrase-based MT (HPB) system leverages thousands of lexicalised features, data-driven source pre-ordering (dependency tree-based), word-based and class-based language models, and n-best re-scoring models based on syntactic and neural language models.

The standard phrase-based MT (SPB) system features an adapted phrase-table combining in-domain and out-domain data, discriminative word lexicon models, multiple language models (word-, POS- and class-based), data-driven source pre-ordering (POS- and constituency syntax-based), n-best re-scoring models based on neural lexicons and neural language models.

Finally, the neural MT (NMT) system is an ensemble of 8 long short-term memory (LSTM) networks of 4 layers featuring 1,000-dimension word embeddings, attention mechanism, source reversing, 50K source and target vocabularies, and out-of-vocabulary word handling. Training with TED data was performed on top of models trained with large out-domain parallel data.

With respect to the use of training data, it is worth noticing that NMT is the only system not employing monolingual data in addition to parallel data. Moreover, NMT and SPB were trained with smaller amounts of parallel data with respect to PBSY and HPB (see Table 1).

3.4 Translation Edit Rate Measures

The *Translation Edit Rate* (TER) (Snover et al., 2006) naturally fits our evaluation framework, where it traces the edits done by post-editors. Also, TER *shift* operations are reliable indicators of reordering errors, in which we are particularly interested. We exploit the available post-edits in two different ways: *(i)* for *Human-targeted TER* (HTER) we compute TER between the machine translation and its manually post-edited version (targeted reference), *(ii)* for *Multi-reference TER* (mTER), we compute TER against the closest translation among all available post-edits (*i.e.* targeted and additional references) for each sentence.

system	BLEU	HTER	mTER
PBSY	25.3	28.0	21.8
HPB	24.6	29.9	23.4
SPB	25.8	29.0	22.7
NMT	31.1*	21.1*	16.2*

Table 2: Overall results on the HE Set: BLEU, computed against the original reference translation, and TER, computed with respect to the targeted post-edit (HTER) and multiple post-edits (mTER).

Throughout sections 4 and 5, we mark a score achieved by NMT with the symbol * if this is better than the score of its best competitor at statistical significance level 0.01. Significance tests for HTER and mTER are computed by bootstrap re-sampling, while differences among proportions are assessed via one-tailed z-score tests.

4 Overall Translation Quality

Table 2 presents overall system results according to HTER and mTER, as well as BLEU computed against the original TED Talks reference translation. We can see that NMT clearly outperforms all other approaches both in terms of BLEU and TER scores. Focusing on mTER results, the gain obtained by NMT over the second best system (PBSY) amounts to 26%. It is also worth noticing that mTER is considerably lower than HTER for each system. This reduction shows that exploiting all the available post-edits as references for TER is a viable way to control and overcome post-editors variability, thus ensuring a more reliable and informative evaluation about the real overall performance of MT systems. For this reason, the two following analyses rely on mTER. In particular, we investigate how specific characteristics of input documents affect the system's overall translation quality, focusing on *(i)* sentence length and *(ii)* the different talks composing the dataset.

4.1 Translation quality by sentence length

Long sentences are known to be difficult to translate by the NMT approach. Following previous work (Cho et al., 2014a; Pouget-Abadie et al., 2014; Bahdanau et al., 2015; Luong et al., 2015), we investigate how sentence length affects overall translation quality. Figure 1 plots mTER scores against source sentence length. NMT clearly outperforms every PBMT system in any length bin, with statistically

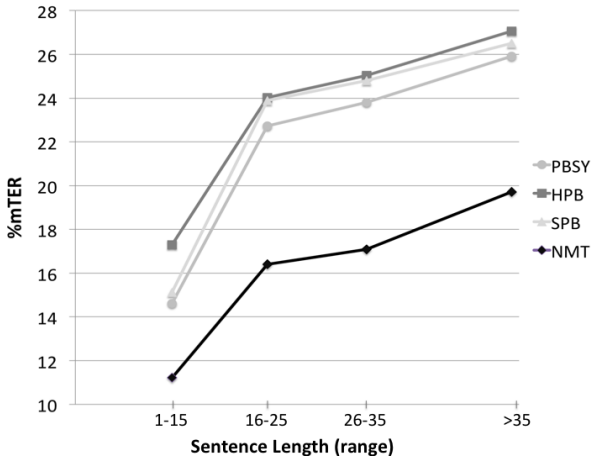

Figure 1: mTER scores on bins of sentences of different length. Points represent the average mTER of the MT outputs for the sentences in each given bin.

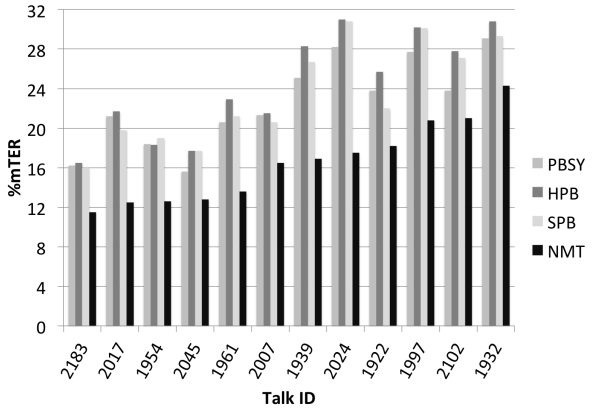

Figure 2: mTER scores per talk, sorted in ascending order of NMT scores.

significant differences. As a general tendency, the performance of all approaches worsens as sentence length increases. However, for sentences longer than 35 words we see that NMT quality degrades more markedly than in PBMT systems. Considering the percentage decrease with respect to the preceding length bin (26-35), we see that the $\%\Delta$ for NMT (-15.4) is much larger than the average $\%\Delta$ for the three PBMT systems (-7.9). Hence, this still seems an issue to be addressed for further improving NMT.

4.2 Translation quality by talk

As we saw in Section 3.1, the TED dataset is very heterogeneous since it consists of talks covering different topics and given by speakers with different styles. It is therefore interesting to evaluate translation quality also at the talk level.

Figure 2 plots the mTER scores for each of the twelve talks included in the HE set, sorted in ascending order of NMT scores. In all talks, the NMT system outperforms the PBMT systems in a statistically significant way.

We analysed different factors which could impact translation quality in order to understand if they correlate with such performance differences. We studied three features which are typically considered as indicators of complexity (see (François and Fairon, 2012) for an overview), namely *(i)* the length of the talk, *(ii)* its average sentence length, and *(iii)* the type-token ratio[6] (TTR) which – measuring lexical diversity – reflects the size of a speaker's vocabulary and the variety of subject matter in a text.

For the first two features we did not find any correlation; on the contrary, we found a moderate Pearson correlation (R=0.7332) between TTR and the mTER gains of NMT over its closest competitor in each talk. This result suggests that NMT is able to cope with lexical diversity better than any other considered approach.

5 Analysis of Translation Errors

We now turn to analyze which types of linguistic errors characterize NMT *vs.* PBMT. In the literature, various error taxonomies covering different levels of granularity have been developed (Flanagan, 1994; Vilar et al., 2006; Farrús Cabeceran et al., 2010; Stymne and Ahrenberg, 2012; Lommel et al., 2014). We focus on three error categories, namely *(i)* morphology errors, *(ii)* lexical errors, and *(iii)* word order errors. As for lexical errors, a number of existing taxonomies further distinguish among translation errors due to missing words, extra words, or incorrect lexical choice. However, given the proven difficulty of disambiguating between these three subclasses (Popović and Ney, 2011; Fishel et al., 2012), we prefer to rely on a more coarse-grained linguistic error classification where lexical errors include all of them (Farrús Cabeceran et al., 2010).

[6]The type-token-ratio of a text is calculated dividing the number of word types (vocabulary) by the total number of word tokens (occurrences).

For error analysis we rely on HTER results under the assumption that, since the targeted translation is generated by post-editing the given MT output, this method is particularly informative to spot MT errors. We are aware that translator subjectivity is still an issue (see Section 4), however in this more fine-grained analysis we prefer to focus on what a human implicitly annotated as a translation error. This particularly holds in our specific evaluation framework, where the goal is not to measure the absolute number of errors made by each system, but to compare systems with each other. Moreover, the post-edits collected for each MT output within IWSLT allow for a fair and reliable comparison since systems were equally post-edited by all translators (see Section 3.2), making all analyses uniformly affected by such variability.

5.1 Morphology errors

A morphology error occurs when a generated word form is wrong but its corresponding base form (lemma) is correct. Thus, we assess the ability of systems to deal with morphology by comparing the HTER score computed on the surface forms (*i.e.* morphologically inflected words) with the HTER score obtained on the corresponding lemmas. The additional matches counted on lemmas with respect to word forms indicate morphology errors. Thus, the closer the two HTER scores, the more accurate the system in handling morphology.

To carry out this analysis, the lemmatized (and POS tagged) version of both MT outputs and corresponding post-edits was produced with the German parser ParZu (Sennrich et al., 2013). Then, the HTER-based evaluation was slightly adapted in order to be better suited to an accurate detection of morphology errors. First, punctuation was removed since – not being subject to morphological inflection – it could smooth the results. Second, *shift* errors were not considered. A word form or a lemma that matches a corresponding word or lemma in the post-edit, but is in the wrong position with respect to it, is counted as a *shift* error in TER. Instead – when focusing on morphology – exact matches are not errors, regardless their position in the text.[7]

[7]Note that the TER score calculated by setting to 0 the cost of shifts approximates the Position-independent Error Rate (Tillmann et al., 1997).

system	HTERnoShft		
	word	lemma	%Δ
PBSY	27.1	22.5	-16.9
HPB	28.7	23.5	-18.4
SPB	28.3	23.2	-18.0
NMT	21.7*	18.7*	-13.7

Table 3: HTER ignoring shift operations computed on words and corresponding lemmas, and their % difference.

Table 3 presents HTER scores on word forms and lemmas, as well as their percentage difference which gives an indication of morphology errors. We can see that NMT generates translations which are morphologically more correct than the other systems. In particular, the %Δ for NMT (-13.7) is lower than that of the second best system (PBSY, -16.9) by 3.2% absolute points, leading to a percentage gain of around 19%. We can thus say that NMT makes at least 19% less morphology errors than any other PBMT system.

5.2 Lexical errors

Another important feature of MT systems is their ability to choose lexically appropriate words. In order to compare systems under this aspect, we consider HTER results at the lemma level as a way to abstract from morphology errors and focus only on actual lexical choice problems. The evaluation on the lemmatised version of the data performed to identify morphology errors fits this purpose, since its driving assumptions (*i.e.* punctuation can be excluded and lemmas in the wrong order are not errors) hold for lexical errors too.

The lemma column of Table 3 shows that NMT outperforms the other systems. More precisely, the NMT score (18.7) is better than the second best (PBSY, 22.5) by 3.8% absolute points. This corresponds to a relative gain of about 17%, meaning that NMT makes at least 17% less lexical errors than any PBMT system. Similarly to what observed for morphology errors, this can be considered a remarkable improvement over the state of the art.

5.3 Word order errors

To analyse reordering errors, we start by focusing on *shift* operations identified by the HTER metrics. The first three columns of Table 4 show, respectively: *(i)* the number of words generated by each system

system	#words	#shifts	%shifts	KRS
PBSY	11,517	354	3.1	84.6
HPB	11,417	415	3.6	84.3
SPB	11,420	398	3.5	84.5
NMT	11,284	173	1.5*	88.3*

Table 4: Word reordering evaluation in terms of shift operations in HTER calculation and of KRS. For each system, the number of generated words, the number of shift errors and their corresponding percentages are reported.

(ii) the number of shifts required to align each system output to the corresponding post-edit; and *(iii)* the corresponding percentage of shift errors. Notice that the *shift* error percentages are incorporated in the HTER scores reported in Table 2. We can see in Table 4 that *shift* errors in NMT translations are definitely less than in the other systems. The error reduction of NMT with respect to the second best system (PBSY) is about 50% (173 *vs.* 354).

It should be recalled that these numbers only refer to *shifts* detected by HTER, that is (groups of) words of the MT output and corresponding post-edit that are identical but occurring in different positions. Words that had to be moved and modified at the same time (for instance replaced by a synonym or a morphological variant) are not counted in HTER *shift* figures, but are detected as *substitution*, *insertion* or *deletion* operations. To ensure that our reordering evaluation is not biased towards the alignment between the MT output and the post-edit performed by HTER, we run an additional assessment using KRS – Kendall Reordering Score (Birch et al., 2010) – which measures the similarity between the source-reference reorderings and the source-MT output reorderings.[8] Being based on bilingual word alignment via the source sentence, KRS detects reordering errors also when post-edit and MT words are not identical. Also unlike TER, KRS is sensitive to the *distance* between the position of a word in the MT output and that in the reference.

Looking at the last column of Table 4, we can say that our observations on HTER are confirmed by the KRS results: the reorderings performed by NMT are much more accurate than those performed by any PBMT system.[9] Moreover, according to the approximate randomization test, KRS differences are statistically significant between NMT and all other systems, but not among the three PBMT systems.

Given the concordant results of our two quantitative analyses, we conclude that one of the major strengths of the NMT approach is its ability to place German words in the right position even when this requires considerable reordering. This outcome calls for a deeper investigation, which is carried out in the following section.

6 Fine-grained Word Order Error Analysis

We have observed that word reordering is a very strong aspect of NMT compared to PBMT, according to both HTER and KRS. To better understand this finding, we investigate whether reordering errors concentrate on specific linguistic constructions across our systems. Using the POS tagging and dependency parsing of the post-edits produced by ParZu, we classify the *shift* operations detected by HTER and count how often a word with a given POS label was misplaced by each of the systems (alone or as part of a shifted block). For each word class, we also compute the percentage order error reduction of NMT with respect to the PBMT system that has highest reordering accuracy overall, that is PBSY. Results are presented in Table 5, ranked by NMT-vs-PBSY gain. Punctuation is omitted as well as word classes that were shifted less than 10 times by all systems. Examples of salient word order error types are presented in Table 6.

The upper part of Table 5 shows that verbs are by far the most often misplaced word category in all PBMT systems – an issue already known to affect standard phrase-based SMT between German and English (Bisazza and Federico, 2013). Reordering is particularly difficult when translating *into* German, since the position of verbs in this language varies according to the clause type (*e.g.* main *vs.* subordinate). Our results show that even syntax-informed PBMT does not solve this issue. Using syntax at decoding time, as done by one of the systems combined within PBSY, appears to be a better strategy

[8] To compute the word alignments required by KRS, we used the FastAlign tool (Dyer et al., 2013).

[9] To put our results into perspective, note that Birch (2011) reports a difference of 5 KRS points between the translations of a PBMT system and those produced by four *human* translators tested against each other, in a Chinese-English experiment.

Table 5: Main POS tags and dependency labels of words occurring in shifted blocks detected by HTER. NMT-vs-PBSY denotes the reduction of reordering errors in NMT *vs.* PBSY system. Only word classes that were shifted 10 or more times in at least one system output are shown.

than using it for source pre-ordering, as done by the HPB and SPB systems. However this only results in a moderate reduction of verb reordering errors (-12% and -25% *vs.* HPB and SPB respectively). On the contrary, NMT reduces verb order errors by an impressive -70% with respect to PBSY (-74% and -77% *vs.* HPB and SPB respectively) despite being trained on raw parallel data without any syntactic annotation, nor explicit modeling of word reordering. This result shows that the recurrent neural language model at the core of the NMT architecture is very successful at generating well-formed sentences even in languages with less predictable word order, like German (see examples in Table 6(a,b)). NMT, though, gains notably less on nouns (-47%), which is the second most often misplaced word category in PBSY. More insight on this is provided by the lower part of the table, where reordering errors are divided by their dependency label as well as POS tag. Here we see that order errors on nouns are notably reduced by NMT when they act as syntactic objects (-65% obja:N) but less when they act as preposition complements (-36% pn:N) or subjects (-33% subj:N).

The smallest NMT-*vs*-PBSY gains are observed on prepositions (-18% PREP), negation particles (-17% PTKNEG) and articles (-4% ART). Manual inspection of a data sample reveals that misplaced prepositions are often part of misplaced prepositional phrases acting, for instance, as temporal or instrumental adjuncts (e.g. *'in my life'*, *'with this video'*). In these cases, the original MT output is overall understandable and grammatical, but does not conform to the order of German semantic arguments that is consistently preferred by post-editors (see example in Table 6(c)). Articles, due to their commonness, are often misaligned by HTER and marked as *shift* errors instead of being marked as two unrelated substitutions. Finally, negation particles account for less than 1% of the target tokens but play a key role in determining the sentence meaning. Looking closely at some error examples, we found that the correct placement of the German particle *nicht* was determined by the focus of negation in the source sentence, which is difficult to detect in English. For instance in Table 6(d) two interpretations are possible (*'that did not work'* or *'that worked, but not for systematic reasons'*), each resulting in a different, but equally grammatical, location of *nicht*. In fact, negation-focus detection calls for a deep understanding of the sentence semantics, often requiring extra-sentential context (Blanco and Moldovan, 2011). When faced with this kind of translation decisions, NMT performs as poorly as its competitors.

In summary, our fine-grained analysis confirms that NMT concentrates its word order improvements on important linguistic constituents and, specifically in English-German, is very close to solving the infamous problem of long-range verb reordering which so many PBMT approaches have only poorly managed to handle. On the other hand, NMT still struggles with more subtle translation decisions depending, for instance, on the semantic ordering of adjunct prepositional phrases or on the focus of negation.

7 Conclusions

We analysed the output of four state-of-the-art MT systems that participated in the English-to-German task of the IWSLT 2015 evaluation campaign. Our selected runs were produced by three phrase-based MT systems and a neural MT system. The analysis leveraged high quality post-edits of the MT outputs, which allowed us to profile systems with respect to reliable measures of post-editing effort and translation error types.

The outcomes of the analysis confirm that NMT has significantly pushed ahead the state of the art, especially in a language pair involving rich morphology prediction and significant word reordering. To summarize our findings: *(i)* NMT generates outputs that considerably lower the overall post-edit effort with respect to the best PBMT system (-26%); *(ii)* NMT outperforms PBMT systems on all sentence lengths, although its performance degrades faster with the input length than its competitors; *(iii)* NMT seems to have an edge especially on lexically rich texts; *(iv)* NMT output contains less morphology errors (-19%), less lexical errors (-17%), and substantially less word order errors (-50%) than its closest competitor for each error type; *(v)* concerning word order, NMT shows an impressive improvement in the placement of verbs (-70% errors).

While NMT proved superior to PBMT with respect to all error types that were investigated, our analysis also pointed out some aspects of NMT that deserve further work, such as the handling of long sentences and the reordering of particular linguistic constituents requiring a deep semantic understanding of text. Machine translation is definitely not a solved problem, but the time is finally ripe to tackle its most intricate aspects.

Abstract

In this paper, we propose a novel finetuning algorithm for the recently introduced multi-way, multilingual neural machine translate that enables zero-resource machine translation. When used together with novel many-to-one translation strategies, we empirically show that this finetuning algorithm allows the multi-way, multilingual model to translate a zero-resource language pair (1) as well as a single-pair neural translation model trained with up to 1M direct parallel sentences of the same language pair and (2) better than pivot-based translation strategy, while keeping only one additional copy of attention-related parameters.

1 Introduction

A recently introduced neural machine translation (Forcada and Ñeco, 1997; Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014) has proven to be a platform for new opportunities in machine translation research. Rather than word-level translation with language-specific preprocessing, neural machine translation has found to work well with statistically segmented subword sequences as well as sequences of characters (Chung et al., 2016; Luong and Manning, 2016; Sennrich et al., 2015b; Ling et al., 2015). Also, recent works show that neural machine translation provides a seamless way to incorporate multiple modalities other than natural language text in translation (Luong et al., 2015a; Caglayan et al., 2016). Furthermore, neural machine translation has been found to translate between multiple languages, achieving better translation quality by exploiting positive language transfer (Dong et al., 2015; Firat et al., 2016; Zoph and Knight, 2016).

In this paper, we conduct in-depth investigation into the recently proposed multi-way, multilingual neural machine translation (Firat et al., 2016). Specifically, we are interested in its potential for zero-resource machine translation, in which there does not exist any direct parallel examples between a target language pair. Zero-resource translation has been addressed by pivot-based translation in traditional machine translation research (Wu and Wang, 2007; Utiyama and Isahara, 2007; Habash and Hu, 2009), but we explore a way to use the multi-way, multilingual neural model to translate directly from a source to target language.

In doing so, we begin by studying different translation strategies available in the multi-way, multilingual model in Sec. 3–4. The strategies include a usual one-to-one translation as well as variants of many-to-one translation for multi-source translation (Zoph and Knight, 2016). We empirically show that the many-to-one strategies significantly outperform the one-to-one strategy.

We move on to zero-resource translation by first evaluating a vanilla multi-way, multilingual model on a zero-resource language pair, which revealed that the vanilla model cannot do zero-resource translation in Sec. 6.1. Based on the many-to-one strategies we proposed earlier, we design a novel finetun-

[⋆] Work carried out while the author was at IBM Research.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 268–277,
Austin, Texas, November 1-5, 2016.

ing strategy that does not require any direct parallel corpus between a target, zero-resource language pair in Sec. 5.2, which uses the idea of generating a pseudo-parallel corpus (Sennrich et al., 2015a). This strategy makes an additional copy of the attention mechanism and finetunes only this small set of parameters.

Large-scale experiments with Spanish, French and English show that the proposed finetuning strategy allows the multi-way, multilingual neural translation model to perform zero-resource translation as well as a single-pair neural translation model trained with up to 1M true parallel sentences. This result re-confirms the potential of the multi-way, multilingual model for low/zero-resource language translation, which was earlier argued by Firat et al. (2016).

2 Multi-Way, Multilingual Neural Machine Translation

Recently Firat et al. (2016) proposed an extension of attention-based neural machine translation (Bahdanau et al., 2015) that can handle multi-way, multilingual translation with a shared attention mechanism. This model was designed to handle multiple source and target languages. In this section, we briefly overview this multi-way, multilingual model. For more detailed exposition, we refer the reader to (Firat et al., 2016).

2.1 Model Description

The goal of multi-way, multilingual model is to build a neural translation model that can translate a source sentence given in one of N languages into one of M target languages. Thus to handle those N source and M target languages, the model consists of N encoders and M decoders. Unlike these language-specific encoders and decoders, only a single attention mechanism is shared across all $M \times N$ language pairs.

Encoder An encoder for the n-th source language reads a source sentence $X = (x_1, \ldots, x_{T_x})$ as a sequence of linguistic symbols and returns a set of context vectors $C^n = \left\{\mathbf{h}^n_1, \ldots, \mathbf{h}^n_{T_x}\right\}$. The encoder is usually implemented as a bidirectional recurrent network (Schuster and Paliwal, 1997), and each context vector $\mathbf{h}^n_t$ is a concatenation of the forward and reverse recurrent networks' hidden states at time t. Without loss of generality, we assume that the dimensionalities of the context vector for all source languages are all same.

Decoder and Attention Mechanism A decoder for the m-th target language is a conditional recurrent language model (Mikolov et al., 2010). At each time step t', it updates its hidden state by

$$\mathbf{z}^m_{t'} = \varphi^m(\mathbf{z}^m_{t'-1}, \tilde{y}^m_{t'-1}, \mathbf{c}^m_{t'}),$$

based on the previous hidden state $\mathbf{z}^m_{t'-1}$, previous target symbol $\tilde{y}^m_{t'-1}$ and the time-dependent context vector $\mathbf{c}^m_{t'}$. φ^m is a gated recurrent unit (GRU, (Cho et al., 2014)).

The time-dependent context vector is computed by the shared attention mechanism as a weighted sum of the context vectors from the encoder C^n:

$$\mathbf{c}^m_{t'} = \mathbf{U} \sum_{t=1}^{T_x} \alpha^{m,n}_{t,t'} \mathbf{h}^n_t + \mathbf{b}, \tag{1}$$

where

$$\alpha^{m,n}_{t,t'} \propto \exp\left(f_{\text{score}}(\mathbf{W}^n \mathbf{h}^n_t, \mathbf{W}^m \mathbf{z}^m_{t'-1}, \tilde{y}^m_{t'-1})\right). \tag{2}$$

The scoring function f_{score} returns a scalar and is implemented as a feedforward neural network with a single hidden layer. For more variants of the attention mechanism for machine translation, see (Luong et al., 2015b).

The initial hidden state of the decoder is initialized as

$$\mathbf{z}^m_0 = \phi^m_{\text{init}}(\mathbf{W}^n \mathbf{h}^n_t). \tag{3}$$

With the new hidden state $\mathbf{z}^m_{t'}$, the probability distribution over the next symbol is computed by

$$p(y_t = w | \tilde{y}_{<t}, X^n) \propto \exp(g^m_w(\mathbf{z}^m_t, \mathbf{c}^m_t, \mathbf{E}^m_y[\tilde{y}_{t-1}]), \tag{4}$$

where g^m_w is a decoder specific parametric function that returns the unnormalized probability for the next target symbol being w.

2.2 Learning

Training this multi-way, multilingual model does not require multi-way parallel corpora but only a

set of bilingual corpora. For each bilingual pair, the conditional log-probability of a ground-truth translation given a source sentence is maximize by adjusting the relevant parameters following the gradient of the log-probability.

3 Translation Strategies

3.1 One-to-One Translation

In the original paper by Firat et al. (2016), only one translation strategy was evaluated, that is, *one-to-one translation*. This one-to-one strategy works on a source sentence given in one language by taking the encoder of that source language, the decoder of a target language and the shared attention mechanism. These three components are glued together as if they form a single-pair neural translation model and translates the source sentence into a target language.

We however notice that this is not the only translation strategy available with the multi-way, multilingual model. As we end up with multiple encoders, multiple decoders and a shared attention mechanism, this model naturally enables us to exploit a source sentence given in multiple languages, leading to a *many- to-one translation* strategy which was proposed recently by Zoph and Knight (2016) in the context of neural machine translation.

Unlike (Zoph and Knight, 2016), the multi-way, multilingual model is not trained with multi-way parallel corpora. This however does not necessarily imply that the model cannot be used in this way. In the remainder of this section, we propose two alternatives for doing multi-source translation with the multi-way, multilingual model, which eventually pave the way towards zero-resource translation.

3.2 Many-to-One Translation

In this section, we consider a case where a source sentence is given in two languages, X_1 and X_2. However, any of the approaches described below applies to more than two source languages trivially.

In this multi-way, multilingual model, multi-source translation can be thought of as averaging two separate translation paths. For instance, in the case of Es+Fr to En, we want to combine Es→En and Fr→En so as to get a better English translation. We notice that there are two points in the multi-way, multilingual model where this averaging may happen.

Early Average The first candidate is to averaging two translation paths when computing the time-dependent context vector (see Eq. (1).) At each time t in the decoder, we compute a time-dependent context vector for each source language, $\mathbf{c}_t^1$ and $\mathbf{c}_t^2$ respectively for the two source languages. In this early averaging strategy, we simply take the average of these two context vectors:

$$\mathbf{c}_t = \frac{\mathbf{c}_t^1 + \mathbf{c}_t^2}{2}. \tag{5}$$

Similarly, we initialize the decoder's hidden state to be the average of the initializers of the two encoders:

$$\mathbf{z}_0 = \frac{1}{2}\left(\phi_{\text{init}}(\phi_{\text{init}}^1(\mathbf{h}_{T_{x_1}}^1)) + \phi_{\text{init}}(\phi_{\text{init}}^2(\mathbf{h}_{T_{x_1}}^2))\right), \tag{6}$$

where ϕ_{init} is the decoder's initializer (see Eq. (3).)

Late Average Alternatively, we can average those two translation paths (e.g., Es→En and Fr→En) at the output level. At each time t, each translation path computes the distribution over the target vocabulary, i.e., $p(y_t = w|y_{<t}, X_1)$ and $p(y_t = w|y_{<t}, X_2)$. We then average them to get the multi-source output distribution:

$$p(y_t = w|y_{<t}, X_1, X_2) = \frac{1}{2}(p(y_t = w|y_{<t}, X_1) + p(y_t = w|y_{<t})). \tag{7}$$

An advantage of this late averaging strategy over the early averaging one is that this can work even when those two translation paths were not from a single multilingual model. They can be two separately trained single-pair models. In fact, if X_1 and X_2 are same and the two translation paths are simply two different models trained on the same language pair–direction, this is equivalent to constructing an ensemble, which was found to greatly improve translation quality (Sutskever et al., 2014; Jean et al., 2015)

Early+Late Average The two strategies above can be further combined by late-averaging the output distributions from the early averaged model and the late averaged one. We empirically evaluate this early+late average strategy as well.

4 Experiments: Translation Strategies and Multi-Source Translation

Before continuing on with zero-resource machine translation, we first evaluate the translation strategies described in the previous section on multi-source translation, as these translation strategies form a basic foundation on which we extend the multi-way, multilingual model for zero-resource machine translation.

4.1 Settings

When evaluating the multi-source translation strategies, we use English, Spanish and French, and focus on a scenario where only En-Es and En-Fr parallel corpora are available.

4.1.1 Corpora

En-Es We combine the following corpora to form 34.71m parallel Es-En sentence pairs: UN (8.8m), Europarl-v7 (1.8m), news-commentary-v7 (150k), LDC2011T07-T12 (2.9m) and internal technical-domain data (21.7m).

En-Fr We combine the following corpora to form 65.77m parallel En-Fr sentence pairs: UN (9.7m), Europarl-v7 (1.9m), news-commentary-v7 (1.2m), LDC2011T07-T10 (1.6m), ReutersUN (4.5m), internal technical-domain data (23.5m) and Gigaword R2 (20.66m).

Evaluation Sets We use newstest-2012 and newstest-2013 from WMT as development and test sets, respectively.

Monolingual Corpora We do not use any additional monolingual corpus.

Preprocessing All the sentences are tokenized using the tokenizer script from Moses (Koehn et al., 2007). We then replace special tokens, such as numbers, dates and URL's with predefined markers, which will be replaced back with the original tokens *after* decoding. After using byte pair encoding (BPE, (Sennrich et al., 2015b)) to get subword symbols, we end up with 37k, 43k and 45k unique tokens for English, Spanish and French, respectively. For training, we only use sentence pairs in which both sentences are only up to 50 symbols long.

See Table 1 for the detailed statistics.

# Sents	Train	Dev†	Test‡
En-Es	34.71m	3003	3000
En-Fr	65.77m	3003	3000
En-Es-Fr	11.32m	3003	3000

Table 1: Data statistics. †: newstest-2012. ‡: newstest-2013

4.2 Models and Training

We start from the code made publicly available as a part of (Firat et al., 2016)[1]. We made two changes to the original code. First, we replaced the decoder with the conditional gated recurrent network with the attention mechanism as outlines in (Firat and Cho, 2016). Second, we feed a binary indicator vector of which encoder(s) the source sentence was processed by to the output layer of each decoder (g_w^m in Eq. (4)). Each dimension of the indicator vector corresponds to one source language, and in the case of multi-source translation, there may be more than one dimensions set to 1.

We train the following models: four single-pair models (Es↔En and Fr↔En) and one multi-way, multilingual model (Es,Fr,En↔Es,Fr,En). As proposed by Firat et al. (2016), we share one attention mechanism for the latter case.

Training We closely follow the setup from (Firat et al., 2016). Each symbol is represented as a 620-dimensional vector. Any recurrent layer, be it in the encoder or decoder, consists of 1000 gated recurrent units (GRU, (Cho et al., 2014)), and the attention mechanism has a hidden layer of 1200 $\tanh$ units (f_{score} in Eq. (2)). We use Adam (Kingma and Ba, 2015) to train a model, and the gradient at each update is computed using a minibatch of at most 80 sentence pairs. The gradient is clipped to have the norm of at most 1 (Pascanu et al., 2012). We early-stop any training using the T-B score on a development set[2].

4.3 One-to-One Translation

We first confirm that the multi-way, multilingual translation model indeed works as well as single-pair models on the translation paths that were considered during training, which was the major claim

[1] https://github.com/nyu-dl/dl4mt-multi

[2] T-B score is defined as $\frac{\text{TER}-\text{BLEU}}{2}$ which we found to be more stable than either TER or BLEU alone for the purpose of early-stopping (Zhao and Chen, 2009).

	Src	Trgt	Multi Dev	Multi Test	Single Dev	Single Test
(a)	Es	En	30.73	28.32	29.74	27.48
(b)	Fr	En	26.93	27.93	26.00	27.21
(c)	En	Es	30.63	28.41	31.31	28.90
(d)	En	Fr	22.68	23.41	22.80	24.05

Table 2: One-to-one translation qualities using the multi-way, multilingual model and four separate single-pair models.

		Multi Dev	Multi Test	Single Dev	Single Test
(a)	Early	31.89	31.35	–	–
(b)	Late	32.04	31.57	32.00	31.46
(c)	E+L	32.61	31.88	–	–

Table 3: Many-to-one quality (Es+Fr→En) using three translation strategies. Compared to Table 2 (a–b) we observe a significant improvement (up to 3+ BLEU), although the model was never trained in these many-to-one settings. The second column shows the quality by the ensemble of two separate single-pair models.

in (Firat et al., 2016). In Table 2, we present the results on four language pair-directions (Es↔En and Fr↔En).

It is clear that the multi-way, multilingual model indeed performs comparably on all the four cases with less parameters (due to the shared attention mechanism.) As observed earlier in (Firat et al., 2016), we also see that the multilingual model performs better when a target language is English.

4.4 Many-to-One Translation

We consider translating from a pair of source sentences in Spanish (Es) and French (Fr) to English (En). It is important to note that the multilingual model was *not* trained with any multi-way parallel corpus. Despite this, we observe that the early averaging strategy improves the translation quality (measured in BLEU) by 3 points in the case of the test set (compare Table 2 (a–b) and Table 3 (a).) We conjecture that this happens as training the multilingual model has implicitly encouraged the model to find a *common context vector* space across multiple source languages.

The late averaging strategy however outperforms the early averaging in both cases of multilingual model and a pair of single-pair models (see Table 3 (b)) albeit marginally. The best quality was observed when the early and late averaging strategies were combined at the output level, achieving up to +3.5 BLEU (compare Table 2 (a) and Table 3 (c).)

We emphasize again that there was *no* multi-way parallel corpus consisting of Spanish, French and English during training[3]. The result presented in this section shows that the multi-way, multilingual model can exploit multiple sources effectively without requiring any multi-way parallel corpus, and we will rely on this property together with the proposed many-to-one translation strategies in the later sections where we propose and investigate zero-resource translation.

5 Zero-Resource Translation Strategies

The network architecture of multi-way, multilingual model suggests the potential for translating between two languages *without* any direct parallel corpus available. In the setting considered in this paper (see Sec. 4.1,) these translation paths correspond to Es↔Fr, as only parallel corpora used for training were Es↔En and Fr↔En.

The most naive approach for translating along a zero-resource path is to simply treat it as any other path that was included as a part of training. This corresponds to the one-to-one strategy from Sec. 3.1. In our experiments, it however turned out that this naive approach does not work at all, as can be seen in Table 4 (a).

In this section, we investigate this potential of zero-resource translation with the multi-way, multilingual model in depth. More specifically, we propose a number of approaches that enable zero-resource translation without requiring any additional bilingual or multi-way corpora.

5.1 Pivot-based Translation

The first set of approaches exploits the fact that the target zero-resource translation path can be decomposed into a sequence of high-resource translation paths (Wu and Wang, 2007; Utiyama and Isahara, 2007; Habash and Hu, 2009). For instance, in our

[3]We do not assume the availability of annotation on multi-way parallel sentence pairs. It is likely that there will be some sentence (or a set of very close variants of a single sentence) translated into multiple languages (eg. Europarl). One may decide to introduce a mechanism for exploiting these (Zoph and Knight, 2016), or as we present here, it may not be necessary at all to do so.

case, Es→Fr can be decomposed into a sequence of Es→En and En→Fr. In other words, we translate a source sentence (Es) into a pivot language (En) and then translate the English translation into a target language (Fr), all within the same multi-way, multilingual model trained by using bilingual corpora.

One-to-One Translation The most basic approach here is to perform each translation path in the decomposed sequence independently from each other. This one-to-one approach introduces only a minimal computational complexity (the multiplicative factor of two.) We can further improve this one-to-one pivot-based translation by maintaining a set of k-best translations from the first stage (Es→En), but this increase the overall computational complexity by the factor of k, making it impractical in practice. We therefore focus only on the former approach of keeping the best pivot translation in this paper.

Many-to-One Translation With the multi-way, multilingual model considered in this paper, we can extend the naive one-to-one pivot-based strategy by replacing the second stage (En→Fr) to be many-to-one translation from Sec. 4.4 using both the original source language and the pivot language as a pair of source languages. We first translate the source sentence (Es) into English, and use both the original source sentence and the English translation (Es+En) to translate into the final target language (Fr).

Both approaches described and proposed above do not require any additional action on an already-trained multilingual model. They are simply different translation strategies specifically aimed at zero-resource translation.

5.2 Finetuning with Pseudo Parallel Corpus

The failure of the naive zero-resource translation earlier (see Table 4 (a)) suggests that the context vectors returned by the encoder are not compatible with the decoder, when the combination was not included during training. The good translation qualities of the translation paths included in training however imply that the representations learned by the encoders and decoders are good. Based on these two observations, we conjecture that all that is needed for a zero-resource translation path is a simple adjustment that makes the context vectors from the encoder to be compatible with the target decoder. Thus, we propose to adjust this zero-resource translation path however without any additional parallel corpus.

First, we generate a small set of *pseudo bilingual pairs* of sentences for the zero-resource language pair (Es→Fr) in interest. We randomly select N sentences pairs from a parallel corpus between the target language (Fr) and a pivot language (En) and translate the pivot side (En) into the source language (Es). Then, the pivot side is discarded, and we construct a *pseudo* parallel corpus consisting of sentence pairs of the source and target languages (Es-Fr).

We make a copy of the existing attention mechanism, to which we refer as *target-specific attention mechanism*. We then finetune only this target-specific attention mechanism while keeping all the other parameters of the encoder and decoder intact, using the generated pseudo parallel corpus. We do not update any other parameters in the encoder and decoder, because they are already well-trained (evidenced by high translation qualities in Table 2) and we want to avoid disrupting the well-captured structures underlying each language.

Once the model has been finetuned with the pseudo parallel corpus, we can use any of the translation strategies described earlier in Sec. 3 for the finetuned zero-resource translation path. We expect a similar gain by using many-to-one translation, which we empirically confirm in the next section.

6 Experiments: Zero-Resource Translation

6.1 Without Finetuning

6.1.1 Settings

We use the same multi-way, multilingual model trained earlier in Sec. 4.2 to evaluate the zero-resource translation strategies. We emphasize here that this model was trained only using Es-En and Fr-En *bilingual* parallel corpora without any Es-Fr parallel corpus.

We evaluate the proposed approaches to zero-resource translation with the same multi-way, multilingual model from Sec. 4.1. We specifically select the path from Spanish to French (Es→Fr) as a target zero-resource translation path.

	Pivot	Many-to-1	Dev	Test
(a)			< 1	< 1
(b)	$\surd$		20.64	20.4
(c)	$\surd$	Early	9.24	10.42
(d)	$\surd$	Late	18.22	19.14
(e)	$\surd$	E+L	13.29	14.56

Table 4: Zero-resource translation from Spanish (Es) to French (Fr) *without* finetuning, using multi-way, multilingual model. When pivot is $\surd$, English is used as a pivot language.

6.1.2 Result and Analysis

As mentioned earlier, we observed that the multi-way, multilingual model *cannot* directly translate between two languages when the translation path between those two languages was not included in training (Table 4 (a).) On the other hand, the model was able to translate decently with the pivot-based one-to-one translation strategy, as can be seen in Table 4 (b). Unsurprisingly, all the many-to-one strategies resulted in worse translation quality, which is due to the inclusion of the useless translation path (direct path between the zero-resource pair, Es-Fr). Another interesting trend we observe is the Early+Late averaging (Table 4 (e)) seems to perform worse than Late averaging (Table 4 (d)) alone, opposite of the results in Table 3 (b-c). We conjecture that, by simply averaging two model outputs (as in E+L), when one of them is drastically worse than the other, has the effect of pulling down the performance of final results. But early averaging can still recover from this deficiency, upto some extent, since the decoder output probability function g_w^m (Eq. (4).) is a smooth function not only using the averaged context vectors (Eq. (5).).

These results clearly indicate that the multi-way, multilingual model trained with only bilingual parallel corpora is not capable of direct zero-resource translation *as it is*.

6.2 Finetuning with a Pseudo Parallel Corpus

6.2.1 Settings

The proposed finetuning strategy raises a number of questions. First, it is unclear how many pseudo sentence pairs are needed to achieve a decent translation quality. Because the purpose of this finetuning stage is simply to adjust the shared attention mechanism so that it can properly bridge from the source-side encoder to the target-side decoder, we expect it to work with only a small amount of pseudo pairs. We validate this by creating pseudo corpora of different sizes–1k, 10k, 100k and 1m.

Second, we want to know how detrimental it is to use the generated pseudo sentence pairs compared to using true sentence pairs between the target language pair. In order to answer this question, we compiled a true multi-way parallel corpus by combining the subsets of UN (7.8m), Europarl-v7 (1.8m), OpenSubtitles-2013 (1m), news-commentary-v7 (174k), LDC2011T07 (335k) and news-crawl (310k), and use it to finetune the model[4]. This allows us to evaluate the effect of the pseudo and true parallel corpora on finetuning for zero-resource translation.

Lastly, we train single-pair models translating directly from Spanish to French by using the true parallel corpora. These models work as a baseline against which we compare the multi-way, multilingual models.

Training Unlike the usual training procedure described in Sec. 4.2, we compute the gradient for each update using 60 sentence pairs only, when finetuning the model with the multi-way parallel corpus (either pseudo or true.)

6.2.2 Result and Analysis

Table 5 summarizes all the result. The most important observation is that the proposed finetuning strategy with *pseudo*-parallel sentence pairs outperforms the pivot-based approach (using the early averaging strategy from Sec. 4.4) even when we used only 10k such pairs (compare (b) and (d).) As we increase the size of the pseudo-parallel corpus, we observe a clear improvement. Furthermore, these models perform comparably to or better than the single-pair model trained with 1M *true* parallel sentence pairs, *although they never saw a single true bilingual sentence pair* of Spanish and French (compare (a) and (d).)

Another interesting finding is that it is only beneficial to use true parallel pairs for finetuning the multi-way, mulitilingual models when there are enough of them (1m or more). When there are only a small number of true parallel sentence pairs, we

[4] See the last row of Table 1.

	Pivot	Many-to-1		Pseudo Parallel Corpus 1k	10k	100k	1m	True Parallel Corpus 1k	10k	100k	1m
(a)	Single-Pair Models		Dev	–	–	–	–	–	–	11.25	21.32
			Test	–	–	–	–	–	–	10.43	20.35

			Test	20.5	20.71	21.06	21.19	15.42	17.95	20.16	20.9

Table 5: Zero-resource translation from Spanish (Es) to French (Fr) *with* finetuning. When pivot is √, English is used as a pivot language. Row (b) is from Table 4 (b).

even found using pseudo pairs to be more beneficial than true ones. This effective as more apparent, when the direct one-to-one translation of the zero-resource pair was considered (see (c) in Table 5.) This applies that the misalignment between the encoder and decoder can be largely fixed by using pseudo-parallel pairs only, and we conjecture that it is easier to learn from pseudo-parallel pairs as they better reflect the inductive bias of the trained model and as the pseudo- parallel corpus is expected to be more noisy, this may be an implicit regularization effect. When there is a large amount of true parallel sentence pairs available, however, our results indicate that it is better to exploit them.

Unlike we observed with the multi-source translation in Sec. 3.2, we were not able to see any improvement by further averaging the early-averaged and late-average decoding schemes (compare (d) and (e).) This may be explained by the fact that the context vectors computed when creating a pseudo source (e.g., En from Es when Es→Fr) already contains all the information about the pseudo source. It is simply enough to take those context vectors into account via the early averaging scheme.

These results clearly indicate and verify the potential of the multi-way, multilingual neural translation model in performing zero-resource machine translation. More specifically, it has been shown that the translation quality can be improved even without any direct parallel corpus available, and if there is a small amount of direct parallel pairs available, the quality may improve even further.

7 Conclusion: Implications and Limitations

Implications There are two main results in this paper. First, we showed that the multi-way, multilingual neural translation model by Firat et al. (2016) is able to exploit common, underlying structures across many languages in order to better translate when a source sentence is given in multiple languages. This confirms the usefulness of positive language transfer, which has been believed to be an important factor in human language learning (Odlin, 1989; Ringbom, 2007), in machine translation. Furthermore, our result significantly expands the applicability of multi-source translation (Zoph and Knight, 2016), as it does not assume the availability of multi-way parallel corpora for training and relies only on *bilingual* parallel corpora.

Second, the experiments on zero-resource translation revealed that it is not necessary to have a direct parallel corpus, or deep linguistic knowledge, between two languages in order to build a machine translation system. Importantly we observed that the proposed approach of zero-resource translation is better both in terms of translation quality and data efficiency than a more traditional pivot-based translation (Wu and Wang, 2007; Utiyama and Isahara, 2007). Considering that this is the first attempt at such zero-resource, or extremely low-resource, translation using neural machine translation, we expect a large progress in near future.

Limitations Despite the promising empirical results presented in this paper, there are a number of shortcomings that needs to addressed in follow-up research. First, our experiments have been done only with three European languages–Spanish, French and English. More investigation with a diverse set of languages needs to be done in order to make a more solid conclusion, such as was done in (Firat et al., 2016; Chung et al., 2016). Furthermore, the effect of varying sizes of available parallel corpora on the performance of zero-resource translation must be studied more in the future.

Second, although the proposed many-to-one translation is indeed generally applicable to any number of source languages, we have only tested a source sentence in two languages. We expect even higher improvement with more languages, but it must be tested thoroughly in the future.

Lastly, the proposed finetuning strategy requires the model to have an additional set of parameters relevant to the attention mechanism for a target, zero-resource pair. This implies that the number of parameters may grow linearly with respect to the number of target language pairs. We expect future research to address this issue by, for instance, mixing in the parallel corpora of high-resource language pairs during finetuning as well.

Abstract

We propose to enhance the RNN decoder in a neural machine translator (NMT) with external memory, as a natural but powerful extension to the state in the decoding RNN. This memory-enhanced RNN decoder is called MEMDEC. At each time during decoding, MEMDEC will read from this memory and write to this memory once, both with content-based addressing. Unlike the unbounded memory in previous work(Bahdanau et al., 2014) to store the representation of source sentence, the memory in MEMDEC is a matrix with pre-determined size designed to better capture the information important for the decoding process at each time step. Our empirical study on Chinese-English translation shows that it can improve by 4.8 BLEU upon Groundhog and 5.3 BLEU upon on Moses, yielding the best performance achieved with the same training set.

1 Introduction

The introduction of external memory has greatly expanded the representational capability of neural network-based model on modeling sequences(Graves et al., 2014), by providing flexible ways of storing and accessing information. More specifically, in neural machine translation, one great improvement came from using an array of vectors to represent the source in a sentence-level memory and dynamically accessing relevant segments of them (alignment) (Bahdanau et al., 2014) through content-based addressing (Graves et al., 2014). The success of RNNsearch demonstrated the advantage of saving the entire sentence of arbitrary length in an unbounded memory for operations of next stage (e.g., decoding).

In this paper, we show that an external memory can be used to facilitate the decoding/generation process thorough a memory-enhanced RNN decoder, called MEMDEC. The memory in MEMDEC is a direct extension to the state in the decoding, therefore functionally closer to the memory cell in LSTM(Hochreiter and Schmidhuber, 1997). It takes the form of a matrix with pre-determined size, each column ("a memory cell") can be accessed by the decoding RNN with content-based addressing for both reading and writing during the decoding process. This memory is designed to provide a more flexible way to select, represent and synthesize the information of source sentence and previously generated words of target relevant to the decoding. This is in contrast to the set of hidden states of the entire source sentence (which can viewed as another form of memory) in (Bahdanau et al., 2014) for attentive read, but can be combined with it to greatly improve the performance of neural machine translator. We apply our model on English-Chinese translation tasks, achieving performance superior to any published results, SMT or NMT, on the same training data (Xie et al., 2011; Meng et al., 2015; Tu et al., 2016; Hu et al., 2015)

Our contributions are mainly two-folds

- we propose a memory-enhanced decoder for

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 278–286,
Austin, Texas, November 1-5, 2016.

neural machine translator which naturally extends the RNN with vector state.

- our empirical study on Chinese-English translation tasks show the efficacy of the proposed model.

Roadmap In the remainder of this paper, we will first give a brief introduction to attention-based neural machine translation in Section 2, presented from the view of encoder-decoder, which treats the hidden states of source as an unbounded memory and the attention model as a content-based reading. In Section 3, we will elaborate on the memory-enhanced decoder MEMDEC. In Section 4, we will apply NMT with MEMDEC to a Chinese-English task. Then in Section 5 and 6, we will give related work and conclude the paper.

2 Neural machine translation with attention

Our work is built on attention-based NMT(Bahdanau et al., 2014), which represents the source sentence as a sequence of vectors after being processed by RNN or bi-directional RNNs, and then conducts dynamic alignment and generation of the target sentence with another RNN simultaneously.

Attention-based NMT, with RNNsearch as its most popular representative, generalizes the conventional notion of encoder-decoder in using a unbounded memory for the intermediate representation of source sentence and content-based addressing read in decoding, as illustrated in Figure 1. More specifically, at time step t, RNNsearch first get context vector $\mathbf{c}_t$ after reading from the source representation $\mathbf{M}^{\mathrm{s}}$, which is then used to update the state, and generate the word y_t (along with the current hidden state $\mathbf{s}_t$, and the previously generated word y_{i-1}).

Formally, given an input sequence $\mathbf{x} = [x_1, x_2, \ldots, x_{T_x}]$ and the previously generated sequence $\mathbf{y}_{<t} = [y_1, y_2, \ldots, y_{t-1}]$, the probability of next word y_t is

$$p(y_t|\mathbf{y}_{<t}; \mathbf{x}) = f(\mathbf{c}_t, y_{t-1}, \mathbf{s}_t), \qquad (1)$$

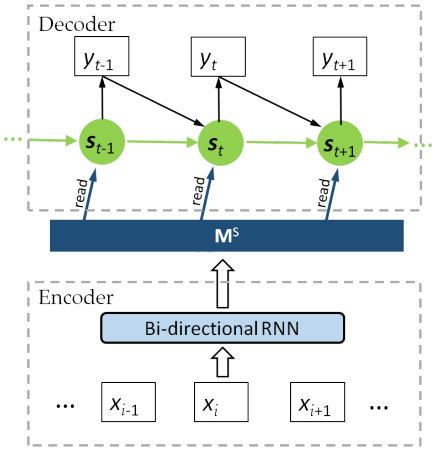

Figure 1: RNNsearch in the encoder-decoder view.

where $\mathbf{s}_t$ is state of decoder RNN at time step t calculated as

$$\mathbf{s}_t = g(\mathbf{s}_{t-1}, y_{t-1}, \mathbf{c}_t). \qquad (2)$$

where $g(\cdot)$ can be an be any activation function, here we adopt a more sophisticated dynamic operator as in Gated Recurrent Unit (GRU, (Cho et al., 2014)). In the remainder of the paper, we will also use GRU to stand for the operator. The reading $\mathbf{c}_t$ is calculated as

$$\mathbf{c}_t = \sum_{j=1}^{j=T_x} \alpha_{t,j}\mathbf{h}_j, \qquad (3)$$

where $\mathbf{h}_j$ is the j^{th} cell in memory $\mathbf{M}^{\mathrm{s}}$. More formally, $\mathbf{h}_j = [\overleftarrow{\mathbf{h}_j}^\top, \overrightarrow{\mathbf{h}_j}^\top]^\top$ is the annotations of x_j and contains information about the whole input sequence with a strong focus on the parts surrounding x_j, which is computed by a bidirectional RNN. The weight $\alpha_{t,j}$ is computed by

$$\alpha_{t,j} = \frac{\exp(e_{t,j})}{\sum_{k=1}^{k=T_x} \exp(e_{t,k})}.$$

where $e_{i,j} = \mathbf{v}_a^T \tanh(\mathbf{W}_a\mathbf{s}_{t-1} + \mathbf{U}_a\mathbf{h}_j)$ scores how well $\mathbf{s}_{t-1}$ and the memory cell $\mathbf{h}_j$ match. This is called automatic alignment (Bahdanau et al., 2014) or attention model (Luong et al., 2015), but it is essentially reading with content-based addressing defined in (Graves et al., 2014). With this addressing strategy the decoder can attend to the source representation that is most relevant to the stage of decoding.

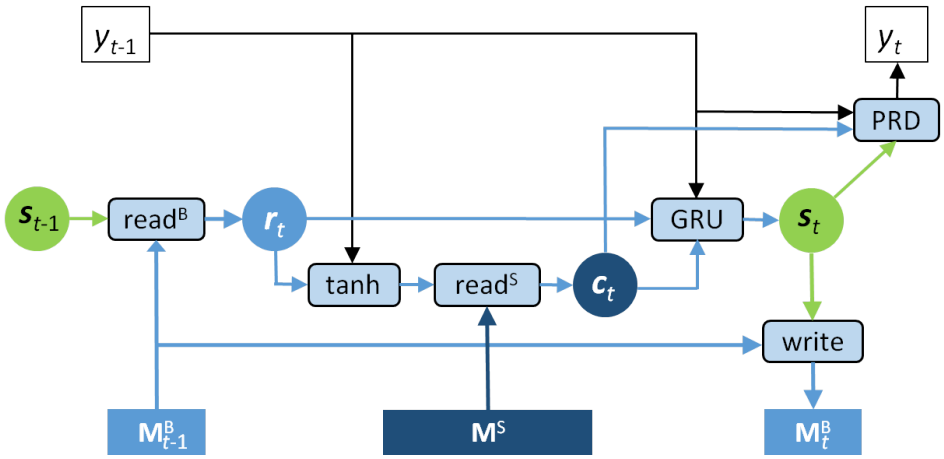

Figure 2: Diagram of the proposed decoder MEMDEC with details.

2.1 Improved Attention Model

The alignment model $\alpha_{t,j}$ scores how well the output at position t matches the inputs around position j based on $\mathbf{s}_{t-1}$ and h_j. It is intuitively beneficial to exploit the information of y_{t-1} when reading from $\mathbf{M}^S$, which is missing from the implementation of attention-based NMT in (Bahdanau et al., 2014). In this work, we build a more effective alignment path by feeding both previous hidden state $\mathbf{s}_{t-1}$ and the context word y_{t-1} to the attention model, inspired by the recent implementation of attention-based NMT[1]. Formally, the calculation of $e_{t,j}$ becomes

$$e_{t,j} = \mathbf{v}_a^T \tanh(\mathbf{W}_a \tilde{\mathbf{s}}_{t-1} + \mathbf{U}_a \mathbf{h}_j),$$

where

- $\tilde{\mathbf{s}}_{t-1} = \mathcal{H}(\mathbf{s}_{t-1}, \mathbf{e}_{y_{t-1}})$ is an intermediate state tailored for reading from $\mathbf{M}^S$ with the information of y_{t-1} (its word embedding being $\mathbf{e}_{y_{t-1}}$) added;

- $\mathcal{H}$ is a nonlinear function, which can be as simple as tanh or as complex as GRU. In our preliminary experiments, we found GRU works slightly better than tanh function, but we chose the latter for simplicity.

[1] github.com/nyu-dl/dl4mt-tutorial/tree/master/session2

3 Decoder with External Memory

In this section we will elaborate on the proposed memory-enhanced decoder MEMDEC. In addition to the source memory $\mathbf{M}^S$, MEMDEC is equipped with a buffer memory $\mathbf{M}^B$ as an extension to the conventional state vector. Figure 3 contrasts MEMDEC with the decoder in RNNsearch (Figure 1) on a high level.

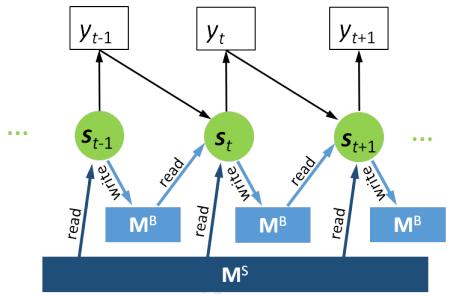

Figure 3: High level digram of MEMDEC.

In the remainder of the paper, we will refer to the conventional state as vector-state (denoted $\mathbf{s}_t$) and its memory extension as memory-state (denoted as $\mathbf{M}^B_t$). Both states are updated at each time step in a interweaving fashion, while the output symbol y_t is predicted based solely on vector-state $\mathbf{s}_t$ (along with $\mathbf{c}_t$ and y_{t-1}). The diagram of this memory-enhanced decoder is given in Figure 2.

Vector-State Update At time t, the vector-state $\mathbf{s}_t$ is first used to read $\mathbf{M}^{\text{B}}$

$$\mathbf{r}_{t-1} = \text{read}^{\text{B}}(\mathbf{s}_{t-1}, \mathbf{M}^{\text{B}}_{t-1}) \quad (4)$$

which then meets the previous prediction y_{t-1} to form an "intermediate" state-vector

$$\widetilde{\mathbf{s}}_t = \tanh(\mathbf{W}^r \mathbf{r}_{t-1} + \mathbf{W}^y \mathbf{e}_{y_{t-1}}). \quad (5)$$

where $\mathbf{e}_{y_{t-1}}$ is the word-embedding associated with the previous prediction y_{t-1}. This pre-state $\widetilde{\mathbf{s}}_t$ is used to read the source memory $\mathbf{M}^{\text{S}}$

$$\mathbf{c}_t = \text{read}^{\text{S}}(\widetilde{\mathbf{s}}_t, \mathbf{M}^{\text{S}}). \quad (6)$$

Both readings in Eq. (4) & (6) follow content-based addressing(Graves et al., 2014) (details later in Section 3.1). After that, $\mathbf{r}_{t-1}$ is combined with output symbol y_{t-1} and $\mathbf{c}_t$ to update the new vector-state

$$\mathbf{s}_t = \text{GRU}(\mathbf{r}_{t-1}, \mathbf{y}_{t-1}, \mathbf{c}_t) \quad (7)$$

The update of vector-state is illustrated in Figure 4.

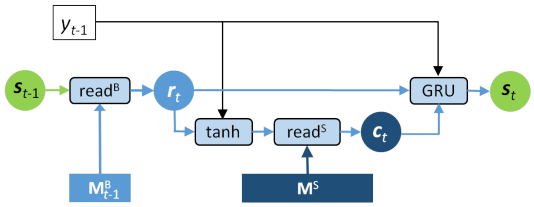

Figure 4: Vector-state update at time t.

Memory-State Update As illustrated in Figure 5, the update for memory-state is simple after the update of vector-state: with the vector-state $\mathbf{s}_{t+1}$ the updated memory-state will be

$$\mathbf{M}^{\text{B}}_t = \text{write}(\mathbf{s}_t, \mathbf{M}^{\text{B}}_{t-1}) \quad (8)$$

The writing to the memory-state is also content-based, with same forgetting mechanism suggested in (Graves et al., 2014), which we will elaborate with more details later in this section.

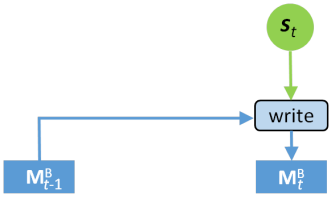

Figure 5: Memory-state update at time t.

Prediction As illustrated in Figure 6, the prediction model is same as in (Bahdanau et al., 2014), where the score for word y is given by

$$\text{score}(y) = \text{DNN}([\mathbf{s}_t, \mathbf{c}_t, \mathbf{e}_{y_{t-1}}])^\top \omega_y \quad (9)$$

where ω_y is the parameters associated with the word y. The probability of generating word y at time t is then given by a softmax over the scores

$$p(y|\mathbf{s}_t, \mathbf{c}_t, y_{t-1}) = \frac{\exp(\text{score}(y))}{\sum_{y'} \exp(\text{score}(y'))}.$$

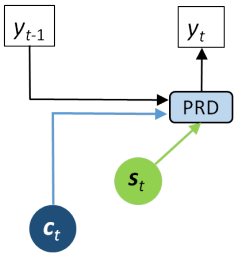

Figure 6: Prediction at time t.

3.1 Reading Memory-State

Formally $\mathbf{M}^{\text{B}}_{t'} \in \mathbb{R}^{n \times m}$ is the memory-state at time t' after the memory-state update, where n is the number of memory cells and m is the dimension of vector in each cell. Before the vector-state update at time t, the output of reading $\mathbf{r}_t$ is given by

$$\mathbf{r}_t = \sum_{j=1}^{j=n} \mathbf{w}^{\text{R}}_t(j) \mathbf{M}^{\text{B}}_{t-1}(j)$$

where $\mathbf{w}^{\text{R}}_t \in \mathbb{R}^n$ specifies the *normalized* weights assigned to the cells in $\mathbf{M}^{\text{B}}_t$. Similar with the reading from $\mathbf{M}^{\text{S}}$ (a.k.a. attention model), we use content-based addressing in determining $\mathbf{w}^{\text{R}}_t$.

More specifically, $\mathbf{w}_t^{\text{R}}$ is also updated from the one from previous time $\mathbf{w}_{t-1}^{\text{R}}$ as

$$\mathbf{w}_t^{\text{R}} = g_t^{\text{R}} \mathbf{w}_{t-1}^{\text{R}} + (1 - g_t^{\text{R}}) \widetilde{\mathbf{w}}_t^{\text{R}}, \qquad (10)$$

where

- $g_t^{\text{R}} = \sigma(\mathbf{w}_g^{\text{R}} \mathbf{s}_t)$ is the gate function, with parameters $\mathbf{w}_g^{\text{R}} \in \mathbb{R}^m$;
- $\widetilde{\mathbf{w}}_t$ gives the contribution based on the current vector-state $\mathbf{s}_t$

$$\widetilde{\mathbf{w}}_t^{\text{R}} = \text{softmax}(\mathbf{a}_t^{\text{R}}) \qquad (11)$$

$$\mathbf{a}_t^{\text{R}}(i) = \mathbf{v}^\top (\mathbf{W}_a^{\text{R}} \mathbf{M}_{t-1}^{\text{B}}(i) + \mathbf{U}_a^{\text{R}} \mathbf{s}_{t-1}), \qquad (12)$$

with parameters $\mathbf{W}_a^{\text{R}}, \mathbf{U}_a^{\text{R}} \in \mathbb{R}^{m \times m}$ and $\mathbf{v} \in \mathbb{R}^m$.

3.2 Writing to Memory-State

There are two types of operation on writing to memory-state: ERASE and ADD. Erasion is similar to the forget gate in LSTM or GRU, which determines the content to be remove from memory cells. More specifically, the vector $\mu_t^{\text{ERS}} \in \mathbb{R}^m$ specifies the values to be removed on each dimension in memory cells, which is than assigned to each cell through normalized weights $\mathbf{w}_t^{\text{W}}$. Formally, the memory-state after ERASE is given by

$$\widetilde{\mathbf{M}}_t^{\text{B}}(i) = \mathbf{M}_{t-1}^{\text{B}}(i)(1 - \mathbf{w}_t^{\text{W}}(i) \cdot \mu_t^{\text{ERS}}) \qquad (13)$$

$$i = 1, \cdots, n$$

where

- $\mu_t^{\text{ERS}} = \sigma(\mathbf{W}^{\text{ERS}} \mathbf{s}_t)$ is parametrized with $\mathbf{W}^{\text{ERS}} \in \mathbb{R}^{m \times m}$;
- $\mathbf{w}_t^{\text{W}}(i)$ specifies the weight associated with the i^{th} cell in the same parametric form as in Eq. (10)-(12) with generally different parameters.

ADD operation is similar with the update gate in LSTM or GRU, deciding how much current information should be written to the memory.

$$\mathbf{M}_t^{\text{B}}(i) = \widetilde{\mathbf{M}}_t^{\text{B}}(i) + \mathbf{w}_t^{\text{W}}(i) \mu_t^{\text{ADD}}$$

$$\mu_t^{\text{ADD}} = \sigma(\mathbf{W}^{\text{ADD}} \mathbf{s}_t)$$

where $\mu_t^{\text{ADD}} \in \mathbb{R}^m$ and $\mathbf{W}^{\text{ADD}} \in \mathbb{R}^{m \times m}$.

In our experiments, we have a peculiar but interesting observation: it is often beneficial to use the same weights for both reading (i.e., $\mathbf{w}_t^{\text{R}}$ in Section 3.1) and writing (i.e., $\mathbf{w}_t^{\text{W}}$ in Section 3.2) for the same vector-state $\mathbf{s}_t$. We conjecture that this acts like a regularization mechanism to encourage the content of reading and writing to be similar to each other.

3.3 Some Analysis

The writing operation in Eq. (13) at time t can be viewed as an nonlinear way to combine the previous memory-state $\mathbf{M}_{t-1}^{\text{B}}$ and the newly updated vector-state $\mathbf{s}_t$, where the nonlinearity comes from both the content-based addressing and the gating. This is in a way similar to the update of states in regular RNN, while we conjecture that the addressing strategy in MEMDEC makes it easier to selectively change some content updated (e.g., the relatively short-term content) while keeping other content less modified (e.g., the relatively long-term content).

The reading operation in Eq. (10) can "extract" the content from $\mathbf{M}_t^{\text{B}}$ relevant to the alignment (reading from $\mathbf{M}^{\text{S}}$) and prediction task at time t. This is in contrast with the regular RNN decoder including its gated variants, which takes the entire state vector to for this purpose. As one advantage, although only part of the information in $\mathbf{M}_t^{\text{B}}$ is used at t, the entire memory-state, which may store other information useful for later, will be carry over to time $t+1$ for memory-state update (writing).

4 Experiments on Chinese-English Translation

We test the memory-enhanced decoder to task of Chinese-to-English translation, where MEMDEC is put on the top of encoder same as in (Bahdanau et al., 2014).

4.1 Datasets and Evaluation metrics

Our training data for the translation task consists of 1.25M sentence pairs extracted from LDC corpora[2], with 27.9M Chinese words and 34.5M

[2]The corpora include LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07,

English words respectively. We choose NIST 2002 (MT02) dataset as our development set, and the NIST 2003 (MT03), 2004 (MT04) 2005 (MT05) and 2006 (MT06) datasets as our test sets. We use the case-insensitive 4-gram NIST BLEU score as our evaluation metric as our evaluation metric (Papineni et al., 2002).

4.2 Experiment settings

Hyper parameters In training of the neural networks, we limit the source and target vocabularies to the most frequent 30K words in both Chinese and English, covering approximately 97.7% and 99.3% of the two corpora respectively. The dimensions of word embedding is 512 and the size of the hidden layer is 1024. The dimemsion of each cell in $\mathbf{M}^{\text{B}}$ is set to 1024 and the number of cells n is set to 8.

Training details We initialize the recurrent weight matrices as random orthogonal matrices. All the bias vectors were initialize to zero. For other parameters, we initialize them by sampling each element from the Gaussian distribution of mean 0 and variance 0.01^2. Parameter optimization is performed using stochastic gradient descent. Adadelta (Zeiler, 2012) is used to automatically adapt the learning rate of each parameter ($\epsilon = 10^{-6}$ and $\rho = 0.95$). To avoid gradients explosion, the gradients of the cost function which had ℓ_2 norm larger than a predefined threshold 1.0 was normalized to the threshold (Pascanu et al., 2013). Each SGD is of a minibatch of 80 sentences. We train our NMT model with the sentences of length up to 50 words in training data, while for moses system we use the full training data.

Memory Initialization Each memory cell is initialized with the source sentence hidden state computed as

$$\mathbf{M}^{\text{B}}(i) = \mathbf{m} + \nu_i \quad (14)$$

$$\mathbf{m} = \sigma(\mathbf{W}_{\text{INI}} \sum_{i=0}^{i=T_x} \mathbf{h}_i)/T_x \quad (15)$$

where $\mathbf{W}_{\text{INI}} \in \mathbb{R}^{m \times 2 \cdot m}$; σ is $\tanh$ function. $\mathbf{m}$ makes a nonlinear transformation of the source sentence information. ν_i is a random vector sampled from $\mathcal{N}(0, 0.1)$.

Dropout we also use dropout for our NMT baseline model and MEMDEC to avoid overfitting (Hinton et al., 2012). The key idea is to randomly drop units (along with their connections) from the neural network during training. This prevents units from co-adapting too much. In the simplest case, each unit is omitted with a fixed probability p, namely dropout rate. In our experiments, dropout was applied only on the output layer and the dropout rate is set to 0.5. We also try other strategy such as dropout at word embeddings or RNN hidden states but fail to get further improvements.

Pre-training For MEMDEC, the objective function is a highly non-convex function of the parameters with more complicated landscape than that for decoder without external memory, rendering direct optimization over all the parameters rather difficult. Inspired by the effort on easing the training of very deep architectures (Hinton and Salakhutdinov, 2006), we propose a simple pre-training strategyFirst we train a regular attention-based NMT model without external memory. Then we use the trained NMT model to initialize the parameters of encoder and parameters of MEMDEC, except those related to memory-state (i.e., $\{\mathbf{W}^{\text{R}}_a, \mathbf{U}^{\text{R}}_a, \mathbf{v}, \mathbf{w}^{\text{R}}_g, \mathbf{W}^{\text{ERS}}, \mathbf{W}^{\text{ADD}}\}$). After that, we fine-tune all the parameters of NMT with MEMDEC decoder, including the parameters initialized with pre-training and those associated with accessing memory-state.

4.3 Comparison systems

We compare our method with three state-of-the-art systems:

- **Moses:** an open source phrase-based translation system [3]: with default configuration and a 4-gram language model trained on the target portion of training data.

LDC2004T08 and LDC2005T06.

[3] http://www.statmt.org/moses/

SYSTEM	MT03	MT04	MT05	MT06	AVE.
Groundhog	31.92	34.09	31.56	31.12	32.17
RNNsearch⋆	33.11	37.11	33.04	32.99	34.06
RNNsearch⋆ + coverage	34.49	38.34	34.91	34.25	35.49
MEMDEC	**36.16**	**39.81**	**35.91**	**35.98**	**36.95**
Moses	31.61	33.48	30.75	30.85	31.67

Table 1: Case-insensitive BLEU scores on Chinese-English translation. Moses is the state-of-the-art phrase-based statistical machine translation system. For RNNsearch, we use the open source system Groundhog as our baseline. The strong baseline, denoted RNNsearch⋆, also adopts *feedback attention* and *dropout*. The *coverage* model on top of RNNsearch⋆ has significantly improved upon its published version (Tu et al., 2016), which achieves the best published result on this training set. For MEMDEC the number of cells is set to 8.

pre-training	n	MT03	MT04	MT05	MT06	Ave.
N	4	35.29	37.36	34.58	33.32	35.11

Y	10	36.46	38.86	34.46	35.00	36.19
Y	12	35.92	39.09	35.31	35.12	36.37

Table 2: MEMDEC performances of different memory size.

- **RNNSearch:** an attention-based NMT model with default settings. We use the open source system GroundHog as our NMT baseline[4].
- **Coverage model**: a state-of-the-art variant of attention-based NMT model (Tu et al., 2016) which improves the attention mechanism through modelling a soft coverage on the source representation.

4.4 Results

The main results of different models are given in Table 1. Clearly MEMDEC leads to remarkable improvement over Moses (+5.28 BLEU) and Groundhog (+4.78 BLEU). The *feedback attention* gains +1.06 BLEU score on top of Groundhog on average, while together with *dropout* adds another +0.83 BLEU score, which constitute the 1.89 BLEU gain of RNNsearch⋆ over Groundhog. Compared to RNNsearch⋆ MEMDEC is +2.89 BLEU score higher, showing the modeling power gained from the external memory. Finally, we also compare MEMDEC with the state-of-the-art attention-based NMT with COVERAGE mechanism(Tu et al., 2016), which is about 2 BLEU over than the published result after adding fast attention and dropout. In this comparison MEMDEC wins with big margin (+1.46 BLEU score).

[4] https://github.com/lisa-groundhog/GroundHog

4.5 Model selection

Pre-training plays an important role in optimizing the memory model. As can be seen in Tab.2, pre-training improves upon our baseline +1.11 BLEU score on average, but even without pre-training our model still gains +1.04 BLEU score on average. Our model is rather robust to the memory size: with merely four cells, our model will be over 2 BLEU higher than RNNsearch⋆. This further verifies our conjecture the the external memory is mostly used to store part of the source and history of target sentence.

4.6 Case study

We show in Table 5 sample translations from Chinese to English, comparing mainly MEMDEC

src	恩达依兹耶说:“签署(2003年11月停火)协定的各方,最迟必须在元月五日以前把战士的驻扎地点安顿完毕 。”

Table 3: Sample translations-for each example, we show the source(src), the human translation (ref),the translation from our memory model MEMDEC and the translation from RNNsearch(equipped with fast attention and dropout).We italicise some *correct* translation segments and highlight a few **wrong** ones in bold.

and the RNNsearch model for its pre-training. It is appealing to observe that MEMDEC can produce more fluent translation results and better grasp the semantic information of the sentence.

5 Related Work

There is a long thread of work aiming to improve the ability of RNN in remembering long sequences, with the long short-term memory RNN (LSTM) (Hochreiter and Schmidhuber, 1997) being the most salient examples and GRU (Cho et al., 2014) being the most recent one. Those works focus on designing the dynamics of the RNN through new dynamic operators and appropriate gating, while still keeping vector form RNN states. MEMDEC, on top of the gated RNN, explicitly adds matrix-form memory equipped with content-based addressing to the system, hence greatly improving the power of the decoder RNN in representing the information important for the translation task.

MEMDEC is obviously related to the recent effort on attaching an external memory to neural networks, with two most salient examples being Neural Turing Machine (NTM) (Graves et al., 2014) and Memory Network (Weston et al., 2014). In fact MEMDEC can be viewed as a special case of NTM, with specifically designed reading (from two different types of memory) and writing mechanism for the translation task. Quite remarkably MEMDEC is among the rare instances of NTM which significantly improves upon state-of-the-arts on a real-world NLP task with large training corpus.

Our work is also related to the recent work on machine reading (Cheng et al., 2016), in which the machine reader is equipped with a memory tape, enabling the model to directly read all the previous hidden state with an attention mechanism. Different from their work, we use an external bounded memory and make an abstraction of previous information. In (Meng et al., 2015), Meng et. al. also proposed a deep architecture for sequence-to-sequence learning with stacked layers of memory to store the intermediate representations, while our external memory was applied within a sequence.

6 Conclusion

We propose to enhance the RNN decoder in a neural machine translator (NMT) with external memory. Our empirical study on Chinese-English translation shows that it can significantly improve the performance of NMT.

Abstract

We propose a fast and scalable method for semi-supervised learning of sequence models, based on anchor words and moment matching. Our method can handle hidden Markov models with feature-based log-linear emissions. Unlike other semi-supervised methods, no decoding passes are necessary on the unlabeled data and no graph needs to be constructed—only one pass is necessary to collect moment statistics. The model parameters are estimated by solving a small quadratic program for each feature. Experiments on part-of-speech (POS) tagging for Twitter and for a low-resource language (Malagasy) show that our method can learn from very few annotated sentences.

1 Introduction

Statistical learning of NLP models is often limited by the scarcity of annotated data. Weakly supervised methods have been proposed as an alternative to laborious manual annotation, combining large amounts of unlabeled data with limited resources, such as tag dictionaries or small annotated datasets (Merialdo, 1994; Smith and Eisner, 2005; Garrette et al., 2013). Unfortunately, most semi-supervised learning algorithms for the structured problems found in NLP are computationally expensive, requiring multiple decoding passes through the unlabeled data, or expensive similarity graphs. More scalable learning algorithms are in demand.

In this paper, we propose a moment-matching method for semi-supervised learning of sequence models. Spectral learning and moment-matching approaches have recently proved a viable alternative to expectation-maximization (EM) for unsupervised learning (Hsu et al., 2012; Balle and Mohri, 2012; Bailly et al., 2013), supervised learning with latent variables (Cohen and Collins, 2014; Quattoni et al., 2014; Stratos et al., 2013) and topic modeling (Arora et al., 2013; Nguyen et al., 2015). These methods have learnability guarantees, do not suffer from local optima, and are computationally less demanding.

Unlike spectral methods, ours does not require an orthogonal decomposition of any matrix or tensor. Instead, it considers a more restricted form of supervision: words that have unambiguous annotations, so-called **anchor words** (Arora et al., 2013). Rather than identifying anchor words from unlabeled data (Stratos et al., 2016), we extract them from a small labeled dataset or from a dictionary. Given the anchor words, the estimation of the model parameters can be made efficient by collecting moment statistics from unlabeled data, then solving a small quadratic program for each word.

Our contributions are as follows:

- We adapt anchor methods to semi-supervised learning of generative sequence models.
- We show how our method can also handle log-linear feature-based emissions.
- We apply this model to POS tagging. Our experiments on the Twitter dataset introduced by Gimpel et al. (2011) and on the dataset introduced by Garrette et al. (2013) for Malagasy, a low-resource language, show that our method does particularly well with very little labeled data, outperforming semi-supervised EM and self-training.

2 Sequence Labeling

In this paper, we address the problem of sequence labeling. Let $\boldsymbol{x}_{1:L} = \langle x_1, \ldots, x_L \rangle$ be a sequence of L input observations (for example, words in a sentence). The goal is to predict a sequence of labels $\boldsymbol{h}_{1:L} = \langle h_1, \ldots, h_L \rangle$, where each h_i is a label for the observation x_i (for example, the word's POS tag).

We start by describing two generative sequence models: hidden Markov models (HMMs, §2.1), and their generalization with emission features (§2.2). Later, we propose a weakly-supervised method for estimating these models' parameters (§3–§4) based only on observed statistics of words and contexts.

2.1 Hidden Markov Models

We define random variables $\boldsymbol{X} := \langle X_1, \ldots, X_L \rangle$ and $\boldsymbol{H} := \langle H_1, \ldots, H_L \rangle$, corresponding to observations and labels, respectively. Each X_i is a random variable over a set $\mathcal{X}$ (the vocabulary), and each H_i ranges over $\mathcal{H}$ (a finite set of "states" or "labels"). We denote the vocabulary size by $V = |\mathcal{X}|$, and the number of labels by $K = |\mathcal{H}|$. A first-order HMM has the following generative scheme:

$$p(\boldsymbol{X} = \boldsymbol{x}_{1:L}, \boldsymbol{H} = \boldsymbol{h}_{1:L}) := \quad (1)$$
$$\prod_{\ell=1}^{L} p(X_\ell{=}x_\ell \mid H_\ell{=}h_\ell) \prod_{\ell=0}^{L} p(H_{\ell+1}{=}h_{\ell+1} \mid H_\ell{=}h_\ell),$$

where we have defined $h_0 = \text{START}$ and $h_{L+1} = \text{STOP}$. We adopt the following notation for the parameters:

- The **emission matrix** $\mathbf{O} \in \mathbb{R}^{V \times K}$, defined as $O_{x,h} := p(X_\ell = x \mid H_\ell = h), \forall h \in \mathcal{H}, x \in \mathcal{X}$.
- The **transition matrix** $\mathbf{T} \in \mathbb{R}^{(K+2)\times(K+2)}$, defined as $T_{h,h'} := p(H_{\ell+1} = h \mid H_\ell = h')$, for every $h, h' \in \mathcal{H} \cup \{\text{START}, \text{STOP}\}$. This matrix satisfies $\mathbf{T}^\top \mathbf{1} = \mathbf{1}$.[1]

Throughout the rest of the paper we will adopt $X \equiv X_\ell$ and $H \equiv H_\ell$ to simplify notation, whenever the index ℓ is clear from the context. Under this generative process, predicting the most probable label sequence $\boldsymbol{h}_{1:L}$ given observations $\boldsymbol{x}_{1:L}$ is accomplished with the Viterbi algorithm in $O(LK^2)$ time.

If labeled data are available, the model parameters $\mathbf{O}$ and $\mathbf{T}$ can be estimated with the maximum likelihood principle, which boils down to a simple counting of events and normalization. If we only have unlabeled data, the traditional approach is the expectation-maximization (EM) algorithm, which alternately decodes the unlabeled examples and updates the model parameters, requiring multiple passes over the data. The same algorithm can be used in semi-supervised learning when labeled and unlabeled data are combined, by initializing the model parameters with the supervised estimates and interpolating the estimates in the M-step.

2.2 Feature-Based Hidden Markov Models

Sequence models with log-linear emissions have been considered by Smith and Eisner (2005), in a discriminative setting, and by Berg-Kirkpatrick et al. (2010), as generative models for POS induction. Feature-based HMMs (FHMMs) define a feature function for words, $\boldsymbol{\phi}(X) \in \mathbb{R}^W$, which can be discrete or continuous. This allows, for example, to indicate whether an observation, corresponding to a word, starts with an uppercase letter, contains digits or has specific affixes. More generally, it helps with the treatment of out-of-vocabulary words. The emission probabilities are modeled as K conditional distributions parametrized by a log-linear model, where the $\boldsymbol{\theta}_h \in \mathbb{R}^W$ represent feature weights:

$$p(X = x \mid H = h) := \exp(\boldsymbol{\theta}_h^\top \boldsymbol{\phi}(x)) / Z(\boldsymbol{\theta}_h). \quad (2)$$

Above, $Z(\boldsymbol{\theta}_h) := \sum_{x' \in \mathcal{X}} \exp(\boldsymbol{\theta}_h^\top \boldsymbol{\phi}(x'))$ is a normalization factor. We will show in §4 how our moment-based semi-supervised method can also be used to learn the feature weights $\boldsymbol{\theta}_h$.

3 Semi-Supervised Learning via Moments

We now describe our moment-based semi-supervised learning method for HMMs. Throughout, we assume the availability of a small labeled dataset $\mathcal{D}_L$ and a large unlabeled dataset $\mathcal{D}_U$.

The full roadmap of our method is shown as Algorithm 1. Key to our method is the decomposition of a **context-word moment matrix** $\mathbf{Q} \in \mathbb{R}^{C \times V}$, which counts co-occurrences of words and contexts,

[1] That is, it satisfies $\sum_{h=1}^{K} p(H_{\ell+1} = h \mid H_\ell = h') + p(H_{\ell+1} = \text{STOP} \mid H_\ell = h') = 1$; and also $\sum_{h=1}^{K} p(H_1 = h \mid H_0 = \text{START}) = 1$.

Algorithm 1 Semi-Supervised Learning of HMMs with Moments

Input: Labeled dataset $\mathcal{D}_L$, unlabeled dataset $\mathcal{D}_U$
Output: Estimates of emissions $\mathbf{O}$ and transitions $\mathbf{T}$

1: Estimate context-word moments $\widehat{\mathbf{Q}}$ from $\mathcal{D}_U$ (Eq. 5)
2: **for** each label $h \in \mathcal{H}$ **do**
3: Extract set of anchor words $\mathcal{A}(h)$ from $\mathcal{D}_L$ (§3.2)
4: **end for**
5: Estimate context-label moments $\widehat{\mathbf{R}}$ from anchors and $\mathcal{D}_U$ (Eq. 12)
6: **for** each word $w \in [V]$ **do**
7: Solve the QP in Eq. 14 to obtain $\boldsymbol{\gamma}_w$ from $\widehat{\mathbf{Q}}, \widehat{\mathbf{R}}$
8: **end for**
9: Estimate emissions $\mathbf{O}$ from $\boldsymbol{\Gamma}$ via Eq. 15
10: Estimate transitions $\mathbf{T}$ from $\mathcal{D}_L$
11: Return $\langle \mathbf{O}, \mathbf{T} \rangle$

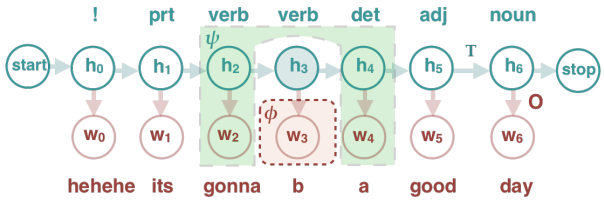

Figure 1: HMM, context (green) conditionally independent of present (red) w_ℓ given state h_ℓ.

and will be formally defined in §3.1. Such co-occurrence matrices are often collected in NLP, for various problems, ranging from dimensionality reduction of documents using latent semantic indexing (Deerwester et al., 1990; Landauer et al., 1998), distributional semantics (Schütze, 1998; Levy et al., 2015) and word embedding generation (Dhillon et al., 2015; Osborne et al., 2016). We can build such a moment matrix entirely from the unlabeled data $\mathcal{D}_U$. The same unlabeled data is used to build an estimate of a **context-label moment matrix** $\mathbf{R} \in \mathbb{R}^{C \times K}$, as explained in §3.3. This is done by first identifying words that are unambiguously associated with each label h, called **anchor words**, with the aid of a few labeled data; this is outlined in §3.2. Finally, given empirical estimates of $\mathbf{Q}$ and $\mathbf{R}$, we estimate the emission matrix $\mathbf{O}$ by solving a small optimization problem independently per word (§3.4). The transition matrix $\mathbf{T}$ is obtained directly from the labeled dataset $\mathcal{D}_L$ by maximizing the likelihood.

3.1 Moments of Contexts and Words

To formalize the notion of "context," we introduce the shorthand $\boldsymbol{Z}_\ell := \langle \boldsymbol{X}_{1:(\ell-1)}, \boldsymbol{X}_{(\ell+1):L} \rangle$. Importantly, the HMM in Eq. 1 entails the following conditional independence assumption: X_ℓ is conditionally independent of the surrounding context Z_ℓ given the hidden state H_ℓ. This is illustrated in Figure 1, using POS tagging as an example task.

We introduce a vector of **context features** $\boldsymbol{\psi}(\boldsymbol{Z}_\ell) \in \mathbb{R}^C$, which may look arbitrarily within the context $\boldsymbol{Z}_\ell$ (left or right), but not at X_ℓ itself. These features could be "one-hot" representations or other reduced-dimensionality embeddings (as described later in §5). Consider the word $w \in \mathcal{X}$ an instance of $X \equiv X_\ell$. A pivotal matrix in our formulation is the matrix $\mathbf{Q} \in \mathbb{R}^{C \times V}$, defined as:

$$Q_{c,w} := \mathbb{E}[\psi_c(\boldsymbol{Z}) \mid X = w]. \tag{3}$$

Expectations here are taken with respect to the probabilistic model in Eq. 1 that generates the data. The following quantities will also be necessary:

$$q_c := \mathbb{E}[\psi_c(\boldsymbol{Z})], \quad p_w := p(X = w). \tag{4}$$

Since all the variables in Eqs. 3–4 are observed, we can easily obtain empirical estimates by taking expectations over the unlabeled data:

$$\widehat{Q}_{c,w} = \frac{\sum_{x,\boldsymbol{z} \in \mathcal{D}_U} \psi_c(\boldsymbol{z}) \mathbb{1}(x = w)}{\sum_{x,\boldsymbol{z} \in \mathcal{D}_U} \mathbb{1}(x = w)}, \tag{5}$$

$$\widehat{q}_c = \sum_{x,\boldsymbol{z} \in \mathcal{D}_U} \psi_c(\boldsymbol{z}) \Big/ |\mathcal{D}_U|, \tag{6}$$

$$\widehat{p}_w = \sum_{x,\boldsymbol{z} \in \mathcal{D}_U} \mathbb{1}(x = w) \Big/ |\mathcal{D}_U|. \tag{7}$$

where we take $\mathbb{1}(x = w)$ to be the indicator for word w. Note that, under our modeling assumptions, $\mathbf{Q}$ decomposes in terms of its hidden states:

$$\mathbb{E}[\psi_c(\boldsymbol{Z}) \mid X = w] = \sum_{h \in \mathcal{H}} p(H = h \mid X = w) \mathbb{E}[\psi_c(\boldsymbol{Z}) \mid H = h] \tag{8}$$

The reason why this holds is that, as stated above, $\boldsymbol{Z}$ and X are conditionally independent given H.

3.2 Anchor Words

Following Arora et al. (2013) and Cohen and Collins (2014), we identify **anchor words** whose hidden

state is assumed to be deterministic, regardless of context. In this work, we generalize this notion to more than one anchor word per label, for improved context estimates. This allows for more flexible forms of anchors with weak supervision. For each state $h \in \mathcal{H}$, let its set of anchor words be

$$\begin{aligned}\mathcal{A}(h) &= \{w \in \mathcal{X} : p(H = h \mid X = w) = 1\} \quad (9)\\ &= \left\{w \in \mathcal{X} : O_{w,h}{>}0 \wedge O_{w,h'}{=}0, \forall h' {\neq} h\right\}.\end{aligned}$$

That is, $\mathcal{A}(h)$ is the set of unambiguous words that always take the label h. This can be estimated from the labeled dataset $\mathcal{D}_L$ by collecting the most frequent unambiguous words for each label.

Algorithms for identifying $\mathcal{A}(h)$ from unlabeled data alone were proposed by Arora et al. (2013) and Zhou et al. (2014), with application to topic models. Our work differs in which we do not aim to discover anchor words from pure unlabeled data, but rather exploit the fact that small amounts of labeled data are commonly available in many NLP tasks—better anchors can be extracted easily from such small labeled datasets. In §5 we give a more detailed description of the selection process.

3.3 Moments of Contexts and Labels

We define the matrix $\mathbf{R} \in \mathbb{R}^{C \times K}$ as follows:

$$R_{c,h} := \mathbb{E}[\psi_c(\boldsymbol{Z}) \mid H = h]. \quad (10)$$

Since the expectation in Eq. 10 is conditioned on the (unobserved) label h, we cannot directly estimate it using moments of observed variables, as we do for $\mathbf{Q}$. However, if we have identified sets of anchor words for each label $h \in \mathcal{H}$, we have:

$$\begin{aligned}&\mathbb{E}[\psi_c(\boldsymbol{Z}) \mid X \in \mathcal{A}(h)] =\\ &= \sum_{h'} \mathbb{E}[\psi_c(\boldsymbol{Z}) \mid H = h'] \underbrace{p(H = h' \mid X \in \mathcal{A}(h))}_{=\mathbb{1}(h'=h)}\\ &= R_{c,h}. \quad (11)\end{aligned}$$

Therefore, given the set of anchor words $\mathcal{A}(h)$, the hth column of $\mathbf{R}$ can be estimated in a single pass over the unlabeled data, as follows:

$$\widehat{R}_{c,h} = \frac{\sum_{x,\boldsymbol{z} \in \mathcal{D}_U} \psi_c(\boldsymbol{z}) \mathbb{1}(x \in \mathcal{A}(h))}{\sum_{x,\boldsymbol{z} \in \mathcal{D}_U} \mathbb{1}(x \in \mathcal{A}(h))} \quad (12)$$

3.4 Emission Distributions

We can now put all the ingredients above together to estimate the emission probability matrix $\mathbf{O}$. The procedure we propose here is computationally very efficient, since only one pass is required over the unlabeled data, to collect the co-occurrence statistics $\widehat{\mathbf{Q}}$ and $\widehat{\mathbf{R}}$. The emissions will be estimated from these moments by solving a small problem independently for each word. Unlike EM and self-training, no decoding is necessary, only counting and normalizing; and unlike label propagation methods, there is requirement to build a graph with the unlabeled data.

The crux of our method is the decomposition in Eq. 8, which is combined with the one-to-one correspondence between labels h and anchor words $\mathcal{A}(h)$. We can rewrite Eq. 8 as:

$$Q_{c,w} = \sum_h R_{c,h}\ p(H = h \mid X = w). \quad (13)$$

In matrix notation, we have $\mathbf{Q} = \mathbf{R}\boldsymbol{\Gamma}$, where $\boldsymbol{\Gamma} \in \mathbb{R}^{K \times V}$ is defined as $\Gamma_{h,w} := p(H = h \mid X = w)$.

If we had infinite unlabeled data, our moment estimates $\widehat{\mathbf{Q}}$ and $\widehat{\mathbf{R}}$ would be perfect and we could solve the system of equations in Eq. 13 to obtain $\boldsymbol{\Gamma}$ exactly. Since we have finite data, we resort to a least squares solution. This corresponds to solving a simple quadratic program (QP) per word, independent from all the other words, as follows. Denote by $\mathbf{q}_w := \mathbb{E}[\boldsymbol{\psi}(\boldsymbol{Z}) \mid X = w] \in \mathbb{R}^C$ and by $\boldsymbol{\gamma}_w := p(H = \cdot \mid X = w) \in \mathbb{R}^K$ the wth columns of $\mathbf{Q}$ and $\boldsymbol{\Gamma}$, respectively. We estimate the latter distribution following Arora et al. (2013):

$$\begin{aligned}\widehat{\boldsymbol{\gamma}}_w \;=\; &\arg\min_{\boldsymbol{\gamma}_w} \quad \|\mathbf{q}_w - \mathbf{R}\boldsymbol{\gamma}_w\|_2^2\\ &\text{s.t.} \qquad \mathbf{1}^\top \boldsymbol{\gamma}_w = 1,\ \boldsymbol{\gamma}_w \geq \mathbf{0}.\end{aligned} \quad (14)$$

Note that this QP is very small—it has only K variables—hence, we can solve it very quickly (1.7 ms on average, in Gurobi, with $K = 12$).

Given the probability tables for $p(H = h \mid X = w)$, we can estimate the emission probabilities $\mathbf{O}$ by direct application of Bayes rule:

$$\widehat{O}_{w,h} = \frac{p(H = h \mid X = w) \times p(X = w)}{p(H = h)} \quad (15)$$

$$= \frac{\widehat{\gamma}_{w,c} \times \overbrace{\widehat{p}_w}^{\text{Eq. 7}}}{\sum_{w'} \widehat{\gamma}_{w',c} \times \widehat{p}_{w'}}. \quad (16)$$

These parameters are guaranteed to lie in the probability simplex, avoiding the need of heuristics for dealing with "negative" and "unnormalized" probabilities required by prior work in spectral learning (Cohen et al., 2013).

3.5 Transition Distributions

It remains to estimate the transition matrix $\mathbf{T}$. For the problems tackled in this paper, the number of labels K is small, compared to the vocabulary size V. The transition matrix has only $O(K^2)$ degrees of freedom, and we found it effective to estimate it using the labeled sequences in $\mathcal{D}_L$ alone, without any refinement. This was done by smoothed maximum likelihood estimation on the labeled data, which boils down to counting occurrences of consecutive labels, applying add-one smoothing to avoid zero probabilities for unobserved transitions, and normalizing.

For problems with numerous labels, a possible alternative is the composite likelihood method (Chaganty and Liang, 2014). Given $\widehat{\mathbf{O}}$, the maximization of the composite log-likelihood function leads to a convex optimization problem that can be efficiently optimized with an EM algorithm. A similar procedure was carried out by Cohen and Collins (2014).[2]

4 Feature-Based Emissions

Next, we extend our method to estimate the parameters of the FHMM in §2.2. Other than contextual features $\boldsymbol{\psi}(\boldsymbol{Z}) \in \mathbb{R}^C$, we also assume a feature encoding function for words, $\boldsymbol{\phi}(X) \in \mathbb{R}^W$. Our framework, illustrated in Algorithm 2, allows for both discrete and continuous word and context features. Lines 2–5 are the same as in Algorithm 1, replacing word occurrences with expected values of word features (we redefine $\mathbf{Q}$ and $\mathbf{\Gamma}$ to cope with features instead of words). The main difference with respect to Algorithm 1 is that we do not estimate emission probabilities; rather, we first estimate the **mean parameters** (feature expectations $\mathbb{E}[\boldsymbol{\phi}(X) \mid H = h]$), by solving one QP for each emission feature; and then we solve a convex optimization problem, for each label h, to recover the log-linear weights over emission features (called **canonical parameters**).

[2] In preliminary experiments, the compositional likelihood method was not competitive with estimating the transition matrices directly from the labeled data, on the datasets described in §6; results are omitted due to lack of space. However, this may be a viable alternative if there is no labeled data and the anchors are extracted from gazetteers or a dictionary.

Algorithm 2 Semi-Supervised Learning of Feature-Based HMMs with Moments

Input: Labeled dataset $\mathcal{D}_L$, unlabeled dataset $\mathcal{D}_U$
Output: Emission log-linear parameters $\mathbf{\Theta}$ and transitions $\mathbf{T}$

1: Estimate context-word moments $\widehat{\mathbf{Q}}$ from $\mathcal{D}_U$ (Eq. 20)
2: **for** each label $h \in \mathcal{H}$ **do**
3: Extract set of anchor words $\mathcal{A}(h)$ from $\mathcal{D}_L$ (§3.2)
4: **end for**
5: Estimate context-label moments $\widehat{\mathbf{R}}$ from the anchors and $\mathcal{D}_U$ (Eq. 12)
6: **for** each word feature $j \in [W]$ **do**
7: Solve the QP in Eq. 22 to obtain $\boldsymbol{\gamma}_j$ from $\widehat{\mathbf{Q}}, \widehat{\mathbf{R}}$
8: **end for**
9: **for** each label $h \in \mathcal{H}$ **do**
10: Estimate the mean parameters $\boldsymbol{\mu}_h$ from $\mathbf{\Gamma}$ (Eq. 24)
11: Estimate the canonical parameters $\boldsymbol{\theta}_h$ from $\boldsymbol{\mu}_h$ by solving Eq. 25
12: **end for**
13: Estimate transitions $\mathbf{T}$ from $\mathcal{D}_L$
14: Return $\langle \mathbf{\Theta}, \mathbf{T} \rangle$

4.1 Estimation of Mean Parameters

First of all, we replace word probabilities by expectations over word features. We redefine the matrix $\mathbf{\Gamma} \in \mathbb{R}^{K \times W}$ as follows:

$$\Gamma_{h,j} := \frac{p(H = h) \times \mathbb{E}[\phi_j(X) \mid H = h]}{\mathbb{E}[\phi_j(X)]}. \quad (17)$$

Note that, with one-hot word features, we have $\mathbb{E}[\phi_w(X) \mid H = h] = P(X = w \mid H = h)$, $\mathbb{E}[\phi_w(X)] = p(X = w)$, and therefore $\Gamma_{h,w} = p(H = h \mid X = w)$, so this can be regarded as a generalization of the framework in §3.4.

Second, we redefine the context-word moment matrix $\mathbf{Q}$ as the following matrix in $\mathbb{R}^{C \times W}$:

$$Q_{c,j} = \mathbb{E}\left[\psi_c(\boldsymbol{Z}) \times \phi_j(X)\right] / \mathbb{E}[\phi_j(X)]. \quad (18)$$

Again, note that we recover the previous $\mathbf{Q}$ if we use one-hot word features. We then have the following generalization of Eq. 13:

$$\mathbb{E}\left[\psi_c(\boldsymbol{Z}) \times \phi_j(X)\right] / \mathbb{E}[\phi_j(X)] = \quad (19)$$
$$\textstyle\sum_h \mathbb{E}\left[\psi_c(\boldsymbol{Z}) \mid H = h\right] \frac{P(H=h)\mathbb{E}[\phi_j(X)|H=h]}{\mathbb{E}[\phi_j(X)]},$$

or, in matrix notation, $\mathbf{Q} = \mathbf{R}\mathbf{\Gamma}$.

Again, matrices $\mathbf{Q}$ and $\mathbf{R}$ can be estimated from data by collecting empirical feature expectations over unlabeled sequences of observations. For $\mathbf{R}$ use Eq. 12 with no change; for $\mathbf{Q}$ replace Eq. 5 by

$$\widehat{Q}_{c,j} = \sum_{x,\boldsymbol{z}\in\mathcal{D}_U} \psi_c(\boldsymbol{z})\phi_j(x) \Big/ \sum_{x,\boldsymbol{z}\in\mathcal{D}_U} \phi_j(x). \quad (20)$$

Let $\mathbf{q}_j \in \mathbb{R}^C$ and $\boldsymbol{\gamma}_j \in \mathbb{R}^K$ be columns of $\widehat{\mathbf{Q}}$ and $\widehat{\mathbf{\Gamma}}$, respectively. Note that we must have

$$\mathbf{1}^\top \boldsymbol{\gamma}_j = \sum_h \frac{P(H=h)\mathbb{E}[\phi_j(X)|H=h]}{\mathbb{E}[\phi_j(X)]} = 1, \quad (21)$$

since $\mathbb{E}[\phi_j(X)] = \sum_h P(H = h)\mathbb{E}\left[\phi_j(X) \mid H = h\right]$. We rewrite the QP to minimize the squared difference for each dimension j independently:

$$\widehat{\boldsymbol{\gamma}}_j = \arg\min_{\boldsymbol{\gamma}_j} \left\|\mathbf{q}_j - \mathbf{R}\boldsymbol{\gamma}_j\right\|_2^2 \text{ s.t. } \mathbf{1}^\top\boldsymbol{\gamma}_j = 1. \quad (22)$$

Note that, if $\boldsymbol{\phi}(x) \geq \mathbf{0}$ for all $x \in \mathcal{X}$, then we must have $\boldsymbol{\gamma}_j \geq \mathbf{0}$, and therefore we may impose this inequality as an additional constraint.

Let $\bar{\boldsymbol{\gamma}} \in \mathbb{R}^K$ be the vector of state probabilities, with entries $\bar{\gamma}_h := p(H = h)$ for $h \in \mathcal{H}$. This vector can also be recovered from the unlabeled dataset and the set of anchors, by solving another QP that aggregates information for all words:

$$\bar{\boldsymbol{\gamma}} = \arg\min_{\bar{\boldsymbol{\gamma}}} \|\bar{\boldsymbol{q}} - \mathbf{R}\bar{\boldsymbol{\gamma}}\|_2^2 \text{ s.t. } \mathbf{1}^\top\bar{\boldsymbol{\gamma}} = 1,\ \bar{\boldsymbol{\gamma}} \geq \mathbf{0}. \quad (23)$$

where $\bar{\boldsymbol{q}} := \widehat{\mathbb{E}}[\boldsymbol{\psi}(\boldsymbol{Z})] \in \mathbb{R}^C$ is the vector whose entries are defined in Eq. 6.

Let $\boldsymbol{\mu}_h := \mathbb{E}[\boldsymbol{\phi}(X) \mid H = h] \in \mathbb{R}^W$ be the mean parameters of the distribution for each state h. These parameters are computed by solving W independent QPs (Eq. 22), yielding the matrix $\mathbf{\Gamma}$ defined in Eq. 17, and then applying the formula:

$$\mu_{h,j} = \Gamma_{j,h} \times \mathbb{E}[\phi_j(X)] / \bar{\gamma}_h, \quad (24)$$

with $\bar{\gamma}_h = p(H = h)$ estimated as in Eq. 23.

4.2 Estimation of Canonical Parameters

To compute a mapping from mean parameters $\boldsymbol{\mu}_h$ to canonical parameters $\boldsymbol{\theta}_h$, we use the well-known Fenchel-Legendre duality between the entropy and the log-partition function (Wainwright and Jordan, 2008). Namely, we need to solve the following convex optimization problem:

$$\widehat{\boldsymbol{\theta}}_h = \arg\max_{\boldsymbol{\theta}_h} \boldsymbol{\theta}_h^\top \boldsymbol{\mu}_h - \log Z(\boldsymbol{\theta}_h) + \epsilon\|\boldsymbol{\theta}_h\|, \quad (25)$$

where ϵ is a regularization constant.[3] In practice, this regularization is important, since it prevents $\boldsymbol{\theta}_h$ from growing unbounded whenever $\boldsymbol{\mu}_h$ falls outside the marginal polytope of possible mean parameters. We solve Eq. 25 with the limited-memory BFGS algorithm (Liu and Nocedal, 1989).

5 Method Improvements

In this section we detail three improvements to our moment-based method that had a practical impact.

Supervised Regularization. We add a supervised penalty term to Eq. 22 to keep the label posteriors $\boldsymbol{\gamma}_j$ close to the label posteriors estimated in the labeled set, $\boldsymbol{\gamma}'_j$, for every feature $j \in [W]$. The regularized least-squares problem becomes:

$$\min_{\boldsymbol{\gamma}_j} (1-\lambda)\|\mathbf{q}_j - \mathbf{R}\boldsymbol{\gamma}_j\|^2 + \lambda\|\boldsymbol{\gamma}_j - \boldsymbol{\gamma}'_j\|^2 \text{ s.t. } \mathbf{1}^\top\boldsymbol{\gamma}_j = 1. \quad (26)$$

CCA Projections. A one-hot feature representation of words and contexts has the disadvantage that it grows with the vocabulary size, making the moment matrix $\mathbf{Q}$ too sparse. The number of contextual features and words can grow rapidly on large text corpora. Similarly to Cohen and Collins (2014) and Dhillon et al. (2015), we use canonical correlation analysis (CCA) to reduce the dimension of these vectors. We use CCA to form low-dimensional projection matrices for features of words $\mathbf{P}_W \in \mathbb{R}^{W\times D}$ and features of contexts $\mathbf{P}_C \in \mathbb{R}^{C\times D}$, with $D \ll \min\{W, C\}$. We use these projections on the original feature vectors and replace the these vectors with their projections.

Selecting Anchors. We collect counts of each word-label pair, and select up to 500 anchors with high conditional probability on the anchoring state $\widehat{p}(h \mid w)$. We tuned the probability threshold to

[3] As shown by Xiaojin Zhu (1999) and Yasemin Altun (2006), this regularization is equivalent, in the dual, to a "soft" constraint $\|\mathbb{E}_{\boldsymbol{\theta}_h}[\boldsymbol{\phi}(X) \mid H = h] - \boldsymbol{\mu}_h\|_2 \leq \epsilon$, as opposed to a strict equality.

select the anchors on the validation set, using steps of 0.1 in the unit interval, and making sure that all tags have at least one anchor. We also considered a frequency threshold, constraining anchors to occur more than 500 times in the unlabeled corpus, and four times in the labeled corpus. Note that past work used a single anchor word per state (i.e., $|\mathcal{A}(h)| = 1$). We found that much better results are obtained when $|\mathcal{A}(h)| \gg 1$, as choosing more anchors increases the number of samples used to estimate the context-label moment matrix $\widehat{\mathbf{R}}$, reducing noise.

6 Experiments

We evaluated our method on two tasks: POS tagging of Twitter text (in English), and POS tagging for a low-resource language (Malagasy). For all the experiments, we used the universal POS tagset (Petrov et al., 2012), which consists of $K = 12$ tags. We compared our method against supervised baselines (HMM and FHMM), which use the labeled data only, and two semi-supervised baselines that exploit the unlabeled data: self-training and EM. For the Twitter experiments, we also evaluated a stacked architecture in which we derived features from our model's predictions to improve a state-of-the-art POS tagger (MEMM).[4]

6.1 Twitter POS Tagging

For the Twitter experiment, we used the *Oct27* dataset of Gimpel et al. (2011), with the provided partitions (1,000 tweets for training and 328 for validation), and tested on the *Daily547* dataset (547 tweets). Anchor words were selected from the training partition as described in §5. We used 2.7M unlabeled tweets (O'Connor et al., 2010) to train the semi-supervised methods, filtering the English tweets as in Lui and Baldwin (2012), tokenizing them as in Owoputi et al. (2013), and normalizing at-mentions, URLs, and emoticons.

We used as word features $\phi(X)$ the word iself, as well as binary features for capitalization, titles, and digits (Berg-Kirkpatrick et al., 2010), the word shape, and the Unicode class of each character. Similarly to Owoputi et al. (2013), we also used suffixes and prefixes (up to length 3), and Twitter-specific features: whether the word starts with @, #, or *http://*. As contextual features $\psi(Z)$, we derive analogous features for the preceding and following words, before reducing dimensionality with CCA. We collect feature expectations for words and contexts that occur more than 20 times in the unlabeled corpus. We tuned hyperparameters on the development set: the supervised interpolation coefficient in Eq. 26, $\lambda \in \{0, 0.1, \ldots, \underline{1.0}\}$, and, for all systems, the regularization coefficient $\epsilon \in \{\underline{0.0001}, 0.001, 0.01, 0.1, 1, 10\}$. (Underlines indicate selected values.) The former controls how much we rely on the supervised vs. unsupervised estimates. For $\lambda = 1.0$ we used supervised estimates only for words that occur in the labeled corpus, all the remaining words rely solely on unsupervised estimates.

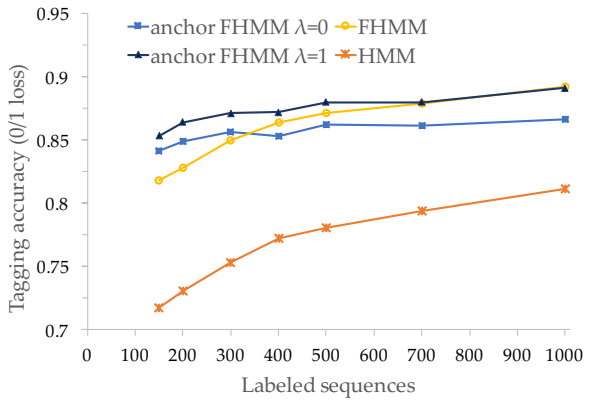

Figure 2: POS tagging accuracy in the Twitter data versus the number of labeled training sequences.

Varying supervision. Figure 2 compares the learning curves of our anchor-word method for the FHMM with the supervised baselines. We show the performance of the anchor methods without interpolation ($\lambda = 0$), and with supervised interpolation coefficient ($\lambda = 1$). When the amount of supervision is small, our method with and without interpolation outperforms all the supervised baselines. This improvement is gradually attenuated when more labeled sequences are used, with the supervised FHMM catching up when the full labeled dataset is used. The best model $\lambda = 1.0$ relies on supervised estimates for words that occur in the labeled corpus, and on anchor estimates for words that occur only in the unlabeled corpus. The unregular-

ized model $\lambda = 0.0$ relies solely on unsupervised estimates given the set of anchors.

Semi-supervised comparison. Next, we compare our method to two other semi-supervised baselines, using both HMMs and FHMMs: EM and self-training. EM requires decoding and counting in multiple passes over the full unlabeled corpus. We initialized the parameters with the supervised estimates, and selected the iteration with the best accuracy on the development set.[5] The self-training baseline uses the supervised system to tag the unlabeled data, and then retrains on all the data.

Results are shown in Table 1. We observe that, for small amounts of labeled data (150 tweets), our method outperforms all the supervised and semi-supervised baselines, yielding accuracies 6.1 points above the best semi-supervised baseline for a simple HMM, and 1.9 points above for the FHMM. With more labeled data (1,000 instances), our method outperforms all the baselines for the HMM, but not with the more sophisticated FHMM, in which our accuracies are 0.3 points below the self-training method.[6] These results suggest that our method is more effective when the amount of labeled data is small.

[5]The FHMM with EM did not perform better than the supervised baseline, so we consider the initial value as the best accuracy under this model.

[6]According to a word-level paired Kolmogorov-Smirnov test, for the FHMM with 1,000 tweets, the self-training method outperforms the other methods with statistical significance at $p < 0.01$; and for the FHMM with 150 tweets the anchor-based and self-training methods outperform the other baselines with the same p-value. Our best HMM outperforms the other baselines at a significance level of $p < 0.01$ for 150 and 1000 sequences.

	150	1000
MEMM (same+clusters)	89.57	**93.36**
MEMM (same+clusters+posteriors)	**91.14**	93.18
MEMM (all+clusters)	91.55	**94.17**
MEMM (all+clusters+posteriors)	**92.06**	94.11

Table 2: Tagging accuracy for the MEMM POS tagger of Owoputi et al. (2013) with additional features from our model's posteriors.

Stacking features. We also evaluated a stacked architecture in which we use our model's predictions as an additional feature to improve the state-of-the-art Twitter POS tagger of Owoputi et al. (2013). This system is based on a semi-supervised discriminative model with Brown cluster features (Brown et al., 1992). We provide results using their full set of features (*all*), and using the same set of features in our anchor model (*same*). We compare tagging accuracy on a model with these features plus Brown clusters (+*clusters*) against a model that also incorporates the posteriors from the anchor method as an additional feature in the MEMM (+*clusters*+*posteriors*). The results in Table 2 show that using our model's posteriors are beneficial in the small labeled case, but not if the entire labeled data is used.

Runtime comparison. The training time of anchor FHMM is 3.8h (hours), for self-training HMM 10.3h, for EM HMM 14.9h and for Twitter MEMM (all+clusters) 42h. As such, the anchor method is much more efficient than all the baselines because it requires a single pass over the corpus to collect the moment statistics, followed by the QPs, without the need to decode the unlabeled data. EM and the Brown clustering method (the latter used to extract features for the Twitter MEMM) require several passes over the data; and the self-training method involves decoding the full unlabeled corpus, which is expensive when the corpus is large. Our analysis adds to previous evidence that spectral methods are more scalable than learning algorithms that require inference (Parikh et al., 2012; Cohen et al., 2013).

6.2 Malagasy POS Tagging

For the Malagasy experiment, we used the small labeled dataset from Garrette et al. (2013), which consists of 176 sentences and 4,230 tokens. We also make use of their tag dictionaries with 2,773 types

Models	Accuracies
supervised FHMM	90.5
EM FHMM	90.5
self-training FHMM	88.7
anchors FHMM (token), λ=1.0	89.4
anchors FHMM (type+token), λ=1.0	**90.9**

Table 3: Tagging accuracies for the Malagasy dataset.

and 23 tags, and their unlabeled data (43.6K sequences, 777K tokens). We converted all the original POS tags to universal tags using the mapping proposed in Garrette et al. (2013).

Table 3 compares our method with semi-supervised EM and self-training, for the FHMM.We tested two supervision settings: token only, and type+token annotations, analogous to Garrette et al. (2013). The anchor method outperformed the baselines when both type and token annotations were used to build the set of anchor words.[7]

7 Conclusion

We proposed an efficient semi-supervised sequence labeling method using a generative log-linear model. We use contextual information from a set of *anchor* observations to disambiguate state, and build a weakly supervised method from this set. Our method outperforms other supervised and semi-supervised methods, with small supervision in POS-tagging for Malagasy, a scarcely annotated language, and for Twitter. Our anchor method is most competitive for learning with large amounts of unlabeled data, under weak supervision, while training an order of magnitude faster than any of the baselines.

Acknowledgments

Support for this research was provided by Fundação para a Ciência e Tecnologia (FCT) through the CMU Portugal Program under grant SFRH/BD/52015/2012. This work has also been partially supported by the European Union under H2020 project SUMMA, grant 688139, and by FCT, through contracts UID/EEA/50008/2013, through the LearnBig project (PTDC/EEI-SII/7092/2014), and the GoLocal project (grant CMUPERI/TIC/0046/2014).

[7] Note that the accuracies are not directly comparable to Garrette et al. (2013), who use a different tag set. However, our supervised baseline trained on those tags is already superior to the best semi-supervised system in Garrette et al. (2013), as we get 86.9% against the 81.2% reported in Garrette et al. (2013) using their tagset.

Abstract

Automatically solving algebra word problems has raised considerable interest recently. Existing state-of-the-art approaches mainly rely on learning from human annotated equations. In this paper, we demonstrate that it is possible to efficiently mine algebra problems and their numerical solutions with little to no manual effort. To leverage the mined dataset, we propose a novel structured-output learning algorithm that aims to learn from both explicit (e.g., equations) and implicit (e.g., solutions) supervision signals *jointly*. Enabled by this new algorithm, our model gains 4.6% absolute improvement in accuracy on the ALG-514 benchmark compared to the one without using implicit supervision. The final model also outperforms the current state-of-the-art approach by 3%.

1 Introduction

Algebra word problems express mathematical relationships via narratives set in a real-world scenario, such as the one below:

> Maria is now four times as old as Kate. Four years ago, Maria was six times as old as Kate. Find their ages now.

The desired output is an *equation system* which expresses the mathematical relationship symbolically: $m = 4 \times n$ and $m - 4 = 6 \times (n - 4)$ where m and n represent the age of Maria and Kate, respectively. The *solution* (i.e., $m = 40, n = 10$) can be found by a *mathematical engine* given the equation systems. Building efficient automatic algebra word problem solvers have clear values for online education scenarios. The challenge itself also provides a good test bed for evaluating an intelligent agent that understands natural languages, a direction advocated by artificial intelligence researchers (Clark and Etzioni, 2016).

One key challenge of solving algebra word problems is the lack of fully annotated data (i.e., the annotated equation system associated with each problem). In contrast to annotating problems with binary or categorical labels, manually solving algebra word problems to provide correct equations is time consuming. As a result, existing benchmark datasets are small, limiting the performance of supervised learning approaches. However, thousands of algebra word problems have been posted and discussed in online forums, where the solutions can be easily mined, despite the fact that some of them could be incorrect. It is thus interesting to ask whether a better algebra problem solver can be learned by leveraging these *noisy* and *implicit* supervision signals, namely the solutions.

In this work, we address the technical difficulty of leveraging implicit supervision in learning an algebra word problem solver. We argue that the effective strategy is to learn from both explicit and implicit supervision signals *jointly*. In particular, we design a novel online learning algorithm based on structured-output Perceptron. By taking both kinds of training signals together as input, the algorithm iteratively improves the model, while at the same time it uses the intermediate model to find candidate equation systems for problems with only numerical solutions.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 297–306,
Austin, Texas, November 1-5, 2016.

Our contributions are summarized as follows.

- We propose a novel learning algorithm (Section 3 and 4) that jointly learns from both explicit and implicit supervision. Under different settings, the proposed algorithm outperforms the existing supervised and weakly supervised algorithms (Section 6) for algebra word problems.
- We mine the problem-solution pairs for algebra word problems from an online forum and show that we can effectively obtain the implicit supervision with little to no manual effort (Section 5).[1]
- By leveraging both implicit and explicit supervision signals, our final solver outperforms the state-of-the-art system by 3% on ALG-514, a popular benchmark data set proposed by (Kushman et al., 2014).

2 Related Work

Automatically solving mathematical reasoning problems expressed in natural language has been a long-studied problem (Bobrow, 1964; Newell et al., 1959; Mukherjee and Garain, 2008). Recently, Kushman et al. (2014) created a template-base search procedure to map word problems into equations. Then, several following papers studied different aspects of the task: Hosseini et al. (2014) focused on improving the generalization ability of the solvers by leveraging extra annotations; Roy and Roth (2015) focused on how to solve arithmetic problems without using any pre-defined template. In (Shi et al., 2015), the authors focused on number word problems and proposed a system that is created using semi-automatically generated rules. In Zhou et al. (2015), the authors simplified the inference procedure and pushed the state-of-the-art benchmark accuracy. The idea of learning from implicit supervision is discussed in (Kushman et al., 2014; Zhou et al., 2015; Koncel-Kedziorski et al., 2015), where the authors train the algebra solvers using only the solutions with little or no annoated equation systems. We discuss this in detail in Section 4.

[1]The new resource and the dataset we used for training is available soon on `https://aka.ms/dataimplicit` and `https://aka.ms/datadraw`

Solving automatic algebra word problems can be viewed as a semantic parsing task. In the semantic parsing community, the technique of learning from implicit supervision signals has been applied (under the name *response-driven learning* (Clarke et al., 2010)) to knowledge base question answering tasks such as Geoquery (Zelle and Mooney, 1996) and WebQuestions (Berant et al., 2013) or mapping instructions to actions (Artzi and Zettlemoyer, 2013). In these tasks, researchers have shown that it is possible to train a semantic parser only from question-answer pairs, such as "*What is the largest state bordering Texas?*" and "*New Mexico*" (Clarke et al., 2010; Liang et al., 2013; Yih et al., 2015).

One key reason that such implicit supervision is effective is because the correct semantic parses of the questions can often be found using the answers and the knowledge base alone, with the help of heuristics developed for the specific domain. For instance, when the question is relatively simple and does not have complex compositional structure, paths in the knowledge graph that connect the answers and the entities in the narrative can be interpreted as legitimate semantic parses. However, as we will show in our experiments, learning from implicit supervision alone is not a viable strategy for algebra word problems. Compared to the knowledge base question answering problems, one key difference is that a large number (potentially infinitely many) of different equation systems could end up having the same solutions. Without a database or special rules for combining variables and coefficients, the number of candidate equation systems cannot be trimmed effectively, given only the solutions.

From the algorithmic point of view, our proposed learning framework is related to several lines of work. Similar efforts have been made to develop latent structured prediction models (Yu and Joachims, 2009; Chang et al., 2013; Zettlemoyer and Collins, 2007) to find latent semantic structures which best explain the answer given the question. Our algorithm is also influenced by the discriminative reranking algorithms (Collins, 2000; Ge and Mooney, 2006; Charniak and Johnson, 2005) and models for learning from intractable supervision (Steinhardt and Liang, 2015).

Recently, Huang et al. (2016) collected a large

number of noisily annotated word problems from online forums. While they collected a large-scale dataset, unlike our work, they did not demonstrate how to utilize the newly crawled dataset to improve existing systems. It will be interesting to see if our proposed algorithm can make further improvements using their newly collected dataset.[2]

3 Problem Definition

Table 1 lists all the symbols representing the components in the process. The input algebra word problem is denoted by $\mathbf{x}$, and the output $\mathbf{y} = (T, A)$ is called a *derivation*, which consists of an *equation system template* T and an *alignment* A. A template T is a family of equation systems parameterized by a set of coefficients $\mathcal{C}(T) = \{c_i\}_{i=1}^{k}$, where each coefficient c_i aligns to a textual number (e.g., *four*) in a word problem. Let $\mathcal{Q}(x)$ be all the *textual numbers* in the problem $\mathbf{x}$, and $\mathcal{C}(T)$ be the coefficients to be determined in the template T. An alignment is a set of tuples $A = \{(q, c) \mid q \in \mathcal{Q}(x), c \in \mathcal{C}(T) \cup \{\epsilon\}\}$, where the tuple (q, ϵ) indicates that the number q is not relevant to the final equation system. By specifying the value of each coefficient, it identifies an equation system belonging to the family represented by template T. Together, T and A generate a complete equation system, and the solution $\mathbf{z}$ can be derived by the mathematical engine E.

Following (Kushman et al., 2014; Zhou et al., 2015), our strategy of mapping a word problem to an equation system is to first choose a template that consists of variables and coefficients, and then align each coefficient to a textual number mentioned in the problem. We formulate the mapping between an algebra word problem and an equation system as a structured learning problem. The output space is the set of all possible derivations using templates that are observed in the training data. Our model maps $\mathbf{x}$ to $\mathbf{y} = (T, A)$ by a linear scoring function $\mathbf{w}^T \Phi(\mathbf{x}, \mathbf{y})$, where $\mathbf{w}$ is the model parameters and Φ is the feature functions. At test time, our model scores all the derivation candidates and picks the best one according to the model score. We often refer to $\mathbf{y}$ as a semantic parse, as it represents the semantics of the algebra word problem.

[2]The dataset has not been made public at the time of publication.

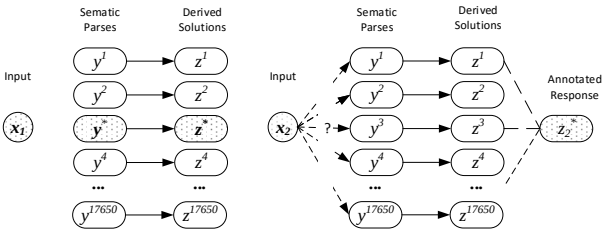

Figure 1: **Left:** Explicit supervision signals. Note that the solution $\mathbf{z}$ can be derived by the semantic parses $\mathbf{y}$. **Right:** Implicit supervision signals. In this case, we only have the annotated response $\mathbf{z}_2^*$. It is difficult to use $\mathbf{z}_2^*$ to find the correct derivation, as multiple derivations may lead to the same solution. Therefore, the learning algorithm has to explore the output space to guide the model in order to match the annotated response.

Properties of Implicit Supervision Signals We discuss some key properties of the implicit supervision signal to explain several design choices of our algorithm. Figure 1 illustrates the main differences between implicit and explicit supervision signals.

Algorithms that learn from implicit supervision signals face the following challenges. First, the learning system usually does not model directly the correlations between the input $\mathbf{x}$ and the solution $\mathbf{z}$. Instead, the mapping is handled by an external procedure such as a mathematical engine. Therefore, $E(\mathbf{y})$ is effectively a one-directional function. As a result, finding semantic parses (derivations) from responses (solutions) $E^{-1}(\mathbf{z})$ can sometimes be very slow or even intractable. Second, in many cases, even if we could find a semantic parse from responses, multiple combinations of templates and alignments could end up with the same solution set (e.g., the solutions of equations $2 + x = 4$ and $2 \times x = 4$ are the same). Therefore, the implicit supervision signals may be incomplete and noisy, and using the solutions alone to guide the training procedure might not be sufficient. Finally, since we need to have a complete derivation before we can observe the response of the mathematical engine E, we cannot design efficient inference methods such as dynamic programming algorithms based on partial feedback. As a result, we have to perform exploration during learning to search for fully constructed semantic parses that can generate the correct solution.

Term	Symbol	Example
Word Problem	$\mathbf{x}$	*Maria is now four times as old as Kate. Four years ago, Maria was six times as old as Kate. Find their ages now.*
Derivation (Semantic Parse)	$\mathbf{y} = (T, A)$	$(\{m - a \times n = -1 \times a \times b + b, m - c \times n = 0\}, A)$
Solution	$\mathbf{z}$	$n = 10, m = 40$
Mathematical Engine	$E : \mathbf{y} \rightarrow \mathbf{z}$	After determining the coefficients, the equation system is $\{m = 4 \times n, m - 4 = 6 \times (n - 4)\}$. The solution is thus $n = 10$, $m = 40$.
Variables	v	m, n
Textual Number[3]	$\mathcal{Q}(x)$	{four, Four, six}
Equation System Template	T	$\{m - a \times n = -1 \times a \times b + b, m - c \times n = 0\}$
Coefficients	$\mathcal{C}(T)$	a, b, c
Alignment	A	six $\rightarrow a$, Four $\rightarrow b$, four $\rightarrow c$

Table 1: Notation used in this paper to formally describe the problem of mapping algebra word problems to equations.

4 Learning from Mixed Supervision

We assume that we have two sets: $D_e = \{(\mathbf{x}_e, \mathbf{y}_e)\}$ and $D_m = \{(\mathbf{x}_m, \mathbf{z}_m)\}$. D_e contains the fully annotated equation system $\mathbf{y}_e$ for each algebra word problem $\mathbf{x}_e$, whereas in D_m, we have access to the numerical solution $\mathbf{z}_m$ to each problem, but not the equation system ($\mathbf{y}_m = \emptyset$). We refer to D_e as the *explicit set* and D_m as the *implicit set*. For the sake of simplicity, we explain our approach by modifying the training procedure of the structured Perceptron algorithm (Collins, 2002).[4]

As discussed in Section 3, the key challenge of learning from implicit supervision is that the mapping $E(\mathbf{y})$ is one-directional. Therefore, the correct equation system cannot be easily derived from the numerical solution. Intuitively, for data with only implicit supervision, we can explore the structure space Y and find the best possible derivation $\tilde{\mathbf{y}} \in Y$ according to the current model. If $E(\tilde{\mathbf{y}})$ matches $\mathbf{z}$, then we can update the model based on $\tilde{\mathbf{y}}$. Following this intuition, we propose *MixedSP* (Algorithm 1).

For each example, we use an approximate search algorithm to collect top scoring candidate structures. The algorithm first ranks the top-K templates according to the model score, and forms a candidate set by expanding all possible derivations that use the K templates (Line 3). The final candidate set is $\Omega = \{\mathbf{y}^1, \mathbf{y}^2, \ldots, \mathbf{y}^K\} \subset Y$.

When the explicit supervision is available (i.e., $(\mathbf{x}_i, \mathbf{y}_i) \in D_e$), our algorithm follows the standard structured prediction update procedure. We find the best scoring structure $\hat{\mathbf{y}}$ in Ω and then update the model using the difference of the feature vectors between the gold output structure $\mathbf{y}_i$ and the best scoring structure $\hat{\mathbf{y}}$ (Line 6).

When only implicit supervision is available (i.e., $(\mathbf{x}_i, \mathbf{z}_i) \in D_m$), our algorithm uses the current model to conduct a guided exploration, which iteratively finds structures that best explain the implicit supervision, and use the explanatory structure for making updates. As mentioned in Section 3, we have to explore and examine each structure in the candidate set Ω. This is due the fact that partial structure cannot be used for finding the right response, as getting response $E(\mathbf{y})$ requires complete derivations. In Line 9, we want to find the derivations $\mathbf{y}$ where its solution $E(\mathbf{y})$ matches the implicit supervision $\mathbf{z}_i$. More specifically,

$$\tilde{\mathbf{y}} = \arg\min_{\mathbf{y} \in \Omega} \Delta(E(\mathbf{y}), \mathbf{z}_i), \quad (1)$$

where Δ is a loss function to estimate the disagreement between $E(\mathbf{y})$ and $\mathbf{z}_i$. In our experiments, we simply set $\Delta(E(\mathbf{y}), \mathbf{z}_i)$ to be 0 if the solution partially matches, and 1 otherwise.[5] If more than one derivation achieves the minimal value of $\Delta(E(\mathbf{y}), \mathbf{z}_i)$, we break ties by choosing the derivation with higher score $\mathbf{w}^T \phi(\mathbf{x}_i, \mathbf{y})$. This tie-

[4] Our approach can be easily extended to other structured learning algorithms such as Structured SVM (Taskar et al., 2004; Tsochantaridis et al., 2004).

[5] The mined solutions are often incomplete for some variables (e.g. solution `y=6` but no value for `x` could be mined). We allow partial matches so that the model can learn from the incomplete implicit signals as well.

Algorithm 1 Structured Perceptron with Mixed Supervision. (**MixedSP**)

4: **if** $\mathbf{y}_i \neq \emptyset$ **then** ▷ explicit supervision
5: $\hat{\mathbf{y}} \leftarrow \arg\max_{\mathbf{y} \in \Omega} \mathbf{w}^T \phi(\mathbf{x}_i, \mathbf{y})$
6: $\mathbf{w} \leftarrow \mathbf{w} + \eta \left(\phi(\mathbf{x}, \mathbf{y}_i) - \phi(\mathbf{x}, \hat{\mathbf{y}})\right)$
7: **else if** $t \geq \gamma N$ **then** ▷ implicit supervision
8: $\hat{\mathbf{y}} \leftarrow \arg\max_{\mathbf{y} \in \Omega} \mathbf{w}^T \phi(\mathbf{x}_i, \mathbf{y})$
9: Pick $\tilde{\mathbf{y}}$ from Ω by Eq. (1). ▷ exploration
10: $\mathbf{w} \leftarrow \mathbf{w} + \eta \left(\phi(\mathbf{x}, \tilde{\mathbf{y}}) - \phi(\mathbf{x}, \hat{\mathbf{y}})\right)$
11: Return the average of $\mathbf{w}$

breaking strategy is important – in practice, several derivations may lead to the gold numerical solution; however, only few of them are correct. The tie-breaking strategy relies on the current model and the structured features $\phi(\mathbf{x}_i, \mathbf{y})$ to filter out incorrect derivations during training. Finally, the model is updated using $\tilde{\mathbf{y}}$ in Line 10.

Similar to curriculum learning (Bengio et al., 2009), it is important to control when the algorithm starts exploring the output space using weak supervision. Exploring too early may mislead the model, as the structured feature weights $\mathbf{w}$ may not be able to help filter out incorrect derivations, while exploring too late may lead to under-utilization of the implicit supervision. We use the parameter γ to control when the model starts to learn from implicit supervision signals. The parameter γ denotes the fraction of the training time that the model uses purely explicit supervision.

Key Properties of Our Algorithm The idea of using solutions to train algebra word problem solvers has been discussed in (Kushman et al., 2014) and (Zhou et al., 2015). However, their implicit supervision signals are created from clean, fully supervised data, and the experiments use little to no explicit supervision examples.[6] While their algorithms are interesting, the experimental setting is somewhat unrealistic as the implicit signals are simulated.

[6]Prior work (Kushman et al., 2014) has used only 5 explicit supervision examples when training with solutions.

On the other hand, the goal of our algorithm is to significantly improve a strong solver with a large quantity of unlabeled data. Moreover, our implicit supervision signals are noisier given that we crawled the data automatically, and the clean labeled equation systems are not available to us. As a result, we have made several design choices to address issues of learning from noisy implicit supervision signals in practice.

First, the algorithm is designed to perform updates *conservatively*. Indeed, in Line 10, the algorithm will not perform an update if the model could not find any parses matching the implicit signals in Line 9. That is, if $\Delta(E(\mathbf{y}), \mathbf{z}_i) = 1$ for all $\mathbf{y} \in \Omega$, $\tilde{\mathbf{y}} = \hat{\mathbf{y}}$ due to the tie-breaking mechanism. This ensures that the algorithm drives the learning using only those structures which lead to the correct solution, avoiding undesirable effects of noise.

Second, the algorithm does *not* use implicit supervision signals in the early stage of model training. Learning only on clean and explicit supervision helps derive a better intermediate model, which later allows exploring the output space more efficiently using the implicit supervision signals.

Existing semantic parsing algorithms typically use either implicit or explicit supervision signals *exclusively* (Zettlemoyer and Collins, 2007; Berant et al., 2013; Artzi and Zettlemoyer, 2013). In contrast, *MixedSP* makes use of both explicit and implicit supervised examples mixed at the training time.

5 Mining Implicit Supervision Signals

In this section, we describe the process of collecting SOL-2K, a data set containing question-solution pairs of algebra word problems from a Web forum[7], where students and tutors interact to solve math problems.

A word problem posted on the forum is often accompanied by a detailed explanation provided by tutors, which includes a list of the relevant equations. However, these posted equations are not suitable for direct use as labeled data, as they are often imprecise or incomplete. For instance, tutors often omit many simplification steps when writing the equations. A commonly observed example is that `(5-3)x+2y` would be directly written as `2x+2y`. Despite being

[7]`http://www.algebra.com`

mathematically equivalent, learning from the latter equation is not desirable as the model may learn that 5 and 3 appearing the text are irrelevant. An extreme case of this is when tutors directly post the solution (such as `x=2` and `y=5`), without writing any equations. Another observation is that tutors often write two-variable equation systems with only one variable. For example, instead of writing `x+y=10, x-y=2`, many tutors pre-compute `x=10-y` using the first equation and substitute it in the second one, which results in `10-y-y=2`. It is also possible that the tutor wrote the incorrect equation system, but while explaining the steps, made corrections to get the right answer. These practical issues make it difficult to use the crawled equations for explicit supervision directly.

On the other hand, it is relatively easy to obtain question-solution pairs with simple heuristics. We use a simple strategy to generate the solution from the extracted equations. We greedily select equations in a top-down manner, declaring success as soon as we find an equation system that can be solved by a mathematical engine (we used SymPy (Sympy Development Team, 2016)). Equations that cause an exception in the solver (due to improper extraction) are rejected. Note that the solution thus found may be incorrect (making the mined supervision noisy), as the equation system used by the solver may contain an incorrect equation. To ensure the quality of the mined supervision, we use several simple rules to further filter the problems. For example, we remove questions that have more than 15 numbers. We found that usually such questions were not a single word problem, but instead concatenations of several problems.

Note that our approach relies only on a few rules and a mathematical engine to generate (noisy) implicit supervision from crawled problems, with no human involvement. Once the solutions are generated, we discarded the equation systems used to obtain them. Using this procedure, we collected 2,039 question-solution pairs. For example, the solution to the following mined problem was "6" (The correct solutions are 6 and 12.):

> Roz is twice as old as Grace. In 5 years the sum of their ages will be 28. How old are they now?

Settings	Explicit sets		Implicit sets
	(D_e)		(D_m)
Dataset	ALG-514	DRAW-1K	SOL-2K
# temp.	24	224	Unknown
# prob.	514	1,000	2,039
Vocab.	1.83k	2.2k	6.8k

Table 2: The statistics of the data sets.

6 Experiments

In this section, we demonstrate the effectiveness of the proposed approach and empirically verify the design choices of the algorithm. We show that our joint learning approach leverages mined implicit supervision effectively, improving system performance without using additional manual annotations (Section 6.1). We also compare our approach to existing methods under different supervision settings (Section 6.2).

Experimental Settings Table 2 shows the statistics of the datasets. The ALG-514 dataset (Kushman et al., 2014) consists of 514 algebra word problems, ranging over a variety of narrative scenarios (object counting, simple interest, etc.). Although it is a popular benchmark for evaluating algebra word solvers, ALG-514 has only 24 templates. To test the generality of different approaches, we thus conduct experiments on a newly released data set, DRAW-1K[8] (Upadhyay and Chang, 2016), which covers more than 200 templates and contains 1,000 algebra word problems. The data is split into training, development, and test sets, with 600/200/200 examples, respectively.

The SOL-2K dataset contains the word problem-solution pairs we mined from online forum (see Section 5). Unlike ALG-514 and DRAW-1K, there are no annotated equation systems in this dataset, and only the solutions are available. Also, no preprocessing or cleaning is performed, so the problem descriptions might contain some irrelevant phrases such as "please help me". Since all the datasets are generated from online forums, we carefully examined and removed problems from SOL-2K that are identical to problems in ALG-514 and DRAW-1K, to ensure fairness. We set the number of iterations

[8] `https://aka.ms/datadraw`

to 15 and the learning rate η to be 1.

For all experiments, we report *solution accuracy* (whether the solution was correct). Following Kushman et al. (2014), we ignore the ordering of answers when calculating the solution accuracy. We report the 5-fold cross validation accuracy on ALG-514 in order to have a fair comparison with previous work. For DRAW-1K, we report the results on the test set. In all the experiments, we only use the templates that appear in the corresponding explicit supervision.

Following (Zhou et al., 2015), we do not model the alignments between noun phrases and variables. We use a similar set of features introduced in (Zhou et al., 2015), except that our solver does not use rich NLP features from dependency parsing or coreference-resolution systems. We follow (Kushman et al., 2014) and set the beam-size K to 10, unless stated otherwise.

6.1 Joint Learning from Mixed Supervision

Supervision Protocols We compare the following training protocols:

- *Explicit* ($D = \{(\mathbf{x}_e, \mathbf{y}_e)\}$): the standard setting, where fully annotated examples are used to train the model (we use the structured Perceptron algorithm as our training algorithm here).

- *Implicit* ($D = \{(\mathbf{x}_m, \mathbf{z}_m))\}$): the model is trained on SOL-2K dataset only (i.e., only implicit supervision). This setting is similar to the one in (Liang et al., 2013; Clarke et al., 2010).

- *Pseudo* ($D = \{(\mathbf{x}_m, \tilde{Z}^{-1}(\mathbf{z}_m, \mathbf{x}_m))\}$): where we use $\tilde{Z}^{-1}(\mathbf{z}, \mathbf{x})$ to denote a pseudo derivation whose solutions match the mined solutions. Similar to the approach in (Yih et al., 2015) for question answering, here we attempts to recover (possibly incorrect) explicit supervision from the implicit supervision by finding parses whose solution matches the mined solution. For each word problem, we generated a pseudo derivation $\tilde{Z}^{-1}(\mathbf{z}, \mathbf{x})$ by finding the equation systems whose solutions that match the mined solutions. We conduct a brute force search to find $\tilde{Z}^{-1}(\mathbf{z}, \mathbf{x})$ by enumerating all possible derivations. Note that this process can be very slow for datasets like DRAW-1K because the brute-force search needs to examine more than 200 templates for each word problem. Ties are broken by random.

- *E+P* ($D = \{(\mathbf{x}_e, \mathbf{y}_e)\} \cup \{(\mathbf{x}_m, \tilde{Z}^{-1}(\mathbf{z}_m, \mathbf{x}_m))\}$): a baseline approach that jointly learns by combining the dataset generated by *Pseudo* with the *Explicit* supervision.

- *MixedSP* ($D = \{(\mathbf{x}_e, \mathbf{y}_e)\} \cup \{(\mathbf{x}_m, \mathbf{z}_m))\}$): the setting used by our proposed algorithm. The algorithm trained the word problem solver using both explicit and implicit supervision jointly. We set the parameter γ to 0.5 unless otherwise stated. In other words, the first half of the training iterations use only explicit supervision.

Note that *Explicit*, *E+P*, and *MixedSP* use the same amount of labeled equations, although *E+P* and *MixedSP* use additional implicit supervised resources.

Results Table 3 lists the main results. With implicit supervision from mined question-solution pairs, *MixedSP* outperforms *Explicit* by around 4.5% on both datasets. This verifies the claim that the joint learning approach can benefit from the noisy implicit supervision. Note that with the same amount of supervision signals, *E+P* performs poorly and even under-performs *Explicit*. The reason is that the derived derivations in SOL-2K can be noisy. Indeed, we found that about 70% of the problems in the implicit set have more than one template that can produce a derivation which matches the mined solutions. Therefore, the pseudo derivation selected by the system might be wrong, even if they generate the correct answers. As a result, *E+P* can commit to the possibly incorrect pseudo derivations before training, and suffer from error propagation. In contrast, *MixedSP* does not commit to a derivation and allows the model to choose the one best explaining the implicit signals as training progresses.

As expected, using only the implicit set D_m performs poorly. The reason is that in both *Implicit* and *Pseudo* settings, the algorithm needs to select one from many derivations that match the labeled solutions, and use the selected derivation to update the model. When there are no explicit supervision

Dataset	D_e	D_m		D_e and D_m	
	Expl.	Pseudo	Impl.	E+P	MixedSP
ALG-514	78.4	54.1	63.7	73.3	**83.0**
DRAW-1K	55.0	33.5	39.0	48.5	**59.5**

Table 3: The solution accuracies of different protocols on ALG-514 and DRAW-1K.

signals, the model can use incorrect derivations to update the model. As a result, models on both *Implicit* and *Pseudo* settings perform significantly worse than the *Explicit* baseline in both datasets, even if the size of SOL-2K is larger than the fully supervised data.

6.2 Comparisons to Previous Work

We now compare to previous approaches for solving algebra word problems, both in fully supervised and weakly supervised settings.

Comparisons of Overall Systems We first compare our systems to the systems that use the same level of explicit supervision (fully labeled examples). The comparison between our system and existing systems are in Fig 2a and 2b. Compared to previous systems that were trained only on explicit signals, our *Explicit* baseline is quite competitive. On ALG-514, the accuracy of our baseline system is 78.4%, which is 1.3% lower than the best reported accuracy achieved by the system ZDC15 (Zhou et al., 2015). We suspect that this is due to the richer feature set used by ZDC15, which includes features based on POS tags, coreference and dependency parses, whereas our system only uses features based on POS tags. Our system is also the best system on DRAW-1K, and performs much better than the system KAZB14 (Kushman et al., 2014). Note that we could not run the system ZDC15 on DRAW-1K because it can only handle limited types of equation systems. Although the *Explicit* baseline is strong, the *MixedSP* algorithm is still able to improve the solver significantly through noisy implicit supervision signals without using manual annotation of equation systems.

Comparisons of Weakly Supervised Algorithms In the above comparisons, *MixedSP* benefits from the mined implicit supervision as well as using Algorithm 1. Since there are several practical limitations for us to run previously proposed weakly supervised algorithms in our settings, in the following, we perform a direct comparison between *MixedSP* and existing algorithms in their corresponding settings. Note that the implicit supervision in weak supervision settings proposed in earlier work is noise-free, as it was simulated by hiding equation systems of a manually annotated dataset.

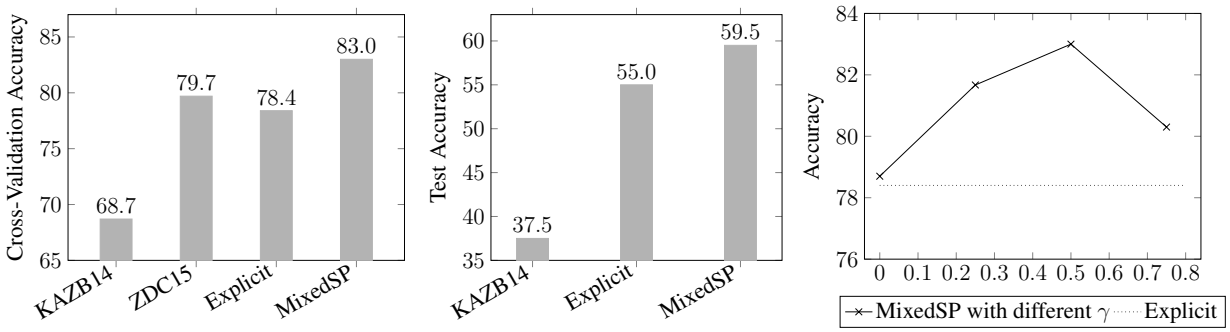
Zhou et al. (2015) proposed a weak supervision setting where the system was provided with the set of all templates, as well as the solutions of all problems during training. Under this setting, they reported 72.3% accuracy on ALG-514. Note that such high accuracy can be achieved mainly because that the complete and correct templates were supplied.

In this setting, running the *MixedSP* algorithm is equivalent to using the *Implicit* setting with clean implicit supervision signals. Surprisingly, *MixedSP* can obtain 74.3% accuracy, surpassing the weakly supervised model in (Zhou et al., 2015) on ALG-514. Compared to the results in Table 3, note that when using noisy implicit signals, it cannot obtain the same level of results, even though we had more training problems (2,000 mined problems instead of 514 problems). This shows that working with real, noisy weak supervision is much more challenging than working on simulated, noise-free, weak supervision.

Kushman et al. (2014) proposed another weak supervision setting (5EQ+ANS in the paper), in which explicit supervision is provided for only 5 problems in the training data. For the rest of problems, only their solutions are provided. The 5 problems are chosen such that their templates constitute the 5 most common templates in the dataset. This weak supervision setting is harder than that of (Zhou et al., 2015), as the solver only has the templates for 5 problems, instead of the templates for all problems. Under this setting, our *MixedSP* algorithm achieves 53.8%, which is better than 46.1% reported in (Kushman et al., 2014).

6.3 Analysis

In Figure 2c, we investigate the impact of tuning γ in *MixedSP* on the dataset ALG-514. Recall that γ controls the fraction of the training time that the model uses solely explicit supervision. At first glance, it may appear that we should utilize the im-



(a) (b) (c)

Figure 2: **(a)** Comparisons between our system to state-of-the-art systems on ALG-514. ZDC15 is the system proposed in (Zhou et al., 2015), and KAZB14 is the system proposed in (Kushman et al., 2014). **(b)** Comparisons between our system and other systems on DRAW-1K. Note that we are not able to run ZDC15 on DRAW-1K because it cannot handle some equation systems in the dataset. **(c)** Analysis of the impact of γ in MixedSP.

plicit supervision throughout training (set $\gamma = 0$). But setting γ to 0 hurts overall performance, suggesting in this setting that the algorithm uses a weak model to guide the exploration for using implicit supervision. On the other hand, by delaying exploration ($\gamma > 0.5$) for too long, the model could not fully utilize the implicit supervision. We observe similar trend on DRAW-1K as well. We found $\gamma = 0.5$ works well across the experiments.

We also analyze the impact of the parameter K, which controls the size of the candidate set Ω in *MixedSP*. Specifically, for DRAW-1K, when setting K to 5 and 10, the accuracy of *MixedSP* is at 59.5%. On setting K to 15, the accuracy of *MixedSP* improves to 61%. We suspect that enlarging K increases the chance to have good structures in the candidate set that can match the correct responses.

7 Conclusion

In this paper, we propose an algorithmic approach for training a word problem solver based on both explicit and implicit supervision signals. By extracting the question answer pairs from a Web-forum, we show that the algebra word problem solver can be improved significantly using our proposed technique, surpassing the current state-of-the-art.

Recent advances in deep learning techniques demonstrate that the error rate of machine learning models can decrease dramatically when large quantities of labeled data are presented (Krizhevsky et al., 2012). However, labeling natural language data has been shown to be expensive, and it has become one of the major bottleneck for advancing natural language understanding techniques (Clarke et al., 2010). We hope the proposed approach can shed light on how to leverage data on the web, and eventually improves other semantic parsing tasks such as knowledge base question answering and mapping natural instructions to actions.

TweeTime: A Minimally Supervised Method for Recognizing and Normalizing Time Expressions in Twitter

Abstract

We describe TweeTIME, a temporal tagger for recognizing and normalizing time expressions in Twitter. Most previous work in social media analysis has to rely on temporal resolvers that are designed for well-edited text, and therefore suffer from reduced performance due to domain mismatch. We present a minimally supervised method that learns from large quantities of unlabeled data and requires no hand-engineered rules or hand-annotated training corpora. TweeTIME achieves 0.68 F1 score on the end-to-end task of resolving date expressions, outperforming a broad range of state-of-the-art systems.[1]

1 Introduction

Temporal expressions are words or phrases that refer to dates, times or durations. Resolving time expressions is an important task in information extraction (IE) that enables downstream applications such as calendars or timelines of events (Derczynski and Gaizauskas, 2013; Do et al., 2012; Ritter et al., 2012; Ling and Weld, 2010), knowledge base population (Ji et al., 2011), information retrieval (Alonso et al., 2007), automatically scheduling meetings from email and more. Previous work in this area has applied rule-based systems (Mani and Wilson, 2000; Bethard, 2013b; Chambers, 2013) or supervised machine learning on small collections of hand-annotated news documents (Angeli et al., 2012; Lee et al., 2014).

[1]Our code and data are publicly available at https://github.com/jeniyat/TweeTime.

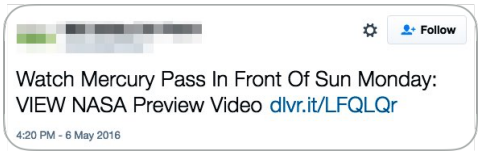

Figure 1: A tweet published on *Friday 5/6/2016* that contains the temporal expression *Monday* referring to the date of the event (*5/9/2016*), which a generic temporal tagger failed to resolve correctly.

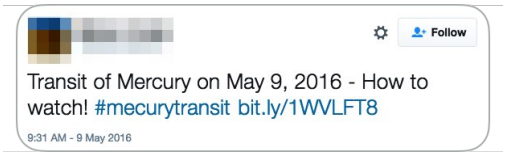

Figure 2: A tweet that contains a simple explicit time mention and an event (*Mercury, 5/9/2016*) that can be identified by an open-domain information extraction system.

Social media especially contains time-sensitive information and requires accurate temporal analysis, for example, for detecting real-time cybersecurity events (Ritter et al., 2015; Chang et al., 2016), disease outbreaks (Kanhabua et al., 2012) and extracting personal information (Schwartz et al., 2015). However, most work on social media simply uses generic temporal resolvers and therefore suffers from suboptimal performance. Recent work on temporal resolution focuses primarily on news articles and clinical texts (UzZaman et al., 2013; Bethard and Savova, 2016).

Resolving time expressions in social media is a non-trivial problem. Besides many spelling variations, time expressions are more likely to refer to future dates than in newswire. For the example in

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 307–318,
Austin, Texas, November 1-5, 2016.

Figure 1, we need to recognize that *Monday* refers to the upcoming Monday and not the previous one to resolve to its correct normalized date (*5/9/2016*). We also need to identify that the word *Sun* is not referring to a Sunday in this context.

In this paper, we present a new minimally supervised approach to temporal resolution that requires no in-domain annotation or hand-crafted rules, instead learning from large quantities of unlabeled text in conjunction with a database of known events. Our approach is capable of learning robust time expression models adapted to the informal style of text found on social media.

For popular events, some related tweets (e.g. Figure 2) may contain explicit or other simple time mentions that can be captured by a generic temporal tagger. An open-domain information extraction system (Ritter et al., 2012) can then identify events (e.g. [*Mercury*, *5/9/2016*]) by aggregating those tweets. To automatically generate temporally annotated data for training, we make the following novel *distant supervision assumption*:[2]

> Tweets posted near the time of a known event that mention central entities are likely to contain time expressions that refer to the date of the event.

Based on this assumption, tweets that contain the same named entity (e.g. Figure 1) are heuristically labeled as training data. Each tweet is associated with multiple overlapping labels that indicate the day of the week, day of the month, whether the event is in the past or future and other time properties of the event date in relation to the tweet's creation date. In order to learn a tagger that can recognize temporal expressions at the word-level, we present a multiple-instance learning approach to model sentence and word-level tags jointly and handle overlapping labels. Using heuristically labeled data and the temporal tags predicted by the multiple-instance learning model as input, we then train a log-linear model that normalizes time expressions to calendar dates.

Building on top of the multiple-instance learning model, we further improve performance using a missing data model that addresses the problem of errors introduced during the heuristic labeling process. Our best model achieves a 0.68 F1 score when resolving date mentions in Twitter. This is a 17% increase over SUTime (Chang and Manning, 2012), outperforming other state-of-the-art time expression resolvers HeidelTime (Strötgen and Gertz, 2013), TempEX (Mani and Wilson, 2000) and UWTime (Lee et al., 2014) as well. Our approach also produces a confidence score that allows us to trade recall for precision. To the best of our knowledge, TweeTIME is the first time resolver designed specifically for social media data.[3] This is also the first time that distant supervision is successfully applied for end-to-end temporal recognition and normalization. Previous distant supervision approaches (Angeli et al., 2012; Angeli and Uszkoreit, 2013) only address the normalization problem, assuming gold time mentions are available at test time.

2 System Overview

Our TweeTIME system consists of two major components as shown in Figure 3:

1. A **Temporal Recognizer** which identifies time expressions (e.g. *Monday*) in English text and outputs 5 different temporal types (described in Table 1) indicating timeline direction, month of year, date of month, day of week or no temporal information (NA). It is realized as a multiple-instance learning model, and in an enhanced version, as a missing data model.

2. A **Temporal Normalizer** that takes a tweet with its creation time and temporal expressions tagged by the above step as input, and outputs their normalized forms (e.g. *Monday* $\rightarrow$ *5/9/2016*). It is a log-linear model that uses both lexical features and temporal tags.

To train these two models without corpora manually annotated with time expressions, we leverage a large database of known events as distant supervision. The event database is extracted automatically from Twitter using the open-domain IE system

[2] We focus on resolving dates, arguably the most important and frequent category of time expressions in social media data, and leave other phenomenon such as times and durations to traditional methods or future work.

[3] The closest work is HeidelTime's colloquial English version (Strötgen and Gertz, 2012) developed from annotated SMS data and slang dictionary. Our TweeTIME significantly outperforms on Twitter data.

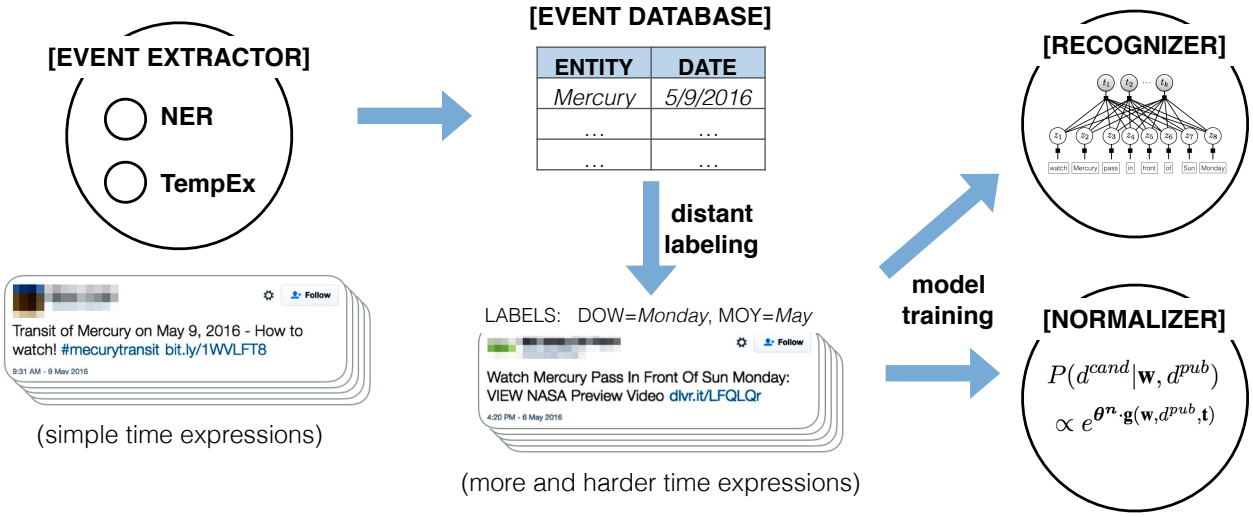

Figure 3: TweeTIME system diagram of model training.

Temporal Types	Possible Values (tags)
Timeline (TL)	$past, present, future$
Day of Week (DOW)	$Mon, Tue, \ldots, Sun$
Day of Month (DOM)	$1, 2, 3, \ldots, 31$
Month of Year (MOY)	$Jan, Feb, \ldots, Dec$
None (NA)	NA

Table 1: Our Temporal Recognizer can extract five different temporal types and assign one of their values to each word of a tweet.

proposed by Ritter et al. (2012). Each event consists of one or more named entities, in addition to the date on which the event takes place, for example [*Mercury*, *5/9/2016*]. Tweets are first processed by a Twitter named entity recognizer (Ritter et al., 2011), and a generic date resolver (Mani and Wilson, 2000). Events are then extracted based on the strength of association between each named entity and calendar date, as measured by a G^2 test on their co-occurrence counts. More details of the **Event Extractor** can be found in Section 5.1.

The following two sections describe the details of our **Temporal Recognizer** and **Temporal Normalizer** separately.

3 Distant Supervision for Recognizing Time Expressions

The goal of the recognizer is to predict the temporal tag of each word, given a sentence (or a tweet) $\mathbf{w} = w_1, \ldots, w_n$. We propose a multiple-instance learning model and a missing data model that are capable of learning word-level taggers given only sentence-level labels.

Our recognizer module in is built using a database of known events as *distant supervision*. We assume tweets published around the time of a known event that mention a central entity are also likely to contain time expressions referring to the event's date. For each event, such as [*Mercury*, *5/9/2016*], we gather all tweets that contain the central entity *Mercury* and are posted within 7 days of *5/9/2016*. We then label each tweet based on the event date in addition to the tweet's creation date. The sentence-level temporal tags for the tweet in Figure 1 are: TL=$future$, DOW=Mon, DOM=9, MOY=May.

3.1 Multiple-Instance Learning Temporal Tagging Model (MultiT)

Unlike supervised learning, where labeled instances are provided to the learner, in multiple instance learning scenarios (Dietterich et al., 1997), the learner is only provided with bags of instances labeled as either positive (where at least one instance is positive) or all negative. This is a close match to our problem setting, in which sentences are labeled with tags that should be assigned to one or more words.

We represent sentences and their labels using a graphical model that is divided into word-level and sentence-level variables (as shown in Figure 4). Unlike the standard supervised tagging prob-

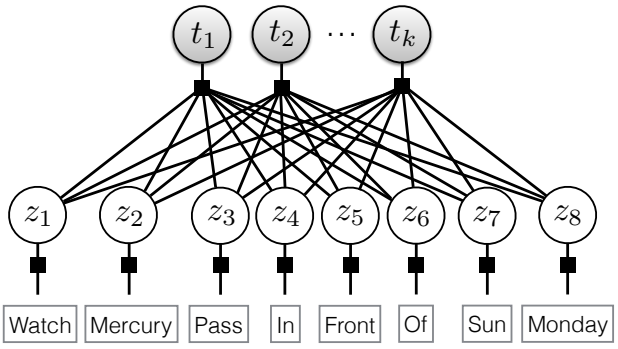

Figure 4: Multiple-Instance Learning Temporal Tagging Model – our approach to learn a word-level tagging model given only sentence-level labels. In this example a sentence-level variable $t_a = 1$ indicates the temporal tag DOW=Mon must be present and $t_b = 1$ indicates that the target date is in the future (TL=$future$). The multiple instance learning assumption implies that at least one word must be tagged with each of these present temporal tags. For example, ideally after training, the model will learn to assign z_8 to tag a and z_1 to tag b.

lem, we never directly observe the words' tags ($\mathbf{z} = z_1, \ldots, z_n$) during learning. Instead, they are latent and we only observe the date of an event mentioned in the text, from which we derive sentence-level binary variables $\mathbf{t} = t_1, \ldots, t_k$ corresponding to temporal tags for the sentence. Following previous work on multiple-instance learning (Hoffmann et al., 2011a; Xu et al., 2014), we model the connection between sentence-level labels and word-level tags using a set of deterministic-OR factors ϕ^{sent}.

The overall conditional probability of our model is defined as:

$$\begin{aligned} & P(\mathbf{t}, \mathbf{z}|\mathbf{w}; \boldsymbol{\theta^r}) \\ &= \frac{1}{Z} \prod_{i=1}^{k} \phi^{sent}(t_i, \mathbf{z}) \times \prod_{j=1}^{n} \phi^{word}(z_j, w_j) \\ &= \frac{1}{Z} \prod_{i=1}^{k} \phi^{sent}(t_i, \mathbf{z}) \times \prod_{j=1}^{n} e^{\boldsymbol{\theta^r} \cdot \mathbf{f}(z_j, w_j)} \end{aligned} \tag{1}$$

where $\mathbf{f}(z_j, w_j)$ is a feature vector and

$$\phi^{sent}(t_i, \mathbf{z}) = \begin{cases} 1 & \text{if } t_i = true \wedge \exists j : z_j = i \\ 1 & \text{if } t_i = false \wedge \forall j : z_j \neq i \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

We include a standard set of tagging features that includes word shape and identity in addition to prefixes and suffixes. To learn parameters $\boldsymbol{\theta^r}$ of the Temporal Tagger, we maximize the likelihood of the sentence-level heuristic labels conditioned on observed words over all tweets in the training corpus. Given a training instance **w** with label **t**, the gradient of the conditional log-likelihood with respect to the parameters is:

$$\begin{aligned} \nabla P(\mathbf{t}|\mathbf{w}) = & \sum_{\mathbf{z}} P(\mathbf{z}|\mathbf{w}, \mathbf{t}; \boldsymbol{\theta^r}) \cdot \mathbf{f}(\mathbf{z}, \mathbf{w}) \\ & - \sum_{\mathbf{t},\mathbf{z}} P(\mathbf{t}, \mathbf{z}|\mathbf{w}; \boldsymbol{\theta^r}) \cdot \mathbf{f}(\mathbf{z}, \mathbf{w}) \end{aligned} \tag{3}$$

This gradient is the difference of two conditional expectations over the feature vector **f**: a "clamped" expectation that is conditioned on the observed words and tags (**w**, **t**) and a "free" expectation that is only conditioned on the words in the text, **w**, and ignores the sentence-level labels. To make the inference tractable, we use a Viterbi approximation that replaces the expectations with maximization. Because each sentence corresponds to more than one temporal tag, the maximization of the "clamped" maximization is somewhat challenging to compute. We use the approximate inference algorithm of Hoffmann et al. (2011a), that views inference as a weighted set cover problem, with worst case running time ($|T| \cdot |W|$), where $|T|$ is the number of all possible temporal tag values and $|W|$ is the number of words in a sentence.

3.2 Missing Data Temporal Tagging Model (MiDaT)

While the multiple-instance learning assumption works well much of the time, it can easily be violated – there are many tweets that mention entities involved in an event but that never explicitly mention its date.

The missing data modeling approach to weakly supervised learning proposed by Ritter et. al. (2013) addresses this problem by relaxing the hard constraints of deterministic-OR factors, such as those described above, as soft constraints. Our missing-data model for weakly supervised tagging splits the sentence-level variables, t into two parts : m which represents whether a temporal tag is mentioned by at least one word of the tweet, and t' which represents

whether a temporal tag can be derived from the event date. A set of pairwise potentials $\psi(m_j, t'_j)$ are introduced that encourage (but don't strictly require) agreement between m_j and t'_j, that is:

$$\psi(m_j, t'_j) = \begin{cases} \alpha_p, \text{ if } t'_j \neq m_j \\ \alpha_r, \text{ if } t'_j = m_j \end{cases} \quad (4)$$

Here, α_p (Penalty), and α_r (Reward) are parameters for the MiDaT model. α_p is the penalty for extracting a temporal tag that is not related to the event-date and α_r is the reward for extracting a tag that matches the date.

During learning, if the local classifier is very confident, it is possible for a word to be labeled with a tag that is not derived from the event-date, and also for a sentence-level tag to be ignored, although either case will be penalized by the agreement potentials, $\psi(m_j, t'_j)$, in the global objective. We use a local-search approach to inference that was empirically demonstrated to nearly always yield exact solutions by Ritter et. al. (2013).

4 A Log-Linear Model for Normalizing Time Expressions

The Temporal Normalizer is built using a log-linear model which takes the tags **t** produced by the Temporal Recognizer as input and outputs one or more dates mentioned in a tweet. We formulate date normalization as a binary classification problem: given a tweet **w** published on date d^{pub}, we consider 22 candidate target dates (**w**, d_l^{cand}) such that $d_l^{cand} = d^{pub} + l$, where $l = -10, \ldots, -1, 0, +1, \ldots, +10$, limiting the possible date references that are considered within 10 days before or after the tweet creation date, in addition to $d_l^{cand} = null$ (the tweet does not mention a date). [4] While our basic approach has the limitation, that it is only able to predict dates within ± 10 days of the target date, we found that in practice the majority of date references on social media fall within this window. Our approach is also able to score dates outside this range that are generated by traditional approaches to resolving time expressions, as described in Section 5.3.3.

[4] Although the temporal recognizer is trained with tweets from ± 7 days around the event date, we found that extending the candidate date range to ± 10 days for the temporal normalizer increased the performance of TweeTIME in the dev set.

The normalizer is similarly trained using the event database as distant supervision. The probability that a tweet mentions a candidate date is estimated using a log-linear model:

$$P(d^{cand}|\mathbf{w}, d^{pub}) \propto e^{\boldsymbol{\theta^n} \cdot \mathbf{g}(\mathbf{w}, d^{pub}, \mathbf{t})} \quad (5)$$

where $\boldsymbol{\theta^n}$ and **g** are the parameter and feature vector respectively in the Temporal Normalizer. For every tweet and candidate date pair (**w**, d_l^{cand}), we extract the following set of features:

Temporal Tag Features that indicate whether the candidate date agrees with the temporal tags extracted by the Temporal Recognizer. Three cases can happen here: The recognizer can extract a tag that can not be derived from the candidate date; The recognizer can miss a tag derived from the candidate date; The recognizer can extract a tag that is derived from the candidate date.

Lexical Features that include two types of binary features from the tweet: 1) **Word Tag** features consist of conjunctions of words in the tweet and tags associated with the candidate date. We remove URLs, stop words and punctuation; 2) **Word POS** features that are the same as above, but include conjunctions of POS tags, words and temporal tags derived from the candidate date.

Time Difference Features are numerical features that indicate the distance between the creation date and the candidate date. They include difference of day ranges form -10 to 10 and the difference of week ranges from -2 to 2.

5 Experiments

In the following sub-sections we present experimental results on learning to resolve time expressions in Twitter using minimal supervision. We start by describing our dataset, and proceed to present our results, including a large-scale evaluation on heuristically-labeled data and an evaluation comparing against human judgements.

5.1 Data Collection

We collected around 120 million tweets posted in a one year window starting from April 2011 to May 2012. These tweets were automatically annotated with named entities, POS tags and TempEx dates (Ritter et al., 2011).

From this automatically-annotated corpus we extract the top $10,000$ events and their corresponding dates using the G^2 test, which measures the strength of association between an entity and date using the log-likelihood ratio between a model in which the entity is conditioned on the date and a model of independence (Ritter et al., 2012). Events extracted using this approach then simply consist of the highest-scoring entity-date pairs, for example [*Mercury, 5/9/2016*].

After automatically extracting the database of events, we next gather all tweets that mention an entity from the list that are also written within ± 7 days of the event. These tweets and the dates of the known events serve as labeled examples that are likely to mention a known date.

We also include a set of pseudo-negative examples, that are unlikely to refer to any event, by gathering a random sample of tweets that do not mention any of the top $10,000$ events and where TempEx does not extract any date.

5.2 Large-Scale Heuristic Evaluation

We first evaluate our tagging model, by testing how well it can predict the heuristically generated labels. As noted in previous work on distant supervision (Mintz et al., 2009a), this type of evaluation usually under-estimates precision, however it provides us with a useful intrinsic measure of performance.

In order to provide even coverage of months in the training and test set, we divide the twitter corpus into 3 subsets based on the mod-5 week of each tweet's creation date. To train system we use tweets that are created in $1st$, $2nd$ or $3rd$ weeks. To tune parameters of the MiDaT model we used tweets from $5th$ weeks, and to evaluate the performance of the trained model we used tweets from $4th$ weeks.

	Precision	Recall	F-value
MultiT	0.61	0.21	0.32
MiDaT	0.67	0.31	0.42

Table 2: Performance comparison of MultiT and MiDaT at predicting heuristically generated tags on the dev set.

The performance of the MiDaT model varies with the penalty and reward parameters. To find a (near) optimal setting of the values we performed a grid search on the dev set and found that a penalty of -25 and reward of 500 works best. A comparison of MultiT and MiDaT's performance at predicting heuristically generated labels is shown in Table 2.

The word level tags predicted by the temporal recognizer are used as the input to the temporal normalizer, which predicts the referenced date from each tweet. The overall system's performance at predicting event dates on the automatically generated test set, compared against SUTime, is shown in Table 3.

	System	Prec.	Recall	F-value
dev set	TweeTIME	0.93	0.69	0.79
	SUTime	0.89	0.64	0.75
test set	TweeTIME	0.97	0.94	0.96
	SUTime	0.85	0.75	0.80

Table 3: Performance comparison of TweeTIME and SUTime at predicting heuristically labeled normalized dates.

5.3 Evaluation Against Human Judgements

In addition to automatically evaluating our tagger on a large corpus of heuristically-labeled tweets, we also evaluate the performance of our tagging and date-resolution models on a random sample of tweets taken from a much later time period, that were manually annotated by the authors.

5.3.1 Word-Level Tags

To evaluate the performance of the MiDaT-tagger we randomly selected 50 tweets and labeled each word with its corresponding tag. Against this hand annotated test set, MiDaT achieves Precision=0.54, Recall=0.45 and F-value=0.49. A few examples of word-level tags predicted by MiDaT are shown in Table 4. We found that because the tags are learned as latent variables inferred by our model, they sometimes don't line up exactly with our intuitions but still provide useful predictions, for example in Table 4, *Christmas* is labeled with the tag MOY=dec.

5.3.2 End-to-end Date Resolution

To evaluate the final performance of our system and compare against existing state-of-the art time resolvers, we randomly sampled 250 tweets from 2014-2016 and manually annotated them with normalized dates; note that this is a separate date range from our weakly-labeled training data which is taken from 2011-2012. We use 50 tweets as a development set and the remaining 200 as a final test set.

test set	TweeTIME	**0.58**	**0.70**	**0.63**
	TweeTIME+SU	**0.62**	**0.76**	**0.68**
	SUTime	0.54	0.64	0.58
	TempEx	0.56	0.58	0.57
	HeidelTime	0.43	0.52	0.47
	UWTime	0.39	0.50	0.44

Table 6: Performance comparison of TweeTIME against state-of-the-art temporal taggers. TweeTIME+SU uses our proposed approach to system combination, re-scoring output from SUTime using extracted features and learned parameters from TweeTIME.

We experimented with different feature sets on the development data. Feature ablation experiments are presented in Table 5.

The final performance of our system, compared against a range of state-of-the-art time resolvers is presented in Table 6. We see that TweeTIME outperforms SUTime, Tempex, HeidelTime (using its COLLOQUIAL mode, which is designed for SMS text) and UWTime. Brief descriptions of each system can be found in Section 6.

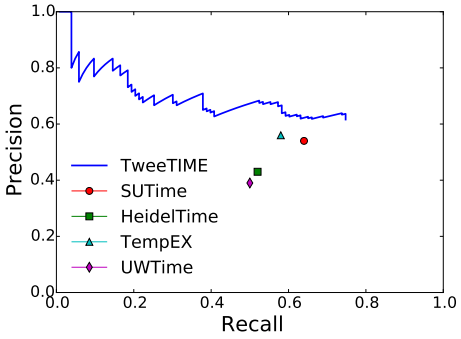

Figure 5: Precision and recall at resolving time expressions compared against human judgements. TweeTIME achieves higher precision at comparable recall than other state-of-the-art systems.

5.3.3 System Combination with SUTime

As our basic TweeTIME system is designed to predict dates within ± 10 days of the creation date, it fails when a tweet refers to a date outside this range. To overcome this limitation we append the date predicted by SUTime in the list of candidate days. We then re-rank SUTime's predictions using our log-linear model, and include its output as a predicted date if the confidence of our normalizer is sufficiently high.

5.3.4 Error Analysis

We manually examined the system outputs and found 7 typical categories of errors (see examples in Table 7):

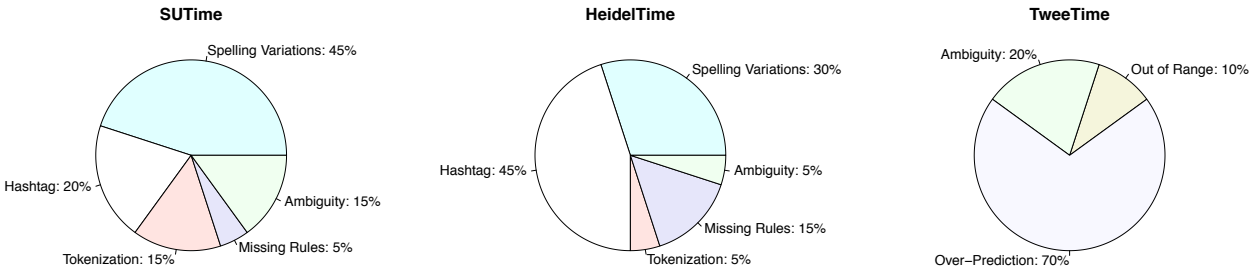

Figure 6: Error analyses for different temporal resolvers

Spelling Variation: Twitter users are very creative in their use of spelling and abbreviations. For example, a large number of variations of the word *tomorrow* can be found in tweets, including *2morrow*, *2mrw*, *tmrw*, *2mrow* and so on. Previous temporal resolvers often fail in these cases, while TweeTIME significantly reduces such errors.

Ambiguity: In many cases, temporal words like *Friday* in the tweet *Is it Friday yet?* may not refer to any specific event or date, but are often predicted incorrectly. Also included in this category are cases where the future and past are confused. For example, predicting the past Friday, when it is actually the coming Friday.

Missing Rule: Cases where specific temporal keywords, such as *April Fools*, are not covered by the rule-based systems.

Tokenization: Traditional systems tend to be very sensitive to incorrect tokenization and have trouble to handle expressions such as *9th-december*, *May 9,2015* or *Jan1*. For the following Tweet:

> JUST IN Delhi high court asks state government to submit data on changes in pollution level since #OddEven rule came into effect on *Jan1*

TweeTIME is able to correctly extract *01/01/2016*, whereas HeidelTime, SUTime, TempEX and UWTime all failed to extract any dates.

Hashtag: Hashtags can carry temporal information, for example, #September11. Only our system that is adapted to social media can resolve these cases.

Out of Range: TweeTIME only predicts dates within 10 days before or after the tweet. Time expressions referring to dates outside this range will not be predicted correctly. System combination with SUTime (Section 5.3.3) only partially addressed this problem.

Over-Prediction: Unlike rule-based systems, TweeTIME has a tendency to over-predict when there is no explicit time expression in the tweets, possibly because of the presence of present tense verbs. Such mistakes could also happen in some past tense verbs.

Because TweeTIME resolves time expressions using a very different approach compared to traditional methods, its distribution of errors is quite distinct, as illustrated in Figure 6.

6 Related Work

Temporal Resolvers primarily utilize either rule-based or probabilistic approaches. Notable rule-based systems such as TempEx (Mani and Wilson, 2000), SUTime (Chang and Manning, 2012) and HeidelTime (Strötgen and Gertz, 2013) provide particularly competitive performance compared to the state-of-the-art machine learning methods. Probabilistic approaches use supervised classifiers trained on in-domain annotated data (Kolomiyets and Moens, 2010; Bethard, 2013a; Filannino et al., 2013) or hybrid with hand-engineered rules (UzZaman and Allen, 2010; Lee et al., 2014). UWTime (Lee et al., 2014) is one of the most recent and competitive systems and uses Combinatory Categorial Grammar (CCG).

Although the recent research challenge TempEval (UzZaman et al., 2013; Bethard and Savova, 2016) offers an evaluation in the clinical domain besides newswire, most participants used the provided annotated corpus to train supervised models in addition to employing hand-coded rules. Previous work on adapting temporal taggers primarily focus on scaling up to more languages. HeidelTime was extended to multilingual (Strötgen and Gertz, 2015), colloquial (SMS) and scientific texts (Strötgen and Gertz, 2012) using dictionaries and additional in-domain

annotated data. One existing work used distant supervision (Angeli et al., 2012; Angeli and Uszkoreit, 2013), but for normalization only, assuming gold time mentions as input. They used an EM-style bootstrapping approach and a CKY parser.

Distant Supervision has recently become popular in natural language processing. Much of the work has focused on the task of relation extraction (Craven and Kumlien, 1999; Bunescu and Mooney, 2007; Mintz et al., 2009b; Riedel et al., 2010; Hoffmann et al., 2011b; Nguyen and Moschitti, 2011; Surdeanu et al., 2012; Xu et al., 2013; Ritter et al., 2013; Angeli et al., 2014). Recent work also shows exciting results on extracting named entities (Ritter et al., 2011; Plank et al., 2014), emotions (Purver and Battersby, 2012), sentiment (Marchetti-Bowick and Chambers, 2012), as well as finding evidence in medical publications (Wallace et al., 2016). Our work is closely related to the joint word-sentence model that exploits multiple-instance learning for paraphrase identification (Xu et al., 2014) in Twitter.

7 Conclusions

In this paper, we showed how to learn time resolvers from large amounts of unlabeled text, using a database of known events as distant supervision. We presented a method for learning a word-level temporal tagging models from tweets that are heuristically labeled with only sentence-level labels. This approach was further extended to account for the case of missing tags, or temporal properties that are not explicitly mentioned in the text of a tweet. These temporal tags were then combined with a variety of other features in a novel date-resolver that predicts normalized dates referenced in a Tweet. By learning from large quantities of in-domain data, we were able to achieve 0.68 F1 score on the end-to-end time normalization task for social media data, significantly outperforming SUTime, TempEx, HeidelTime and UWTime on this challenging dataset for time normalization.

Language as a Latent Variable: Discrete Generative Models for Sentence Compression

Yishu Miao[1], **Phil Blunsom**[1,2]

{yishu.miao, phil.blunsom}@cs.ox.ac.uk

Abstract

In this work we explore deep generative models of text in which the latent representation of a document is itself drawn from a discrete language model distribution. We formulate a variational auto-encoder for inference in this model and apply it to the task of compressing sentences. In this application the generative model first draws a latent summary sentence from a background language model, and then subsequently draws the observed sentence conditioned on this latent summary. In our empirical evaluation we show that generative formulations of both abstractive and extractive compression yield state-of-the-art results when trained on a large amount of supervised data. Further, we explore semi-supervised compression scenarios where we show that it is possible to achieve performance competitive with previously proposed supervised models while training on a fraction of the supervised data.

1 Introduction

The recurrent sequence-to-sequence paradigm for natural language generation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014) has achieved remarkable recent success and is now the approach of choice for applications such as machine translation (Bahdanau et al., 2015), caption generation (Xu et al., 2015) and speech recognition (Chorowski et al., 2015). While these models have developed sophisticated conditioning mechanisms, e.g. attention, fundamentally they are discriminative models trained only to approximate the conditional output distribution of strings. In this paper we explore modelling the joint distribution of string pairs using a deep generative model and employing a discrete variational auto-encoder (VAE) for inference (Kingma and Welling, 2014; Rezende et al., 2014; Mnih and Gregor, 2014). We evaluate our generative approach on the task of sentence compression. This approach provides both alternative supervised objective functions and the opportunity to perform semi-supervised learning by exploiting the VAEs ability to marginalise the latent compressed text for unlabelled data.

Auto-encoders (Rumelhart et al., 1985) are a typical neural network architecture for learning compact data representations, with the general aim of performing dimensionality reduction on embeddings (Hinton and Salakhutdinov, 2006). In this paper, rather than seeking to embed inputs as points in a vector space, we describe them with explicit natural language sentences. This approach is a natural fit for summarisation tasks such as sentence compression. According to this, we propose a generative **auto-encoding sentence compression** (ASC) model, where we introduce a latent language model to provide the variable-length compact summary. The objective is to perform Bayesian inference for the posterior distribution of summaries conditioned on the observed utterances. Hence, in the framework of VAE, we construct an inference network as the variational approximation of the posterior, which generates compression samples to optimise the variational lower bound.

The most common family of variational auto-encoders relies on the reparameterisation trick, which is not applicable for our discrete latent language model. Instead, we employ the REINFORCE algorithm (Mnih et al., 2014; Mnih and Gregor, 2014)

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 319–328,
Austin, Texas, November 1-5, 2016.

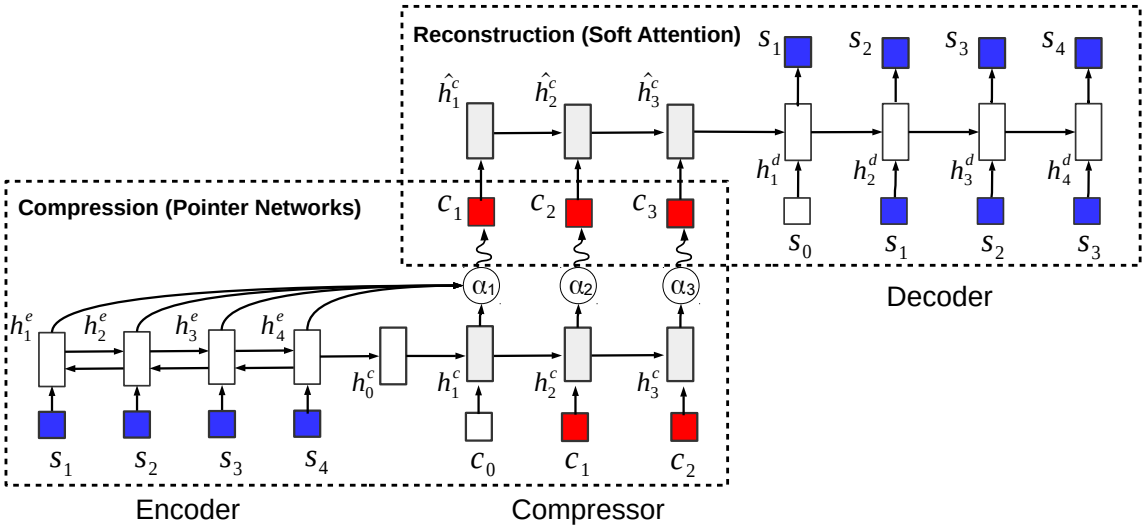

Figure 1: Auto-encoding Sentence Compression Model

to mitigate the problem of high variance during sampling-based variational inference. Nevertheless, when directly applying the RNN encoder-decoder to model the variational distribution it is very difficult to generate reasonable compression samples in the early stages of training, since each hidden state of the sequence would have $|V|$ possible words to be sampled from. To combat this we employ pointer networks (Vinyals et al., 2015) to construct the variational distribution. This biases the latent space to sequences composed of words only appearing in the source sentence (i.e. the size of softmax output for each state becomes the length of current source sentence), which amounts to applying an extractive compression model for the variational approximation.

In order to further boost the performance on sentence compression, we employ a supervised **forced-attention sentence compression** model (FSC) trained on labelled data to teach the ASC model to generate compression sentences. The FSC model shares the pointer network of the ASC model and combines a softmax output layer over the whole vocabulary. Therefore, while training on the sentence-compression pairs, it is able to balance copying a word from the source sentence with generating it from the background distribution. More importantly, by jointly training on the labelled and unlabelled datasets, this shared pointer network enables the model to work in a semi-supervised scenario. In this case, the FSC teaches the ASC to generate reasonable samples, while the pointer network trained on a large unlabelled data set helps the FSC model to perform better abstractive summarisation.

In Section 6, we evaluate the proposed model by jointly training the generative (ASC) and discriminative (FSC) models on the standard Gigaword sentence compression task with varying amounts of labelled and unlabelled data. The results demonstrate that by introducing a latent language variable we are able to match the previous benchmakers with small amount of the supervised data. When we employ our mixed discriminative and generative objective with all of the supervised data the model significantly outperforms all previously published results.

2 Auto-Encoding Sentence Compression

In this section, we introduce the auto-encoding sentence compression model (Figure 1)[1] in the framework of variational auto-encoders. The ASC model consists of four recurrent neural networks – an encoder, a compressor, a decoder and a language model.

Let $\boldsymbol{s}$ be the source sentence, and $\boldsymbol{c}$ be the compression sentence. The **compression** model (encoder-compressor) is the inference network $q_\phi(\boldsymbol{c}|\boldsymbol{s})$ that takes source sentences $\boldsymbol{s}$ as inputs and generates extractive compressions $\boldsymbol{c}$. The **reconstruction**

[1]The language model, layer connections and decoder soft attentions are omitted in Figure 1 for clarity.

model (compressor-decoder) is the generative network $p_\theta(\boldsymbol{s}|\boldsymbol{c})$ that reconstructs source sentences $\boldsymbol{s}$ based on the latent compressions $\boldsymbol{c}$. Hence, the forward pass starts from the encoder to the compressor and ends at the decoder. As the prior distribution, a language model $p(\boldsymbol{c})$ is pre-trained to regularise the latent compressions so that the samples drawn from the compression model are likely to be reasonable natural language sentences.

2.1 Compression

For the compression model (encoder-compressor), $q_\phi(\boldsymbol{c}|\boldsymbol{s})$, we employ a pointer network consisting of a bidirectional LSTM encoder that processes the source sentences, and an LSTM compressor that generates compressed sentences by attending to the encoded source words.

Let $\boldsymbol{s}_i$ be the words in the source sentences, $\boldsymbol{h}_i^e$ be the corresponding state outputs of the encoder. $\boldsymbol{h}_i^e$ are the concatenated hidden states from each direction:

$$\boldsymbol{h}_i^e = f_{\overrightarrow{\text{enc}}}(\vec{\boldsymbol{h}}_{i-1}^e, \boldsymbol{s}_i)||f_{\overleftarrow{\text{enc}}}(\overleftarrow{\boldsymbol{h}}_{i+1}^e, \boldsymbol{s}_i) \quad (1)$$

Further, let $\boldsymbol{c}_j$ be the words in the compressed sentences, $\boldsymbol{h}_j^c$ be the state outputs of the compressor. We construct the predictive distribution by attending to the words in the source sentences:

$$\boldsymbol{h}_j^c = f_{\text{com}}(\boldsymbol{h}_{j-1}^c, \boldsymbol{c}_{j-1}) \quad (2)$$

$$\boldsymbol{u}_j(i) = \boldsymbol{w}_3^T \tanh(\boldsymbol{W}_1\boldsymbol{h}_j^c + \boldsymbol{W}_2\boldsymbol{h}_i^e) \quad (3)$$

$$q_\phi(\boldsymbol{c}_j|\boldsymbol{c}_{1:j-1}, \boldsymbol{s}) = \text{softmax}(\boldsymbol{u}_j) \quad (4)$$

where $\boldsymbol{c}_0$ is the start symbol for each compressed sentence and $\boldsymbol{h}_0^c$ is initialised by the source sentence vector of $\boldsymbol{h}_{|\boldsymbol{s}|}^e$. In this case, all the words $\boldsymbol{c}_j$ sampled from $q_\phi(\boldsymbol{c}_j|\boldsymbol{c}_{1:j-1}, \boldsymbol{s})$ are the subset of the words appeared in the source sentence (i.e. $\boldsymbol{c}_j \in \boldsymbol{s}$).

2.2 Reconstruction

For the reconstruction model (compressor-decoder) $p_\theta(\boldsymbol{s}|\boldsymbol{c})$, we apply a soft attention sequence-to-sequence model to generate the source sentence $\boldsymbol{s}$ based on the compression samples $\boldsymbol{c} \sim q_\phi(\boldsymbol{c}|\boldsymbol{s})$.

Let $\boldsymbol{s}_k$ be the words in the reconstructed sentences and $\boldsymbol{h}_k^d$ be the corresponding state outputs of the decoder:

$$\boldsymbol{h}_k^d = f_{\text{dec}}(\boldsymbol{h}_{k-1}^d, \boldsymbol{s}_{k-1}) \quad (5)$$

In this model, we directly use the recurrent cell of the compressor to encode the compression samples[2]:

$$\hat{\boldsymbol{h}}_j^c = f_{\text{com}}(\hat{\boldsymbol{h}}_{j-1}^c, \boldsymbol{c}_j) \quad (6)$$

where the state outputs $\hat{\boldsymbol{h}}_j^c$ corresponding to the word inputs $\boldsymbol{c}_j$ are different from the outputs $\boldsymbol{h}_j^c$ in the compression model, since we block the information from the source sentences. We also introduce a start symbol $\boldsymbol{s}_0$ for the reconstructed sentence and $\boldsymbol{h}_0^d$ is initialised by the last state output $\hat{\boldsymbol{h}}_{|\boldsymbol{c}|}^c$. The soft attention model is defined as:

$$v_k(j) = \boldsymbol{w}_6^T \tanh(\boldsymbol{W}_4\boldsymbol{h}_k^d + \boldsymbol{W}_5\hat{\boldsymbol{h}}_j^c) \quad (7)$$

$$\gamma_k(j) = \text{softmax}(v_k(j)) \quad (8)$$

$$\boldsymbol{d}_k = \sum\nolimits_j^{|\boldsymbol{c}|} \gamma_k(j)\hat{\boldsymbol{h}}_j^c(v_k(j)) \quad (9)$$

We then construct the predictive probability distribution over reconstructed words using a softmax:

$$p_\theta(\boldsymbol{s}_k|\boldsymbol{s}_{1:k-1}, \boldsymbol{c}) = \text{softmax}(\boldsymbol{W}_7\boldsymbol{d}_k) \quad (10)$$

2.3 Inference

In the ASC model there are two sets of parameters, ϕ and θ, that need to be updated during inference. Due to the non-differentiability of the model, the reparameterisation trick of the VAE is not applicable in this case. Thus, we use the REINFORCE algorithm (Mnih et al., 2014; Mnih and Gregor, 2014) to reduce the variance of the gradient estimator.

The variational lower bound of the ASC model is:

$$\begin{aligned} L &= \mathbb{E}_{q_\phi(\boldsymbol{c}|\boldsymbol{s})}[\log p_\theta(\boldsymbol{s}|\boldsymbol{c})] - D_{KL}[q_\phi(\boldsymbol{c}|\boldsymbol{s})||p(\boldsymbol{c})] \\ &\leqslant \log \int \frac{q_\phi(\boldsymbol{c}|\boldsymbol{s})}{q_\phi(\boldsymbol{c}|\boldsymbol{s})} p_\theta(\boldsymbol{s}|\boldsymbol{c})p(\boldsymbol{c})d\boldsymbol{c} = \log p(\boldsymbol{s}) \end{aligned} \quad (11)$$

Therefore, by optimising the lower bound (Eq. 11), the model balances the selection of keywords for the summaries and the efficacy of the composed compressions, corresponding to the reconstruction error and KL divergence respectively.

In practise, the pre-trained language model prior $p(\boldsymbol{c})$ prefers short sentences for compressions. As one of the drawbacks of VAEs, the KL divergence term in the lower bound pushes every sample drawn

[2]The recurrent parameters of the compressor are not updated by the gradients from the reconstruction model.

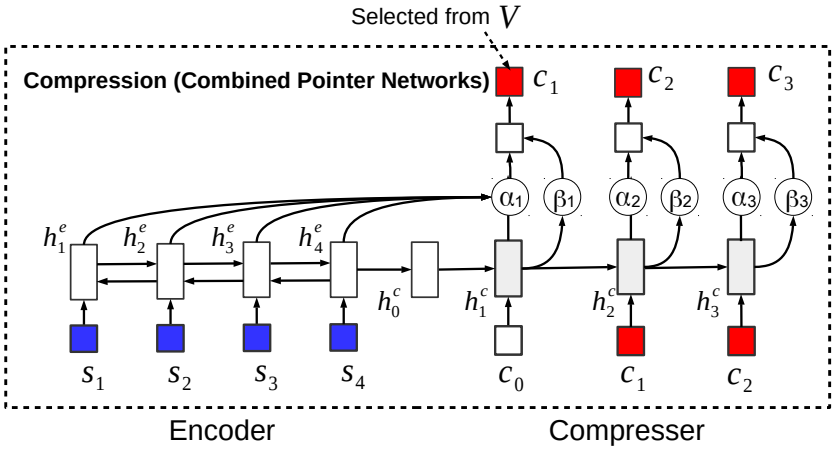

Figure 2: Forced Attention Sentence Compression Model

from the variational distribution towards the prior. Thus acting to regularise the posterior, but also to restrict the learning of the encoder. If the estimator keeps sampling short compressions during inference, the LSTM decoder would gradually rely on the contexts from the decoded words instead of the information provided by the compressions, which does not yield the best performance on sentence compression.

Here, we introduce a co-efficient λ to scale the learning signal of the KL divergence:

$$L=\mathbb{E}_{q_\phi(\boldsymbol{c}|\boldsymbol{s})}[\log p_\theta(\boldsymbol{s}|\boldsymbol{c})]-\lambda D_{KL}[q_\phi(\boldsymbol{c}|\boldsymbol{s})||p(\boldsymbol{c})] \quad (12)$$

Although we are not optimising the exact variational lower bound, the ultimate goal of learning an effective compression model is mostly up to the reconstruction error. In Section 6, we empirically apply $\lambda = 0.1$ for all the experiments on ASC model. Interestingly, λ controls the compression rate of the sentences which can be a good point to be explored in future work.

During the inference, we have different strategies for updating the parameters of ϕ and θ. For the parameters θ in the reconstruction model, we directly update them by the gradients:

$$\frac{\partial L}{\partial \theta} = \mathbb{E}_{q_\phi(\boldsymbol{c}|\boldsymbol{s})}[\frac{\partial \log p_\theta(\boldsymbol{s}|\boldsymbol{c})}{\partial \theta}] \approx \frac{1}{M}\sum_m \frac{\partial \log p_\theta(\boldsymbol{s}|\boldsymbol{c}^{(m)})}{\partial \theta} \quad (13)$$

where we draw M samples $\boldsymbol{c}^{(m)} \sim q_\phi(\boldsymbol{c}|\boldsymbol{s})$ independently for computing the stochastic gradients.

For the parameters ϕ in the compression model, we firstly define the learning signal,

$$l(\boldsymbol{s},\boldsymbol{c}) = \log p_\theta(\boldsymbol{s}|\boldsymbol{c}) - \lambda(\log q_\phi(\boldsymbol{c}|\boldsymbol{s}) - \log p(\boldsymbol{c})).$$

Then, we update the parameters ϕ by:

$$\frac{\partial L}{\partial \phi} = \mathbb{E}_{q_\phi(\boldsymbol{c}|\boldsymbol{s})}[l(\boldsymbol{s},\boldsymbol{c})\frac{\partial \log q_\phi(\boldsymbol{c}|\boldsymbol{s})}{\partial \phi}] \approx \frac{1}{M}\sum_m [l(\boldsymbol{s},\boldsymbol{c}^{(m)})\frac{\partial \log q_\phi(\boldsymbol{c}^{(m)}|\boldsymbol{s})}{\partial \phi}] \quad (14)$$

However, this gradient estimator has a big variance because the learning signal $l(\boldsymbol{s},\boldsymbol{c}^{(m)})$ relies on the samples from $q_\phi(\boldsymbol{c}|\boldsymbol{s})$. Therefore, following the REINFORCE algorithm, we introduce two baselines b and $b(\boldsymbol{s})$, the centred learning signal and input-dependent baseline respectively, to help reduce the variance.

Here, we build an MLP to implement the input-dependent baseline $b(\boldsymbol{s})$. During training, we learn the two baselines by minimising the expectation:

$$\mathbb{E}_{q_\phi(\boldsymbol{c}|\boldsymbol{s})}[(l(\boldsymbol{s},\boldsymbol{c}) - b - b(\boldsymbol{s}))^2]. \quad (15)$$

Hence, the gradients w.r.t. ϕ are derived as,

$$\frac{\partial L}{\partial \phi} \approx \frac{1}{M}\sum_m (l(\boldsymbol{s},\boldsymbol{c}^{(m)}) - b - b(\boldsymbol{s}))\frac{\partial \log q_\phi(\boldsymbol{c}^{(m)}|\boldsymbol{s})}{\partial \phi} \quad (16)$$

which is basically a likelihood-ratio estimator.

3 Forced-attention Sentence Compression

In neural variational inference, the effectiveness of training largely depends on the quality of the inference network gradient estimator. Although we introduce a biased estimator by using pointer networks, it is still very difficult for the compression model to generate reasonable natural language sentences at the early stage of learning, which results in

high-variance for the gradient estimator. Here, we introduce our supervised forced-attention sentence compression (FSC) model to teach the compression model to generate coherent compressed sentences.

Neither directly replicating the pointer network of ASC model, nor using a typical sequence-to-sequence model, the FSC model employs a force-attention strategy (Figure 2) that encourages the compressor to select words appearing in the source sentence but keeps the original full output vocabulary V. The force-attention strategy is basically a combined pointer network that chooses whether to select a word from the source sentence $\boldsymbol{s}$ or to predict a word from V at each recurrent state. Hence, the combined pointer network learns to copy the source words while predicting the word sequences of compressions. By sharing the pointer networks between the ASC and FSC model, the biased estimator obtains further positive biases by training on a small set of labelled source-compression pairs.

Here, the FSC model makes use of the compression model (Eq. 1 to 4) in the ASC model,

$$\alpha_j = \text{softmax}(\boldsymbol{u}_j), \tag{17}$$

where $\alpha_j(i), i \in (1, \ldots, |\boldsymbol{s}|)$ denotes the probability of selecting $\boldsymbol{s}_i$ as the prediction for $\boldsymbol{c}_j$.

On the basis of the pointer network, we further introduce the probability of predicting $\boldsymbol{c}_j$ that is selected from the full vocabulary,

$$\beta_j = \text{softmax}(\boldsymbol{W}\boldsymbol{h}_j^c), \tag{18}$$

where $\beta_j(w), w \in (1, \ldots, |V|)$ denotes the probability of selecting the wth from V as the prediction for $\boldsymbol{c}_j$. To combine these two probabilities in the RNN, we define a selection factor $\boldsymbol{t}$ for each state output, which computes the semantic similarities between the current state and the attention vector,

$$\boldsymbol{\eta}_j = \sum_i^{|\boldsymbol{s}|} \alpha_j(i)\boldsymbol{h}_i^e \tag{19}$$

$$\boldsymbol{t}_j = \sigma(\boldsymbol{\eta}_j^T \boldsymbol{M}\boldsymbol{h}_j^c). \tag{20}$$

Hence, the probability distribution over compressed words is defined as,

$$p(\boldsymbol{c}_j|\boldsymbol{c}_{1:j-1}, \boldsymbol{s}) = \begin{cases} \boldsymbol{t}_j\alpha_j(i) + (1-\boldsymbol{t}_j)\beta_j(\boldsymbol{c}_j), & \boldsymbol{c}_j = \boldsymbol{s}_i \\ (1-\boldsymbol{t}_j)\beta_j(\boldsymbol{c}_j), & \boldsymbol{c}_j \notin \boldsymbol{s} \end{cases} \tag{21}$$

Essentially, the FSC model is the extended compression model of ASC by incorporating the pointer network with a softmax output layer over the full vocabulary. So we employ ϕ to denote the parameters of the FSC model $p_\phi(\boldsymbol{c}|\boldsymbol{s})$, which covers the parameters of the variational distribution $q_\phi(\boldsymbol{c}|\boldsymbol{s})$.

4 Semi-supervised Training

As the auto-encoding sentence compression (ASC) model grants the ability to make use of an unlabelled dataset, we explore a semi-supervised training framework for the ASC and FSC models. In this scenario we have a labelled dataset that contains source-compression parallel sentences, $(\boldsymbol{s}, \boldsymbol{c}) \in \mathbb{L}$, and an unlabelled dataset that contains only source sentences $\boldsymbol{s} \in \mathbb{U}$. The FSC model is trained on $\mathbb{L}$ so that we are able to learn the compression model by maximising the log-probability,

$$F = \sum_{(\boldsymbol{c},\boldsymbol{s})\in\mathbb{L}} \log p_\phi(\boldsymbol{c}|\boldsymbol{s}). \tag{22}$$

While the ASC model is trained on $\mathbb{U}$, where we maximise the modified variational lower bound,

$$L = \sum_{\boldsymbol{s}\in\mathbb{U}} (\mathbb{E}_{q_\phi(\boldsymbol{c}|\boldsymbol{s})}[\log p_\theta(\boldsymbol{s}|\boldsymbol{c})] - \lambda D_{KL}[q_\phi(\boldsymbol{c}|\boldsymbol{s})||p(\boldsymbol{c})]). \tag{23}$$

The joint objective function of the semi-supervised learning is,

$$J = \sum_{\boldsymbol{s}\in\mathbb{U}} (\mathbb{E}_{q_\phi(\boldsymbol{c}|\boldsymbol{s})}[\log p_\theta(\boldsymbol{s}|\boldsymbol{c})] - \lambda D_{KL}[q_\phi(\boldsymbol{c}|\boldsymbol{s})||p(\boldsymbol{c})]) + \sum_{(\boldsymbol{c},\boldsymbol{s})\in\mathbb{L}} \log p_\phi(\boldsymbol{c}|\boldsymbol{s}). \tag{24}$$

Hence, the pointer network is trained on both unlabelled data, $\mathbb{U}$, and labelled data, $\mathbb{L}$, by a mixed criterion of REINFORCE and cross-entropy.

5 Related Work

As one of the typical sequence-to-sequence tasks, sentence-level summarisation has been explored by a series of discriminative encoder-decoder neural models. Filippova et al. (2015) carries out extractive summarisation via deletion with LSTMs, while Rush et al. (2015) applies a convolutional encoder and an

attentional feed-forward decoder to generate abstractive summarises, which provides the benchmark for the *Gigaword* dataset. Nallapati et al. (2016) further improves the performance by exploring multiple variants of RNN encoder-decoder models. The recent works Gulcehre et al. (2016), Nallapati et al. (2016) and Gu et al. (2016) also apply the similar idea of combining pointer networks and softmax output. However, different from all these discriminative models above, we explore generative models for sentence compression. Instead of training the discriminative model on a big labelled dataset, our original intuition of introducing a combined pointer networks is to bridge the unsupervised generative model (ASC) and supervised model (FSC) so that we could utilise a large additional dataset, either labelled or unlabelled, to boost the compression performance. Dai and Le (2015) also explored semi-supervised sequence learning, but in a pure deterministic model focused on learning better vector representations.

Recently variational auto-encoders have been applied in a variety of fields as deep generative models. In computer vision Kingma and Welling (2014), Rezende et al. (2014), and Gregor et al. (2015) have demonstrated strong performance on the task of image generation and Eslami et al. (2016) proposed variable-sized variational auto-encoders to identify multiple objects in images. While in natural language processing, there are variants of VAEs on modelling documents (Miao et al., 2016), sentences (Bowman et al., 2015) and discovery of relations (Marcheggiani and Titov, 2016). Apart from the typical initiations of VAEs, there are also a series of works that employs generative models for supervised learning tasks. For instance, Ba et al. (2015) learns visual attention for multiple objects by optimising a variational lower bound, Kingma et al. (2014) implements a semi-supervised framework for image classification and Miao et al. (2016) applies a conditional variational approximation in the task of factoid question answering. Dyer et al. (2016) proposes a generative model that explicitly extracts syntactic relationships among words and phrases which further supports the argument that generative models can be a statistically efficient method for learning neural networks from small data.

6 Experiments

6.1 Dataset & Setup

We evaluate the proposed models on the standard *Gigaword*[3] sentence compression dataset. This dataset was generated by pairing the headline of each article with its first sentence to create a source-compression pair. Rush et al. (2015) provided scripts[4] to filter out outliers, resulting in roughly 3.8M training pairs, a 400K validation set, and a 400K test set. In the following experiments all models are trained on the training set with different data sizes[5] and tested on a 2K subset, which is identical to the test set used by Rush et al. (2015) and Nallapati et al. (2016). We decode the sentences by $k = 5$ Beam search and test with full-length Rouge score.

For the ASC and FSC models, we use 256 for the dimension of both hidden units and lookup tables. In the ASC model, we apply a 3-layer bidirectional RNN with skip connections as the encoder, a 3-layer RNN pointer network with skip connections as the compressor, and a 1-layer vanilla RNN with soft attention as the decoder. The language model prior is trained on the article sentences of the full training set using a 3-layer vanilla RNN with 0.5 dropout. To lower the computational cost, we apply different vocabulary sizes for encoder and compressor (119,506 and 68,897) which corresponds to the settings of Rush et al. (2015). Specifically, the vocabulary of the decoder is filtered by taking the most frequent 10,000 words from the vocabulary of the encoder, where the rest of the words are tagged as '*<unk>*'. In further consideration of efficiency, we use only one sample for the gradient estimator. We optimise the model by Adam (Kingma and Ba, 2015) with a 0.0002 learning rate and 64 sentences per batch. The model converges in 5 epochs. Except for the pretrained language model, we do not use dropout or embedding initialisation for ASC and FSC models.

6.2 Extractive Summarisation

The first set of experiments evaluate the models on extractive summarisation. Here, we denote the joint

Table 1: Extractive Summarisation Performance. (1) The extractive summaries of these models are decoded by the pointer network (i.e the shared component of the ASC and FSC models). (2) R-1, R-2 and R-L represent the Rouge-1, Rouge-2 and Rouge-L score respectively.

models by ASC+FSC$_1$ and ASC+FSC$_2$ where ASC is trained on unlabelled data and FSC is trained on labelled data. The ASC+FSC$_1$ model employs equivalent sized labelled and unlabelled datasets, where the article sentences of the unlabelled data are the same article sentences in the labelled data, so there is no additional unlabelled data applied in this case. The ASC+FSC$_2$ model employs the full unlabelled dataset in addition to the existing labelled dataset, which is the true semi-supervised setting.

Table 1 presents the test Rouge score on extractive compression. We can see that the ASC+FSC$_1$ model achieves significant improvements on F-1 scores when compared to the supervised FSC model only trained on labelled data. Moreover, fixing the labelled data size, the ASC+FSC$_2$ model achieves better performance by using additional unlabelled data than the ASC+FSC$_1$ model, which means the semi-supervised learning works in this scenario. Interestingly, learning on the unlabelled data largely increases the precisions (though the recalls do not benefit from it) which leads to significant improvements on the F-1 Rouge scores. And surprisingly, the extractive ASC+FSC$_1$ model trained on full labelled data outperforms the abstractive NABS (Rush et al., 2015) baseline model (in Table 4).

6.3 Abstractive Summarisation

The second set of experiments evaluate performance on abstractive summarisation (Table 2). Consistently, we see that adding the generative objective to the discriminative model (ASC+FSC$_1$) results in a significant boost on all the Rouge scores, while employing extra unlabelled data increase performance further (ASC+FSC$_2$). This validates the effectiveness of transferring the knowledge learned on unlabelled data to the supervised abstractive summarisation.

In Figure 3, we present the validation perplexity to compare the abilities of the three models to learn the compression languages. The ASC+FSC$_1$(red) employs the same dataset for unlabelled and labelled training, while the ASC+FSC$_2$(black) employs the full unlabelled dataset. Here, the joint ASC+FSC$_1$ model obtains better perplexities than the single discriminative FSC model, but there is not much difference between ASC+FSC$_1$ and ASC+FSC$_2$ when the size of the labelled dataset grows. From the perspective of language modelling, the generative ASC model indeed helps the discriminative model learn to generate good summary sentences. Table 3 displays the validation perplexities of the benchmark models, where the joint ASC+FSC$_1$ model trained on the full labelled and unlabelled datasets performs the best on modelling compression languages.

Table 4 compares the test Rouge score on abstractive summarisation. Encouragingly, the semi-supervised model ASC+FSC$_2$ outperforms the baseline model NABS when trained on 500K supervised pairs, which is only about an eighth of the supervised data. In Nallapati et al. (2016), the authors exploit the full limits of discriminative RNN encoder-decoder models by incorporating a sampled softmax, expanded vocabulary, additional lexical features, and combined pointer networks[6], which yields the best performance listed in Table 4. However, when all the data is employed with the mixed ob-

[6]The idea of the combined pointer networks is similar to the FSC model, but the implementations are slightly different.

Table 4: Comparison on test Rouge scores

jective ASC+FSC$_1$ model, the result is significantly better than this previous state-of-the-art. As the semi-supervised ASC+FSC$_2$ model can be trained on unlimited unlabelled data, there is still significant space left for further performance improvements.

Table 5 presents the examples of the compression sentences decoded by the joint model ASC+FSC$_1$ and the FSC model trained on the full dataset.

7 Discussion

From the perspective of generative models, a significant contribution of our work is a process for reducing variance for discrete sampling-based variational inference. The first step is to introduce two baselines in the control variates method due to the fact that the reparameterisation trick is not applicable for discrete latent variables. However it is the second step of using a pointer network as the biased estimator that makes the key contribution. This results in a much smaller state space, bounded by the length of the source sentence (mostly between 20 and 50 tokens), compared to the full vocabulary. The final step is to apply the FSC model to transfer the knowledge learned from the supervised data to the pointer network. This further reduces the sampling variance by acting as a sort of bootstrap or constraint on the unsupervised latent space which could encode almost anything but which thus becomes biased towards matching the supervised distribution. By using these variance reduction methods, the ASC model is able to carry out effective variational inference for the latent language model so that it learns to summarise the sentences from the large unlabelled training data.

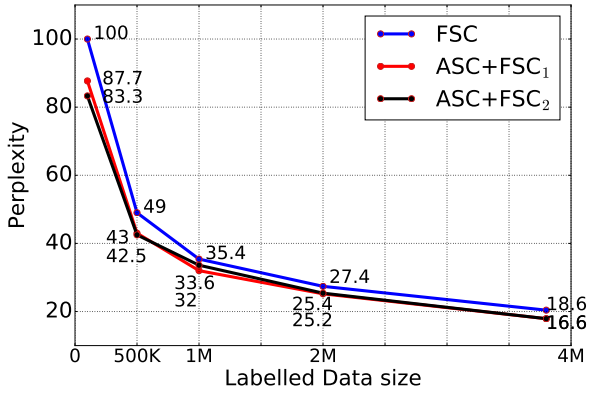

Figure 3: Perplexity on validation dataset.

In a different vein, according to the reinforcement learning interpretation of sequence level training (Ranzato et al., 2016), the compression model of the ASC model acts as an agent which iteratively generates words (takes actions) to compose the com-

pression sentence and the reconstruction model acts as the reward function evaluating the quality of the compressed sentence which is provided as a reward signal. Ranzato et al. (2016) presents a thorough empirical evaluation on three different NLP tasks by using additional sequence-level reward (BLEU and Rouge-2) to train the models. In the context of this paper, we apply a variational lower bound (mixed reconstruction error and KL divergence regularisation) instead of the explicit Rouge score. Thus the ASC model is granted the ability to explore unlimited unlabelled data resources. In addition we introduce a supervised FSC model to teach the compression model to generate stable sequences instead of starting with a random policy. In this case, the pointer network that bridges the supervised and unsupervised model is trained by a mixed criterion of REINFORCE and cross-entropy in an incremental learning framework. Eventually, according to the experimental results, the joint ASC and FSC model is able to learn a robust compression model by exploring both labelled and unlabelled data, which outperforms the other single discriminative compression models that are only trained by cross-entropy reward signal.

8 Conclusion

In this paper we have introduced a generative model for jointly modelling pairs of sequences and evaluated its efficacy on the task of sentence compression. The variational auto-encoding framework provided an effective inference algorithm for this approach and also allowed us to explore combinations of discriminative (FSC) and generative (ASC) compression models. The evaluation results show that supervised training of the combination of these models improves upon the state-of-the-art performance for the Gigaword compression dataset. When we train the supervised FSC model on a small amount of labelled data and the unsupervised ASC model on a large set of unlabelled data the combined model is able to outperform previously reported benchmarks trained on a great deal more supervised data. These results demonstrate that we are able to model language as a discrete latent variable in a variational auto-encoding framework and that the resultant generative model is able to effectively exploit both supervised and unsupervised data in sequence-to-sequence tasks.

Globally Coherent Text Generation with Neural Checklist Models

Chloé Kiddon Luke Zettlemoyer Yejin Choi
Computer Science & Engineering
University of Washington
{chloe, lsz, yejin}@cs.washington.edu

Abstract

Recurrent neural networks can generate locally coherent text but often have difficulties representing what has already been generated and what still needs to be said – especially when constructing long texts. We present the *neural checklist model*, a recurrent neural network that models global coherence by storing and updating an agenda of text strings which should be mentioned somewhere in the output. The model generates output by dynamically adjusting the interpolation among a language model and a pair of attention models that encourage references to agenda items. Evaluations on cooking recipes and dialogue system responses demonstrate high coherence with greatly improved semantic coverage of the agenda.

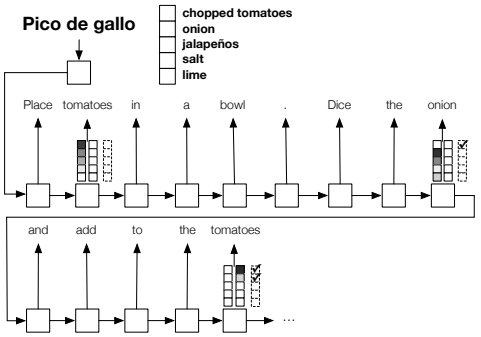

Figure 1: Example checklist recipe generation. A checklist (right dashed column) tracks which agenda items (top boxes; "salt," "lime," etc.) have already been used (checked boxes). The model is trained to interpolate an RNN (e.g., encode "pico de gallo" and decode a recipe) with attention models over new (left column) and used (middle column) items that identify likely items for each time step (shaded boxes; "tomatoes," etc.).

1 Introduction

Recurrent neural network (RNN) architectures have proven to be well suited for many natural language generation tasks (Mikolov et al., 2010; Mikolov et al., 2011; Sordoni et al., 2015; Xu et al., 2015; Wen et al., 2015; Mei et al., 2016). Previous neural generation models typically generate locally coherent language that is on topic; however, overall they can miss information that should have been introduced or introduce duplicated or superfluous content. These errors are particularly common in situations where there are multiple distinct sources of input or the length of the output text is sufficiently long. In this paper, we present a new recurrent neural model that maintains coherence while improving coverage by globally tracking what has been said and what is still left to be said in complete texts.

For example, consider the challenge of generating a cooking recipe, where the title and ingredient list are provided as inputs and the system must generate a complete text that describes how to produce the desired dish. Existing RNN models may lose track of which ingredients have already been mentioned, especially during the generation of a long recipe with many ingredients. Recent work has focused on adapting neural network architectures to improve coverage (Wen et al., 2015) with application to generating customer service responses, such as hotel information, where a single sentence is generated to describe a few key ideas. Our focus is instead on developing a model that maintains coherence while producing longer texts or covering longer

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 329–339,
Austin, Texas, November 1-5, 2016.

input specifications (e.g., a long ingredient list).

More specifically, our *neural checklist model* generates a natural language description for achieving a goal, such as generating a recipe for a particular dish, while using a new checklist mechanism to keep track of an agenda of items that should be mentioned, such as a list of ingredients (see Fig. 1). The checklist model learns to interpolate among three components at each time step: (1) an encoder-decoder language model that generates goal-oriented text, (2) an attention model that tracks remaining agenda items that need to be introduced, and (3) an attention model that tracks the used, or checked, agenda items. Together, these components allow the model to learn representations that best predict which words should be included in the text and when references to agenda items should be checked off the list (see check marks in Fig. 1).

We evaluate our approach on a new cooking recipe generation task and the dialogue act generation from Wen et al. (2015). In both cases, the model must correctly describe a list of agenda items: an ingredient list or a set of facts, respectively. Generating recipes additionally tests the ability to maintain coherence in long procedural texts. Experiments in dialogue generation demonstrate that our approach outperforms previous work with up to a 4 point BLEU improvement. Our model also scales to cooking recipes, where both automated and manual evaluations demonstrate that it maintains the strong local coherence of baseline RNN techniques while significantly improving the global coverage by effectively integrating the agenda items.

2 Task

Given a goal $\mathbf{g}$ and an agenda $E = \{\mathbf{e}_1, \ldots, \mathbf{e}_{|E|}\}$, our task is to generate a goal-oriented text $\mathbf{x}$ by making use of items on the agenda. For example, in the cooking recipe domain, the goal is the recipe title ("pico de gallo" in Fig. 1), and the agenda is the ingredient list (e.g., "lime," "salt"). For dialogue systems, the goal is the dialogue type (e.g., inform or query) and the agenda contains information to be mentioned (e.g., a hotel name and address). For example, if $\mathbf{g}$ ="inform" and $E = \{$name(Hotel Stratford), has_internet(no)$\}$, an output text might be $\mathbf{x}$ ="Hotel Stratford does not have internet."

3 Related Work

Attention models have been used for many NLP tasks such as machine translation (Balasubramanian et al., 2013; Bahdanau et al., 2014), abstractive sentence summarization (Rush et al., 2015), machine reading (Cheng et al., 2016), and image caption generation (Xu et al., 2015). Our model uses new types of attention to record what has been said and to select new agenda items to be referenced.

Recently, other researchers have developed new ways to use attention mechanisms for related generation challenges. Most closely related, Wen et al. (2015) and Wen et al. (2016) present neural network models for generating dialogue system responses given a set of agenda items. They focus on generating short texts (1-2 sentences) in a relatively small vocabulary setting and assume a fixed set of possible agenda items. Our model composes substantially longer texts, such as recipes, with a more varied and open ended set of possible agenda items. We also compare performance for our model on their data.

Maintaining coherence and avoiding duplication have been recurring challenges when generating text using RNNs for other applications, including image captioning (Jia et al., 2015; Xu et al., 2015) and machine translation (Tu et al., 2016b; Tu et al., 2016a). A variety of solutions have been developed to address infrequent or out-of-vocabulary words in particular (Gülçehre et al., 2016; Jia and Liang, 2016). Instead of directly copying input words or deterministically selecting output, our model can learn how to generate them (e.g., it might prefer to produce the word "steaks" when the original recipe ingredient was "ribeyes"). Finally, recent work in machine translation models has introduced new training objectives to encourage attention to all input words (Luong et al., 2015), but these models do not accumulate attention while decoding.

Generating recipes was an early task in planning (Hammond, 1986) and generating referring expression research (Dale, 1988). These can be seen as key steps in classic approaches to generating natural language text: a formal meaning representation is provided as input and the model first does content selection to determine the non-linguistic concepts to be conveyed by the output text (i.e., *what to say*) and then does realization to describe those concepts

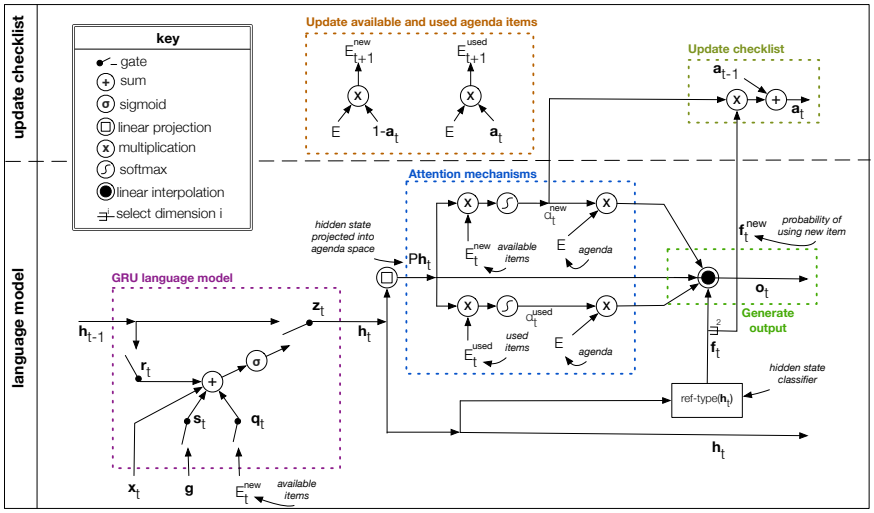

Figure 2: A diagram of the neural checklist model. The bottom portion depicts how the model generates the output embedding $\mathbf{o}_t$. The top portion shows how the checklist and available/used agenda item matrices are updated.

in natural language text (i.e., *how to say it*) (Thompson, 1977; Reiter and Dale, 2000). More recently, machine learning methods have focused on parts of this approach (Barzilay and Lapata, 2005; Liang et al., 2009) or the full two-stage approach (Angeli et al., 2010; Konstas and Lapata, 2013). Most of these models shorter texts, although Mori et al. (2014) did consider longer cooking recipes. Our approach is a joint model that instead operates with textual input and tries to cover all of the content it is given.

4 Model

Fig. 2 shows a graphical representation of the neural checklist model. At a high level, our model uses a recurrent neural network (RNN) language model that encodes the goal as a bag-of-words and then generates output text token by token. It additionally stores a vector that acts as a soft checklist of what agenda items have been used so far during generation. This checklist is updated every time an agenda item reference is generated and is used to compute the available agenda items at each time step. The available items are used as an input to the language model and to constrain which agenda items can still be referenced during generation. Agenda embeddings are also used when generating item references.

4.1 Input variable definitions

We assume the goal $\mathbf{g}$ and agenda items E (see Sec. 2) are each defined by a set of tokens. Goal tokens come from a fixed vocabulary $\mathcal{V}_{goal}$, the item tokens come from a fixed vocabulary $\mathcal{V}_{agenda}$, and the tokens of the text $\mathbf{x}_t$ come from a fixed vocabulary $\mathcal{V}_{text}$. In an abuse of notation, we represent each goal $\mathbf{g}$, agenda item $\mathbf{e}_i$, and text token $\mathbf{x}_t$ as a k-dimensional word embedding vector. We compute these embeddings by creating indicator vectors of the vocabulary token (or set of tokens for goals and agenda items) and embed those vectors using a trained $k \times |\mathcal{V}_z|$ projection matrix, where $z \in \{goal, agenda, text\}$ depending whether we are generating a goal, agenda item, or text token.

Given a goal embedding $\mathbf{g} \in \mathbb{R}^k$, a matrix of L agenda items $E \in \mathbb{R}^{L \times k}$, a checklist soft record of what items have been used $\mathbf{a}_{t-1} \in \mathbb{R}^L$, a previous hidden state $\mathbf{h}_{t-1} \in \mathbb{R}^k$, and the current input word embedding $\mathbf{x}_t \in \mathbb{R}^k$, our architecture computes the next hidden state $\mathbf{h}_t$, an embedding used to generate the output word $\mathbf{o}_t$, and the updated checklist $\mathbf{a}_t$.

4.2 Generating output token probabilities

To generate the output token probability distribution (see "Generate output" box in Fig. 2), $\mathbf{w}_t \in \mathbb{R}^{|V_{text}|}$, we project the *output hidden state* $\mathbf{o}_t$ into the vocabulary space and apply a softmax:

$$\mathbf{w}_t = \text{softmax}(W_o \mathbf{o}_t),$$

where $W_o \in \mathbb{R}^{|V| \times k}$ is a trained projection matrix. The output hidden state is the linear interpolation of (1) content $\mathbf{c}_t^{gru}$ from a Gated Recurrent Unit

(GRU) language model, (2) an encoding $\mathbf{c}_t^{new}$ generated from the new agenda item reference model (Sec. 4.3), and (3) and an encoding $\mathbf{c}_t^{used}$ generated from a previously used item model (Sec. 4.4):

$$\mathbf{o}_t = f_t^{gru}\mathbf{c}_t^{gru} + f_t^{new}\mathbf{c}_t^{new} + f_t^{used}\mathbf{c}_t^{used}.$$

The interpolation weights, f_t^{gru}, f_t^{new}, and f_t^{used}, are probabilities representing how much the output token should reflect the current state of the language model or a chosen agenda item. f_t^{gru} is the probability of a non-agenda-item token, f_t^{new} is the probability of an new item reference token, and f_t^{used} is the probability of a used item reference. In the Fig. 1 example, f_t^{new} is high in the first row when new ingredient references "tomatoes" and "onion" are generated; f_t^{used} is high when the reference back to "tomatoes" is made in the second row, and f_t^{gru} is high the rest of the time.

To generate these weights, our model uses a three-way probabilistic classifier, $ref\text{-}type(\mathbf{h}_t)$, to determine whether the hidden state of the GRU $\mathbf{h}_t$ will generate non-agenda tokens, new agenda item references, or used item references. $ref\text{-}type(\mathbf{h}_t)$ generates a probability distribution $\mathbf{f}_t \in \mathbb{R}^3$ as

$$\mathbf{f}_t = ref\text{-}type(\mathbf{h}_t) = softmax(\beta S\mathbf{h}_t),$$

where $S \in \mathbb{R}^{3\times k}$ is a trained projection matrix and β is a temperature hyper-parameter. $f_t^{gru} = \mathbf{f}_t^1$, $f_t^{new} = \mathbf{f}_t^2$, and $f_t^{used} = \mathbf{f}_t^3$. $ref\text{-}type()$ does not use the agenda, only the hidden state $\mathbf{h}_t$: $\mathbf{h}_t$ must encode when to use the agenda, and $ref\text{-}type()$ is trained to identify that in $\mathbf{h}_t$.

4.3 New agenda item reference model

The two key features of our model are that it (1) predicts which agenda item is being referred to, if any, at each time step and (2) stores those predictions for use during generation. These components allow for improved output texts that are more likely to mention agenda items while avoiding repetition and references to irrelevant items not in the agenda.

These features are enabled by a *checklist vector* $\mathbf{a}_t \in \mathbb{R}^L$ that represents the probability each agenda item has been introduced into the text. The checklist vector is initialized to all zeros at $t = 1$, representing that all items have yet to be introduced. The checklist vector is a soft record with each $\mathbf{a}_{t,i} \in [0, 1]$.[1]

We introduce the remaining items as a matrix $E_t^{new} \in \mathbb{R}^{L\times k}$, where each row is an agenda item embedding weighted by how likely it is to still need to be referenced. For example, in Fig. 1, after the first "tomatoes" is generated, the row representing "chopped tomatoes" in the agenda will be weighted close to 0. We calculate E_t^{new} using the checklist vector (see "Update [...] items" box in Fig. 2):

$$E_t^{new} = ((\mathbf{1}_L - \mathbf{a}_{t-1}) \otimes \mathbf{1}_k) \circ E,$$

where $\mathbf{1}_L = \{1\}^L$, $\mathbf{1}_k = \{1\}^k$, and the outer product $\otimes$ replicates $\mathbf{1}_L - \mathbf{a}_{t-1}$ for each dimension of the embedding space. $\circ$ is the Hadamard product (i.e., element-wise multiplication) of two matrices with the same dimensions.

The model predicts when an agenda item will be generated using $ref\text{-}type()$ (see Sec. 4.2 for details). When it does, the encoding $\mathbf{c}_t^{new}$ approximates which agenda item is most likely. $\mathbf{c}_t^{new}$ is computed using an attention model that generates a learned soft alignment $\boldsymbol{\alpha}_t^{new} \in \mathbb{R}^L$ between the hidden state $\mathbf{h_t}$ and the rows of E_t^{new} (i.e., available items). The alignment is a probability distribution representing how close $\mathbf{h}_t$ is to each item:

$$\boldsymbol{\alpha}_t^{new} \propto \exp(\gamma E_t^{new} P\mathbf{h}_t),$$

where $P \in \mathbb{R}^{k\times k}$ is a learned projection matrix and γ is a temperature hyper-parameter. In Fig. 1, the shaded squares in the top line (i.e., the first "tomatoes" and the onion references) represent this alignment. The attention encoding $\mathbf{c}_t^{new}$ is then the attention-weighted sum of the agenda items:

$$\mathbf{c}_t^{new} = E^T\boldsymbol{\alpha}_t^{new}.$$

At each step, the model updates the checklist vector based on the probability of generating a new agenda item reference, $\mathbf{f}_t^{new}$, and the attention alignment $\boldsymbol{\alpha}_t^{new}$. We calculate the update to checklist, $\mathbf{a}_t^{new}$, as $\mathbf{a}_t^{new} = \mathbf{f}_t^{new} \cdot \boldsymbol{\alpha}_t^{new}$. Then, the new checklist $\mathbf{a}_t$ is $\mathbf{a}_t = \mathbf{a}_{t-1} + \mathbf{a}_t^{new}$.

[1] By definition, $\mathbf{a}_t$ is non-negative. We truncate any values greater than 1 using a hard tanh function.

4.4 Previously used item reference model

We also allow references to be generated for previously used agenda items through the previously used item encoding $\mathbf{c}_t^{used}$. This is useful in longer texts – when agenda items can be referred to more than once – so that the agenda is always responsible for generating its own referring expressions. The example in Fig. 1 refers back to tomatoes when generating to what to add the diced onion.

At each time step t, we use a second attention model to compare $\mathbf{h}_t$ to a used items matrix $E_t^{used} \in \mathbb{R}^{L \times k}$. Like the remaining agenda item matrix E_t^{new}, E_t^{used} is calculated using the checklist vector generated at the previous time step:

$$E_t^{used} = (\mathbf{a}_{t-1} \otimes \mathbf{1}_k) \circ E.$$

The attention over the used items, $\boldsymbol{\alpha}_t^{used} \in \mathbb{R}^L$, and the used attention encoding $\mathbf{c}_t^{used}$ are calculated in the same way as those over the available items (see Sec. 4.3 for comparison):

$$\boldsymbol{\alpha}_t^{used} \propto \exp(\gamma E_t^{used} P \mathbf{h}_t),$$
$$\mathbf{c}_t^{used} = E^T \boldsymbol{\alpha}_t^{used}.$$

4.5 GRU language model

Our decoder RNN adapts a Gated Recurrent Unit (GRU) (Cho et al., 2014). Given an input $\mathbf{x}_t \in \mathbb{R}^k$ at time step t and the previous hidden state $\mathbf{h}_{t-1} \in \mathbb{R}^k$, a GRU computes the next hidden state $\mathbf{h}_t$ as

$$\mathbf{h}_t = (\mathbf{1} - \mathbf{z}_t)\mathbf{h}_{t-1} + \mathbf{z}_t \tilde{\mathbf{h}}_t.$$

The *update gate*, $\mathbf{z}_t$, interpolates between $\mathbf{h}_{t-1}$ and new content, $\tilde{\mathbf{h}}_t$, defined respectively as

$$\mathbf{z}_t = \sigma(W_z \mathbf{x}_t + U_z \mathbf{h}_{t-1}),$$
$$\tilde{\mathbf{h}}_t = \tanh(W \mathbf{x}_t + \mathbf{r}_t \odot U \mathbf{h}_{t-1}).$$

$\odot$ is an element-wise multiplication, and the *reset gate*, $\mathbf{r}_t$, is calculated as

$$\mathbf{r}_t = \sigma(W_r \mathbf{x}_t + U_r \mathbf{h}_{t-1}).$$

W_z, U_z, W, U, W_r, $U_r \in \mathbb{R}^{k \times k}$ are trained projection matrices.

We adapted a GRU to allow extra inputs, namely the goal $\mathbf{g}$ and the available agenda items E_t^{new} (see "GRU language model" box in Fig. 2). These extra inputs help guide the language model stay on topic. Our adapted GRU has a change to the computation of the new content $\tilde{\mathbf{h}}_t$ as follows:

$$\begin{aligned}\tilde{\mathbf{h}}_t \;=\; & \tanh(W_h x_t + \mathbf{r}_t \odot U_h \mathbf{h}_{t-1} \\ & + \mathbf{s}_t \odot Y \mathbf{g} + \mathbf{q}_t \odot (\mathbf{1}_L^T Z E_t^{new})^T,\end{aligned}$$

where $\mathbf{s}_t$ is a *goal select* gate and $\mathbf{q}_t$ is a *item select* gate, respectively defined as

$$\mathbf{s}_t = \sigma(W_s \mathbf{x}_t + U_s \mathbf{h}_{t-1}),$$
$$\mathbf{q}_t = \sigma(W_q \mathbf{x}_t + U_q \mathbf{h}_{t-1}).$$

$\mathbf{1}_L$ sums the rows of the available item matrix E_t^{new}. Y, Z, W_s, U_s, W_q, $U_q \in \mathbb{R}^{k \times k}$ are trained projection matrices. The goal select gate controls when the goal should be taken into account during generation: for example, the recipe title may be used to decide what the imperative verb for a new step should be. The item select gate controls when the available agenda items should be taken into account (e.g., when generating a list of ingredients to combine). The GRU hidden state is initialized with a projection of the goal: $\mathbf{h}_0 = U_g \mathbf{g}$, where $U_g \in \mathbb{R}^{k \times k}$.

The content vector $\mathbf{c}_t^{gru}$ that is used to compute the output hidden state $\mathbf{o}_t$ is a linear projection of the GRU hidden state, $\mathbf{c}_t^{gru} = P\mathbf{h}_t$, where P is the same learned projection matrix used in the computation of the attention weights (see Sections 4.3 and 4.4).

4.6 Training

Given a training set of (goal, agenda, output text) triples $\{(\mathbf{g}^{(1)}, E^{(1)}, \mathbf{x}^{(1)}), \ldots, (\mathbf{g}^{(J)}, E^{(J)}, \mathbf{x}^{(J)})\}$, we train model parameters by minimizing negative log-likelihood: $NLL(\theta) =$

$$-\sum_{j=1}^{J} \sum_{i=2}^{N_j} \log p(\mathbf{x}_i^{(j)} | \mathbf{x}_1^{(j)}, \ldots, \mathbf{x}_{i-1}^{(j)}, \mathbf{g}^{(j)}, E^{(j)}; \theta),$$

where $\mathbf{x}_1^{(j)}$ is the start symbol. We use mini-batch stochastic gradient descent, and back-propagate through the goal, agenda, and text embeddings.

It is sometimes the case that weak heuristic supervision on latent variables can be easily gathered to improve training. For example, for recipe generation, we can approximate the linear interpolation weights $\mathbf{f}_t$ and the attention updates $\mathbf{a}_t^{new}$ and $\mathbf{a}_t^{used}$ using string match heuristics comparing tokens in

the text to tokens in the ingredient list.[2] When this extra signal is available, we add mean squared loss terms to $NLL(\theta)$ to encourage the latent variables to take those values; for example, if $\mathbf{f}_t^*$ is the true value and $\mathbf{f}_t$ is the predicted value, a loss term $-(\mathbf{f}_t^* - \mathbf{f}_t)^2$ is added. When this signal is not available, as is the case with our dialogue generation task, we instead introduce a mean squared loss term that encourages the final checklist $\mathbf{a}_{N_j}^{(j)}$ to be a vector of 1s (i.e., every agenda item is accounted for).

4.7 Generation

We generate text using beam search, which has been shown to be fast and accurate for RNN decoding (Graves, 2012; Sutskever et al., 2014). When the beam search completes, we select the highest probability sequence that uses the most agenda items. This is the count of how many times the three-way classifier, $ref\text{-}type(\mathbf{h}_t)$, chose to generate an new item reference with high probability (i.e., $> 50\%$).

5 Experimental setup

Our model was implemented and trained using the Torch scientific computing framework for Lua.[3]

Experiments We evaluated neural checklist models on two natural language generation tasks. The first task is cooking recipe generation. Given a recipe title (i.e., the name of the dish) as the goal and the list of ingredients as the agenda, the system must generate the correct recipe text. Our second evaluation is based on the task from Wen et al. (2015) for generating dialogue responses for hotel and restaurant information systems. The task is to generate a natural language response given a query type (e.g., informing or querying) and a list of facts to convey (e.g., a hotel's name and address).

Parameters We constrain the gradient norm to 5.0 and initialize parameters uniformly on $[-0.35, 0.35]$. We used a beam of size 10 for generation. Based on dev set performance, a learning rate of 0.1 was chosen, and the temperature hyperparameters (β, γ) were $(5, 2)$ for the recipe task and $(1, 10)$ for the dialogue task. The models for the recipe task had a hidden state size of $k = 256$; the models for the dialogue task had $k = 80$ to compare to previous models. We use a batch size 30 for the recipe task and 10 for the dialogue task.

Recipe data and pre-processing We use the Now You're Cooking! recipe library: the data set contains over 150,000 recipes in the Meal-Master™ format.[4] We heuristically removed sentences that were not recipe steps (e.g., author notes, nutritional information, publication information). 82,590 recipes were used for training, and 1,000 each for development and testing. We filtered out recipes to avoid exact duplicates between training and dev (test) sets.

We collapsed multi-word ingredient names into single tokens using word2phrase[5] ran on the training data ingredient lists. Titles and ingredients were cleaned of non-word tokens. Ingredients additionally were stripped of amounts (e.g., "1 tsp"). As mentioned in Sec. 4.6, we approximate true values for the interpolation weights and attention updates for recipes based on string match between the recipe text and the ingredient list. The first ingredient reference in a sentence cannot be the first token or after a comma (e.g., the bold tokens cannot be ingredients in "**oil** the pan" and "in a large bowl, **mix** [...]").

Recipe data statistics Automatic recipe generation is difficult due to the length of recipes, the size of the vocabulary, and the variety of possible dishes. In our training data, the average recipe length is 102 tokens, and the longest recipe has 814 tokens. The vocabulary of the recipe text from the training data (i.e., the text of the recipe not including the title or ingredient list) has 14,103 unique tokens. About 31% of tokens in the recipe vocabulary occur at least 100 times in the training data; 8.6% of the tokens occur at least 1000 times. The training data also represents a wide variety of recipe types, defined by the recipe titles. Of 3793 title tokens, only 18.9% of the title tokens in the title vocabulary occur at least 100 times in the training data, which demonstrates the large variability in the titles.

Dialogue system data and processing We used the hotel and restaurant dialogue system corpus and the same train-development-test split from Wen et al. (2015). We used the same pre-processing, sets

[2] Similar to $\mathbf{a}_t^{new}$, $\mathbf{a}_t^{used} = \mathbf{f}_t^{used} \cdot \boldsymbol{\alpha}_t^{used}$.

[3] http://torch.ch/

[5] See https://code.google.com/p/word2vec/

of reference samples, and baseline output, and we were given model output to compare against.[6] For training, slot values (e.g., "Red Door Cafe") were replaced by generic tokens (e.g., "NAME_TOKEN"). After generation, generic tokens were swapped back to specific slot values. Minor post-processing included removing duplicate determiners from the relexicalization and merging plural "-s" tokens onto their respective words. After replacing specific slot values with generic tokens, the training data vocabulary size of the hotel corpus is 445 tokens, and that of the restaurant corpus is 365 tokens. The task has eight goals (e.g., *inform*, *confirm*).

Models Our main baseline *EncDec* is a model using the RNN Encoder-Decoder framework proposed by Cho et al. (2014) and Sutskever et al. (2014). The model encodes the goal and then each agenda item in sequence and then decodes the text using GRUs. The encoder has two sets of parameters: one for the goal and the other for the agenda items. For the dialogue task, we also compare against the *SC-LSTM* system from Wen et al. (2015) and the handcrafted rule-based generator described in that paper.

For the recipe task, we also compare against three other baselines. The first is a basic attention model, *Attention*, that generates an attention encoding by comparing the hidden state $\mathbf{h}_t$ to the agenda. That encoding is added to the hidden state, and a nonlinear transformation is applied to the result before projecting into the output space. We also present a nearest neighbor baseline (*NN*) that simply copies over an existing recipe text based on the input similarity computed using cosine similarity over the title and the ingredient list. Finally, we present a hybrid approach (*NN-Swap*) that revises a nearest neighbor recipe using the neural checklist model. The neural checklist model is forced to generate the returned recipe nearly verbatim, except that it can generate new strings to replace any extraneous ingredients.

Our neural checklist model is labeled *Checklist*. We also present the *Checklist+* model, which interactively re-writes a recipe to better cover the input agenda: if the generated text does not use every agenda item, embeddings corresponding to missing items are multiplied by increasing weights and a new recipe is generated. This process repeats until the new recipe does not contain new items.

[6] We thank the authors for sharing their system outputs.

Model	BLEU-4	METEOR	Avg. % given items	Avg. extra items
Attention	2.8	8.6	22.8%	3.0
EncDec	3.1	9.4	26.9%	2.0
NN	**7.1**	12.1	40.0%	4.2
NN-Swap	**7.1**	**12.8**	58.2%	2.1
Checklist	3.0	10.3	67.9%	**0.6**
- $\mathbf{o}_t = \mathbf{h}_t$	2.1	8.3	29.1%	2.4
- no used	3.0	10.4	62.2%	1.9
- no supervision	3.7	10.1	38.9%	1.8
Checklist+	3.8	11.5	**83.4%**	0.8

Table 1: Quantitative results on the recipe task. The line with $\mathbf{o}_t = \mathbf{h}_t$ has the results for the non-interpolation ablation.

We also report the performance of our checklist model without the additional weak supervision of heuristic ingredient references (- *no supervision*) (see Sec. 4.6).[7] we also evaluate two ablations of our checklist model on the recipe task. First, we remove the linear interpolation and instead use $\mathbf{h}_t$ as the output (see Sec. 4.2). Second, we remove the previously used item reference model by changing $ref\text{-}type()$ to a 2-way classifier between new ingredient references and all other tokens (see Sec. 4.4).

Metrics We include commonly used metrics like BLEU-4,[8] and METEOR (Denkowski and Lavie, 2014). Because neither of these metrics can measure how well the generated recipe follows the input goal and the agenda, we also define two additional metrics. The first measures the percentage of the agenda items corrected used, while the second measures the number of extraneous items incorrectly introduced. Both these metrics are computed based on simple string match and can miss certain referring expressions (e.g., "meat" to refer to "pork"). Because of the approximate nature of these automated metrics, we also report a human evaluation.

6 Recipe generation results

Fig. 1 results for recipe generation. All BLEU and METEOR scores are low, which is expected for long texts. Our checklist model performs better than both neural network baselines (Attention and EncDec) in all metrics. Nearest neighbor baselines (NN and NN-Swap) perform the best in terms of BLEU and

[7] For this model, parameters were initialized on [-0.2, 0.2] to maximize development accuracy.

Checklist+	4.39	**3.95**	**4.10**
Truth	4.39	4.03	4.34

Table 2: Human evaluation results on the generated and true recipes. Scores range in $[1, 5]$.

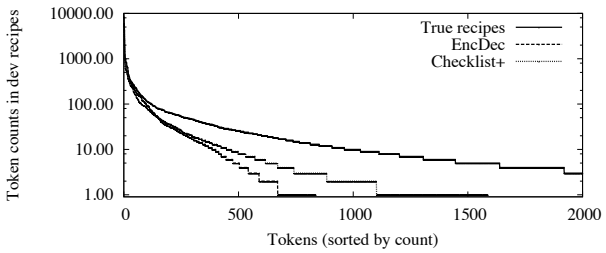

Figure 3: Counts of the most used vocabulary tokens (sorted by count) in the true dev set recipes and in generated recipes.

METEOR; this is due to a number of recipes that have very similar text but make different dishes.

However, NN baselines are not successful in generating a goal-oriented text that follows the given agenda: compared to Checklist+ (83.4%), they use substantially less % of the given ingredients (40% - 58.2%) while also introducing extra ingredients not provided. EncDec and Attention baselines similarly generate recipes that are not relevant to the given input, using only 22.8% - 26.9% of the agenda items. Checklist models rarely introduce extraneous ingredients not provided (0.6 - 0.8), while other baselines make a few mistakes on average (2.0 - 4.2).

The ablation study demonstrates the empirical contribution of different model components. ($\mathbf{o}_t = \mathbf{h}_t$) shows the usefulness of the attention encodings when generating the agenda references, while (*-no used*) shows the need for separate attention mechanisms between new and used ingredient references for more accurate use of the agenda items. Similarly, (*-no supervision*) demonstrates that the weak supervision encourages the model to learn more accurate management of the agenda items.

Human evaluation Because neither BLEU nor METEOR is suitable for evaluating generated text in terms of their adherence to the provided goal and the agenda, we also report human evaluation using Amazon Mechanical Turk. We evaluate the generated recipes on (1) grammaticality, (2) how well the recipe adheres to the provided ingredient list, and (3) how well the generated recipe accomplishes the desired dish. We selected 100 random test recipes. For each question we used a Likert scale ($\in [1, 5]$) and report averaged ratings among five turkers.

Table 2 shows the averaged scores over the responses. The checklist models outperform all baselines in generating recipes that follow the provided agenda closely and accomplish the desired goal, where NN in particular often generates the wrong dish. Perhaps surprisingly, both the Attention and EncDec baselines and the Checklist model beat the true recipes in terms of having better grammar. This can partly be attributed to noise in the parsing of the true recipes, and partly because the neural models tend to generate shorter, simpler texts.

Fig. 3 shows the counts of the most used vocabulary tokens in the true dev set recipes compared to the recipes generated by EncDec and Checklist+. Using the vocabulary from the training data, the true dev recipes use 5206 different tokens. The EncDec's vocabulary is only $\sim$16% of that size, while the Checklist+ model is a third of the size.

An error analysis on the dev set shows that the EncDec baseline over-generates catch-all phrases like "all ingredients" or "the ingredients," used in 21% of the generated recipes, whereas only 7.8% of true recipes use that construction. This phrase type simplifies the recipe, but using all ingredients in one step reduces the chance of accomplishing the desired dish correctly. The Checklist model only generates those phrases 13% of the time.

Qualitative analysis Fig. 4 shows two dev set recipes with generations from the EncDec and Checklist+ models. The EncDec model is much more likely to both use incorrect ingredients and to introduce ingredients more than once (e.g., "baking power" and "salt" in the bottom example are not in the ingredient list, and "milk" in the top example is duplicated). In the top example, the Checklist+ model refers to both Parmesean and Swiss cheese as "cheese"; generating more precise referring expressions is an important area for future work. The Checklist+ recipes generate the correct dishes to an extent: for example, the top recipe makes a casserole but does not cook the ingredients together before baking and mixes in biscuits instead of putting

Title: Casino royale casserole
Ingredients: 10 oz chopped broccoli, 2 tbsp butter, 2 tbsp flour, 1/2 tsp salt, 1/4 tsp black pepper, 1/4 tsp ground nutmeg, 1 cup milk, 1 1/2 cup shredded swiss cheese, 2 tsp lemon juice, 2 cup cooked cubed turkey, 4 oz mushrooms, 1/4 cup grated Parmesan cheese, 1 can refrigerated biscuits

Truth	EncDec	Checklist+
Preheat oven to 375. Melt butter in saucepan. Blend in flour, salt, pepper, and nutmeg; cook 1-2 minutes. Gradually add milk; cook, stirring, until slightly thickened. Stir in frozen vegetables. Remove from heat; stir in cheese until melted. Add lemon juice, turkey, mushrooms, and broccoli. Pour mixture into a lightly greased 8"x8" baking dish; sprinkle with parmesean and top with biscuits. Bake 20 minutes, or until biscuits are golden brown.	Cook broccoli according to package directions; drain. In medium saucepan, melt butter. Stir in flour, salt and pepper. Gradually add milk, stirring constantly. Cook over medium heat, stirring constantly, until mixture comes to a boil. Reduce heat to low. Cook, stirring constantly, until mixture boils and thickens, about 5 minutes. Stir in **milk**. Gradually heat to boiling; reduce heat. Cover; simmer 10 minutes or until heated through. Serve immediately.	Mix the turkey with the flour, salt, pepper, milk and lemon juice. Stir in the cheese. Add broccoli, mushrooms, nutmeg, and cheese. Mix well. Add the butter and mix well. Add the biscuits and mix well. Spread in a greased 13x9 inch baking pan. Bake in a 350f oven for 35 to 40 minutes, or until pick inserted in the center comes out clean. Serve hot.

Title: Kathie Frieman's cheese cake
Ingredients: 2 lb cream cheese, 1 3/4 cups sugar, 5 eggs, 15 oreo cookies, 1/2 tsp vanilla, 1/2 tsp almond extract

Truth	EncDec	Checklist+
Butter pan well. Whip cheese until soft and add sugar, combine until fluffy. Add extracts and eggs. Chop oreos into pieces and fold into mixture. Pour into pan and place in a pan of 1 or more inches of water. Bake at 350 1 1/2 hours (check after 1 1/4 hours) until center is set. Cool in pan of water. When cool turn upside-down on plate. Sprinkle with cookie crumbs.	Beat cream cheese and sugar together until light and fluffy. Add eggs, one at a time, beating well after each addition. Blend in vanilla. Sift flour, measure, and sift with **baking power** and **salt**. Add to creamed mixture alternately with **milk**. Fold in stiffly beaten **egg whites**. Pour into 9x13 pan. Bake at 350 degrees for 25 to 30 minutes.	Cream sugar and cream cheese until smooth. Add eggs, one at a time, beating well after each addition. Add vanilla, almond extract, and cookies. Mix well. Pour into greased and floured tube pan. Bake at 350 degrees for 30 minutes.

Figure 4: Example dev set generated recipes. Tokenization, newlines, and capitalization changed for space and readability. Bolded ingredient references are either ingredients not in the list and/or duplicated initial ingredient references.

Model	Hotel		Restaurant	
	BLEU	**METEOR**	**BLEU**	**METEOR**
HDC	55.52	48.10	44.39	43.42
SC-LSTM	86.53	60.84	74.49	54.31
Checklist	**90.61**	**62.10**	**77.82**	**54.42**

Table 3: Quantitative evaluation of the top generations in the hotel and restaurant domains

them on top. Future work could better model the full set of steps needed to achieve the overall goal.

7 Dialogue system results

Figure 3 shows our results on the hotel and restaurant dialogue system generation tasks. HDC is the rule-based baseline from Wen et al. (2015). For both domains, the checklist model achieved the highest BLEU-4 and METEOR scores, but both neural systems performed very well. The power of our model is in generating long texts, but this experiment shows that our model can generalize well to other tasks with different kinds of agenda items and goals.

8 Future work and conclusions

We present the neural checklist model that generates globally coherent text by keeping track of what has been said and still needs to be said from a provided agenda. Future work includes incorporating referring expressions for sets or compositions of agenda items (e.g., "vegetables"). The neural checklist model is sensitive to hyperparameter initialization, which should be investigated in future work. The neural checklist model can also be adapted to handle multiple checklists, such as checklists over composite entities created over the course of a recipe (see Kiddon (2016) for an initial proposal).

Abstract

We introduce a manually-created, multi-reference dataset for abstractive sentence and short paragraph compression. First, we examine the impact of single- and multi-sentence level editing operations on human compression quality as found in this corpus. We observe that substitution and rephrasing operations are more meaning preserving than other operations, and that compressing in context improves quality. Second, we systematically explore the correlations between automatic evaluation metrics and human judgments of meaning preservation and grammaticality in the compression task, and analyze the impact of the linguistic units used and precision versus recall measures on the quality of the metrics. Multi-reference evaluation metrics are shown to offer significant advantage over single reference-based metrics.

1 Introduction

Automated sentence compression condenses a sentence or paragraph to its most important content in order to enhance writing quality, meet document length constraints, and build more accurate document summarization systems (Berg-Kirkpatrick et al., 2011; Vanderwende et al., 2007). Though word deletion is extensively used (e.g., (Clarke and Lapata, 2008)), state-of-the-art compression models (Cohn and Lapata, 2008; Rush et al., 2015) benefit crucially from data that can represent complex abstractive compression operations, including substitution of words and phrases and reordering.

This paper has two parts. In the first half, we introduce a manually-created *multi-reference* dataset for *abstractive* compression of sentences and short paragraphs, with the following features:

- It contains approximately 6,000 source texts with multiple compressions (about 26,000 pairs of source and compressed texts), representing business letters, newswire, journals, and technical documents sampled from the Open American National Corpus (OANC[1]).
- Each source text is accompanied by up to five crowd-sourced rewrites constrained to a preset compression ratio and annotated with quality judgments. Multiple rewrites permit study of the impact of operations on human compression quality and facilitate automatic evaluation.
- This dataset is the first to provide compressions at the multi-sentence (two-sentence paragraph) level, which may present a stepping stone to whole document summarization. Many of these two-sentence paragraphs are compressed both as paragraphs and separately sentence-by-sentence, offering data that may yield insights into the impact of multi-sentence operations on human compression quality.
- A detailed edit history is provided that may allow fine-grained alignment of original and compressed texts and measurement of the cognitive load of different rewrite operations.

Our analysis of this dataset reveals that abstraction has a significant positive impact on meaning preservation, and that application of trans-sentential

*This research was conducted during the author's internship at Microsoft Research.

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 340–350,
Austin, Texas, November 1-5, 2016.

context has a significant positive impact on both meaning preservation and grammaticality.

In the second part, we provide a systematic empirical study of eighty automatic evaluation metrics for text compression using this dataset, correlating them with human judgments of meaning and grammar. Our study shows strong correlation of the best metrics with human judgments of meaning, but weaker correlations with judgments of grammar. We demonstrate significant gains from multiple references. We also provide analyses of the impact of the linguistics units used (surface n-grams of different sizes versus parse-based triples), and the use of precision versus recall-based measures.

2 Related Work

Prior studies of human compression: Clarke (2008) studied the properties of manually-collected deletion-based compressions in the news genre, comparing them with automatically-mined data from the Ziff-Davis corpus in terms of compression rate, length of deleted spans, and deletion probability by syntactic constituent type. Jing and McKeown (1999) identified abstractive operations (other than word deletion) employed by professional writers, including paraphrasing and re-ordering of phrases, and merging and reordering sentences, but did not quantify their impact on compression quality.

Deletion-based compression corpora: Currently available automatically-mined deletion corpora are single-reference and have varying (uncontrolled) compression rates. Knight and Marcu (2002) automatically mined a small parallel corpus (1,035 training and 32 test sentences) by aligning abstracts to sentences in articles. Filippova and Altun (2013) extracted deletion-based compressions by aligning news headlines to first sentences, yielding a corpus of 250,000 parallel sentences. The same approach was used by Filippova et al. (2015) to create a set of 2M sentence pairs. Only a subset of 10,000 parallel sentences from the latter has been publicly released. Clarke and Lapata (2006) and Clarke and Lapata (2008) provide two manually-created two-reference corpora for deletion-based compression:[2] their sizes are 1,370 and 1,433 sentences, respectively.

[2] http://jamesclarke.net/research/resources

Abstractive compression corpora: Rush et al. (2015) have mined 4 million compression pairs from news articles and released their code to extract data from the Annotated Gigaword (Napoles et al., 2012). A news-domain parallel sentence corpus containing 1,496 parallel examples has been culled from multi-reference Chinese-English translations by Ganitkevitch et al. (2011). The only publicly-available manually-created abstractive compression corpus is that described by Cohn and Lapata (2008), which comprises 575 single-reference sentence pairs.

Automatic metrics: Early automatic metrics for evaluation of compressions include success rate (Jing, 2000), defined as accuracy of individual word or constituent deletion decisions; Simple String Accuracy (string edit distance), introduced by Bangalore et al. (2000) for natural language generation tasks; and Word Accuracy (Chiori and Furui, 2004), which generalizes Bangalore et al. (2000) to multiple references. Riezler et al. (2003) introduced the use of F-measure over grammatical relations. Word unigram and word-bigram F-measure have also been used (Unno et al., 2006; Filippova et al., 2015). Variants of ROUGE (Lin, 2004), used for summarization evaluation, have also been applied to sentence compressions (Rush et al., 2015).

Riezler et al. (2003) show that F-measure over grammatical relations agrees with human ratings on the relative ranking of three systems at the corpus level. Clarke and Lapata (2006) evaluate two deletion-based automatic compression systems against a deletion-based gold-standard on sets of 20 sentences. Parse-based F-1 was shown to have high sentence-level Pearson's ρ correlation with human judgments of overall quality, and to have higher ρ than Simple String Accuracy.

Napoles et al. (2011) have pointed to the need of multiple references and studies of evaluation metrics. For the related tasks of document and multi-document summarization, Graham (2015) provides a fine-grained comparison of automated evaluation methods. However, to the best of our knowledge, no studies of automatic evaluation metrics exist for abstractive compression of shorter texts.

Length		Text	Operations
1-Sent	Source	Think of all the ways everyone in your household will benefit from your membership in Audubon.	N/A
	Ref-1	Imagine how your household will benefit from your Audubon membership.	paraphrase + deletion + transformation
	Ref-2	Everyone in your household will benefit from membership in Audubon.	deletion
2-Sent	Source	Will the administration live up to its environmental promises? Can we save the last of our ancient forests from the chainsaw?	N/A
	Ref-1	Can the administration keep its promises? Can we save the last of our forests from loss?	two-sentences + deletion + paraphrase
	Ref-2	Will the administration live up to its environmental promises to save our ancient forests?	merge + deletion

Table 1: Examples of 1- and 2-sentence crowd-sourced compressions, illustrating different rewrite types.

	Newswire	Letters	Journal	Non-fiction
#texts	695	1,591	1,871	2,012

Table 2: Overview of the dataset by genre.

3 Dataset: Annotation and Properties

We sampled single sentences and two-sentence paragraphs from several genres in the written text section of the Manually Annotated Sub-Corpus (MASC) (Ide et al., 2008; Ide et al., 2010) of the Open American National Corpus (OANC), supplemented by additional data from the written section of OANC. Two-sentence paragraphs account for approximately 23% of multi-sentence paragraphs in the OANC. The two-sentence paragraphs we sampled contain at least 25 words. Table 2 breaks the sampled texts down by genre. Non-news genres are better represented in our sample than the newswire typically used in compression tasks. The *Letters* examples are expected to be useful for learning to compress emails. The *Journal* texts are likely to be challenging as their purpose is often more than to convey information. The *Non-Fiction* collection includes material from technical academic publications, such as PLoS Medicine, an open access journal.[3]

3.1 Annotation

Compressions were created using UHRS, an in-house crowd-sourcing system similar to Amazon's Mechanical Turk, in two annotation rounds, one for shortening and a second to rate compression quality.

Generating compressions: In the first round, we asked five workers (*editors*) to abridge each source text by at least 25%, while remaining grammatical and fluent, and retaining the meaning of the original. This requirement was enforced programmatically on the basis of character count. The 25% rate is intended to reflect practical editing scenarios (e.g., shrink 8 pages to 6). To facilitate meeting this requirement, the minimum source text length presented to editors was 15 words. For a subset of paragraphs, we collected compressions both as independent rewrites of their component sentences, and of the paragraph as a whole. Table 1 show compression examples and strategies.

Evaluating compression quality: In the second round, we asked 3-5 judges (*raters*) to evaluate the grammaticality of each compression on a scale from 1 (major errors, disfluent) through 3 (fluent), and again analogously for meaning preservation on a scale from 1 (orthogonal) through 3 (most important meaning-preserving).[4] We later used the same process to evaluate compressions produced by automatic systems. The full guidelines for the editors and raters are available with the data release.

Quality controls: All editors and raters were based in the US, and the raters were required to pass a qualification test which asked them to rate the meaning and grammaticality for a set of examples with known answers. To further improve the quality of the data, we removed low-quality compressions. We computed the quality of each compression as the average of the grammar and meaning quality as judged by the raters. We then computed the mean quality for each editor, and removed compressions authored by the bottom 10% of editors. We did the same for the bottom 10% of the raters.[5]

[3] http://journals.plos.org/plosmedicine/

[4] Pilot studies suggested that a scale of 1-3 offered better inter-annotator agreement than the standard 5-point Likert-type scale, at the cost of granularity.

[5] This was motivated by the observation that the quality of work produced by judges is relatively constant (Gao et al., 2015).

Description	Texts			Quality	
	Source	Target	Avg CPS	Meaning	Grammar
All	6,169	26,423	4.28	2.78	2.82
Per Source Length					
1-Sent	3,764	15,523	4.12	2.78	2.81
2-Sent	2,405	10,900	4.53	2.78	2.83

Table 3: Overview of the dataset, presenting the overall number of source and target texts, the average quality of the compressed texts, and breakdown by length of source (number of sentences).

Table 3 shows the number of compressions in the cleaned dataset, as well as the average number of compressions per source text (CPS) and the average meaning and grammar scores. Meaning quality and grammaticality scores are relatively good, averaging 2.78 and 2.82 respectively. The filtered crowdsourced compressions were most frequently judged to retain the most important meaning (80% of the time), or much of the meaning (17% of the time), with the lowest rating of 1 appearing only 3% of the time. This distribution is quite different from that of automatic compression systems in Section 4.

We provide a standard split of the data into training, development and test sets.[6] There are 4,936 source texts in the training, 448 in the development, and 785 in the test set.

3.2 Inter-Annotator Agreement

Crowd Workers: Since a different set of judges performs each task, large sets of inputs judged by the same two raters are unavailable. To simulate two raters, we follow Pavlick and Tetrault (2016): for each sentence, we randomly choose one annotator's output as the category for annotator A, and select the rounded average ranking for the remaining annotators as the category for annotator B. We then compute quadratic weighted κ (Cohen, 1968) for this pair over the whole corpus. We repeat the process 1000 times to compute the mean and variance of κ. The first row of the Table 4 reports the absolute agreement and κ, where the absolute agreement measures the fraction of times that A is equal to B. The 95% confidence intervals for κ are narrow, with width at most .01.

[6]The dataset can be downloaded from the project's website `https://www.microsoft.com/en-us/research/project/intelligent-editing/`.

Description	**Meaning**		**Grammar**	
	Agreement	κ	**Agreement**	κ
worker versus worker	.721	.306	.784	.381
expert versus expert	.888	.518	.890	.514
expert versus worker	.946	.549	.930	.344

Table 4: Agreement on meaning preservation and grammatically between crowd workers and experts.

Expert Raters: A small sample of 116 sentence pairs was rated by two expert judges. We used quadratic weighted κ directly, without sampling. To assess agreement between experts and non-experts, we computed weighted κ between the (rounded) average of the expert judgments and the (rounded) average of the crowd judgments, using 25,000 bootstrap replications each. The results are shown in the last two rows of Table 4. The confidence intervals for κ are wide due to the small sample size, and span values up to .17 away from the mean. Overall, agreement of experts with the average crowdsourced ratings is moderate (approaching substantial) for meaning, and fair for grammar.

3.3 Analysis of Editing Operations

Frequency analysis: To analyze the editing operations used, we applied the state-of-the-art monolingual aligner Jacana (Yao et al., 2013) to align input to compressed texts. Out of the 26,423 compressions collected, 25.2% contained only token deletions. Those containing deletion and reordering amounted to a mere 9.1%, while those that also contain substitution or rephrasing (abstractive compressions) is 65.6%. Although abstraction is present in the large majority of compressions, these statistics do not indicate that paraphrasing is more prevalent than copying at the token level. The word alignments for target compression words indicate that 7.1% of target tokens were inserted, 75.4% were copied and 17.3% were paraphrased. From the alignments for source text words, we see that 31% of source words were deleted. The fraction of inserted and deleted words is probably overestimated by this approach, as it is likely that sequences of source words were abstracted as shorter sequences of target words in many-to-one or many-to-many alignment patterns that are difficult to detect automatically.

For the subset of examples where the input text

Operation	Meaning		Grammar

1-Sentence	2.78	2.82

Table 6: Meaning and grammaticality judgments for compressing two sentences jointly versus individually. **p $<$ 0.0001.

contained more than one sentence, we computed the frequency of sentence-merging and sentence deletion when compressing. Of the compressions for two-sentence paragraphs, 72.4% had two sentences in the output, 0.4% had one sentence deleted, and 27.3% had the two source sentences merged.

Impact of operations: Because the dataset contains multiple compressions of the same sources, we are able to estimate the impact of different editing operations. These were classified using the Jacana word alignment tool. Table 5 presents the average judgment scores for meaning preservation and grammaticality for four operations. The upper two rows apply to all texts, the lower two to two-sentence paragraphs only. The statistical significance of their impact was tested using the Wilcoxon signed-rank test on paired observations. It appears that raters view compressions that involve substitutions as significantly more meaning-preserving than those that do not ($p < 0.0001$), but judge their grammaticality to be lower than that of deletion-based compressions. Note that the reduced grammaticality may be due to typographical errors that have been introduced during rephrasing, which could have been avoided had a more powerful word processor been used as an editing platform. Reordering has no significant impact on meaning, but leads to substantial degradation in grammatically. Conversely, abridgments that merge or delete sentences are rated as significantly less meaning preserving, but score higher for grammaticality, possibly reflecting greater skill on the part of those editors..

Impact of sentence context: Table 6 shows that the context provided by 2-sentence sources yields significantly improved scores for both meaning and grammaticality. Here we used the matched pairs design to compare the average quality of two-sentence paragraph compressions with the average quality of the compressions of the same paragraphs produced by separately compressing the two sentences.

4 Evaluating Evaluation Metrics

Progress in automated text compression is standardly measured by comparing model outputs at the *corpus* level. To train models discriminatively and to perform fine-grained system comparisons, however, it is also necessary to have evaluation of system outputs at the *individual input* level. Below, we examine automated metric correlation with human judgments at both levels of granularity.

4.1 Automatic Metrics

The goal of this analysis is to develop an understanding of the performance of automatic evaluation metrics for text compression, and the factors contributing to their performance. To this end, we group automatic metrics according to three criteria. The first is the *linguistic units* used to compare system and reference compressions. Prior work on compression evaluation has indicated that a parse-based metric is superior to one based on surface substrings (Clarke and Lapata, 2006), but the contribution of the linguistic units has not been isolated, and surface n-gram units have otherwise been successfully used for evaluation in related tasks (Graham, 2015). Accordingly, we empirically compare metrics based on surface uni-grams (LR-1), bi-grams (LR-2), tri-grams (LR-3), and four-grams (LR-4), as well skip bi-grams (with a maximum of four intervening words as in ROUGE-S4) (SKIP-2), and dependency tree triples obtained from collapsed dependencies output from the Stanford parser (PARSE-2).[7] The second criterion is the *scoring measure* used to evaluate the match between two sets of linguistic units corresponding to a system output and a reference compression. We compare Precision, Recall, F-measure, and Precision+Brevity penalty (as

[7] Clarke and Lapata (2006) used the RASP parser (Briscoe and Carroll, 2002), but we expect that the Stanford parser is similarly robust and would lead to similar correlations.

in BLEU). The third criterion is whether *multiple references* or a *single reference* is used, and in the case of multiple references, the method used to aggregate information from multiple references. We investigate two previously applied methods and introduce a novel approach that often outperforms the standard methods.

To illustrate, we introduce some notation and use a simple example. Consider a sub-phrase of one of the sentences in Table 1, *think about your household*, as an input text to compress. Let us assume that we have two reference compressions, R1: *imagine your household*, and R2: *your household*. Each metric m is a function from a pair of a system output o and a list of references $r_1, r_2, \ldots, r_k$ to the reals. To compute most metrics, we first compute a linguistic unit feature vector for each reference $\Phi(r_j)$, as well as for the set of references $\Phi(r_1, r_2, \ldots, r_k)$. Similarly, we compute a linguistic unit vector for the output $\Phi(o)$ and measure the overlap between the system and reference vectors. The vectors of the example references, if we use surface bigram units, would be, for R1, {`imagine_your:1`, `your_household:1`}, and for R2, {`your_household:1`}. The weights of all n-grams in individual references and system outputs are equal to 1.[8] If we use dependency-parse triples instead, the vector of R2 would be {`nmod:poss(household, your):1`}.

The precision of a system output against a reference is defined as the match $\Phi(r)^T\Phi(o)$ divided by the number of units in the vector of o; the latter can be expressed as the L_1 norm of $\Phi(o)$ because all weights are positive: $\text{Precision}(o, r) = \frac{\Phi(r)^T\Phi(o)}{|\Phi(o)|_1}$. The recall against a single reference can be similarly defined as the match divided by the number of units in the reference: $\text{Recall}(o, r) = \frac{\Phi(r)^T\Phi(o)}{|\Phi(r)|_1}$.

We distinguish three methods for aggregating information from multiple references: MULT-MAX which uses the single reference out of a set that results in the highest single-reference score, and two further methods, MULT-ALL and MULT-PROB, that construct an aggregate linguistic unit vector $\Phi(r_1, \ldots, r_k)$ before matching. MULT-ALL is the standard method used in multi-reference BLEU, where the vector for a set of references is defined as the union of the features of the set. For our example, the combined vector of R1 and R2 is equal to the vector of R1, because R2 adds no new bigrams. MULT-PROB, a new method that we propose here, is motivated by the observation that although judgments of importance of content are subjective, the more annotators assert some information is important, the more this information should contribute to the matching score.[9] In MULT-PROB we define the weight of a linguistic unit in the combined reference vector as the proportion of references that include the unit. For our example, $\Phi_{\text{MULT-PROB}}(R1, R2)$ is {`imagine_your`:.5, `your_household`:1}.

4.2 Models for Text Compression

For the purpose of analysis, we trained and evaluated four compression systems. These include both deletion-based and abstractive models: (1) ILP, an integer linear programing approach for deletion-based compression (Clarke and Lapata, 2008), (2) T3, a tree transducer-based model for abstractive compression (Cohn and Lapata, 2008), (3) Seq2seq, a neural network model for deletion-based compression (Filippova et al., 2015), and (4) NAMAS, a neural model for abstractive compression and summarization (Rush et al., 2015). We are not concerned with the relative performance of these models so much as we are concerned with evaluating the automatic evaluation metrics themselves. We have sought to make the models competitive, but have not required that all systems use identical training data.

All of the models are evaluated on the test set portion of our dataset. All models use the training portion of the data for training, and two models (Seq2Seq and NAMAS[10]) additionally use external training data. The external data is summarized in Table 7. The Gigaword set was extracted from the Annotated Gigaword (Napoles et al., 2012), using the implementation provided by Rush et al. (2015). The Headline data was extracted in similar fashion using an in-house news collection.

[8] We handle repeating n-grams by assigning each subsequent n-gram of the same type a distinct type, so that the i-th *the* of a system output can match the i-th *the* of a reference.

[9] A similar insight was used in one of the component metrics of the SARI evaluation metric used for text simplification evaluation (Xu et al., 2016).

[10] The original works introducing these models employed much larger training corpora, believed to be key to improving the accuracy of neutral network models with large parameter spaces.

Data		#src tokens	#trg tokens	#sents
Abstractive	Gigaword	114.1M	30.0M	3.6M
	Headline	6.0M	1.4M	0.2M
Deletion-based	Gigaword	1,353K	329K	47K
	Headline	59K	11K	2K

Table 7: External data statistics.

ILP: We use an open-source implementation[11] of the semi-supervised ILP model described in (Clarke and Lapata, 2008). The model uses a trigram language model trained on a 9 million token subset of the OANC corpus. The ILP model requires parsed sentences coupled with deletion-based compressions for training, so we filtered and preprocessed our dataset to satisfy these constraints. We used all single sentence inputs with their corresponding deletion-based compressions, and additionally used two-sentence paragraph input/output pairs split into sentences by heuristically aligning source to target sentences in the paragraphs.

T3: We use the authors' implementation of the tree transducer system described in Cohn and Lapata (2008). T3 similarly requires sentence-level input/output pairs, but can also learn from abstractive compressions. We thus used a larger set of approximately 28,000 examples (single sentences with abstractive compressions taken directly from the data or as a result of heuristic sentence-level alignment of two-sentence paragraphs). We obtained parse trees using the Stanford parser (Klein and Manning, 2003), and used Jacana (Yao et al., 2013) for word alignment. The performance obtained by T3 in our experiments is substantially weaker (relative to ILP) than that reported in prior work (Cohn and Lapata, 2008). We therefore interpret this system output solely as data for evaluating automatic metrics.

NAMAS: We run the publicly available implementation of NAMAS[12] with the settings described by Rush et al. (2015). We modified the beam search algorithm to produce output with a compression ratio similar to that of the human references, since this ratio is a large factor in compression quality (Napoles et al., 2011), and systems generally perform better if allowed to produce longer output, up to the maximum length limit. We enforced output length between 50% and 75% of input length, which resulted in improved performance.

Seq2seq: We implemented the sequence-to-sequence model[13] described in Filippova et al. (2015). A deletion-based model, it uses the deletion-based subset of our training dataset and the deletion-based subset from the external data in Table 7. The encoder and decoder have three stacked LSTM layers, the hidden dimension size is 512, and the vocabulary size is 30,000. The compression rate was controlled in the same range as for the NAMAS model.

All models produce output on all inputs in the test set. For all models, we generated outputs for multi-sentence inputs by concatenating outputs for each individual sentence.[14]

4.3 Results

Overall, we consider 80 metric variants, consisting of combinations of six types of linguistic units, combined with three scoring methods (Precision, Recall, and F-measure) and four settings of single reference SINGLE-REF or three ways of scoring against multiple references MULT-ALL,MULT-MAX,MULT-PROB. Additionally, we include the standard single and multi-reference versions of BLEU-2,BLEU-3,BLEU-4, and ROUGE-L.

We compare automatic metrics to human judgements at the level of individual outputs or groups of outputs (the whole corpus). For a single output o, the human quality judgment is defined as the average assigned by up to five human raters. We denote the meaning, grammar, and combined quality values by $M(o)$, $G(o)$, and $C(o) = .5M(o) + .5G(o)$, respectively. We define the quality for a group of outputs as the arithmetic mean of judgments over the outputs in the group. We use the arithmetic mean of automating metrics at the individual output level to define automatic corpus quality metrics as well.[15] To compare different metrics and establish statistical significance of the difference between two metrics, we use Williams test of the significance of the difference

[11] https://github.com/cnap/sentence-compression

[12] https://github.com/facebook/NAMAS

[13] https://github.com/ketranm/tardis

[14] In small scale preliminary manual evaluation, we found that, although some models are theoretically able to make use of context beyond the sentence boundary, they performed better if they compressed each sentence in a sequence independently.

[15] This method has been standard for ROUGE, but has not for BLEU. We find that averaging sentence-level metrics is also advantageous for BLEU .

System	Meaning	Grammar	Combined
T3	1.14	1.40	1.26
NAMAS	1.56	1.30	1.43
Seq2Seq	1.64	1.51	1.57
ILP	2.28	2.22	2.25

between dependent Pearson correlations with human judgments (Williams, 1959) as recommended for summarization evaluation (Graham, 2015) and other NLP tasks (e.g. (Yannakoudakis et al., 2011)).

4.3.1 Corpus-level metrics

Table 8 shows the average human ratings of the four systems, separately in meaning and grammar, as well as the combined measure (an arithmetic mean of meaning and grammar judgments). Even though the performance of some systems is similar, the differences between all pairs of systems in meaning and grammar are significant $p < 0.0001$ according to a paired t-test. It is interesting to note that ILP outperforms the more recently developed neural network systems Seq2Seq and NAMAS. This might seem to contradict recent results showing that the new models are superior to traditional baselines, such as ILP. We note however that performance on the test corpus in our study might not substantially improve through the use of large automatically mined data-sets of headlines and corresponding news article sentences, due to differences in genre and domain. Using such data-sets for effective training of neural network models for non-newswire domains remains an open problem.

For each of the 80 metrics, we compared the ranking of the four systems with the ranking according to average human quality. Fifty three of the metrics achieved perfect Spearman ρ and Kendall τ_B correlation with human judgments of combined meaning and grammar quality. Due to the small sample size (four systems), we are unable to find statistically significant differences among metrics at the corpus level. We only note that precision-based metrics involving large linguistic units (four-grams) had negative correlations with human judgments. We can conclude, however, that evaluation at the corpus level is robust for a wide variety of standard metrics using linguistic units of size three or smaller.

4.3.2 Single input-level pairwise system comparisons

We can garner greater insight into the difference of metric performance when we compare metrics at the single input level. To gauge the ability of metrics to comparatively evaluate the quality of two systems, we compute single input-level correlations of automatic metrics with human judgments following the protocol of Galley et al. (2015). Each system A produces a sequence of outputs ${o_1}^A, \ldots, {o_n}^A$, corresponding to inputs $x_1, \ldots, x_n$. For each system output, we use $Q(a)$ to denote a generic human quality metric, varying over meaning, grammar, and their combination. For each pair of systems A and B, and each metric m, we compute the difference in quality for corresponding system outputs for each input x_i: $m({o_i}^A) - m({o_i}^B)$ and the difference in quality according to human judgments: $Q({o_i}^A) - Q({o_i}^B)$, and compute the correlation between these two sequences. We can thus compute the single input-level correlation between m and Q for each pair of systems A and B, resulting in a total of six correlation values (for the six pairs of systems) for each metric. For each pair of metrics m_1 and m_2, and for each pair of systems A and B, we compute the statistical significance of the difference between the Pearson correlations of these metrics with human judgements. We say that m_1 is significantly better than m_2 on the A vs. B comparison if its Pearson correlation with human quality Q is significantly better (according to the Williams test of the difference in dependent correlations) than that of m_2 with a p-value less than .05. We say that m_1 dominates m_2 overall if it is significantly better than m_2 on at least 80% of the pair-wise system comparisons.

Table 9 shows the main correlation results at the level of individual inputs. We report correlations with meaning, grammar, and combined quality separately. For each human quality metric, we see the top automatic metrics in the first group of rows. The top metrics are ones that, for at least 80% of the system comparisons, are not significantly dominated by any other metric. In addition, we show the impact of each of the three criteria: linguistic units, scoring measure, and multiple references, in corresponding groups of rows. For each linguistic unit type, we show the best-performing metric that uses units of

Table 9: Left to right: Pearson correlation of automatic metrics with human ratings for meaning, grammar, and combined quality.

this type. Similarly, for the other criteria, we show the best performing metric for each value of the criterion. Metrics with a * suffix in each group significantly dominate metrics with a $^{-}$ suffix. Metrics with a $^{-}$ suffix in a group are dominated by at least one other metric, possibly outside of the group. The lowest group of rows in each main column presents the performance of other metrics that cannot be classified directly based on the three criteria.

A high-level observation that can be made is that the correlations with meaning are much higher than the correlations with grammar. The best correlations in meaning can be classified as "strong", whereas the best correlations in grammar are in the "medium" range. Unigrams are heavily dominated by higher order n-grams in all settings. Four-grams are also weaker that other units in measuring meaning preservation. Dependency triple (parse-based) metrics are strong, in particular in measuring grammaticality, but do not significantly dominate skip bi-grams or contiguous bi-grams. The scoring measure used has a strong impact. We see that precision-based metrics are substantially dominated by metrics that incorporate recall, except for grammar evaluation. Importantly, we see that multiple references contribute substantially to metric quality, as all methods that use multiple references outperform single-reference metrics. In both meaning and combined evaluation, this difference was statistically significant. Finally, we observe that standard BLEU metrics and ROUGE-L were not competitive.

5 Conclusion

We have introduced a large manually collected multi-reference abstractive dataset and quantified the impact of editing operations and context on human compression quality, showing that substitution and rephrasing operations are more meaning preserving than other operations, and that compression in context improves quality. Further, in the first systematic study of automatic evaluation metrics for text compression, we have demonstrated the importance of utilizing multiple references and suitable linguistic units, and incorporating recall.

PaCCSS–IT: A Parallel Corpus of Complex–Simple Sentences for Automatic Text Simplification

Dominique Brunato, Andrea Cimino, Felice Dell'Orletta, Giulia Venturi
Istituto di Linguistica Computazionale "Antonio Zampolli" (ILC–CNR)
ItaliaNLP Lab - *www.italianlp.it*
{name.surname}@ilc.cnr.it

Abstract

In this paper we present PaCCSS–IT, a Parallel Corpus of Complex–Simple Sentences for ITalian. To build the resource we develop a new method for automatically acquiring a corpus of complex–simple paired sentences able to intercept structural transformations and particularly suitable for text simplification. The method requires a wide amount of texts that can be easily extracted from the web making it suitable also for less–resourced languages. We test it on the Italian language making available the biggest Italian corpus for automatic text simplification.

1 Introduction

The availability of monolingual parallel corpora is a prerequisite for research on automatic text simplification (ATS), i.e. the task of reducing sentence complexity by preserving the original meaning. This has been recently shown for different languages, e.g. English (Zhu et al., 2010; Woodsend and Lapata, 2011; Wubben et al., 2012; Siddharthan and Angrosh, 2014), Spanish (Bott and Saggion, 2011; Bott and Saggion, 2014), French (Brouwers et al., 2014), Portuguese (Caseli et al., 2009), Danish (Klerke and Søgaard, 2012), Italian (Brunato et al., 2015). While English can rely on large datasets like the well-known Parallel Wikipedia Simplification corpus (Coster and Kauchak, 2011; Zhu et al., 2010) and, more recently, the Newsela corpus (Xu et al., 2015), for other languages similar resources are difficult to acquire and tend to be very small, thus preventing the application of data–driven techniques to automatically induce simplification operations. This is true for the language we are considering, i.e. Italian, where the only documented corpus for text simplification contains approximately 1,000 aligned original and manually simplified sentences (Brunato et al., 2015).

In this paper we present *PaCCSS–IT*, a Parallel Corpus of Complex–Simple Aligned Sentences for ITalian. To build the resource we developed a new approach for automatically acquiring a large corpus of paired sentences containing structural transformations which can be used as a developmental resource for text simplification systems. The proposed approach relies on monolingual sentence alignment techniques which have been exploited in different scenarios such as e.g. paraphrase detection (Ganitkevitch et al., 2013; Barzilay and Lee, 2003; Dolan et al., 2004) and evaluation (Chen and Dolan, 2011), question answering (Fader et al., 2013), textual entailment (Bosma and Callison-Burch, 2007), machine translation (Marton et al., 2009), short answer scoring (Koleva et al., 2014), domain adaptation of dependency parsing (Choe and McClosky, 2015). Specifically in ATS, these techniques are typically applied to already existing parallel corpora; in this case the task of aligning the original sentence to its corresponding simple version can be tackled by applying similarity metrics that consider the TF/IDF score of the words in the sentence (Barzilay and Elhadad, 2003; Nelken and Shieber, 2006; Coster and Kauchak, 2011) or methods taking into account also the order in which information is presented (Bott and Saggion, 2011).

Differently from these methods, our approach

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 351–361,
Austin, Texas, November 1-5, 2016.

contains two important novelties: the typology of the starting data and consequently the methodology developed to build the complex–simple aligned corpus. To overcome the scarcity of large parallel corpora of complex and simple texts in less–resourced languages like Italian, we started from a wide amount of texts that can be easily extracted from the web for all languages. This makes our method less expensive since it does not need a manually created corpus of aligned documents.

The proposed alignment method has been strongly shaped by the perspective from which we investigate text simplification, i.e. syntactic rather than lexical simplification. While lexical simplification aims at the substitution of complex words by simpler synonyms, syntactic simplification attempts to reduce complexity at grammatical level (Bott and Saggion, 2014). As shown by comparative analyses of monolingual parallel corpora in many languages, syntactic simplification concerns transformations affecting e.g. verbal features, the order of phrases or the deletion of redundant or unnecessary words (Brunato et al., 2015; Bott and Saggion, 2014; Coster and Kauchak, 2011; Caseli et al., 2009). Following this second perspective we define a method for bootstrapping and pairing sentences that intercepts simplification operations at morpho–syntactic and syntactic level typically used by human experts when simplify real texts.

Section 2 illustrates the approach to automatically acquire the corpus of complex–simple aligned sentences. In Section 3, the approach is tested and tuned on a development corpus. In Section 4, our approach is applied on a large corpus thus obtaining the final corpus of paired sentences, named PaCCSS–IT. In this last section, we also provide a global evaluation of the whole process and a qualitative analysis of the linguistic phenomena related to sentence complexity that we intercepted.

2 The Approach

Our approach for automatically acquiring the collection of paired sentences combines three steps. In a first step, we devised an unsupervised methodology *i)* to collect pools of sentences from a large corpus with overlapping lexicon but possible different structures; *ii)* to rank the resulting candidate sentences according to a similarity metric intended to bootstrap lexical–equivalent pairs undergoing structural transformations. In the second step, the top–list of the ranked pairs was manually revised and used to develop a classifier based on lexical, morpho–syntactic and syntactic features to detect the sentences correctly paired. In the third step, the individual sentences of each pair were ordered with respect to linguistic complexity computed by using an automatic readability assessment tool.

This approach has been tuned on PAISÀ[1] (Lyding et al., 2014) and tested on ItWaC (Baroni et al., 2009). The two analysed corpora were automatically POS tagged by the Part–Of–Speech tagger described in Dell'Orletta (2009) and dependency–parsed by the DeSR parser (Attardi et al., 2009).

PAISÀ is a freely distributed corpus of texts with Creative Commons license automatically harvested from the web. This corpus includes approximately 388,000 documents for a total of 250 millions of tokens and it is a large existing corpus of authentic contemporary texts in Italian which is free of copyright restrictions. ItWaC is the largest existing corpus of authentic contemporary texts in Italian. It is a 2 billion word corpus constructed from the Web limiting the crawl to the .it domain and using medium-frequency words from *La Repubblica* journalistic corpus and Basic Italian Vocabulary lists as seeds.

2.1 Unsupervised Step

The first step is aimed at clustering all sentences contained in a large corpus. To be included in the same cluster, the sentences have to share all lemmas tagged with the Part–Of–Speech (POS) "noun", "verb", "numeral", "personal pronoun" and "negative adverb". Nouns and verbs were selected because they capture the informational content of a sentence. The other functional categories have also to be shared, otherwise the meaning of the sentence would be altered. For example, the deletion of the negative adverb *non* (not) in one of the two following sentences would convey the opposite meaning: *Non farei mai una cosa del genere!* (I would never do something like that) *Non potevo fare una cosa del genere.* (I could not do something like that). In

[1] http://www.corpusitaliano.it/

the overlapping process we did not take into account the linear order of the considered lemma POS. This was meant to capture lexically–equivalent sentences undergoing potential structural transformations (e.g. passivization, topicalization).

All sentences within the same cluster were paired and the pairs were ranked for similarity by calculating the cosine distance between the sentence vectors. Each vector is constituted by the frequencies in the cluster of all lemma of the sentence. The cosine similarity served to discard different and equal or quasi–equal sentences.

The whole unsupervised step was used to select the set of candidate pairs reducing the number of pairs on which the following supervised step had been applied.

2.2 Supervised Step

The supervised step is meant to classify whether candidate pairs were correctly or incorrectly aligned. To this end, we built a classifier based on Support Vector Machines with a quadratic kernel using LIBSVM (Chang and Lin, 2001) that was trained on a corpus of paired sentences correctly aligned. The classifier used different types of linguistic features, i.e. lexical, morpho–syntactic and syntactic, meant to mainly capture structural transformations occurring in the paired sentences.

These features were extracted both calculating their distribution in each sentence and considering their overlap between the two paired sentences. They can be classified into the following types:

cosine similarity feature: it refers to the cosine value calculated for each pair of sentences;

raw text feature: it refers to the sentence length calculated in terms of i) tokens of each of the two paired sentences and ii) the different number of tokens between the two sentences;

lexical features: they refer to i) the lemma unigrams contained in the two sentences excluding the PoS already considered in the pairing process (i.e. nouns, verbs, numerals, personal pronouns, negative adverbs); ii) the distribution of word unigrams overlapping between the two paired sentences considering all PoS.

morpho–syntactic feature: it refers to the distribution of up to 4–grams of coarse grained Parts–Of–Speech;

syntactic features: they refer to i) the distribution of up to 4–grams of dependency types calculated with respect to the hierarchical parse tree structure and the surface linear ordering of words; ii) the distribution of up to 4–grams of coarse grained Parts–Of–Speech of a dependent (d) involved in a dependency relation and the dependency relation type (t) with respect to the hierarchical parse tree structure.

2.3 Readability Assessment Step

In the third step, the individual sentences of each classified pair were ordered with respect to linguistic complexity computed by using an automatic readability assessment tool. In text simplification research it is widely accepted the use of readability assessment metrics for evaluating the transformations that reduce sentence complexity (Zhu et al., 2010; Woodsend and Lapata, 2011; Vajjala and Meurers, 2016). Since our approach is devoted to building resources for developing ATS systems, we relied on readability assessment techniques to rank the individual sentences of the pair. To this aim, we used READ–IT (Dell'Orletta et al., 2011), the only existing NLP–based readability assessment tool devised for Italian. It operates on syntactically parsed texts and assigns to each sentence a score quantifying its readability. The assigned readability score ranges between 0 (easy–to–read) and 1 (difficult–to–read) referring to the percentage probability for the documents or sentences to belong to the class of difficult–to–read documents. The two poles were defined on two typologies of texts belonging to the same textual genre (i.e. newswire texts) but intended for different users: adults with a rudimentary literacy level or with mild intellectual disabilities for the easy–to–read pole and readers of a national daily newspaper considered of medium difficulty for $\sim$70% of Italian laymen for the difficult–to–read pole.

3 Tuning Process and Evaluation

In order to tune and evaluate each step of the proposed approach, we tested it on PAISÀ. We first pruned from the corpus the sentences with a number of tokens <5 and >40. The resulting sentences were then grouped with respect to their shared POS (i.e. nouns, verbs, numerals, personal pronouns and negative adverbs) and paired using cosine similarity.

Cosine	nº *correct* pairs	% *correct* pairs
0.92	54	12.03
0.91	151	29.49
0.90	91	26.76
0.89	157	23.36
0.88	331	48.04
0.87	336	68.15
0.86	674	57.36
0.85	107	57.22
0.84	176	61.75
0.83	1096	40.35
0.71	1092	38.97
0.70	62	27.80
	Total: 4,327	

Table 1: Absolute number and % distribution of *correct* extracted pairs for each manually reviewed cosine threshold in PAISÁ.

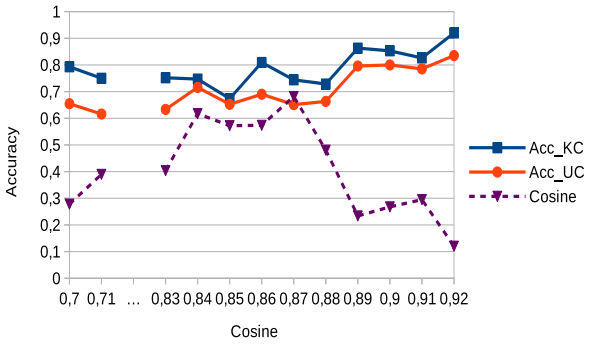

Figure 1: Accuracy of the *KC* and *UC* experiments compared with the distribution of correctly paired sentences at different cosine similarity scores.

We obtained 256,383 clusters containing at least two sentences. In order to discard different and equal or quasi–equal sentences we empirically set two cosine pruning thresholds: we discarded pairs with cosine below 0.4 since they were too lexically different and above 0.93 since they were too identical.

To build the training set for the supervised step we selected a subset of pairs resulting from the unsupervised step at different cosine similarity scores. This subset was manually reviewed by two native–speaker linguists with a background in text simplification. Specifically, they reviewed a subset of 10,543 pairs at different cosine similarity scores, i.e. those comprised between 0.92 and 0.83. In order to evaluate sentence similarity at lower values we also selected cosine scores 0.71 and 0.70. In the end, we obtained 4,327 correct pairs (i.e. about 41% of the whole set of candidate sentence pairs) distributed as in Table 1.

This manually revised set of pairs was then used to test the classifier in two different experimental scenarios. In the first one, named *Known Cosine, KC*, we tested the classifier in a five–fold cross validation process where pairs of sentences belonging to all the cosine scores were contained in each training and test set. In the second experiment, named *Unknown Cosine, UC*, the manually–revised corpus was differently split. In this case, the test set was composed by pairs of sentences with a cosine similarity score not contained in the training set and consequently twelve classification runs were performed.

In order to assess the discriminating power of the linguistic features used in the classification, we carried out an Information Gain analysis. This analysis showed the effectiveness of all the selected features in both experiments (i.e. KC, UC). In particular, we observed that the best ranked features are the morpho–syntactic and syntactic ones. This might suggest that our classification approach is intercepting pairs of sentences undergoing different typologies of structural transformations involving e.g. the use of verbal features or the order of phrases. Sentence length and lexical features play a lower discriminative role with respect to the grammatical features; this follows from the constraints we put on the unsupervised sentence pairing process. As it can be expected, the best ranked features are those providing information about the overlapping characteristics of the paired sentences.

Figure 1 and 2 report the results for each cosine threshold considered in the manual revision of the two experiments respectively in terms of *i)* Accuracy in the classification of the *correct* and *incorrect* alignments, and of *ii)* Precision, Recall of the classification of the *correct* alignments. As it can be noted in Figure 1, in both experiments the classifier is able to outperform the process of sentence pairing based only on the cosine (i.e. line *Cosine*, that represents the unsupervised step of the pairing process). As we can expect, Precision, Recall and Accuracy of the *KC* experiment are higher than the classification results obtained in the *UC*. The latter represents a more

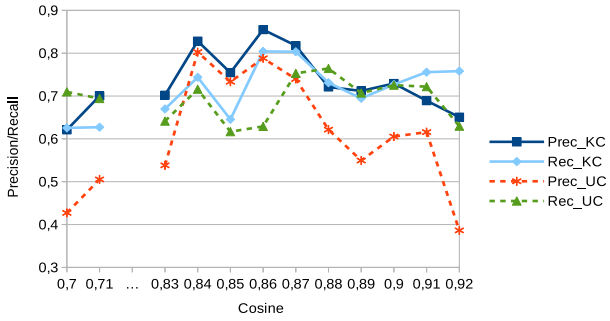

Figure 2: Precision and Recall of the two experiments (*KC* and *UC*) in the classification of the *correct alignments*.

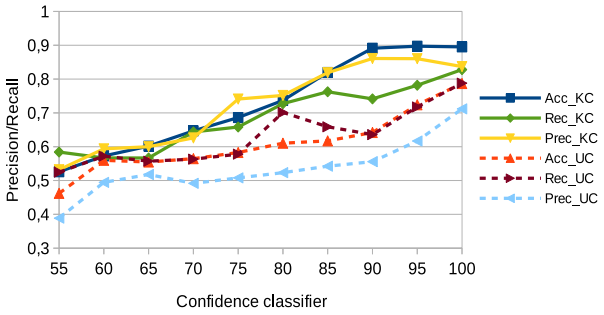

Figure 3: Classifier performance in the *KC* and *UC* experiments with probability intervals reported along the *x* axis.

challenging experimental scenario where the classifier is tested on a cosine threshold unseen in training. The overall results for the *KC* and the *UC* experiments are respectively 73.95% and 58.71% in terms of Precision, 70.3% and 68.1% in terms of Recall; and respectively 77.64% and 67.2% in terms of Accuracy. These results are significantly higher when compared with the accuracy of 41% reported for the unsupervised alignment (i.e. line *Cosine*). Interestingly, in the *KC* experiment, Precision and Recall lines are close and they remain stable with respect to all cosines even if the distribution of correct pairs varies in the different cosine values.

Figure 3 shows the accuracy of our classifier at different confidence thresholds (i.e. the probability assigned by the classifier for the *correct* alignments) for both the *KC* and *UC* experiments. Note that for each confidence intervals we have a different number of total pairs, and of gold-correct alignments and gold-incorrect alignments. As expected, the performance grows as the confidence grows. Interestingly, in the *KC* scenario, the classifier reached up to 90% of accuracy in discriminating the *correct* from the *incorrect* alignments when the classifier has a confidence score $\geq$0.90. These results look very promising if we consider that 30% of the pairs of the whole test set classified as correct alignments is comprised in the subset for which the classifier is more confident. This is also the case of the *UC* experiment, where, even if with lower accuracies, more than 56% of the *correct* alignments occurs when the classifier has a confidence score $\geq$0.90.

We carried out a last evaluation to estimate the classifier performance in the *UC* scenario for low cosine ranges not comprised in the manually revised portion of the corpus (from 0.45 to 0.75, excluding cosines 0.70 and 0.71). We considered only the pairs classified as *correct* with a confidence score of $\geq$85%. As expected, the system performance grows as the cosine grows: only few correct pairs occur at cosine $<$0.60, at cosine 0.60–0.65 the classifier assigns the *correct* class 237 times with an accuracy of 62.97%, at 0.65–0.69 330 times with 71.82% and at 0.72–0.75 256 times with an accuracy of 87.89%. According to these evaluations, we extracted from PAISÁ those pairs with a confidence score $\geq$ 85% and cosine similarity between 0.6 and 0.93, resulting in a collection of about 20,000 pairs.

In the last step, the sentences in each pair were ranked according to the readability score automatically assigned by READ–IT making a collection of complex–simple aligned sentences. However, the average difference of the readability score between the complex and simple sentences is only 0.13, making this collection not so useful for ATS. For this reason, we selected only pairs with a difference of readability score higher than a significant threshold set at 0.2. We defined this threshold on the basis of previous empirical experiments carried out using READ-IT on different typologies of texts. Lower variations of READ-IT score are scarcely perceived by human subjects. Since the construction of this resource has been specifically designed to develop ATS systems for human target, this READ-IT variation is a fundamental parameter of PaCCSS-IT. We thus obtained about 4,450 pairs.

4 PaCCSS–IT

The unsupervised step applied to ItWaC resulted in ∼28 million of clusters with overlapping lexicon for a total of ∼35 million of single sentences. From this initial set we pruned sentences with a number of tokens <5 and >40 and clusters containing less than two sentences. We obtained 419,252 clusters for a total of ∼8,5 million of single sentences and an average number of pairs in each cluster of 1,613. Filtering the pairs according to the cosine similarity range defined in the development step, we obtained a subset of 73,142 clusters with an average of ∼112 pairs for each. The classifier with the same model tested on PAISÁ recognised about 1 million of *correct* aligned pairs. Excluding pairs below the confidence score $\geq$ 85% we obtained ∼284,000 pairs. This collection was further pruned selecting only those pairs with at least 0.2 points in terms of variation in readability score. PaCCSS–IT is the resulting resource. It is a freely available resource [2] composed of ∼63,000 pairs of sentences (∼126k sentences) ranked with respect to the readability score of the two sentences. For each pair the cosine similarity, the probability score of the classifier and the readability level of the sentences are provided.

The following sections report the evaluation and the qualitative analysis we carried out on PaCCSS–IT. The evaluation was performed to assess the reliability of sentence alignment and of the sentence ranking with respect to readability level. The qualitative analysis was focused on studying which linguistic phenomena typically related to text simplification are successfully intercepted by our approach in order to show the applicability of the resource in a ATS scenario.

4.1 Evaluation

The evaluation process was intended to calculate the accuracy of i) the automatic classification process in predicting correct sentence alignments and ii) the automatic readability ranking of each pair.

The alignment evaluation was carried out by two trained linguists who manually revised 40 pairs of randomly selected sentences for each cosine score (1,088 paired sentences). It resulted that 85% of pairs were correctly classified (i.e. 921 pairs) and precision increases as cosine grows (from 73.2% at cosine 0.65-0.69 to 90.8% at cosine 0.90-0.92).

The subset of 921 pairs correctly classified was further investigated with respect to the readability level automatically assigned. To this aim we elicited human judgements through the crowdsourcing platform CrowdFlower[3]. We collected judgements from 7 workers that were asked to rate for each pair which of the two individual sentences was simpler. We considered the majority label to be true label for each pair. Comparing the score obtained by our system with the human judgements we obtained an accuracy of 74%. Restricting the evaluation only to pairs with the same label assigned by at least five out seven annotators (i.e. 79% of the whole pairs), the system achieved an accuracy of 78%.

4.2 Qualitative Analysis

Two qualitative analyses were carried out on PaCCSS–IT. The first analysis took into account the subset of 921 revised pairs with the aim of manually investigating what kinds of sentence transformations previously observed in the literature on text simplification were intercepted by our approach. In the second one, the whole resource was automatically investigated to study how the alignment process impacts on the distribution of multi–level linguistic features correlated to sentence complexity.

4.2.1 Analysis of Simplification Operations

Following the classification of simplification operations proposed in the literature (Brunato et al., 2015; Bott and Saggion, 2014; Coster and Kauchak, 2011; Caseli et al., 2009), we identified the major types of operations occurring in the subset of revised pairs [4], namely:

Deletion: the second sentence (S) does not contain one or more than two words occurring in the first one (C):

- C: *Ma c'è un altro problema, ancora più grave*. [Lit: But there is another problem, even more serious.]

[2] http://www.italianlp.it/software-data/

[3] www.crowdflower.com

[4] In each of the following examples the first sentence (C) is the complex sentence and the second (S) the simple one. We underlined the text span affected by the operation.

- S: *Poi c'è un altro problema*. [Lit: Then there is another problem.]

Verbal Features: the two sentences differ with respect to verbal mood and tense:

- C: *I suoi libri sono stati tradotti in molte lingue*. [Lit: His books have been translated in many languages.]

- S: *I suoi libri sono tradotti in diverse lingue*. [Lit: His books have been translated in different languages.]

Lexical Substitution: the two sentences contain synonyms of words tagged with POS which were not considered in the clustering step based on POS overlapping, e.g. adjectives, adverbs:

- C: *Il colore è un rosso rubino fittissimo, quasi impenetrabile, limpido*. [Lit: The color is a rubyred very dense, almost impenetrable, clear.]

- S: *Il colore è un rosso rubino vivo quasi impenetrabile*. [Lit: The color is a bright red ruby almost impenetrable.]

Reordering: the two sentences contain a different word order both at single word (e.g. subject in pre- vs. post-verbal position) and phrase level (e.g a subordinate clause proceeds vs. follows the main clause):

- C: *Ringraziandola per la sua cortese attenzione, resto in attesa di risposta*. [Lit: Thanking you for your kind attention, I look forward to your answer.]

- S: *Resto in attesa di una risposta e ringrazio vivamente per l'attenzione*. [Lit: I look forward to your answer and I thank you greatly for your attention.]

Insertion: the second sentence contains one or *n*-words more than the first one:

- C: *In attesa di un sollecito riscontro, distinti saluti*. [Lit: Waiting for an early reply, yours faithfully.]

- S: *In attesa di un riscontro porgiamo distinti saluti*. [Lit: Waiting for a reply, we offer our regards.]

Sentence Type: the two sentences differ with respect to their form (i.e. affirmative vs. interrogative):

- C: *Quale consiglio darebbe ai genitori?* [Lit: Which advice would you give to parents?]

- S: *Diamo un consiglio ai genitori*. [Lit: Let's give an advice to parents.]

For each operation there can be different degrees of sentence transformation. For example, focusing on *Verbal Feature*, the example reported above represents a "light" transformation while a "stronger" transformation can occur when the verb changes from the conditional to the indicative mood (or vice versa), as in the following pair:

- C: *Sarebbe un grave un errore*. [Lit: It would be a serious error.]

- S: *Ma è un grave errore*. [Lit: But it is a serious error.]

Figure 4 reports the distribution of these sentence operations in the manually revised portion of the corpus. The distribution in *All cosines* shows that the two most frequent operations are deletion (30.74%) and changes affecting verbal features (26.30%). According to the literature, the deletion of redundant information (e.g. adjectives, adverbs) is one of the main phenomena typically related to reduction of complexity. Also transformations of verbal features are likely to intercept simplification operations in a language like Italian with a rich inflectional paradigm. The third most frequent operation is lexical substitution (15.52%). According to the POS filter used in the unsupervised step of sentence alignment, this operation affects morpho–syntactic categories such as e.g. adverbs, adjectives, conjunctions or prepositions which are substituted with a simpler synonym. Reordering and insertion of words or phrases are respectively the fourth and the fifth types of transformation. Reordering can be expected as a simplification strategy especially when it yields a more canonical word order. The distribution of reordering here reported, i.e. 14.24%,

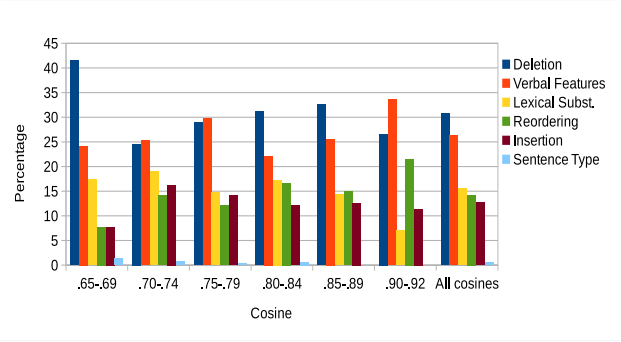

Figure 4: Distribution of sentence operations at different cosine ranges.

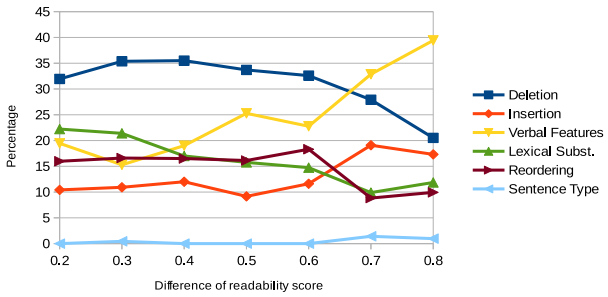

Figure 5: Distribution of sentence operations at different readability scores.

is quite high if compared to the distribution of the same operation found in hand-crafted simplified corpora where it represents about 8% of sentence operations (Brunato et al., 2015). This result gives evidence that our approach succeeds in automatically intercepting this kind of syntactic transformation. In the manually revised portion of PaCCSS–IT insertion represents 12.72% of the whole operations. Despite inserting words or phrases could make more complex a sentence, this operation is used in the simplification process e.g. when it makes explicit missing arguments in elliptical clauses more frequently used in non–standard language varieties or sublanguages such as legal language. This is the case of the heterogeneous nature of the corpus from which PaCCSS–IT derives, where documents characterized by non–canonical languages (e.g. blogs, e–mails) or domain–specific documents (e.g. administrative acts) are mixed to texts representative of more standard varieties, e.g. newspapers, novels.

Let us consider the relation between simplification operations, cosine values and readability levels. For what concerns the distribution of the operations at different cosines (Figure 4), we observe that deletion is the most frequent operation at all cosines, in particular at lower cosines i.e. $<.70$. At high cosines, i.e. $>.90$, operations affecting word order and verbal features increase. The relation between readability score and sentence operations is shown in Figure 5. Specifically, we calculated how the distribution of operations changes with increasing differences between the readability score assigned to the complex and the simple sentence of each pair. Although it is difficult to study the effect of each single operation on the readability score variation since these operations are usually applied in combination, we observe some clear tendencies. In particular, operations concerning deletion and verbal features are the most frequent ones both at lower and higher readability scores differences. However, they have an opposite distribution: transformations of verbal features increase at higher readability differences (>0.6) while deletions decrease. For what concerns the other operations, the trend is quite homogeneous along with the different readability scores. In particular, this is the case of reordering thus showing the proposed approach is able to intercept syntactic transformations which impact at different readability variations.

4.2.2 Analysis of Linguistic Phenomena

The second qualitative analysis focused on the whole resource which was searched for linguistic phenomena correlating with the process of sentence alignment. To this end, we compared the distribution of a set of different linguistic features, i.e. raw text, lexical, morpho–syntactic and syntactic, automatically extracted from the set of complex and simple sentences of PaCCSS–IT, which was previously tagged and dependency–parsed. In Table 2 we report a selection of the features with a statistically significant variation[5] between the complex and the simple sentences. As expected, the average sentence length (feature [1]) of the *Simple* sentence is lower than the *Complex* one. The higher distribution of adjectives [2], adverbs [3] and determiners [4] might be

[5]Wilcoxon's signed rank test was used to evaluate statistical significance.

related to the insertion of simple lexicon belonging to the Basic Italian Vocabulary (De Mauro, 2000). The distribution of verbal moods is also significantly correlated to a higher readability level: simple sentences have a higher percentage of indicatives [6] (a simple mood indicating a state of being or reality) and less participles [7] and gerundives [8] which are non finite moods and thus can be more ambiguous with respect to the reference. In addition, sentences classified as complex have higher parse trees [13], longer dependency links [14] and longer embedded complement chains modifying a noun [15], all features correlated with syntactic complexity (Gibson, 1998; Lin, 1986; Frazier, 1985). On the contrary, sentences classified as simple are characterised by a more canonical word order (Subject–Verb–Object in Italian) i.e. a lower distribution of post-verbal subjects [16] and of pre-verbal objects [17]. These sentences also contain a higher distribution of subordinate clauses following the main clause [18], an order easier to process.

Since syntactic features intercepting the structure of the sentence (e.g. parse tree depth and dependency length) heavily depend on the overall sentence length, we carried out an analysis only on pairs of sentences where the complex and the simple sentence have the same number of tokens (i.e. 15,958 pairs in PaCCSS–IT) and we compared how linguistic features vary between the complex and the simple sentences of these pairs. We observed that simple sentences have a more canonical position of the subject (i.e. a lower percentage distribution of post-verbal subjects: *C*: 18.14%, *S*: 15.72%) and of the object (i.e. a lower percentage distribution of pre-verbal objects: *C*: 1.52%, *S*: 1.18%). Simple sentences have also lower parsed trees (*C*: 2.42, *S*: 2.37) and shorter embedded complement chains modifying a noun (*C*: 0.27, *S*: 0.26). Since these variations cannot be due to sentence shortening, they rather follow from reordering phenomena e.g. changing from active to passive voice.

The distribution of linguistic features here reported has already been observed in hand–crafted corpora of complex and simple sentences for Italian (Brunato et al., 2015). This is a further evidence of the reliability of our method for automatically creating corpora of complex–simple sentences.

Feature	*Complex*	*Simple*	*Variation*
[1]	8.98	7.80	0.97
[2]	4.10	7.90	-3.80
[3]	9.10	10.0	-0.85
[4]	0.34	1.43	-1.10
[5]	10.70	20.30	-9.61
[6]	5.20	2.72	2.49

5 Conclusion

In this paper we have presented PaCCSS–IT, a corpus of complex–simple aligned sentences for Italian containing ∼63,000 paired sentences. To our knowledge, PaCCSS–IT is the biggest corpus of complex–simple aligned sentences, with the exception of English. It resulted from a new method for automatically acquiring corpora of parallel sentences able to capture structural transformations and particularly suitable for text simplification systems. A comparative analysis of the multi–level linguistic features in the complex and simple sentences showed that this method intercepts linguistic phenomena characterising simplification operations previously observed in manually–created complex–simple corpora. A main novelty of the proposed approach is that it does not rely on a large pre-existing corpus of aligned complex–simple documents like e.g. the English and Simple English Wikipedia. This makes it very appropriate for less–resourced languages. In addition, since the method does not need parallel corpora, the dimension of the web is the only limitation to the size of the corpus that could be created.

Abstract

RST-style document-level discourse parsing remains a difficult task and efficient deep learning models on this task have rarely been presented. In this paper, we propose an attention-based hierarchical neural network model for discourse parsing. We also incorporate tensor-based transformation function to model complicated feature interactions. Experimental results show that our approach obtains comparable performance to the contemporary state-of-the-art systems with little manual feature engineering.

1 Introduction

A document is formed by a series of coherent text units. Document-level discourse parsing is a task to identify the relations between the text units and to determine the structure of the whole document the text units form. Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) is one of the most influential discourse theories. According to RST, the discourse structure of a document can be represented by a Discourse Tree (DT). Each leaf of a DT denotes a text unit referred to as an Elementary Discourse Unit (EDU) and an inner node of a DT represents a text span which is constituted by several adjacent EDUs. DTs can be utilized by many NLP tasks including automatic document summarization (Louis et al., 2010; Marcu, 2000), question-answering (Verberne et al., 2007) and sentiment analysis (Somasundaran, 2010) etc.

Much work has been devoted to the task of RST-style discourse parsing and most state-of-the-art approaches heavily rely on manual feature engineering (Joty et al., 2013; Feng and Hirst, 2014; Ji and Eisenstein, 2014). While neural network models have been increasingly focused on for their ability to automatically extract efficient features which reduces the burden of feature engineering, there is little neural network based work for RST-style discourse parsing except the work of Li et al. (2014a). Li et al. (2014a) propose a recursive neural network model to compute the representation for each text span based on the representations of its subtrees. However, vanilla recursive neural networks suffer from gradient vanishing for long sequences and the normal transformation function they use is weak at modeling complicated interactions which has been stated by Socher et al. (2013). As many documents contain more than a hundred EDUs which form quite a long sequence, those weaknesses may lead to inferior results on this task.

In this paper, we propose to use a hierarchical bidirectional Long Short-Term Memory (bi-LSTM) network to learn representations of text spans. Comparing with vanilla recursive/recurrent neural networks, LSTM-based networks can store information for a long period of time and don't suffer from gradient vanishing problem. We apply a hierarchical bi-LSTM network because the way words form an EDU and EDUs form a text span is different and thus they should be modeled separately and hierarchically. On top of that, we apply attention mechanism to attend over all EDUs to pick up prominent semantic information of a text span. Besides, we use tensor-based transformation function to model complicated feature interactions and thus it can produce

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 362–371,
Austin, Texas, November 1-5, 2016.

combinatorial features.

We summarize contributions of our work as follows:

- We propose to use a hierarchical bidirectional LSTM network to learn the compositional semantic representations of text spans, which naturally matches and models the intrinsic hierarchical structure of text spans.
- We extend our hierarchical bi-LSTM network with attention mechanism to allow the network to focus on the parts of input containing prominent semantic information for the compositional representations of text spans and thus alleviate the problem caused by the limited memory of LSTM for long text spans.
- We adopt a tensor-based transformation function to allow explicit feature interactions and apply tensor factorization to reduce the parameters and computations.
- We use two level caches to intensively accelerate our probabilistic CKY-like parsing process.

The rest of this paper is organized as follows: Section 2 gives the details of our parsing model. Section 3 describes our parsing algorithm. Section 4 gives our training criterion. Section 5 reports the experimental results of our approach. Section 6 introduces the related work. Conclusions are given in section 7.

2 Parsing Model

Given two successive text spans, our parsing model evaluates the probability to combine them into a larger span, identifies which one is the nucleus and determines what is the relation between them. As with the work of Ji and Eisenstein (2014), we set three classifiers which share the same features as input to deal with those problems. The whole parsing model is shown in Figure 1. Three classifiers are on the top. The semantic representations of the two given text spans which come from the output of attention-based hierarchical bi-LSTM network with tensor-based transformation function is the main part of input to the classifiers. Additionally, following the previous practice of Li et al. (2014a), a small set of handcrafted features is introduced to enhance the model.

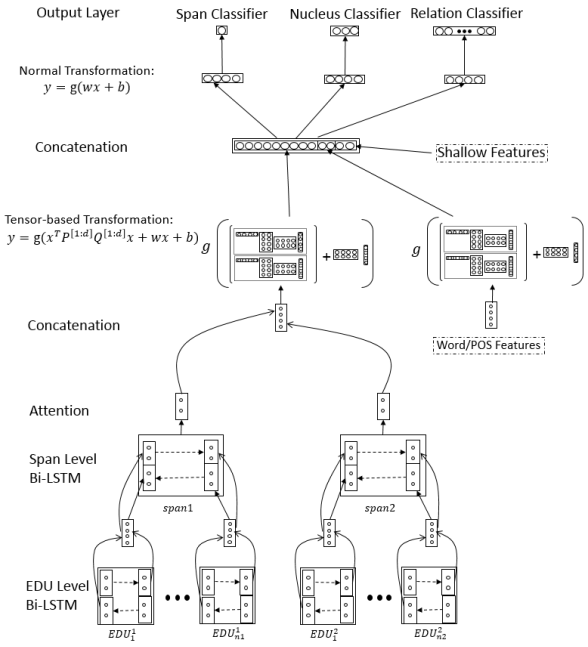

Figure 1: Schematic structure of our parsing model.

2.1 Hierarchical Bi-LSTM Network for Text Span Representations

Long Short-Term Memory (LSTM) networks have been successfully applied to a wide range of NLP tasks for the ability to handle long-term dependencies and to mitigate the curse of gradient vanishing (Hochreiter and Schmidhuber, 1997; Bahdanau et al., 2014; Rocktäschel et al., 2015; Hermann et al., 2015). A basic LSTM can be described as follows. A sequence $\{x_1, x_2, ..., x_n\}$ is given as input. At each time-step, the LSTM computation unit takes in one token x_t as input and it keeps some information in a cell state C_t and gives an output h_t. They are calculated in this way:

$$i_t = \sigma(W_i[h_{t-1}; x_t] + b_i) \quad (1)$$

$$f_t = \sigma(W_f[h_{t-1}; x_t] + b_f) \quad (2)$$

$$\tilde{C}_t = tanh(W_C[h_{t-1}; x_t] + b_C) \quad (3)$$

$$C_t = f_t \odot C_{t-1} + i_t \odot \tilde{C}_t \quad (4)$$

$$o_t = \sigma(W_o[h_{t-1}; x_t] + b_o) \quad (5)$$

$$h_t = o_t \odot tanh(C_t) \quad (6)$$

where $W_i, b_i, W_f, b_f, W_c, b_C, W_o, b_o$ are LSTM parameters, $\odot$ denotes element-wise product and σ denotes sigmoid function. The output at the last token, i.e., h_n is taken as the representation of the whole sequence.

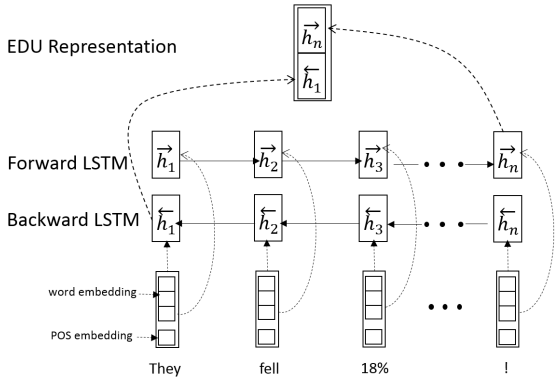

Figure 2: Bi-LSTM for computing the compositional semantic representation of an EDU.

Since an EDU is a sequence of words, we derive the representation of an EDU from the sequence constituted by concatenation of word embeddings and the POS tag embeddings of the words as Figure 2 shows. Previous work on discourse parsing tends to extract some features from the beginning and end of text units partly because discourse clues such as discourse markers(e.g., because, though) are often situated at the beginning or end of text units(Feng and Hirst, 2014; Ji and Eisenstein, 2014; Li et al., 2014a; Li et al., 2014b; Heilman and Sagae, 2015). Considering the last few tokens of a sequence normally have more influence on the representation of the whole sequence learnt with LSTM because they get through less times of forget gate from the LSTM computation unit, to effectively capture the information from both beginning and end of an EDU, we use bidirectional LSTM to learn the representation of an EDU. In other words, one LSTM takes the word sequence in forward order as input, the other takes the word sequence in reversed order as input. The representation of a sequence is the concatenation of the two vector representations calculated by the two LSTMs.

Since a text span is a sequence of EDUs, its meaning can be computed from the meanings of the EDUs. So we use another bi-LSTM to derive the compositional semantic representation of a text span from the EDUs it contains. The two bi-LSTM networks form a hierarchical structure as Figure 1 shows.

2.2 Attention

The representation of a sequence computed by bi-LSTMs is always a vector with fixed dimension despite the length of the sequence. Thus when dealing with a text span with hundreds of EDUs, bi-LSTM may not be enough to capture the whole semantic information with its limited output vector dimension. Attention mechanism can attend over the output at every EDU with global context and pick up prominent semantic information and drop the subordinate information for the compositional representation of the span, so we employ attention mechanism to alleviate the problem caused by the limited memory of LSTM networks. The attention mechanism is inspired by the work of Rocktäschel et al. (2015). Our attention-based bi-LSTM network is shown in Figure 3.

We combine the last outputs of the span level bi-LSTM to be $h_s = [\overrightarrow{h}_{e_n}, \overleftarrow{h}_{e_1}]$. We also combine the outputs of the two LSTM at every EDU of the span: $h_t = [\overrightarrow{h}_t, \overleftarrow{h}_t]$ and thus get a matrix $H = [h_1; h_2; ...; h_n]^T$. Taking $H \in \mathbb{R}^{d \times n}$ and $h_s \in \mathbb{R}^d$ as inputs, we get a vector $\alpha \in \mathbb{R}^n$ standing for weights of EDUs to the text span and use it to get a weighted representation of the span $r \in \mathbb{R}^d$:

$$M = tanh(W_y H + W_l h_s \otimes e_n) \quad (7)$$

$$\alpha = softmax(w_\alpha^T M) \quad (8)$$

$$r = H\alpha \quad (9)$$

where $\otimes$ denotes Cartesian product , $M \in \mathbb{R}^{k \times n}$, e_n is a n dimensional vector of all 1s and we use the Cartesian product $W_l h_s \otimes e_n$ to repeat the result of $W_l h_s$ n times in column to form a matrix and $W_y \in \mathbb{R}^{k \times d}, W_l, \in \mathbb{R}^{k \times d}, w_\alpha \in \mathbb{R}^k$ are parameters.

We synthesize the information of r and h_s to get the final representation of the span:

$$w_h = \sigma(W_{hr} r + W_{hh} h_s) \quad (10)$$

$$h = w_h \odot h_s + (1 - w_h) \odot r \quad (11)$$

where $W_{hr}, W_{hh} \in \mathbb{R}^{d \times d}$ are parameters, $w_h \in \mathbb{R}^d$ is a computed vector representing the element-wise weight of h_s and the element-wise weighted summation $h \in \mathbb{R}^d$ is the final representation of the text span computed by the attention-based bidirectional LSTM network.

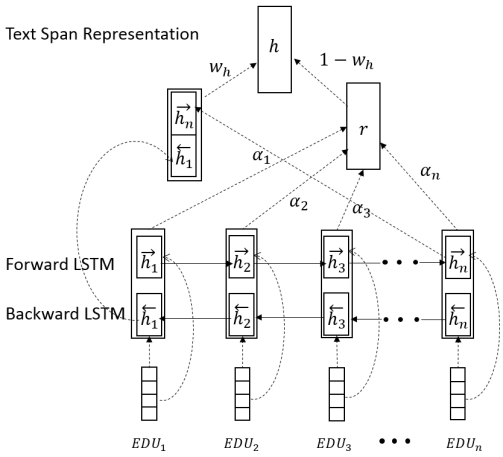

Figure 3: Attention-based bi-LSTM for computing the compositional semantic representation of a text span.

2.3 Classifiers

We concatenate the representations of the two given spans: $h = [h_{s1}, h_{s2}]$ and feed h into a full connection hidden layer to obtain a higher level representation v which is the input to the three classifiers:

$$v = Relu(W_h[h_{s1}, h_{s2}] + b_h) \quad (12)$$

For each classifier, we firstly transform $v \in \mathbb{R}^l$ into a hidden layer:

$$v_{sp} = Relu(W_{hs}v + b_{hs}) \quad (13)$$
$$v_{nu} = Relu(W_{hn}v + b_{hn}) \quad (14)$$
$$v_{rel} = Relu(W_{hr}v + b_{hr}) \quad (15)$$

where $W_{hs}, W_{hn}, W_{hr} \in \mathbb{R}^{h \times l}$ are transformation matrices and $b_{hs}, b_{hn}, b_{hr} \in \mathbb{R}^h$ are bias vectors.

Then we feed these vectors into the respective output layer:

$$y_{sp} = \sigma(w_s v_{sp} + b_s) \quad (16)$$
$$y_{nu} = softmax(W_n v_{nu} + b_n) \quad (17)$$
$$y_{rel} = softmax(W_r v_{rel} + b_r) \quad (18)$$

where $w_s \in \mathbb{R}^h, b_s \in \mathbb{R}, W_n \in \mathbb{R}^{3 \times h}, W_n \in \mathbb{R}^{3 \times h}, b_n \in \mathbb{R}^3, W_r \in \mathbb{R}^{n_r \times h}, b_n \in \mathbb{R}^{n_r}$ are parameters and n_r is the number of different discourse relations.

The first classifier is a binary classifier which outputs the probability the two spans should be combined. The second classifier is a multiclass classifier which identifies the nucleus to be span 1, span 2 or both. The third classifier is also a multiclass classifier which determines the relation between the two spans.

2.4 Tensor-based Transformation

Tensor-based transformation function has been successfully utilized in many tasks to allow complicated interaction between features (Sutskever et al., 2009; Socher et al., 2013; Pei et al., 2014). Based on the intuition that allowing complicated interaction between the features of the two spans may help to identify how they are related, we adopt tensor-based transformation function to strengthen our model.

A tensor-based transformation function on $x \in \mathbb{R}^{d_1}$ is as follows:

$$y = Wx + x^T T^{[1:d_2]} x + b \quad (19)$$
$$y_i = \sum_j W_{ij} x_j + \sum_{j,k} T^{[i]}_{j,k} x_j x_k + b_i \quad (20)$$

where $y \in \mathbb{R}^{d_2}$ is the output vector, $y_i \in \mathbb{R}$ is the ith element of y, $W \in \mathbb{R}^{d_2 \times d_1}$ is the transformation matrix, $T^{[1:d_2]} \in \mathbb{R}^{d_1 \times d_1 \times d_2}$ is a 3rd-order transformation tensor. A normal transformation function in neural network models only has the first term Wx with the bias term. It means for normal transformation function each unit of the output vector is the weighted summation of the input vector and this only allows additive interaction between the units of the input vector. With the tensor multiplication term, each unit of the output vector is augmented with the weighted summation of the multiplication of the input vector units and thus we incorporate multiplicative interaction between the units of the input vector.

Inevitably, the incorporation of tensor leads to side effects which include the increase in parameter number and computational complexity. To remedy this, we adopt tensor factorization in the same way as Pei et al. (2014): we use two low rank matrices to approximate each tensor slice $T^{[i]} \in \mathbb{R}^{d_1 \times d_1}$:

$$T^{[i]} \Rightarrow P^{[i]} Q^{[i]} \quad (21)$$

where $P^{[i]} \in \mathbb{R}^{d_1 \times r}$, $Q^{[i]} \in \mathbb{R}^{r \times d_1}$ and $r \ll d_1$. In this way, we drastically reduce parameter number and computational complexity.

We apply the factorized tensor-based transformation function to the combined text span representation $h = [h_{s1}, h_{s2}]$ to make the features of the two spans explicitly interact with each other:

$$v = Relu(W_h[h_{s1}, h_{s2}] + [h_{s1}, h_{s2}]^T P_h^{[1:d]} Q_h^{[1:d]} [h_{s1}, h_{s2}] + b_h) \quad (22)$$

Comparing with Eq. 12, the transformation function is added with a tensor term.

2.5 Handcrafted Features

Most previously proposed state-of-the-art systems heavily rely on handcrafted features (Hernault et al., 2010; Feng and Hirst, 2014; Joty et al., 2013; Ji and Eisenstein, 2014; Heilman and Sagae, 2015). Li et al. (2014a) show that some basic features are still necessary to get a satisfactory result for their recursive deep model. Following their practice, we adopt minimal basic features which are utilized by most systems to further strengthen our model. We list these features in Table 1. We apply the factorized tensor-based transformation function to Word/POS features to allow more complicated interaction between them.

3 Parsing Algorithm

In this section, we describe our parsing algorithm which utilizes the parsing model to produce the global optimal DT for a segmented document.

3.1 Probabilistic CKY-like Algorithm

We adopt a probabilistic CKY-like bottom-up algorithm which is also adopted in (Joty et al., 2013; Li et al., 2014a) to produce a DT for a document. This parsing algorithm is a dynamic programming algorithm and produces the global optimal DT with our parsing model. Given a text span which is constituted by $[e_i, e_{i+1}, ..., e_j]$ and the possible subtrees of $[e_i, e_{i+1}, ..., e_k]$ and $[e_{k+1}, e_{k+2}, ..., e_j]$ for all $k \in \{i, i+1, ..., j-1\}$ with their probabilities, we choose k and combine the corresponding subtrees to form a combined DT with the following recurrence formula:

$$k = \arg\max_k \{P_{sp}(i, k, j) P_{i,k} P_{k+1,j}\} \quad (23)$$

where $P_{i,k}$ and $P_{k+1,j}$ are the probabilities of the most probable subtrees of $[e_i, e_{i+1}, ..., e_k]$ and $[e_{k+1}, e_{k+2}, ..., e_j]$ respectively, $P_{sp}(i, k, j)$ is the probability which is predicted by our parsing model to combine those two subtrees to form a DT.

The probability of the most probable DT of $[e_i, e_{i+1}, ..., e_j]$ is:

$$P_{i,j} = \max_k \{P_{sp}(i, k, j) P_{i,k} P_{k+1,j}\} \quad (24)$$

3.2 Parsing Acceleration

Computational complexity of the original probabilistic CKY-like algorithm is $O(n^3)$ where n is the number of EDUs of the document. But in this work, given each pair of text spans, we compute the representations of them with hierarchical bi-LSTM network at the expense of an additional $O(n)$ computations. So the computational complexity of our parser becomes $O(n^4)$ and it is unacceptable for long documents. However, most computations are duplicated, so we use two level caches to drastically accelerate parsing.

Firstly, we cache the outputs of the EDU level bi-LSTM which are the semantic representations of EDUs. As for the forward span level LSTM, after we get the semantic representation of a span, we cache it too and use it to compute the representation of an extended span. For example, after we get the representation of span constituted by $[e_1, e_2, e_3]$, we take it with semantic representation of e_4 to compute the representation of the span constituted by $[e_1, e_2, e_3, e_4]$ in one LSTM computation step. For the backward span level LSTM, we do it the same way just in reversed order. Thus we decrease the computational complexity of computing the semantic representations for all possible span pairs which is the most time-consuming part of the original parsing process from $O(n^4)$ to $O(n^2)$.

Secondly, it can be seen that before we apply $Relu$ to the tensor-based transformation function, many calculations from the two spans which include a large part of tensor multiplication are independent. The multiplication between the elements of the representations of the two spans caused by the tensors and the element-wise non-linear activation function $Relu$ terminate the independence between them. So we can further cache the independent calculation results before $Relu$ operation for each span. Thus we decrease the computational complexity of a large part of tensor-based transformation from $O(n^3)$ to

Word/POS Features
One-hot representation of the first two words and of the last word of each span.
One-hot representation of POS tags of the first two words and of the last word of each span.
Shallow Features
Number of EDUs of each span.
Number of words of each span.
Predicted relations of the two subtrees' roots.
Whether each span is included in one sentence.
Whether both spans are included in one sentence.

Table 1: Handcrafted features used in our parsing model.

$O(n^2)$ which is the second time-consuming part of the original parsing process.

The remaining $O(n^3)$ computations include a little part of tensor-based transformation computations, $Relu$ operation and the computations from the three classifiers. These computations take up only a little part of the original parsing model computations and thus we greatly accelerate our parsing process.

4 Max-Margin Training

We use Max-Margin criterion for our model training. We try to learn a function that maps: $X \rightarrow Y$, where X is the set of documents and Y is the set of possible DTs. We define the loss function for predicting a DT $\hat{y_i}$ given the correct DT y_i as:

$$\triangle(y_i, \hat{y_i}) = \sum_{r \in \hat{y_i}} \kappa \mathbf{1}\{r \notin y_i\} \tag{25}$$

where r is a span specified with nucleus and relation in the predicted DT, κ is a hyperparameter referred to as discount parameter and $\mathbf{1}$ is indicator function. We expect the probability of the correct DT to be a larger up to a margin to other possible DTs:

$$Prob(x, y_i) \geq Prob(x_i, \hat{y_i}) + \triangle(y_i, \hat{y_i}) \tag{26}$$

The objective function for m training examples is as follows:

$$J(\theta) = \frac{1}{m} \sum_{i=1}^{m} l_i(\theta), where \tag{27}$$

$$l_i(\theta) = \max_{\hat{y_i}} (Prob(x_i, \hat{y_i}) + \triangle(y_i, \hat{y_i})) - Prob(x_i, y_i) \tag{28}$$

where θ denotes all the parameters including our neural network parameters and all embeddings.

The probabilities of the correct DTs increase and the probabilities of the most probable incorrect DTs decrease during training. We adopt Adadelta (Zeiler, 2012) with mini-batch to minimize the objective function and set the initial learning rate to be 0.012.

5 Experiments

We evaluate our model on RST Discourse Treebank[1] (RST-DT) (Carlson et al., 2003). It is partitioned into a set of 347 documents for training and a set of 38 documents for test. Non-binary relations are converted into a cascade of right-branching binary relations. The standard metrics of RST-style discourse parsing evaluation include blank tree structure referred to as span (S), tree structure with nuclearity (N) indication and tree structure with rhetorical relation (R) indication. Following other RST-style discourse parsing systems, we evaluate the relation metric in 18 coarse-grained relation classes. Since our work focus does not include EDU segmentation, we evaluate our system with gold-standard EDU segmentation and we apply the same setting on this to other discourse parsing systems for fair comparison.

5.1 Experimental Setup

The dimension of word embeddings is set to be 50 and the dimension of POS embeddings is set to be 10. We pre-trained the word embeddings with GloVe (Pennington et al., 2014) on English Gigaword[2] and we fine-tune them during training. Considering some words are pretrained by GloVe but

[1] https://catalog.ldc.upenn.edu/LDC2002T07

[2] https://catalog.ldc.upenn.edu/LDC2011T07

don't appear in the RST-DT training set, we want to use their embeddings if they appear in test set. Following Kiros et al. (2015), we expand our vocabulary with those words using a matrix $W \in \mathbb{R}^{50\times 50}$ that maps word embeddings from the pre-trained word embedding space to the fine-tuned word embedding space. The objective function for training the matrix W is as follows:

$$\min_{W,b} ||V_{tuned} - V_{pretrained}W - b||_2^2 \qquad (29)$$

where $V_{tuned}, V_{pretrained} \in \mathbb{R}^{|V|\times 50}$ contain fine-tuned and pre-trained embeddings of words appearing in training set respectively, $|V|$ is the size of RST-DT training set vocabulary and b is the bias term also to be trained.

We lemmatize all the words appeared and represent all numbers with a special token. We use Stanford CoreNLP toolkit (Manning et al., 2014) to preprocess the text including lemmatization, POS tagging etc. We use Theano library (Bergstra et al., 2010) to implement our parsing model. We randomly initialize all parameters within (-0.012, 0.012) except word embeddings. We adopt dropout strategy (Hinton et al., 2012) to avoid overfitting and we set the dropout rate to be 0.3.

5.2 Results and Analysis

To show the effectiveness of the components incorporated into our model, we firstly test the performance of the basic hierarchical bidirectional LSTM network without attention mechanism (ATT), tensor-based transformation (TE) and handcrafted features (HF). Then we add them successively. The results are shown in Table 2.

The performance is improved by adding each component to our basic model and that shows the effectiveness of attention mechanism and tensor-based transformation function. Even without handcrafted features, the performance is still competitive. It indicates that the semantic representations of text spans produced by our attention-based hierarchical bi-LSTM network are effective and the handcrafted features are complementary to semantic representations produced by the network.

We also experiment without mapping the OOV word embeddings and use the same embedding for all OOV words. The result is shown in Table 3. Without mapping the OOV word embeddings the performance decreases slightly, which demonstrates that the relation between pre-trained embedding space and the fine-tuned embedding space can be learnt and it is beneficial to train a matrix to transform OOV word embeddings from the pre-trained embedding space to the fine-tuned embedding space.

System Setting	S	N	R
Basic	82.7	69.7	55.6

We compare our system with other state-of-the-art systems including (Joty et al., 2013; Ji and Eisenstein, 2014; Feng and Hirst, 2014; Li et al., 2014a; Li et al., 2014b; Heilman and Sagae, 2015). Systems proposed by Joty et al. (2013), Heilman (2015) and Feng and Hirst (2014) are all based on variants of CRFs. Ji and Eisenstein (2014) use a projection matrix acting on one-hot representations of features to learn representations of text spans and build Support Vector Machine (SVM) classifier on them. Li et al. (2014b) adopt dependency parsing methods to deal with this task. These systems are all based on handcrafted features. Li et al. (2014a) adopt a recursive deep model and use some basic handcrafted features to improve their performances which has been stated before.

Table 4 shows the performance for our system and those systems. Our system achieves the best result in span and relatively lower performance in nucleus and relation identification comparing with the corresponding best results but still better than

System	S	N	R
Joty et al. (2013)	82.7	68.4	55.7
Ji and Eisenstein (2014)	82.1	71.1	**61.6**
Feng and Hirst (2014)	**85.7**	71.0	58.2
Li et al. (2014a)	84.0	70.8	58.6
Li et al. (2014b)	83.4	**73.8**	57.8

most systems. No system achieves the best result on all three metrics. To further show the effectiveness of the deep learning model itself without handcrafted features, we compare the performance between our model and the model proposed by Li et al. (2014a) without handcrafted features and the results are shown in Table 5. It shows our overall performance outperforms the model proposed by Li et al. (2014a) which illustrates our model is effective.

Table 6 shows an example of the weights (W) of EDUs (see Eq. 8) derived from our attention model. For span1 the main semantic meaning is expressed in EDU32 under the condition described in EDU31. Besides, it is EDU32 that explicitly manifests the contrast relation between the two spans. As can be seen, our attention model assigns less weight to EDU30 and focuses more on EDU32 which is reasonable according to our analysis above.

Span1 (EDU30∼EDU32)	W
That means that	0.13
if the offense deals with one part of the business,	0.38
you don't attempt to seize the whole business;	0.49
Span2 (EDU33)	**W**
you attempt to seize assets related to the crime,	1.0

Table 6: An example of the weights derived from our attention model. The relation between span1 and span2 is Contrast.

6 Related Work

Two most prevalent discourse parsing treebanks are RST Discourse Treebank (RST-DT) (Carlson et al., 2003) and Penn Discourse TreeBank (PDTB) (Prasad et al., 2008). We evaluate our system on RST-DT which is annotated in the framework of Rhetorical Structure Theory (Mann and Thompson, 1988). It consists of 385 Wall Street Journal articles and is partitioned into a set of 347 documents for training and a set of 38 documents for test. 110 fine-grained and 18 coarse-grained relations are defined on RST-DT. Parsing algorithms published on RST-DT can mainly be categorized as shift-reduce parsers and probabilistic CKY-like parsers. Shift-reduce parsers are widely used for their efficiency and effectiveness and probabilistic CKY-like parsers lead to the global optimal result for the parsing models. State-of-the-art systems belonging to shift-reduce parsers include (Heilman and Sagae, 2015; Ji and Eisenstein, 2014). Those belonging to probabilistic CKY-like parsers include (Joty et al., 2013; Li et al., 2014a). Besides, Feng and Hirst (2014) adopt a greedy bottom-up approach as their parsing algorithm. Lexical, syntactic, structural and semantic features are extracted in these systems. SVM and variants of Conditional Random Fields (CRFs) are mostly used in these models. Li et al. (2014b) distinctively propose to use dependency structure to represent the relations between EDUs. Recursive deep model proposed by Li et al. (2014a) has been the only proposed deep learning model on RST-DT.

Incorporating attention mechanism into RNN (e.g., LSTM, GRU) has been shown to learn better representation by attending over the output vectors and picking up important information from relevant positions of a sequence and this approach has been utilized in many tasks including neural machine translation (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2014; Hermann et al., 2015), text entailment recognition (Rocktäschel et al., 2015) etc. Some work also uses tensor-based transformation function to make stronger interaction between features and learn combinatorial features and they get performance boost in their tasks (Sutskever et

al., 2009; Socher et al., 2013; Pei et al., 2014).

7 Conclusion

In this paper, we propose an attention-based hierarchical neural network for discourse parsing. Our attention-based hierarchical bi-LSTM network produces effective compositional semantic representations of text spans. We adopt tensor-based transformation function to allow complicated interaction between features. Our two level caches accelerate parsing process significantly and thus make it practical. Our proposed system achieves comparable results to state-of-the-art systems. We will try extending attention mechanism to obtain the representation of a text span by referring to another text span at minimal additional cost.

Abstract

In this paper, we study the task of response selection for multi-turn human-computer conversation. Previous approaches take word as a unit and view context and response as sequences of words. This kind of approaches do not explicitly take each utterance as a unit, therefore it is difficult to catch utterance-level discourse information and dependencies. In this paper, we propose a multi-view response selection model that integrates information from two different views, i.e., word sequence view and utterance sequence view. We jointly model the two views via deep neural networks. Experimental results on a public corpus for context-sensitive response selection demonstrate the effectiveness of the proposed multi-view model, which significantly outperforms other single-view baselines.

1 Introduction

Selecting a potential response from a set of candidates is an important and challenging task for open-domain human-computer conversation, especially for the retrieval-based human-computer conversation. In general, a set of candidate responses from the indexed conversation corpus are retrieved, and then the best one is selected from the candidates as the system's response (Ji et al., 2014).

Previous Deep Neural Network (DNN) based approaches to response selection represent context and response as two embeddings. The response is selected based on the similarity of these two embeddings (Lowe et al., 2015; Kadlec et al., 2015). In these work, context and response are taken as two separate word sequences without considering the relationship among utterances in the context and response. The response selection in these models is largely influenced by word-level information. We called this kind of models as *word sequence model* in this paper. Besides word-level dependencies, utterance-level semantic and discourse information are also very important to catch the conversation topics to ensure coherence (Grosz and Sidner, 1986). For example an utterance can be an affirmation, negation or deduction to the previous utterances, or starts a new topic for discussion. This kind of utterance-level information is generally ignored in word sequence model, which may be helpful for selecting the next response. Therefore, it is necessary to take each utterance as a unit and model the context and response from the view of utterance sequence.

This paper proposes a multi-view response selection model, which integrates information from both **word sequence view** and **utterance sequence view**. Our assumption is that each view can represent relationships between context and response from a particular aspect, and features extracted from the word sequence and the utterance sequence provide complementary information for response selection. An effective integration of these two views is expected to improve the model performance. To the best of our knowledge, this is the first work to improve the response selection for multi-turn human-computer conversation in a multi-view manner.

We evaluate the performance of the multi-view response selection model on a public corpus containing about one million context-response-label triples.

*These two authors contributed equally

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 372–381,
Austin, Texas, November 1-5, 2016.

This corpus was extracted from an online chatting room for Ubuntu troubleshooting, which is called the Ubuntu Corpus in this paper (Lowe et al., 2015). Experimental results show that the proposed multi-view response selection model significantly outperforms the current best single-view models for multi-turn human-computer conversation.

The rest of this paper is organized as follows. In Section 2, we briefly introduce related works. Then we move on to a detailed description of our model in Section 3. Experimental results are described in Section 4. Analysis of our models is shown in Section 5. We conclude the paper in Section 6.

2 Related Work

2.1 Conversation System

Establishing a machine that can interact with human beings via natural language is one of the most challenging problems in Artificial Intelligent (AI). Early studies of conversation models are generally designed for specific domain, like booking restaurant, and require numerous domain knowledge as well as human efforts in model design and feature engineering (Walker et al., 2001). Hence it is too costly to adapt those models to other domains. Recently leveraging "big dialogs" for open domain conversation draws increasing research attentions. One critical issue for open domain conversation is to produce a reasonable response. Responding to this challenge, two promising solutions have been proposed: 1) retrieval-based model which selects a response from a large corpus (Ji et al., 2014; Yan et al., 2016; Yan et al.,). 2) generation-based model which directly generates the next utterance (Wen et al., 2015a; Wen et al., 2015b).

2.2 Response Selection

Research on response selection for human-computer conversation can be classified into two branches, i.e., single-turn and multi-turn response selection. Single-turn models only leverage the last utterance in the context for selecting resposne and most of them take the word sequence view. Lu and Li (2013) proposed a DNN-based matching model for response selection. Hu et al., (2014) improved the performance using Convolutional Neural Networks (CNN) (LeCun et al., 1989). In 2015, a further study conducted by Wang et al. (2015a) achieved better results using tree structures as the input of a DNN model. Nevertheless, those models built for single-turn response selection ignore the whole context information, which makes it difficult to be implemented in the multi-turn response selection tasks.

On the other hand, research on multi-turn response selection usually takes the whole context into consideration and views the context and response as word sequences. Lowe et al., (2015) proposed a Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) based response selection model for multi-turn conversation, where words from context and response are modeled with LSTM. The selection of a response is based on the similarity of embeddings between the context and response. Similar to the work of Lowe et al., Kadlec et al., (2015) replaced LSTM with Temporal Convolutional Neural Networks (TCNN) (Kim, 2014) and Bidirect-LSTM. Their experimental results show that models with LSTM perform better than other neural networks. However, the utterance-level discourse information and dependencies have been left out in these studies since they view the context and response as word sequences.

2.3 Response Generation

Another line of related research focuses on generating responses for human-computer conversation. Ritter et al., (2011) trained a phrase-based statistical machine translation model on a corpus of utterance pairs extracted from Twitter human-human conversation and used it as a response generator for single-turn conversation. Vinyals and Le (2015) regarded single-turn conversation as a sequence-to-sequence problem and proposed an encoder-decoder based response generation model, where the post response is first encoded using LSTM and its embedding used as the initialization state of another LSTM to generate the response. Shang et al., (2015) improved the encoder-decoder based model using attention signals. Sordoni et al., (2015) proposed a context-sensitive response generation model, where the context is represented by bag-of-words and fed into a recurrent language model to generate the next response.

In this paper, we focused on the task of response selection.

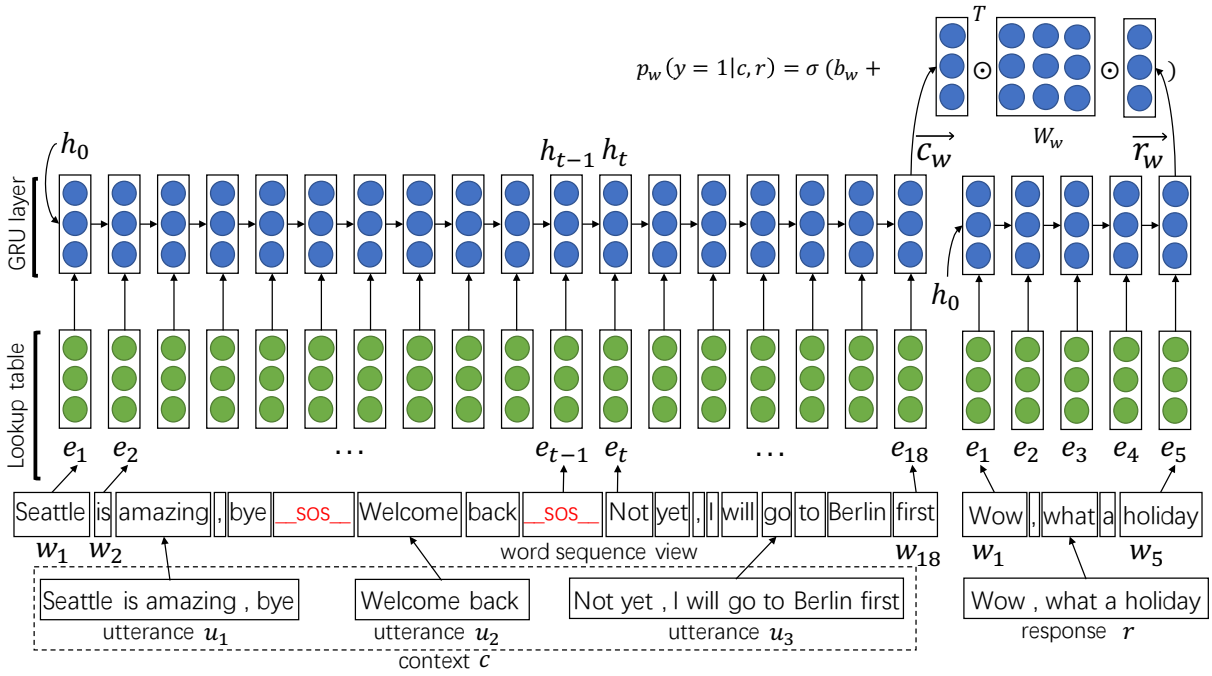

Figure 1: Word sequence model for response selection

3 Response Selection Model

In the task of response selection, a conventional DNN-based architecture represents the context and response as low dimensional embeddings with deep learning models. The response is selected based on the similarity of these two embeddings. We formulate it as

$$p(y = 1|c, r) = \sigma(\overrightarrow{c}^T W \overrightarrow{r} + b) \quad (1)$$

where c and r denote the context and response, $\overrightarrow{c}$ and $\overrightarrow{r}$ are their embeddings constructed with DNNs. $\sigma(x)$ is a sigmoid function defined as $\sigma(x) = \frac{1}{1+e^{-x}}$. $p(y = 1|c, r)$ is the confidence of selecting response r for context c. The matrix W and the scalar b are metric parameters to be learned to measure the similarity between the context and response.

We extend this architecture in a multi-view manner, which jointly models the context and response in two views. In this section, we first briefly describe the word sequence model. Then we introduce the utterance sequence model and multi-view response selection model in details.

3.1 Word Sequence Model

The word sequence model in this paper is similar to the LSTM-based model proposed in Lowe et al. (2015). As shown in Figure 1, three utterances of context c, written as u_1, u_2 and u_3, are connected as a sequence of words. A special word *__sos__* is inserted between every two adjacent utterances, denoting the boundary between utterances. Given the word sequences of context and response, words are mapped into word embeddings through a shared lookup table. A Gated Recurrent Unit neural network (GRU) (Chung et al., 2014) is employed to construct the context embedding and response embedding. It operates recurrently on the two word embedding sequences as Equation 2 to Equation 5, where h_{t-1} is the hidden state of GRU when it reads a word embedding e_{t-1} of word w_{t-1}, h_0 is a zero vector as the initiation state, z_t is an *update gate* and r_t is a *reset gate*. The new hidden state h_t for embedding e_t is a combination of the previous hidden state h_{t-1} and the input embedding e_t, controlled by the update gate z_t and reset gate r_t. U, U_z, U_r, W, W_z and W_r are model parameters of GRU to be learned. $\otimes$ denotes element-wise multiplication.

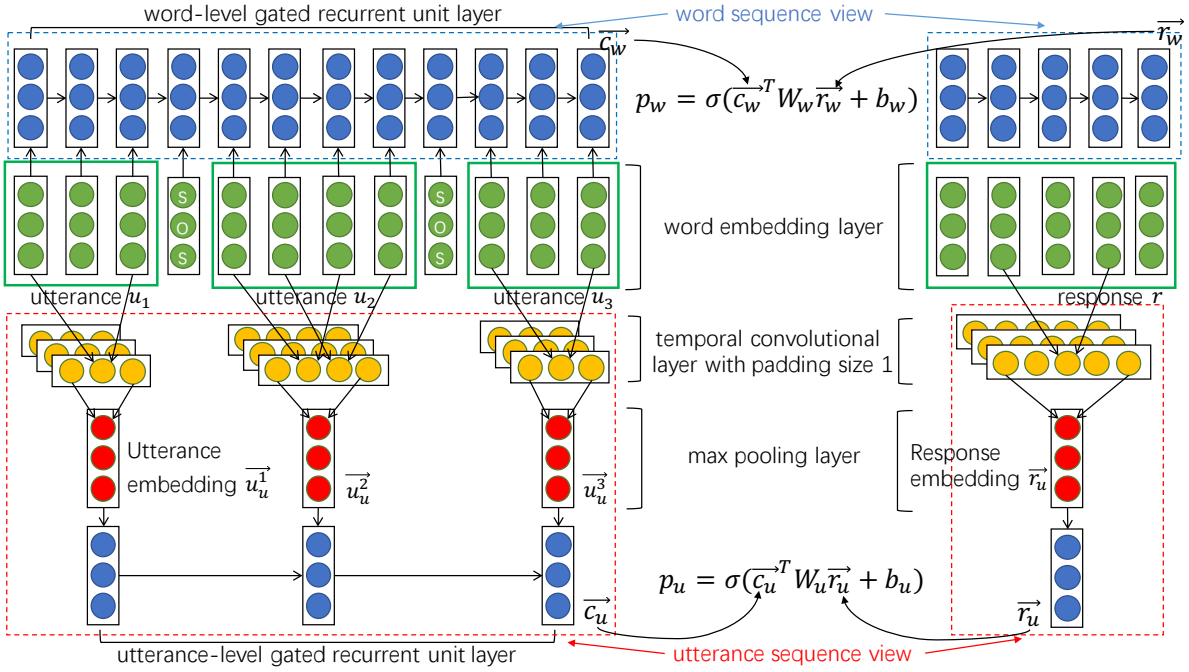

Figure 2: Multi-view response selection model

$$h_t = (\mathbf{1} - z_t) \otimes h_{t-1} + z_t \otimes \hat{h}_t \quad (2)$$

$$z_t = \sigma(W_z e_t + U_z h_{t-1}) \quad (3)$$

$$\hat{h}_t = tanh(W e_t + U(r_t \otimes h_{t-1})) \quad (4)$$

$$r_t = \sigma(W_r e_t + U_r h_{t-1}) \quad (5)$$

After reading the whole word embedding sequence, word-level semantic and dependencies in the whole sequence are encoded in the hidden state of GRU, which represents the meaning of the whole sequence (Karpathy et al., 2015). Therefore we use the last hidden state of GRU as the context embedding and response embedding in word sequence model, named $\overrightarrow{c_w}$ and $\overrightarrow{r_w}$ respectively[1]. The confidence of selecting response in word sequence model is then calculated as in Equation 6:

$$p_w(y = 1|c, r) = \sigma(\overrightarrow{c_w}^T W_w \overrightarrow{r_w} + b_w) \quad (6)$$

where W_w and b_w are metric parameters to be trained in word sequence model. $\overrightarrow{c_w}$ and $\overrightarrow{r_w}$ are constructed by a same GRU in word sequence model.

[1]We use two subscripts, i.e., w and u, to distinguish notation in the two views.

3.2 Utterance Sequence Model

Utterance sequence model regards the context as a hierarchical structure, where the response and each utterance are first represented based on word embeddings, then the context embedding is constructed for the confidence calculation of response selection. As the lower part of Figure 2 illustrates, the construction of the utterance embedding and response embedding is in a convolutional manner, which contains the following layers:

Padding Layer: Given a word embedding sequence belonging to a certain utterance (response), namely $[e_1, ..., e_m]$, the padding layer makes its outer border with $\lfloor n/2 \rfloor$ zero vectors, the padded sequence is $[0_1, .., 0_{\lfloor n/2 \rfloor}, e_1, ..., e_m, 0_1, .., 0_{\lfloor n/2 \rfloor}]$, where n is the size of convolution window used in temporal convolutional layer.

Temporal Convolutional Layer: Temporal convolutional layer reads the padded word embedding sequence through a sliding convolution window with size n. For every step that the sliding window moves, a *region vector* is produced by concatenating the word embeddings within the sliding window, denoted as $[e_i \oplus ... \oplus$

$e_{i+n-1}] \in \mathbb{R}^{n|e|}$, where $\oplus$ denotes the concatenation of embeddings, $|e|$ is the size of word embedding. The temporal convolutional layer consists of k kernels, each of which implies a certain dimension and maps the *region vector* to a value in its dimension by convolution operation. The convolution result of each kernel, termed $conv_i$, is further activated with the *RELU* non-linear activation function (Xu et al., 2015), which is formulated as:

$$f_{relu}(conv_i) = max(conv_i, 0) \quad (7)$$

Pooling Layer: Because utterance and response are naturally variable-sized, we put a *max-over-time pooling layer* on the top of temporal convolutional layer (Kim, 2014), which extracts the max value for each kernel, and gets a fix-sized representation of length k for utterance and response.

In particular, representations constructed by CNN with max-pooling reflect the core meanings of utterance and response. The embeddings of utterance u_i and response r in utterance sequence view are referred to as $\overrightarrow{u_u^i}$ and $\overrightarrow{r_u}$. Utterance embeddings are connected in the sequence and fed into a GRU, which captures utterance-level semantic and discourse information in the whole context and encodes those information as context embedding, written as $\overrightarrow{c_u}$. The confidence of selecting response r for context c in utterance sequence model, named $p_u(y = 1|c, r)$, is calculated using Equation 8:

$$p_u(y = 1|c, r) = \sigma(\overrightarrow{c_u}^T W_u \overrightarrow{r_u} + b_u) \quad (8)$$

It is worth noticing that the TCNN used here is shared in constructing the utterance embedding and response embedding. The word embeddings are also shared for both the context and response. The $\_\_sos\_\_$ tag in word sequence view is not used in the utterance sequence model.

3.3 Multi-view Model

Organic integration of different views has been proven to be very effective in the field of recommendation, representation learning and other research areas (Elkahky et al., 2015; Wang et al., 2015b). Most existing multi-view models integrate different views via a linear/nonlinear combination. Researchers have demonstrated that jointly minimizing two factors, i.e., 1) the *training error* of each view and 2) the *disagreement* between complementary views can significantly improve the performance of the combination of multi-views (Xu et al., 2013).

Our multi-view response selection model is designed as shown in Figure 2. As we can see, the context and response are jointly represented as semantic embeddings in these two views. The underlying word embeddings are shared across the context and response in these two views. The complementary information of these two views is exchanged via the shared word embeddings. The utterance embeddings are modeled through a TCNN in the utterance sequence view. Two independent Gated Recurrent Units are used to model the word embeddings and utterance embeddings separately on word sequence view and utterance sequence view, the former of which captures dependencies in word level and the latter captures utterance-level semantic and discourse information. Confidences for selecting the response in these two views are calculated separately. We optimize the multi-view model by minimizing the following loss:

$$\mathcal{L} = \mathcal{L}_{\mathcal{D}} + \mathcal{L}_{\mathcal{L}} + \frac{\lambda}{2}\|\theta\| \quad (9)$$

$$\mathcal{L}_{\mathcal{D}} = \sum_i (p_w(l_i)\bar{p_u}(l_i) + p_u(l_i)\bar{p_w}(l_i)) \quad (10)$$

$$\mathcal{L}_{\mathcal{L}} = \sum_i (1 - p_w(l_i)) + \sum_i (1 - p_u(l_i)) \quad (11)$$

where the object function of the multi-view model $\mathcal{L}$ is comprised of the *disagreement loss* $\mathcal{L}_{\mathcal{D}}$, the *likelihood loss* $\mathcal{L}_{\mathcal{L}}$ and the regular term $\frac{\lambda}{2}\|\theta\|$. $p_w(l_i) = p_w(y = l_i|c, r)$ and $p_u(l_i) = p_u(y = l_i|c, r)$ denote the likelihood of the i-th instance with label l_i from training set in these two views. Only two labels, $\{0, 1\}$, denote the correctness of the response during training. $\bar{p}_w(l_i)$ and $\bar{p}_u(l_i)$ denote the probability $p_w(y \neq l_i)$ and $p_u(y \neq l_i)$ respectively. The multi-view model is trained to jointly minimize the *disagreement loss* and the *likelihood loss*. θ denotes all the parameters of the multi-view model.

The unweighted summation of confidences from these two views is used during prediction, defined as

Model/Metrics	1 in 10 R@1	1 in 10 R@2	1in 10 R@5	1 in 2 R@1

Utter-seq-GRU	62.19%	76.56%	93.42%	88.83%
Multi-view	**66.15%**	**80.12%**	**95.09%**	**90.80%**

Table 1: Performance comparison between our models and baseline models. In the table, **Word-seq-LSTM** is the experiment result of the LSTM-based word sequence model reported by Lowe et at (2015). **Word-seq GRU** is the word sequence model that we implement with GRU. **Utter-seq-GRU** is the proposed utterance-sequence model. The **Multi-view** is our multi-view response selection model. In addition, we list the performance of **Random-guess** and **TF-IDF**

in Equation 12:

$$s_{mtv}(y = 1|c, r) = p_w(y = 1|c, r) + p_u(y = 1|c, r) \quad (12)$$

The response with larger $s_{mtv}(y = 1|c, r)$ is more likely to be selected. We will investigate other combination models in our future work.

4 Experiment

4.1 Dataset

Our model is evaluated on the public Ubuntu Corpus (Lowe et al., 2015), designed for response selection study of multi-turn human-computer conversation (Serban et al., 2015). The dataset contains 0.93 million human-human dialogues crawled from an Internet chatting room for Ubuntu trouble shooting. Around 1 million context-response-labeled triples, namely $< c, r, l >$, are generated for training after preprocessing[2], where the original context and the corresponding response are taken as the positive instances while the random utterances in the data set taken as the negative instances, and the number of positive instance and negative instance in training set is balanced. The validation set and testing set are constructed in a similar way to the training set, with one notable difference that for each context and the corresponding positive response, 9 negative responses are randomly selected for further evaluation.

4.2 Experiment Setup

Following the work of Lowe et al., (2015), the evaluation metric is 1 in m Recall@k (denoted 1 in m R@k), where a response selection model is designed to select k most likely responses among m candidates, and it gets the score "1" if the correct response is in the k selected ones. This metric can be seen as an adaptation of the precision and recall metrics previously applied to dialogue datasets (Schatzmann et al., 2005). It is worth noticing that 1 in 2 R@1 equals to precision and recall in binary classification.

4.3 Model Training and Hyper-parameters

We initialize word embeddings with a pre-trained embedding matrix through GloVe (Pennington et al., 2014) [3]. We use Stochastic Gradient Descent (SGD) for optimizing. Hidden size for a gated recurrent unit is set to 200 in both word sequence model and utterance sequence model. The number of convolutional kernels is set to 200. Our initial learning rate is 0.01 with mini-batch size of 32. Other hyper-parameters are set exactly the same as the baseline. We train our models with a single machine using 12 threads and each model will converge after 4-5 epochs of training data. The best model is selected with a holdout validation dataset.

4.4 Comparison Approaches

We consider the word sequence model implemented by Lowe et at., (2015) with LSTM as our baseline, the best model in context-sensitive response selection so far. Moreover, we also implement the word sequence model and the utterance sequence model with GRU for further analysis. Two simple approaches are also implemented, i.e., the Random-

[2]Preprocessing includes tokenization, recognition of named entity, urls and numbers.

(b) 1 in 10 R@1

(c) 1 in 10 R@2

(d) 1 in 10 R@5

Figure 3: Performance comparison between word sequence model (with/without $\_\_sos\_\_$ tags) and utterance sequence model. We choose the number of utterances in range of [2,6], since most samples in testset fall in this interval

guess and the TF-IDF, as the bottom line for performance comparison. The performance of Random-guess is calculated by mathematics with an assumption that each response in candidates has the equal probability to be selected. The TF-IDF is implemented in the same way in Lowe et al., (2015). TF for a word is calculated as the count of times it appears in a certain context or response. IDF for each word w is $log(\frac{N}{|d \in D : w \in d|})$, where D denotes the whole training set, N is the size of D, d is a conversation in D. The context and the response in testset are represented as a bag-of-words according to TF-IDF. The selection confidence is estimated as the cosine score between context and response.

4.5 Experimental Result

We summarize the experiment result in Table 1. As shown in Table 1, all DNN-based models achieve significant improvements compared to Random-guess and TF-IDF, which implies the effectiveness of DNN models in the task of response selection. The word sequence models implemented with GRU and LSTM achieve similar performance. The utterance sequence model significantly outperforms word sequence models for 1 in 10 R@1. Multi-view model significantly outperforms all the other models, especially for 1 in 10 R@1, which is more difficult and closer to the real world scenario than other metrics. The experimental result demonstrates the effectiveness of multi-view model and proves that word sequence view and utterance sequence view can bring complementary information for each other.

5 Analysis

We examine the complementarity between word sequence model and utterance sequence model in two folds, i.e., via statistic analysis and case study.

5.1 Statistical Analysis

We compare the performance of word sequence model[4] and utterance sequence model for different number of utterances in the contexts. In addition, we also examine what the contribution $\_\_sos\_\_$ tag makes in word sequence view. The performance

[4]The GRU-based word sequence model that we implemented is used for comparison.

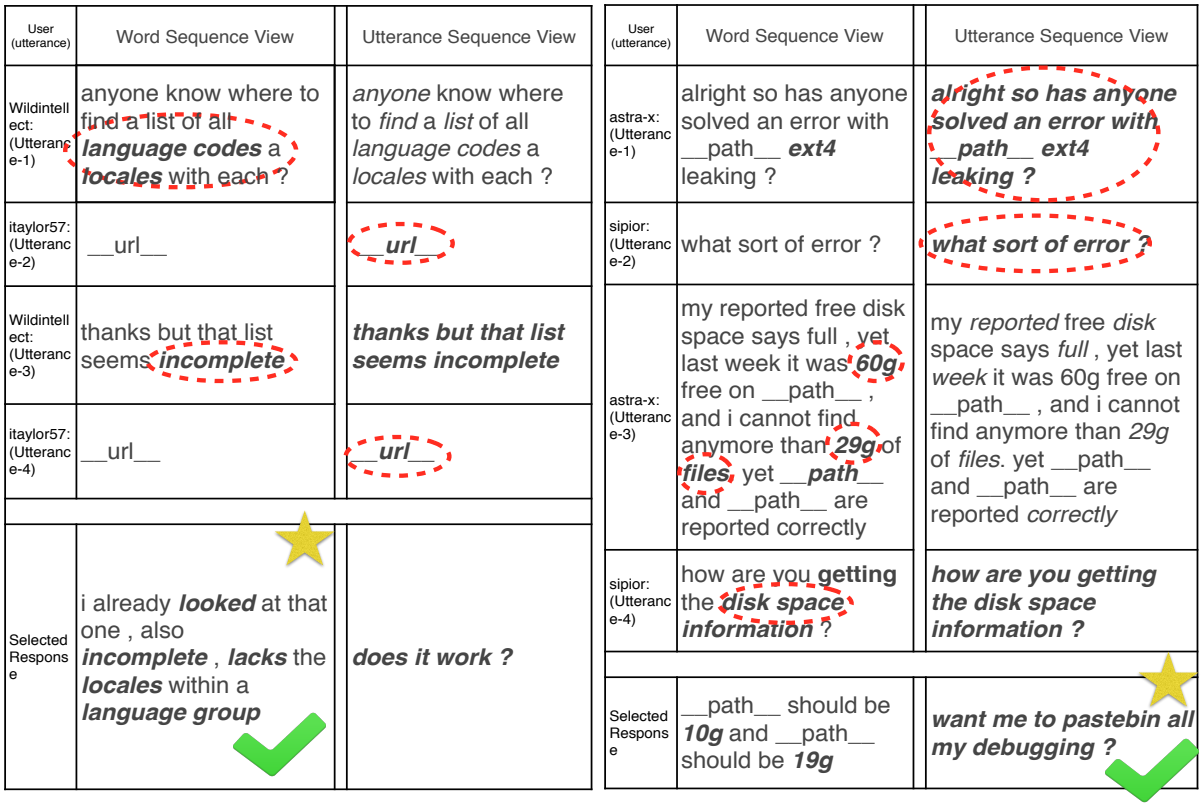

Figure 4: Case studies for analysis of word sequence model and utterance sequence model. The context and the selected responses are collected from testset. Response with a green checkmark means it is a correct one, otherwise it is incorrect. Words (Utterances) in **bold** are the important elements recognized by our importance analysis approach. The yellow start denotes the selection of multi-view model.

is shown in Figure 3. We can see that as the number of turns increases, the utterance sequence model outperforms word sequence model more significantly, which implies that utterance sequence model can provide complementary information to word sequence model for a long context. Furthermore, word sequence model without $\_\_sos\_\_$ tag has an obvious fall in performance compared with word sequence model with $\_\_sos\_\_$, which implies its crucial role in distinguishing utterances for modeling context.

5.2 Case Study

We analyze samples from testset to examine the complementarity between these two views. The key words for word sequence model and core utterances for utterance sequence model are extracted for analysis. These important elements are recognized based on the work of Li et al. (2015), where the gradients of their embeddings are used for importance analysis. After studying the testset, we find that the word sequence model selects responses according to the **matching of key words** while the utterance sequence model selects responses based on the **matching of core utterances**. We list two cases in Figure 4 as examples.

As it shows, the word sequence model prefers to select the response that shares similar key words to the context, such as the words *"incomplete"* and *"locales"* in example 1 or *"60g"* and *"19g"* in example 2. Although key word matching is a useful feature in selecting response for cases such as example 1, it fails in cases like example 2, where incorrect response happens to share similar words with the context. Utterance sequence model, on the other side, leverages core utterances for selecting response. As shown in example 2, utterance-1 and utterance-2 are recognized as the core utterances, the main topic of the two utterance is *"solved"* and *"error"*, which is close to the topic of the correct re-

sponse. However, for cases like example 1, where the core meaning of correct response is jointly combined with different words in different utterances, the utterance sequence model does not perform well.

The multi-view model can successfully select the correct responses in both two examples, which implies its ability to jointly leverage information from these two views.

6 Conclusion

In this paper, we propose a multi-view response selection model for multi-turn human-computer conversation. We integrate the existing word sequence view and a new view, i.e., utterance sequence view, into a unified multi-view model. In the view of utterance sequence, discourse information can be learnt through utterance-level recurrent neural network, different from word sequence view. The representations learnt from the two views provide complementary information for each other in the task of response selection. Experiments show that our multi-view model significantly outperforms the state-of-the-art word sequence view models. We will extend our framework to response generation approaches in our future work. We believe it will help construct a better representation of context in the encoding phrase of DNN-based generation model and thus improve the performance.

Abstract

Implicit discourse relation recognition is a crucial component for automatic discourse-level analysis and nature language understanding. Previous studies exploit discriminative models that are built on either powerful manual features or deep discourse representations. In this paper, instead, we explore generative models and propose a variational neural discourse relation recognizer. We refer to this model as *VarNDRR*. VarNDRR establishes a directed probabilistic model with a latent continuous variable that generates both a discourse and the relation between the two arguments of the discourse. In order to perform efficient inference and learning, we introduce neural discourse relation models to approximate the prior and posterior distributions of the latent variable, and employ these approximated distributions to optimize a reparameterized variational lower bound. This allows VarNDRR to be trained with standard stochastic gradient methods. Experiments on the benchmark data set show that VarNDRR can achieve comparable results against state-of-the-art baselines without using any manual features.

1 Introduction

Discourse relation characterizes the internal structure and logical relation of a coherent text. Automatically identifying these relations not only plays an important role in discourse comprehension and generation, but also obtains wide applications in many other relevant natural language processing tasks, such as text summarization (Yoshida et al., 2014), conversation (Higashinaka et al., 2014), question answering (Verberne et al., 2007) and information extraction (Cimiano et al., 2005). Generally, discourse relations can be divided into two categories: explicit and implicit, which can be illustrated in the following example:

> *The company was disappointed by the ruling.* <u>*because*</u> *The obligation is totally unwarranted.* (adapted from wsj_0294)

With the discourse connective *because*, these two sentences display an explicit discourse relation CONTINGENCY which can be inferred easily. Once this discourse connective is removed, however, the discourse relation becomes implicit and difficult to be recognized. This is because almost no surface information in these two sentences can signal this relation. For successful recognition of this relation, in the contrary, we need to understand the deep semantic correlation between *disappointed* and *obligation* in the two sentences above. Although explicit discourse relation recognition (DRR) has made great progress (Miltsakaki et al., 2005; Pitler et al., 2008), implicit DRR still remains a serious challenge due to the difficulty in semantic analysis.

Conventional approaches to implicit DRR often treat the relation recognition as a classification problem, where discourse arguments and relations are regarded as the inputs and outputs respectively. Generally, these methods first generate a representation for a discourse, denoted as $\mathbf{x}$[1] (e.g., manual fea-

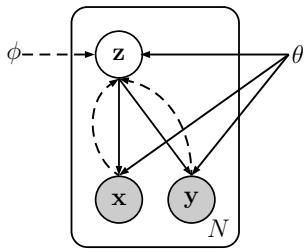

Figure 1: Graphical illustration for VarNDRR. Solid lines denote the generative model $p_\theta(\mathbf{x}|\mathbf{z})p_\theta(\mathbf{y}|\mathbf{z})$, dashed lines denote the variational approximation $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$ to the posterior $p(\mathbf{z}|\mathbf{x},\mathbf{y})$ and $q'_\phi(\mathbf{z}|\mathbf{x})$ to the prior $p(\mathbf{z})$ for inference. The variational parameters ϕ are learned jointly with the generative model parameters θ.

tures in SVM-based recognition (Pitler et al., 2009; Lin et al., 2009) or sentence embeddings in neural networks-based recognition (Ji and Eisenstein, 2015; Zhang et al., 2015)), and then directly model the conditional probability of the corresponding discourse relation $\mathbf{y}$ given $\mathbf{x}$, i.e. $p(\mathbf{y}|\mathbf{x})$. In spite of their success, these discriminative approaches rely heavily on the goodness of discourse representation $\mathbf{x}$. Sophisticated and good representations of a discourse, however, may make models suffer from overfitting as we have no large-scale balanced data.

Instead, we assume that there is a latent continuous variable $\mathbf{z}$ from an underlying semantic space. It is this latent variable that generates both discourse arguments and the corresponding relation, i.e. $p(\mathbf{x},\mathbf{y}|\mathbf{z})$. The latent variable enables us to jointly model discourse arguments and their relations, rather than conditionally model $\mathbf{y}$ on $\mathbf{x}$. However, the incorporation of the latent variable makes the modeling difficult due to the intractable computation with respect to the posterior distribution.

Inspired by Kingma and Welling (2014) as well as Rezende et al. (2014) who introduce a variational neural inference model to the intractable posterior via optimizing a reparameterized variational lower bound, we propose a variational neural discourse relation recognizer (VarNDRR) with a latent continuous variable for implicit DRR in this paper. The key idea behind VarNDRR is that although the posterior distribution is intractable, we can approximate it via a deep neural network. Figure 1 illustrates the graph structure of VarNDRR. Specifically, there are two essential components:

- *neural discourse recognizer* As a discourse $\mathbf{x}$ and its corresponding relation $\mathbf{y}$ are independent with each other given the latent variable $\mathbf{z}$ (as shown by the solid lines), we can formulate the generation of $\mathbf{x}$ and $\mathbf{y}$ from $\mathbf{z}$ in the equation $p_\theta(\mathbf{x},\mathbf{y}|\mathbf{z}) = p_\theta(\mathbf{x}|\mathbf{z})p_\theta(\mathbf{y}|\mathbf{z})$. These two conditional probabilities on the right hand side are modeled via deep neural networks (see section 3.1).
- *neural latent approximator* VarNDRR assumes that the latent variable can be inferred from discourse arguments $\mathbf{x}$ and relations $\mathbf{y}$ (as shown by the dash lines). In order to infer the latent variable, we employ a deep neural network to approximate the posterior $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$ as well as the prior $q'_\phi(\mathbf{z}|\mathbf{x})$ (see section 3.2), which makes the inference procedure efficient. We further employ a reparameterization technique to sample z from $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$ that not only bridges the gap between the recognizer and the approximator but also allows us to use the standard stochastic gradient ascent techniques for optimization (see section 3.3).

The main contributions of our work lie in two aspects. 1) We exploit a generative graphic model for implicit DRR. To the best of our knowledge, this has never been investigated before. 2) We develop a neural recognizer and two neural approximators specifically for implicit DRR, which enables both the recognition and inference to be efficient.

We conduct a series of experiments for English implicit DRR on the PDTB-style corpus to evaluate the effectiveness of our proposed VarNDRR model. Experiment results show that our variational model achieves comparable results against several strong baselines in term of F1 score. Extensive analysis on the variational lower bound further reveals that our model can indeed fit the data set with respect to discourse arguments and relations.

2 Background: Variational Autoencoder

The variational autoencoder (VAE) (Kingma and Welling, 2014; Rezende et al., 2014), which forms the basis of our model, is a generative model that can be regarded as a regularized version of the standard

treat them as univariate variables in most cases. Additionally, we use bold symbols to denote variables, and plain symbols to denote values.

autoencoder. With a latent random variable $\mathbf{z}$, VAE significantly changes the autoencoder architecture to be able to capture the variations in the observed variable $\mathbf{x}$. The joint distribution of $(\mathbf{x}, \mathbf{z})$ is formulated as follows:

$$p_\theta(\mathbf{x}, \mathbf{z}) = p_\theta(\mathbf{x}|\mathbf{z})p_\theta(\mathbf{z}) \tag{1}$$

where $p_\theta(\mathbf{z})$ is the prior over the latent variable, usually equipped with a simple Gaussian distribution. $p_\theta(\mathbf{x}|\mathbf{z})$ is the conditional distribution that models the probability of $\mathbf{x}$ given the latent variable $\mathbf{z}$. Typically, VAE parameterizes $p_\theta(\mathbf{x}|\mathbf{z})$ with a highly nonlinear but flexible function approximator such as a neural network.

The objective of VAE is to maximize a variational lower bound as follows:

$$\begin{aligned}\mathcal{L}_{VAE}(\theta, \phi; \mathbf{x}) = &-\mathrm{KL}(q_\phi(\mathbf{z}|\mathbf{x})||p_\theta(\mathbf{z})) \\ &+\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] \leq \log p_\theta(\mathbf{x})\end{aligned} \tag{2}$$

where $\mathrm{KL}(Q||P)$ is Kullback-Leibler divergence between two distributions Q and P. $q_\phi(\mathbf{z}|\mathbf{x})$ is an approximation of the posterior $p(\mathbf{z}|\mathbf{x})$ and usually follows a diagonal Gaussian $\mathcal{N}(\mu, \mathrm{diag}(\sigma^2))$ whose mean μ and variance σ^2 are parameterized by again, neural networks, conditioned on $\mathbf{x}$.

To optimize Eq. (2) stochastically with respect to both θ and ϕ, VAE introduces a reparameterization trick that parameterizes the latent variable $\mathbf{z}$ with the Gaussian parameters μ and σ in $q_\phi(\mathbf{z}|\mathbf{x})$:

$$\tilde{z} = \mu + \sigma \odot \epsilon \tag{3}$$

where ϵ is a standard Gaussian variable, and $\odot$ denotes an element-wise product. Intuitively, VAE learns the representation of the latent variable not as single points, but as soft ellipsoidal regions in latent space, forcing the representation to fill the space rather than memorizing the training data as isolated representations. With this trick, the VAE model can be trained through standard backpropagation technique with stochastic gradient ascent.

3 The VarNDRR Model

This section introduces our proposed VarNDRR model. Formally, in VarNDRR, there are two observed variables, $\mathbf{x}$ for a discourse and $\mathbf{y}$ for the corresponding relation, and one latent variable $\mathbf{z}$. As illustrated in Figure 1, the joint distribution of the three variables is formulated as follows:

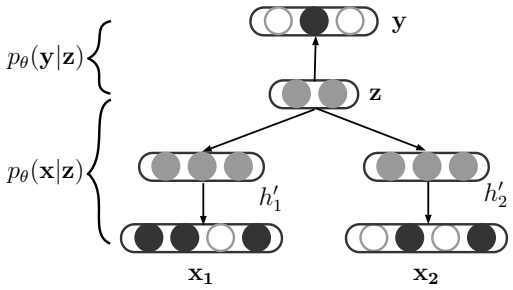

Figure 2: Neural networks for conditional probabilities $p_\theta(\mathbf{x}|\mathbf{z})$ and $p_\theta(\mathbf{y}|\mathbf{z})$. The gray color denotes real-valued representations while the white and black color 0-1 representations.

$$p_\theta(\mathbf{x}, \mathbf{y}, \mathbf{z}) = p_\theta(\mathbf{x}, \mathbf{y}|\mathbf{z})p(\mathbf{z}) \tag{4}$$

We begin with this distribution to elaborate the major components of VarNDRR.

3.1 Neural Discourse Recognizer

The conditional distribution $p(\mathbf{x}, \mathbf{y}|\mathbf{z})$ in Eq. (4) shows that both discourse arguments and the corresponding relation are generated from the latent variable. As shown in Figure 1, $\mathbf{x}$ is d-separated from $\mathbf{y}$ by $\mathbf{z}$. Therefore the discourse $\mathbf{x}$ and the corresponding relation $\mathbf{y}$ is independent given the latent variable $\mathbf{z}$. The joint probability can be therefore formulated as follows:

$$p_\theta(\mathbf{x}, \mathbf{y}, \mathbf{z}) = p_\theta(\mathbf{x}|\mathbf{z})p_\theta(\mathbf{y}|\mathbf{z})p(\mathbf{z}) \tag{5}$$

We use a neural model $q'_\phi(\mathbf{z}|\mathbf{x})$ to approximate the prior $p(\mathbf{z})$ conditioned on the discourse $\mathbf{x}$ (see the following section). With respect to the other two conditional distributions, we parameterize them via neural networks as shown in Figure 2.

Before we describe these neural networks, it is necessary to briefly introduce how discourse relations are annotated in our training data. The PDTB corpus, used as our training data, annotates implicit discourse relations between two neighboring arguments, namely *Arg1* and *Arg2*. In VarNDRR, we represent the two arguments with bag-of-word representations, and denote them as $\mathbf{x_1}$ and $\mathbf{x_2}$.

To model $p_\theta(\mathbf{x}|\mathbf{z})$ (the bottom part in Figure 2), we project the representation of the latent variable

$z \in \mathbb{R}^{d_z}$ onto a hidden layer:

$$\begin{aligned} h'_1 &= f(W_{h'_1} z + b_{h'_1}) \\ h'_2 &= f(W_{h'_2} z + b_{h'_1}) \end{aligned} \tag{6}$$

where $h'_1 \in \mathbb{R}^{d_{h'_1}}, h'_2 \in \mathbb{R}^{d_{h'_2}}$, W_* is the transformation matrix, b_* is the bias term, d_u denotes the dimensionality of vector representations of u and $f(\cdot)$ is an element-wise activation function, such as $tanh(\cdot)$, which is used throughout our model.

Upon this hidden layer, we further stack a Sigmoid layer to predict the probabilities of corresponding discourse arguments:

$$\begin{aligned} x'_1 &= \text{Sigmoid}(W_{x'_1} h'_1 + b_{x'_1}) \\ x'_2 &= \text{Sigmoid}(W_{x'_2} h'_2 + b_{x'_2}) \end{aligned} \tag{7}$$

here, $x'_1 \in \mathbb{R}^{d_{x_1}}$ and $x'_2 \in \mathbb{R}^{d_{x_2}}$ are the real-valued representations of the reconstructed x_1 and x_2 respectively.[2] We assume that $p_\theta(\mathbf{x}|\mathbf{z})$ is a multivariate Bernoulli distribution because of the bag-of-word representation. Therefore the logarithm of $p(x|z)$ is calculated as the sum of probabilities of words in discourse arguments as follows:

$$\begin{aligned} &\log\ p(x|z) \\ &= \sum_i x_{1,i} \log x'_{1,i} + (1 - x_{1,i}) \log(1 - x'_{1,i}) \\ &+ \sum_j x_{2,j} \log x'_{2,j} + (1 - x_{2,j}) \log(1 - x'_{2,j}) \end{aligned} \tag{8}$$

where $u_{i,j}$ is the jth element in u_i.

In order to estimate $p_\theta(\mathbf{y}|\mathbf{z})$ (the top part in Figure 2), we stack a softmax layer over the multilayer-perceptron-transformed representation of the latent variable z:

$$y' = \text{SoftMax}(W_{y'}\text{MLP}(z) + b_{y'}) \tag{9}$$

$y' \in \mathbb{R}^{d_y}$, and d_y denotes the number of discourse relations. MLP projects the representation of latent variable $\mathbf{z}$ into a d_m-dimensional space through four internal layers, each of which has dimension d_m. Suppose that the true relation is $y \in \mathbb{R}^{d_y}$, the logarithm of $p(y|z)$ is defined as:

$$\log\ p(y|z) = \sum_{i=1}^{d_y} y_i \log y'_i \tag{10}$$

[2]Notice that the equality of $d_{x_1} = d_{x_2}, d_{h'_1} = d_{h'_2}$ is not necessary though we assume so in our experiments.

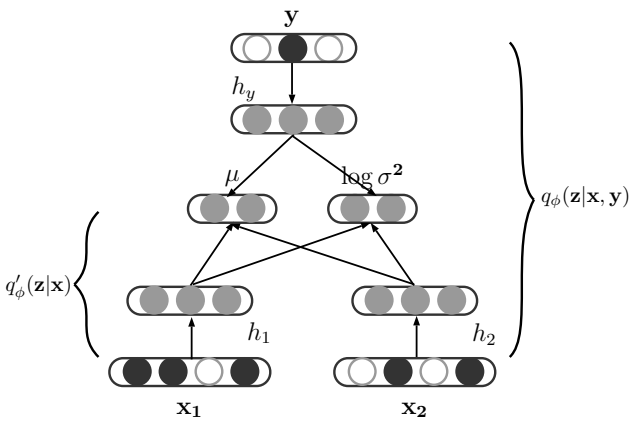

Figure 3: Neural networks for Gaussian parameters μ and $\log \sigma$ in the approximated posterior $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$ and prior $q'_\phi(\mathbf{z}|\mathbf{x})$.

In order to precisely estimate these conditional probabilities, our model will force the representation z of the latent variable to encode semantic information for both the reconstructed discourse x' (Eq. (8)) and predicted discourse relation y' (Eq. (10)), which is exactly what we want.

3.2 Neural Latent Approximator

For the joint distribution in Eq. (5), we can define a variational lower bound that is similar to Eq. (2). The difference lies in two aspects: the approximate prior $q'_\phi(\mathbf{z}|\mathbf{x})$ and posterior $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$. We model both distributions as a multivariate Gaussian distribution with a diagonal covariance structure:

$$\mathcal{N}(\mathbf{z}; \mu, \sigma^2\mathbf{I})$$

The mean μ and s.d. σ of the approximate distribution are the outputs of the neural network as shown in Figure 3, where the prior and posterior have different conditions and independent parameters.

Approximate Posterior $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})$ is modeled to condition on both observed variables: the discourse arguments $\mathbf{x}$ and relations $\mathbf{y}$. Similar to the calculation of $p_\theta(\mathbf{x}|\mathbf{z})$, we first transform the input $\mathbf{x}$ and $\mathbf{y}$ into a hidden representation:

$$\begin{aligned} h_1 &= f(W_{h_1} x_1 + b_{h_1}) \\ h_2 &= f(W_{h_2} x_2 + b_{h_2}) \\ h_y &= f(W_{h_y} y + b_{h_y}) \end{aligned} \tag{11}$$

where $h_1 \in \mathbb{R}^{d_{h_1}}, h_2 \in \mathbb{R}^{d_{h_2}}$ and $h_y \in \mathbb{R}^{d_{h_y}}$.[3]

[3]Notice that d_{h_1}/d_{h_2} are not necessarily equal to $d_{h'_1}/d_{h'_2}$.

We then obtain the Gaussian parameters of the posterior μ and $\log \sigma^2$ through linear regression:

$$\begin{aligned} \mu &= W_{\mu_1} h_1 + W_{\mu_2} h_2 + W_{\mu_y} h_y + b_\mu \\ \log \sigma^2 &= W_{\sigma_1} h_1 + W_{\sigma_2} h_2 + W_{\sigma_y} h_y + b_\sigma \end{aligned} \quad (12)$$

where $\mu, \sigma \in \mathbb{R}^{d_z}$. In this way, this posterior approximator can be efficiently computed.

Approximate Prior $q'_\phi(\mathbf{z}|\mathbf{x})$ is modeled to condition on discourse arguments $\mathbf{x}$ alone. This is based on the observation that discriminative models are able to obtain promising results using only $\mathbf{x}$. Therefore, assuming the discourse arguments encode the prior information for discourse relation recognition is meaningful.

The neural model for prior $q'_\phi(\mathbf{z}|\mathbf{x})$ is the same as that (i.e. Eq (11) and (12)) for posterior $q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})$ (see Figure 3), except for the absence of discourse relation $\mathbf{y}$. For clarity , we use μ' and σ' to denote the mean and s.d. of the approximate prior.

With the parameters of Gaussian distribution, we can access the representation z using different sampling strategies. However, traditional sampling approaches often breaks off the connection between recognizer and approximator, making the optimization difficult. Instead, we employ the reparameterization trick (Kingma and Welling, 2014; Rezende et al., 2014) as in Eq. (3). During training, we sample the latent variable using $\tilde{z} = \mu + \sigma \odot \epsilon$; during testing, however, we employ the expectation of $\mathbf{z}$ in the approximate prior distribution, i.e. set $\tilde{z} = \mu'$ to avoid uncertainty.

3.3 Parameter Learning

We employ the Monte Carlo method to estimate the expectation over the approximate posterior, that is $\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})}[\log p_\theta(\mathbf{x}, \mathbf{y}|\mathbf{z})]$. Given a training instance $(x^{(t)}, y^{(t)})$, the joint training objective is defined:

$$\begin{aligned} \mathcal{L}(\theta, \phi) \simeq & -\mathrm{KL}(q_\phi(\mathbf{z}|x^{(t)}, y^{(t)})||q'_\phi(\mathbf{z}|x^{(t)})) \\ & + \frac{1}{L} \sum_{l=1}^{L} \log p_\theta(x^{(t)}, y^{(t)}|\tilde{z}^{(t,l)}) \end{aligned} \quad (13)$$

where $\tilde{z}^{(t,l)} = \mu^{(t)} + \sigma^{(t)} \odot \epsilon^{(l)}$ and $\epsilon^{(l)} \sim \mathcal{N}(0, \mathbf{I})$

L is the number of samples. The first term is the KL divergence of two Gaussian distributions which can be computed and differentiated without estimation. Maximizing this objective will minimize the difference between the approximate posterior and prior, thus making the setting $\tilde{z} = \mu'$ during testing reasonable. The second term is the approximate expectation of $\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x},\mathbf{y})}[\log p_\theta(\mathbf{x}, \mathbf{y}|\mathbf{z})]$, which is also differentiable.

As the objective function in Eq. (13) is differentiable, we can optimize both the model parameters θ and variational parameters ϕ jointly using standard gradient ascent techniques. The training procedure for VarNDRR is summarized in Algorithm 1.

Algorithm 1 Parameter Learning Algorithm of VarNDRR.

Inputs: A, the maximum number of iterations;
M, the number of instances in one batch;
L, the number of samples;
$\theta, \phi \leftarrow$ Initialize parameters
repeat
  $\mathcal{D} \leftarrow$ getRandomMiniBatch(M)
  $\epsilon \leftarrow$ getRandomNoiseFromStandardGaussian()
  $g \leftarrow \nabla_{\theta,\phi} \mathcal{L}(\theta, \phi; \mathcal{D}, \epsilon)$
  $\theta, \phi \leftarrow$ parameterUpdater($\theta, \phi; g$)
until convergence of parameters (θ, ϕ) or reach the maximum iteration A

4 Experiments

We conducted experiments on English implicit DRR task to validate the effectiveness of VarNDRR.[4]

4.1 Dataset

We used the largest hand-annotated discourse corpus *PDTB 2.0*[5] (Prasad et al., 2008) (PDTB hereafter). This corpus contains discourse annotations over 2,312 Wall Street Journal articles, and is organized in different sections. Following previous work (Pitler et al., 2009; Zhou et al., 2010; Lan et

Table 2: Classification results of different models on the implicit DRR task. **Acc**=Accuracy, **P**=Precision, **R**=Recall, and **F1**=F1 score.

al., 2013; Zhang et al., 2015), we used sections 2-20 as our training set, sections 21-22 as the test set. Sections 0-1 were used as the development set for hyperparameter optimization.

In PDTB, discourse relations are annotated in a predicate-argument view. Each discourse connective is treated as a predicate that takes two text spans as its arguments. The discourse relation tags in PDTB are arranged in a three-level hierarchy, where the top level consists of four major semantic *classes*: TEMPORAL (TEM), CONTINGENCY (CON), EXPANSION (EXP) and COMPARISON (COM). Because the top-level relations are general enough to be annotated with a high inter-annotator agreement and are common to most theories of discourse, in our experiments we only use this level of annotations.

We formulated the task as four separate one-against-all binary classification problems: each top level class vs. the other three discourse relation classes. We also balanced the training set by resampling training instances in each class until the number of positive and negative instances are equal. In contrast, all instances in the test and development set are kept in nature. The statistics of various data sets is listed in Table 1.

4.2 Setup

We tokenized all datasets using *Stanford NLP Toolkit*[6]. For optimization, we employed the Adam algorithm (Kingma and Ba, 2014) to update parameters. With respect to the hyperparameters M, L, A and the dimensionality of all vector representations, we set them according to previous work (Kingma and Welling, 2014; Rezende et al., 2014) and preliminary experiments on the development set. Finally, we set $M = 16, A = 1000, L = 1, d_z = 20, d_{x_1} = d_{x_2} = 10001, d_{h_1} = d_{h_2} = d_{h'_1} = d_{h'_2} = d_m = d_{h_y} = 400, d_y = 2$ for all experiments.[7]. All parameters of VarNDRR are initialized by a Gaussian distribution ($\mu = 0, \sigma = 0.01$). For Adam, we set $\beta_1 = 0.9$, $\beta_2 = 0.999$ with a learning rate 0.001. Additionally, we tied the following parameters in practice: W_{h_1} and W_{h_2}, $W_{x'_1}$ and $W_{x'_2}$.

We compared VarNDRR against the following two different baseline methods:

- **SVM:** a support vector machine (SVM) classifier[8] trained with several manual features.
- **SCNN:** a shallow convolutional neural network proposed by Zhang et al. (2015).

We also provide results from two state-of-the-art systems:

- **Rutherford and Xue (2015)** convert explicit discourse relations into implicit instances.
- **Ji and Eisenstein (2015)** augment discourse representations via entity connections.

Horizontal axis: the epoch numbers; Vertical axis: the F1 score for relation classification (left) and the estimated average variational lower bound per datapoint (right).

Features used in **SVM** are taken from the state-of-the-art implicit discourse relation recognition model, including *Bag of Words*, *Cross-Argument Word Pairs*, *Polarity*, *First-Last, First3*, *Production Rules*, *Dependency Rules* and *Brown cluster pair* (Rutherford and Xue, 2014). In order to collect bag of words, production rules, dependency rules, and cross-argument word pairs, we used a frequency cut-off of 5 to remove rare features, following Lin et al. (2009).

4.3 Classification Results

Because the development and test sets are imbalanced in terms of the ratio of positive and negative instances, we chose the widely-used F1 score as our major evaluation metric. In addition, we also provide the precision, recall and accuracy for further analysis. Table 2 summarizes the classification results.

From Table 2, we observe that the proposed VarNDRR outperforms **SVM** on COM/EXP/TEM and **SCNN** on EXP/COM according to their F1 scores. Although it fails on CON, VarNDRR achieves the best result on EXP/COM among these three models. Overall, VarNDRR is competitive in comparison with these two baselines. With respect to the accuracy, our model does not yield substantial improvements over the two baselines. This may be because that we used the F1 score rather than the accuracy, as our selection criterion on the development set. With respect to the precision and recall, our model tends to produce relatively lower precisions but higher recalls. This suggests that the improvements of VarNDRR in terms of F1 scores mostly benefits from the recall values.

Comparing with the state-of-the-art results of previous work (Ji and Eisenstein, 2015; Rutherford and Xue, 2015), VarNDRR achieves comparable results in term of the F1 scores. Specifically, VarNDRR outperforms Rutherford and Xue (2015) on EXP, and Ji and Eisenstein (2015) on TEM. However, the accuracy of our model fails to surpass these models. We argue that this is because both baselines use many manual features designed with prior human knowledge, but our model is purely neural-based.

Additionally, we find that the performance of our model is proportional to the number of training instances. This suggests that collecting more training instances (in spite of the noises) may be beneficial to our model.

4.4 Variational Lower Bound Analysis

In addition to the classification performance, the efficiency in learning and inference is another concern

for variational methods. Figure 4 shows the training procedure for four tasks in terms of the variational lower bound on the training set. We also provide F1 scores on the development set to investigate the relations between the variational lower bound and recognition performance.

We find that our model converges toward the variational lower bound considerably fast in all experiments (within 100 epochs), which resonates with the previous findings (Kingma and Welling, 2014; Rezende et al., 2014). However, the change trend of the F1 score does not follow that of the lower bound which takes more time to converge. Particularly to the four discourse relations, we further observe that the change paths of the F1 score are completely different. This may suggest that the four discourse relations have different properties and distributions.

In particular, the number of epochs when the best F1 score reaches is also different for the four discourse relations. This indicates that dividing the implicit DRR into four different tasks according to the type of discourse relations is reasonable and better than performing DRR on the mixtures of the four relations.

5 Related Work

There are two lines of research related to our work: *implicit discourse relation recognition* and *variational neural model*, which we describe in succession.

Implicit Discourse Relation Recognition Due to the release of Penn Discourse Treebank (Prasad et al., 2008) corpus, constantly increasing efforts are made for implicit DRR. Upon this corpus, Pilter et al. (2009) exploit several linguistically informed features, such as polarity tags, modality and lexical features. Lin et al. (2009) further incorporate context words, word pairs as well as discourse parse information into their classifier. Following this direction, several more powerful features have been exploited: entities (Louis et al., 2010), word embeddings (Braud and Denis, 2015), Brown cluster pairs and co-reference patterns (Rutherford and Xue, 2014). With these features, Park and Cardie (2012) perform feature set optimization for better feature combination.

Different from feature engineering, predicting discourse connectives can indirectly help the relation classification (Zhou et al., 2010; Patterson and Kehler, 2013). In addition, selecting explicit discourse instances that are similar to the implicit ones can enrich the training corpus for implicit DRR and gains improvement (Wang et al., 2012; Lan et al., 2013; Braud and Denis, 2014; Fisher and Simmons, 2015; Rutherford and Xue, 2015). Very recently, neural network models have been also used for implicit DRR due to its capability for representation learning (Ji and Eisenstein, 2015; Zhang et al., 2015).

Despite their successes, most of them focus on the discriminative models, leaving the field of generative models for implicit DRR a relatively uninvestigated area. In this respect, the most related work to ours is the latent variable recurrent neural network recently proposed by Ji et al. (2016). However, our work differs from theirs significantly, which can be summarized in the following three aspects: 1) they employ the recurrent neural network to represent the discourse arguments, while we use the simple feed-forward neural network; 2) they treat the discourse relations directly as latent variables, rather than the underlying semantic representation of discourses; 3) their model is optimized in terms of the data likelihood, since the discourse relations are observed during training. However, VarNDRR is optimized under the variational theory.

Variational Neural Model In the presence of continuous latent variables with intractable posterior distributions, efficient inference and learning in directed probabilistic models is required. Kingma and Welling (2014) as well as Rezende et al. (2014) introduce variational neural networks that employ an approximate inference model for intractable posterior and reparameterized variational lower bound for stochastic gradient optimization. Kingma et al. (2014) revisit the approach to semi-supervised learning with generative models and further develop new models that allow effective generalization from a small labeled dataset to a large unlabeled dataset. Chung et al. (2015) incorporate latent variables into the hidden state of a recurrent neural network, while Gregor et al. (2015) combine a novel spatial attention mechanism that mimics the foveation of human eyes, with a sequential variational auto-encoding framework that allows the iterative construction of

complex images.

We follow the spirit of these variational models, but focus on the adaptation and utilization of them onto implicit DRR, which, to the best of our knowledge, is the first attempt in this respect.

6 Conclusion and Future Work

In this paper, we have presented a variational neural discourse relation recognizer for implicit DRR. Different from conventional discriminative models that directly calculate the conditional probability of the relation $\mathbf{y}$ given discourse arguments $\mathbf{x}$, our model assumes that it is a latent variable from an underlying semantic space that generates both $\mathbf{x}$ and $\mathbf{y}$. In order to make the inference and learning efficient, we introduce a neural discourse recognizer and two neural latent approximators as our generative and inference model respectively. Using the reparameterization technique, we are able to optimize the whole model via standard stochastic gradient ascent algorithm. Experiment results in terms of classification and variational lower bound verify the effectiveness of our model.

In the future, we would like to exploit the utilization of discourse instances with explicit relations for implicit DRR. For this we can start from two directions: 1) converting explicit instances into pseudo implicit instances and retraining our model; 2) developing a semi-supervised model to leverage semantic information inside discourse arguments. Furthermore, we are also interested in adapting our model to other similar tasks, such as nature language inference.

Event Detection and Co-reference with Minimal Supervision

Abstract

An important aspect of natural language understanding involves recognizing and categorizing events and the relations among them. However, these tasks are quite subtle and annotating training data for machine learning based approaches is an expensive task, resulting in supervised systems that attempt to learn complex models from small amounts of data, which they over-fit. This paper addresses this challenge by developing an event detection and co-reference system with minimal supervision, in the form of a few event examples. We view these tasks as semantic similarity problems between event mentions or event mentions and an ontology of types, thus facilitating the use of large amounts of out of domain text data. Notably, our semantic relatedness function exploits the structure of the text by making use of a semantic-role-labeling based representation of an event.

We show that our approach to event detection is competitive with the top supervised methods. More significantly, we outperform state-of-the-art supervised methods for event co-reference on benchmark data sets, and support significantly better transfer across domains.

1 Introduction

Natural language understanding involves, as a key component, the need to understand events mentioned in texts. This entails recognizing elements such as agents, patients, actions, location and time, among others. Understanding events also necessitates understanding relations among them and, as a minimum, determining whether two snippets of text represent the same event or not – the event co-reference problem. Events have been studied for years, but they still remain a key challenge. One reason is that the frame-based structure of events necessitates addressing multiple coupled problems that are not easy to study in isolation. Perhaps an even more fundamental difficulty is that it is not clear whether our current set of events' definitions is adequate (Hovy et al., 2013). Thus, given the complexity and fundamental difficulties, the current evaluation methodology in this area focuses on a limited domain of events, e.g. 33 types in ACE 2005 (NIST, 2005) and 38 types in TAC KBP (Mitamura et al., 2015). Consequently, this allows researchers to train supervised systems that are tailored to these sets of events and that overfit the small domain covered in the annotated data, rather than address the realistic problem of understanding events in text.

In this paper, we pursue an approach to understanding events that we believe to be more feasible and scalable. Fundamentally, event detection is about identifying whether an event in context is semantically related to a set of events of a specific type; and, event co-reference is about whether two event mentions are semantically similar enough to indicate that the author intends to refer to the same thing. Therefore, if we formulate event detection and co-reference as semantic relatedness problems, we can scale it to deal with a lot more types and, potentially, generalize across domains. Moreover, by doing so, we facilitate the use of a lot of data that is not part of the existing annotated event collections and not even from the same domain. The key chal-

	Supervised	Unsupervised	MSEP
Guideline	✓	✓	✓
In-domain Data	✓	✓	✗
Data Annotation	✓	✗	✗

Table 1: **Comparing requirements of MSEP and other methods.** Supervised methods need all three resources while MSEP only needs an annotation guideline (as event examples).

lenges we need to address are those of how to represent events, and how to model event similarity; both are difficult partly since events have *structure*.

We present a general event detection and coreference framework, which essentially requires no labeled data. In practice, in order to map an event mention to an event ontology, as a way to communicate with a user, we just need a few event examples, in plain text, for each type a user wants to extract. This is a reasonable setting; after all, giving examples is the easiest way of defining event types, and is also how information needs are defined to annotators - by providing examples in the annotation guideline.[1] Our approach makes less assumptions than standard *unsupervised* methods, which typically require a *collection* of instances and exploit similarities among them to eventually learn a model. Here, given event type definitions (in the form of a few examples), we can classify a *single* event into a provided ontology and determine whether two events are co-referent. In this sense, our approach is similar to what has been called *dataless classification* (Chang et al., 2008; Song and Roth, 2014). Table 1 summarizes the difference between our approach, **MSEP** (Minimally Supervised Event Pipeline)[2], and other methods.

Our approach builds on two key ideas. First, to represent event structures, we use the general purpose nominal and verbial semantic role labeling (SRL) representation. This allows us to develop a structured representation of an event. Second, we embed event components, while maintaining the structure, into multiple semantic spaces, induced at a contextual, topical, and syntactic levels. These semantic representations are induced from large amounts of text in a way that is completely independent of the tasks at hand, and are used to represent both event mentions and event types into which we classify our events. The combination of these semantic spaces, along with the structured vector representation of an event, allow us to directly determine whether a candidate event mention is a valid event or not and, if it is, of which type. Moreover, with the same representation, we can evaluate event similarities and decide whether two event mentions are co-referent. Consequently, the proposed MSEP, can also adapt to new domains without any training.

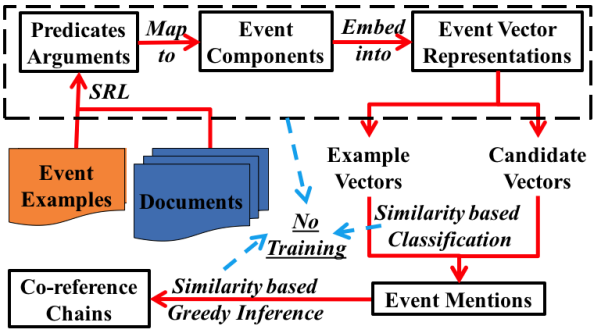

Figure 1: An overview of the end-to-end MSEP system. "Event Examples" are the only supervision here, which produce "Example Vectors". No training is needed for MSEP.

An overview of the system is shown in Figure 1. A few event examples are *all* the supervision MSEP needs; even the few decision thresholds needed to be set are determined on these examples, once and for all, and are used for *all* test cases we evaluate on. We use two benchmark datasets to compare MSEP with baselines and supervised systems. We show that MSEP performs favorably relative to state-of-the-art supervised systems; the co-reference module, in fact, outperforms supervised approaches on B^3 and CEAF metrics. The superiority of MSEP is also demonstrated in across domain settings.

2 The MSEP System

2.1 Structured Vector Representation

There is a parallel between event structures and sentence structures. Event triggers are mostly predicates of sentences or clauses. Predicates can be sense disambiguated, which roughly corresponds to

[1] Event examples also serve for disambiguation purposes. For example, using "U.S. forces bombed Baghdad." to exemplify an *attack* type, disambiguates it from a *heart attack*.

[2] Available at http://cogcomp.cs.illinois.edu/page/download_view/eventPipeline .

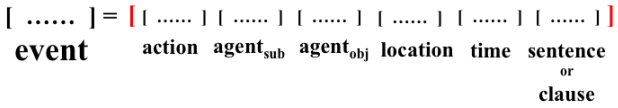

Figure 2: **Basic event vector representation.** Event vector is the concatenation of vectors corresponding to action, agent$_{sub}$, agent$_{obj}$, location, time and sentence/clause.

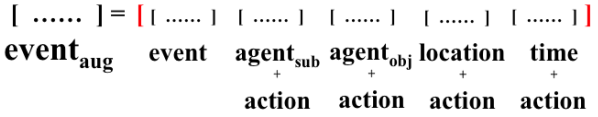

Figure 3: **Augmented event vector representation.** Event vector is the concatenation of vectors corresponding to basic event vector representation, agent$_{sub}$ + action, agent$_{obj}$ + action, location + action and time + action. Here, "+" means that we first put text fragments together and then convert the combined text fragment into an ESA vector.

event types. Event arguments are largely entity mentions or temporal/spatial arguments. They serve as specific roles in events, similarly to SRL arguments that are assigned role labels for predicates.

We use the Illinois SRL (Punyakanok et al., 2004) tool to pre-process the text. We evaluate the SRL coverage on both event triggers and event arguments, shown in Table 2.[3] For event triggers, we only focus on recall since we expect the event mention detection module to filter out most non-trigger predicates. Results show a good coverage of SRL predicates and arguments on event triggers and arguments. Even though we only get approximate event arguments, it is easier and more reliable to categorize them into five abstract roles, than to determine the exact role label with respect to event triggers.

We identify the five most important and abstract event semantic components: action, agent$_{sub}$, agent$_{obj}$, location and time. To map SRL arguments to these event arguments, we run through the following procedures: 1) set predicates as actions, and preserve SRL negations for actions, 2) set SRL subject as agent$_{sub}$, 3) set SRL object and indirect object as agent$_{obj}$, 4) set SRL spatial argument as event location. If there is no such SRL label, we then scan for any NER location label within the sentence/clause to which the action belongs. We set the location according to NER information if it exists. 5) We set the SRL temporal argument as event time. If there is no such SRL label, we then use the Illinois Temporal Expression Extractor (Zhao et al., 2012) to find the temporal argument within an event's sentence/clause. 6) We allow one or more missing event arguments among agent$_{sub}$, agent$_{obj}$, location or time, but require actions to always exist.

Given the above structured information, we convert each event component to its corresponding vector representation, discussed in detail in Section 3. We then concatenate the vectors of all components together in a specific order: action, agent$_{sub}$, agent$_{obj}$, location, time and sentence/clause. We treat the whole sentence/clause, to which the "ac-

ACE		Precision	Recall	F1

Table 2: **Semantic role labeling coverage.** We evaluate both "Predicates over Triggers" and "SRL Arguments over Event Arguments". "All" stands for the combination of Verb-SRL and Nom-SRL. The evaluation is done on all data.

[3] We place events in two categories, verb or noun, according to the part-of-speech tag of the trigger. We evaluate verb-SRL on events with verb triggers, nom-SRL on events with noun triggers, and the overall performance on all events. When evaluating, we allow partial overlaps.

tion" belongs, as context, and we append its corresponding vector to the event representation. This basic event vector representation is illustrated in Fig. 2. If there are missing event arguments, we set the corresponding vector to be "NIL" (we set each position as "NaN"). We also augment the event vector representation by concatenating more text fragments to enhance the interactions between the action and other arguments, as shown in Fig. 3. Essentially, we flatten the event structure to preserve the alignment of event arguments so that the structured information can be reflected in our vector space.

2.2 Event Mention Detection

Motivated by the seed-based event trigger labeling technique employed in Bronstein et al. (2015), we turn to ACE annotation guidelines for event examples described under each event type label. For instance, the ACE-2005 guidelines list the example "Mary Smith joined Foo Corp. in June 1998." for label "START-POSITION". Altogether, we collect 172 event examples from 33 event types (5 each on average).[4] We can then get vector representations for these example events following the procedures in Sec. 2.1. We define the *event type representation* as the numerical average of all vector representations corresponding to example events under that type. We use the similarity between an event candidate with the event type representation to determine whether the candidate belongs to an event type:

$$S(e_1, e_2) = \frac{vec(e_1) \cdot vec(e_2)}{\|vec(e_1)\| \cdot \|vec(e_2)\|} = \frac{\sum_a vec(a_1) \cdot vec(a_2)}{\sqrt{\sum_a \|vec(a_1)\|^2} \cdot \sqrt{\sum_a \|vec(a_2)\|^2}}, \quad (1)$$

where e_1 is the candidate, e_2 the type ($vec(e_2)$ is computed as average of event examples), a_1, a_2 are components of e_1, e_2 respectively. We use the notation $vec(\cdot)$ for corresponding vectors. Note that there may be missing event arguments (NIL). In such cases, we use the average of all non-NIL similarity scores for that particular component as the contributed score. Formally, we define $S_{pair}(a = \text{NIL})$ and $S_{single}(a = \text{NIL})$ as follows:

$$\begin{aligned} S_{pair}(a = \text{NIL}) &= vec(\text{NIL}) \cdot vec(a_2) \\ &= vec(a_1) \cdot vec(\text{NIL}) \\ &= \sum_{a_1, a_2 \neq \text{NIL}} \frac{vec(a_1) \cdot vec(a_2)}{\#|a_1, a_2 \neq \text{NIL}|}, \end{aligned}$$

$$S_{single}(a = \text{NIL}) = \sqrt{\frac{\sum_{a \neq \text{NIL}} \|vec(a)\|^2}{\#|a \neq \text{NIL}|}}.$$

Thus, when we encounter missing event arguments, we use $S_{pair}(a = \text{NIL})$ to replace the corresponding term in the numerator in $S(e_1, e_2)$ while using $S_{single}(a = \text{NIL})$ in the denominator. These average contributed scores are corpus independent, and can be pre-computed ahead of time. We use a cut-off threshold to determine that an event does not belong to any event types, and can thus be eliminated. This threshold is set by tuning only on the set of event examples, which is corpus independent.[5]

2.3 Event Co-reference

Similar to the mention-pair model in entity coreference (Ng and Cardie, 2002; Bengtson and Roth, 2008; Stoyanov et al., 2010), we use cosine similarities computed from pairs of event mentions: $S(e_1, e_2)$ (as in Eq. (1)).

Before applying the co-reference model, we first use external knowledge bases to identify conflict events. We use the Illinois Wikification (Cheng and Roth, 2013) tool to link event arguments to Wikipedia pages. Using the Wikipedia IDs, we map event arguments to Freebase entries. We view the top-level Freebase type as the event argument type. An event argument can contain multiple wikified entities, leading to multiple Wikipedia pages and thus a set of Freebase types. We also augment the argument type set with NER labels: PER (person) and ORG (organization). We add either of the NER labels if we detect such a named entity.

For each pair of events, we check event arguments agent$_{sub}$ and agent$_{obj}$ respectively. If none of the types for the aligned event arguments match, this pair is determined to be in conflict. If the event argument is missing, we deem it compatible with any type. In this procedure, we generate a set of event pairs Set_{conflict} that will not get co-reference links.

[4] See supplementary materials for the full list of examples.

[5] See Sec. 4.4 for details.

Given the event mention similarity as well as the conflicts, we perform event co-reference inference via a left-linking greedy algorithm, i.e. co-reference decisions are made on each event from left to right, one at a time. Without loss of generality, for event $e_{k+1}, \forall k \geq 1$, we first choose a linkable event to its left with the highest event-pair similarity:

$$e_p = \arg \max_{\substack{e \in \{e_1, e_2, \ldots, e_k\} \\ e \notin Set_{\text{conflict}}}} S(e, e_{k+1}).$$

We make co-reference links when $S(e_p, e_{k+1})$ is higher than a cut-off threshold, which is also tuned only on event examples ahead of time. Otherwise, event e_{k+1} is not similar enough to any of its antecedents, and we make it the start of a new cluster.

3 Vector Representations

We experiment with different methods to convert event components into vector representations. Specifically, we use Explicit Semantic Analysis (ESA), Brown Cluster (BC), Word2Vec (W2V) and Dependency-Based Word Embedding (DEP) respectively to convert text into vectors. We then concatenate all components of an event together to form a structured vector representation.

Explicit Semantic Analysis ESA uses Wikipedia as an external knowledge base to generate concepts for a given fragment of text (Gabrilovich and Markovitch, 2009). ESA first represents a given text fragment as a TF-IDF vector, then uses an inverted index for each word to search the Wikipedia corpus. The text fragment representation is thus a weighted combination of the concept vectors corresponding to its words. We use the same setting as in Chang et al. (2008) to filter out pages with fewer than 100 words and those containing fewer than 5 hyperlinks. To balance between the effectiveness of ESA representations and its cost, we use the 200 concepts with the highest weights. Thus, we convert each text fragment to a very sparse vector of millions of dimensions (but we just store 200 non-zero values).

Brown Cluster BC was proposed by Brown et al. (1992) as a way to support abstraction in NLP tasks, measuring words' distributional similarities. This method generates a hierarchical tree of word clusters by evaluating the word co-occurrence based on a n-gram model. Then, paths traced from root to leaves can be used as word representations. We use the implementation by Song and Roth (2014), generated over the latest Wikipedia dump. We set the maximum tree depth to 20, and use a combination of path prefixes of length 4,6 and 10 as our BC representation. Thus, we convert each word to a vector of $2^4 + 2^6 + 2^{10} = 1104$ dimensions.

Word2Vec We use the skip-gram tool by Mikolov et al. (2013) over the latest Wikipedia dump, resulting in word vectors of dimensionality 200.

Dependency-Based Embedding DEP is the generalization of the skip-gram model with negative sampling to include arbitrary contexts. In particular, it deals with dependency-based contexts, and produces markedly different embeddings. DEP exhibits more functional similarity than the original skip-gram embeddings (Levy and Goldberg, 2014). We directly use the released 300-dimension word embeddings[6].

Note that it is straightforward text-vector conversion for ESA. But for BC, W2V and DEP, we first remove stop words from the text and then average, element-wise, all remaining word vectors to produce the resulting vector representation of the text fragment.

4 Experiments

4.1 Datasets

ACE The ACE-2005 English corpus (NIST, 2005) contains fine-grained event annotations, including event trigger, argument, entity, and time-stamp annotations. We select 40 documents from newswire articles for event detection evaluation and the rest for training (same as Chen et al. (2015)). We do 10-fold cross-validation for event co-reference.

TAC-KBP The TAC-KBP-2015 corpus is annotated with event nuggets that fall into 38 types and co-reference relations between events. [7] We use the train/test data split provided by the official TAC-

[6] https://levyomer.wordpress.com/2014/04/25/dependency-based-word-embeddings

[7] The event ontology of TAC-KBP (based on ERE annotation) is almost the same to that of ACE. To adapt our system to the TAC-KBP corpus, we use all ACE event seeds of "Contact.Phone-Write" for "Contact.Correspondence" and separate ACE event seeds of "Movement.Transport" into "Movement.TransportPerson" and "Movement.TransportArtifact" by manual checking. So, we use exactly the same set of event seeds for TAC-KBP with only these two changes.

	#Doc	#Sent.	#Men.	#Cluster
ACE(All)	599	15,494	5,268	4,046
ACE(Test)	40	672	289	222
TAC-KBP(All)	360	15,824	12,976	7,415
TAC-KBP(Test)	202	8,851	6,438	3,779

Table 3: **Statistics for the ACE and TAC-KBP corpora.** #Sent. is the number of sentences, #Men. is the number of event mentions, and #Cluster is the number of event clusters (including singletons). Note that the proposed MSEP does not need any training data.

2015 Event Nugget Evaluation Task.

Statistics for the ACE and TAC-KBP corpora is shown in Table 3. Note that the training set and cross-validation is only for competing supervised methods. For MSEP, we only need to run on each corpus once for testing.

4.2 Compared Systems

For event detection, we compare with **DM-CNN** (Chen et al., 2015), the state-of-art supervised event detection system. We also implement another supervised model, named *supervised structured event detection* **SSED** system following the work of Sammons et al. (2015). The system utilizes rich semantic features and applies a trigger identification classifier on every SRL predicate to determine the event type. For event co-reference, **Joint** (Chen et al., 2009) is an early work based on supervised learning. We also report **HDP-Coref** results as an unsupervised baseline (Bejan and Harabagiu, 2010), which utilizes nonparametric Bayesian models. Moreover, we create another unsupervised event co-reference baseline (**Type+SharedMen**): we treat events of the same type which share at least one co-referent entity (inside event arguments) as co-referred. On TAC-KBP corpus, we report results from the top ranking system of the TAC-2015 Event Nugget Evaluation Task as **TAC-TOP**.

We name our event mention detection module in MSEP *similarity-based event mention detection* **MSEP-EMD** system. For event co-reference, the proposed similarity based co-reference detection **MSEP-Coref** method has a number of variations depending on the modular text-vector conversion method (**ESA, BC, W2V, DEP**), whether we use augmented ESA vector representation (**AUG**)[8], and whether we use knowledge during co-reference inference (**KNOW**). We also develop a supervised event co-reference system following the work of Sammons et al. (2015), namely **Supervised$_{\textbf{Base}}$**. We also add additional event vector representations[9] as features to this supervised system and get **Supervised$_{\textbf{Extend}}$**.

4.3 Evaluation Metrics

For event detection, we use standard precision, recall and F1 metrics. For event co-reference, we compare all systems using standard F1 metrics: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), Entity-based CEAF (CEAF$_e$) (Luo, 2005) and BLANC (Recasens and Hovy, 2011). We use the average scores (AVG) of these four metrics as the main comparison metric.[10]

4.4 Results for Event detection

The performance comparison for event detection is presented in Table 4. On both ACE and TAC-KBP, parameters of SSED are tuned on a development set (20% of randomly sampled training documents). The cut-off threshold for MSEP-EMD is tuned on the 172 event examples ahead of time by optimizing the F1 score on the event seed examples. Note that different text-vector conversion methods lead to different cut-off thresholds, but they remain fixed for all the test corpus. Results show that SSED achieves state-of-the-art performance. Though MSEP-EMD's performance is below the best supervised system, it is very competitive. Note that both SSED and MSEP-EMD use SRL predicates as input and thus can further improve with a better SRL module.

4.5 Results for Event Co-reference

The performance of different systems for event co-reference based on gold event triggers is shown in Table 5. The co-reference cut-off threshold is tuned by optimizing the CoNLL average score on ten se-

[8]It is only designed for ESA because the ESA vector for two concatenated text fragments is different from the sum of the ESA vectors of individual text fragments, unlike other methods.

[9]We add the best event vector representation empirically.

[10]We use the latest scorer (v1.7) provided by TAC-2015 Event Nugget Evaluation for all metrics.

ACE (Test Data)		Precision	Recall	F1
Span	DMCNN	80.4	67.7	73.5
	SSED	76.6	71.5	**74.0**
	MSEP-EMD	75.6	69.8	72.6
Span+Type	DMCNN	75.6	63.6	**69.1**
	SSED	71.3	66.5	68.8
	MSEP-EMD	70.4	65.0	67.6
TAC-KBP (Test Data)		Precision	Recall	F1

	TAC-TOP	—	—	**65.3**
	MSEP-EMD	76.5	54.5	63.5
Span+Type	SSED	69.9	48.8	57.5
	TAC-TOP	—	—	**58.4**
	MSEP-EMD	69.2	47.8	56.6

Table 4: **Event detection (trigger identification) results.** "Span"/"Type" means span/type match respectively.

lected ACE documents. The threshold is then fixed, thus we do not change it when evaluating on the TAC-KBP corpus. As we do cross-validation on ACE, we exclude these ten documents from test at all times.[11] Results show that the proposed MSEP event co-reference system significantly outperforms baselines and achieves the same level of performance of supervised methods (82.9 v.s. 83.3 on ACE and 73.8 v.s. 74.4 on TAC-KBP). MSEP achieves better results on B^3 and $CEAF_e$ than supervised methods. Note that supervised methods usually generate millions of features (2.5M on ACE and 1.8M on TAC-KBP for $Supervised_{Base}$). In contrast, MSEP only has several thousands of non-zero dimensions in event representations. This means that our structured vector representations, through derived without explicit annotations, are far more expressive than traditional features. When we add the event vector representation (augmented ESA) as features in $Supervised_{Extend}$, we improve the overall performance by more than 1 point. When tested individually, DEP performs the best among the four text-vector conversion methods while BC performs the worst. A likely reason is that BC has too few dimensions while DEP constructs the longest vector. However, the results show that our augmented ESA representation (Fig. 2) achieves even better results.

When we use knowledge to detect conflicting events during inference, the system further improves. Note that event arguments for the proposed MSEP are predicted by SRL. We show that replacing them with gold event arguments, only slightly improves the overall performance, indicating that SRL arguments are robust enough for the event co-reference task.

4.6 End-to-End Event Co-reference Results

Table 6 shows the performance comparison for end-to-end event co-reference. We use both SSED and MSEP-EMD as event detection modules and we evaluate on standard co-reference metrics. Results on TAC-KBP show that "SSED+$Supervised_{Extend}$" achieves similar performance to the TAC top ranking system while the proposed MSEP event co-reference module helps to outperform supervised methods on B^3 and $CEAF_e$ metrics.

4.7 Domain Transfer Evaluation

To demonstrate the superiority of the adaptation capabilities of the proposed MSEP system, we test its performance on new domains and compare with the supervised system. TAC-KBP corpus contains two genres: newswire (NW) and discussion forum (DF), and they have roughly equal number of documents. When trained on NW and tested on DF, supervised methods encounter out-of-domain situations. However, the MSEP system can adapt well.[12] Table 7 shows that MSEP outperforms supervised methods in out-of-domain situations for both tasks. The differences are statistically significant with $p < 0.05$.

5 Related Work

Event detection has been studied mainly in the newswire domain as the task of detecting event triggers and determining event types and arguments. Most earlier work has taken a pipeline approach where local classifiers identify triggers first, and then arguments (Ji and Grishman, 2008; Liao and

[11] We regard this tuning procedure as "independent" and "ahead of time" because of the following reasons: 1) We could have used as threshold-tuning co-reference examples a few news documents from other sources; we just use ACE documents as a data source for simplicity. 2) We believe that the threshold only depends on event representation (the model) rather than data. 3) Tuning a single decision threshold is much cheaper than tuning a whole set of model parameters.

[12] Note that the supervised method needs to be re-trained and its parameters re-tuned while MSEP does not need training and its cut-off threshold is fixed ahead of time using event examples.

Table 5: **Event Co-reference Results on Gold Event Triggers.** "$MSEP\text{-}Coref_{ESA,BC,W2V,DEP}$" are variations of the proposed MSEP event co-reference system using ESA, Brown Cluster, Word2Vec and Dependency Embedding representations respectively. "$MSEP\text{-}Coref_{ESA+AUG}$" uses augmented ESA event vector representation and "$MSEP\text{-}Coref_{ESA+AUG+KNOW}$" applies knowledge to detect conflicting events. (GA) means that we use gold event arguments instead of approximated ones from SRL.

Grishman, 2010; Hong et al., 2011; Huang and Riloff, 2012a; Huang and Riloff, 2012b). Li et al. (2013) presented a structured perceptron model to detect triggers and arguments jointly. Attempts have also been made to use a Distributional Semantic Model (DSM) to represent events (Goyal et al., 2013). A shortcoming of DSMs is that they ignore the structure within the context, thus reducing the distribution to a bag of words. In our work, we preserve event structure via structured vector representations constructed from event components.

Event co-reference is much less studied in comparison to the large body of work on entity co-reference. Our work follows the event co-reference definition in Hovy et al. (2013). All previous work on event co-reference except Cybulska and Vossen (2012) deals only with full co-reference. Early works (Humphreys et al., 1997; Bagga and Baldwin, 1999) performed event co-reference on scenario specific events. Both Naughton (2009) and Elkhlifi and Faiz (2009) worked on sentence-level co-reference, which is closer to the definition of Danlos and Gaiffe (2003). Pradhan et al. (2007) dealt with both entity and event coreference by taking a three-layer approach. Chen and Ji (2009) proposed a clustering algorithm using a maximum entropy model with a range of features. Bejan and Harabagiu (2010) built a class of nonparametric Bayesian models using a (potentially infinite) number of features to resolve both within and cross document event co-reference. Lee et al. (2012) formed a system with deterministic layers to make co-reference decisions iteratively while jointly resolving entity and event co-reference. More recently, Hovy et al. (2013) presented an unsupervised model to capture semantic relations and co-reference resolution, but they did not show quantitatively how well their system performed in each of these two cases. Huang et al. (2016) also considered

Table 7: **Domain Transfer Results.** We conduct the evaluation on TAC-KBP corpus with the split of newswire (NW) and discussion form (DF) documents. Here, we choose MSEP-EMD and MSEP-$Coref_{ESA+AUG+KNOW}$ as the MSEP approach for event detection and co-reference respectively. We use SSED and $Supervised_{Base}$ as the supervised modules for comparison. For event detection, we compare F1 scores of span plus type match while we report the average F1 scores for event co-reference.

the problem of event clustering. They represented event structures based on AMR (Abstract Meaning Representation) and distributional semantics, and further generated event schemas composing event triggers and argument roles. Recently, TAC has organized Event Nugget Detection and Co-reference Evaluations, resulting in interesting works, some of which contributed to our comparisons (Liu et al., 2015; Mitamura et al., 2015; Hsi et al., 2015; Sammons et al., 2015).

6 Conclusion

This paper proposes a novel event detection and co-reference approach with minimal supervision, addressing some of the key issues slowing down progress in research on events, including the difficulty to annotate events and their relations. At the heart of our approach is the design of structured vector representations for events which, as we show, supports a good level of generalization within and across domains. The resulting approach outperforms state-of-art supervised methods on some of the key metrics, and adapts significantly better to a new domain. One of the key research directions is to extend this unsupervised approach to a range of other relations among events, including temporal and causality relations, as is (Do et al., 2011; Do et al., 2012).

Abstract

Taxonomic relation identification aims to recognize the *'is-a'* relation between two terms. Previous works on identifying taxonomic relations are mostly based on statistical and linguistic approaches, but the accuracy of these approaches is far from satisfactory. In this paper, we propose a novel supervised learning approach for identifying taxonomic relations using term embeddings. For this purpose, we first design a *dynamic weighting neural network* to learn term embeddings based on not only the hypernym and hyponym terms, but also the contextual information between them. We then apply such embeddings as features to identify taxonomic relations using a supervised method. The experimental results show that our proposed approach significantly outperforms other state-of-the-art methods by 9% to 13% in terms of accuracy for both general and specific domain datasets.

1 Introduction

Taxonomies which serve as the backbone of structured knowledge are useful for many NLP applications such as question answering (Harabagiu et al., 2003) and document clustering (Fodeh et al., 2011). However, the hand-crafted, well-structured taxonomies including WordNet (Miller, 1995), OpenCyc (Matuszek et al., 2006) and Freebase (Bollacker et al., 2008) that are publicly available may not be complete for new or specialized domains. It is also time-consuming and error prone to identify taxonomic relations manually. As such, methods for automatic identification of taxonomic relations is highly desirable.

The previous methods for identifying taxonomic relations can be generally classified into two categories: statistical and linguistic approaches. The statistical approaches rely on the idea that frequently co-occurring terms are likely to have taxonomic relationships. While such approaches can result in taxonomies with relatively high coverage, they are usually heavily dependent on the choice of feature types, and suffer from low accuracy. The linguistic approaches which are based on lexical-syntactic patterns (e.g. *'A such as B'*) are simple and efficient. However, they usually suffer from low precision and coverage because the identified patterns are unable to cover the wide range of complex linguistic structures, and the ambiguity of natural language compounded by data sparsity makes these approaches less robust.

Word embedding (Bengio et al., 2001), also known as distributed word representation, which represents words with high-dimensional and real-valued vectors, has been shown to be effective in exploring both linguistic and semantic relations between words. In recent years, word embedding has been used quite extensively in NLP research, ranging from syntactic parsing (Socher et al., 2013a), machine translation (Zou et al., 2013) to sentiment analysis (Socher et al., 2013b). The current methods for learning word embeddings have focused on learning the representations from word co-occurrence so that similar words will have similar embeddings. However, using the co-occurrence based similarity learning alone is not effective for the purpose of identifying taxonomic relations.

Recently, Yu et al. (2015) proposed a super-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 403–413,
Austin, Texas, November 1-5, 2016.

vised method to learn term embeddings based on pre-extracted taxonomic relation data. However, this method is heavily dependent on the training data to discover all taxonomic relations, i.e. if a pair of terms is not in the training set, it may become a negative example in the learning process, and will be classified as a non-taxonomic relation. The dependency on training data is a huge drawback of the method as no source can guarantee that it can cover all possible taxonomic relations for learning. Moreover, the recent studies (Velardi et al., 2013; Levy et al., 2014; Tuan et al., 2015) showed that contextual information between hypernym and hyponym is an important indicator to detect taxonomic relations. However, the term embedding learning method proposed in (Yu et al., 2015) only learns through the pairwise relations of terms without considering the contextual information between them. Therefore, the resultant quality is not good in some specific domain areas.

In this paper, we propose a novel approach to learn term embeddings based on *dynamic weighting neural network* to encode not only the information of hypernym and hyponym, but also the contextual information between them for the purpose of taxonomic relation identification. We then apply the identified embeddings as features to find the positive taxonomic relations using the supervised method SVM. The experimental results show that our proposed term embedding learning approach outperforms other state-of-the-art embedding learning methods for identifying taxonomic relations with much higher accuracy for both general and specific domains. In addition, another advantage of our proposed approach is that it is able to generalize from the training dataset the taxonomic relation properties for unseen pairs. Thus, it can recognize some true taxonomic relations which are not even defined in dictionary and training data. For the rest of this paper, we will discuss the proposed term embedding learning approach and its performance results.

2 Related work

Previous works on taxonomic relation identification can be roughly divided into two main approaches of statistical learning and linguistic pattern matching. Statistical learning methods include co-occurrence analysis (Lawrie and Croft, 2003), hierarchical latent Dirichlet allocation (LDA) (Blei et al., 2004; Petinot et al., 2011), clustering (Li et al., 2013), linguistic feature-based semantic distance learning (Yu et al., 2011), distributional representation (Roller et al., 2014; Weeds et al., 2014; Kruszewski et al., 2015) and co-occurrence subnetwork mining (Wang et al., 2013). Supervised statistical methods (Petinot et al., 2011) rely on hierarchical labels to learn the corresponding terms for each label. These methods require labeled training data which is costly and not always available in practice. Unsupervised statistical methods (Pons-Porrata et al., 2007; Li et al., 2013; Wang et al., 2013) are based on the idea that terms that frequently co-occur may have taxonomic relationships. However, these methods generally achieve low accuracies.

Linguistic approaches rely on lexical-syntactic patterns (Hearst, 1992) (e.g. *'A such as B'*) to capture textual expressions of taxonomic relations, and match them with the given documents or Web information to identify the relations between a term and its hypernyms (Kozareva and Hovy, 2010; Navigli et al., 2011; Wentao et al., 2012). These patterns can be manually created (Kozareva and Hovy, 2010; Wentao et al., 2012) or automatically identified (Snow et al., 2004; Navigli et al., 2011). Such liguistic pattern matching methods can generally achieve higher precision than the statistical methods, but they suffer from lower coverage. To balance the precision and recall, Zhu *et al.* (2013) and Tuan *et al.* (2014) have combined both unsupervised statistical and linguistic methods for finding taxonomic relations.

In recent years, there are a few studies on taxonomic relation identification using word embeddings such as the work of Tan et al. (2015) and Fu et al. (2014). These studies are based on word embeddings from the Word2Vec model (Mikolov et al., 2013a), which is mainly optimized for the purpose of analogy detection using co-occurrence based similarity learning. As such, these studies suffer from poor performance on low accuracy for taxonomic relation identification.

The approach that is closest to our work is the one proposed by Yu et al. (2015), which also learns term embeddings for the purpose of taxonomic relation

identification. In the approach, a distance-margin neural network is proposed to learn term embeddings based on the pre-extracted taxonomic relations from the Probase database (Wentao et al., 2012). However, the neural network is trained using only the information of the term pairs (i.e. hypernym and hyponym) without considering the contextual information between them, which has been shown to be an important indicator for identifying taxonomic relations from previous studies (Velardi et al., 2013; Levy et al., 2014; Tuan et al., 2014). Moreover, if a pair of terms is not contained in the training set, there is high possibility that it will become a negative example in the learning process, and will likely be recognized as a non-taxonomic relation. The key assumption behind the design of this approach is not always true as no available dataset can possibly contain all taxonomic relations.

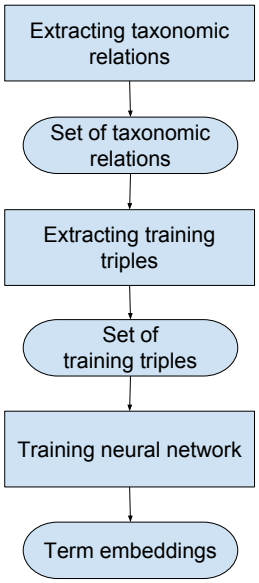

Figure 1: Proposed approach for learning term embeddings.

3 Methodology

In this section, we first propose an approach for learning term embeddings based on hypernym, hyponym and the contextual information between them. We then discuss a supervised method for identifying taxonomic relations based on the term embeddings.

3.1 Learning term embeddings

As shown in Figure 1, there are three steps for learning term embeddings: (i) extracting taxonomic relations; (ii) extracting training triples; and (iii) training neural network. First, we extract from WordNet all taxonomic relations as training data. Then, we extract from Wikipedia all sentences which contain at least one pair of terms involved in a taxonomic relation in the training data, and from that we identify the triples of hypernym, hyponym and contextual words between them. Finally, using the extracted triples as input, we propose a *dynamic weighting neural network* to learn term embeddings based on the information of these triples.

3.1.1 Extracting taxonomic relations

This step aims to extract a set of taxonomic relations for training. For this purpose, we use WordNet hierarchies for extracting all (direct and indirect) taxonomic relations between noun terms in WordNet. However, based on our experience, the relations involving with top-level terms such as 'object', 'entity' or 'whole' are usually ambiguous and become noise for the learning purpose. Therefore, we exclude from the training set all relations which involve with those top-level terms. Note that we also exclude from training set all taxonomic relations that are happened in the datasets used for testing in Section 4.1. As a result, the total number of extracted taxonomic relations is 236,058.

3.1.2 Extracting training triples

This step aims to extract the triples of hypernym, hyponym and the contextual words between them. These triples will serve as the inputs to the neural network for training. In this research, we define contextual words as *all words located between the hypernym and hyponym in a sentence*. We use the latest English Wikipedia corpus as the source for extracting such triples.

Using the set of taxonomic relations extracted from the first step as reference, we extract from the Wikipedia corpus all sentences which contain at least two terms involved in a taxonomic relation. Specifically, for each sentence, we use the Stanford parser (Manning et al., 2014) to parse it, and check whether there is any pair of terms which are nouns or noun phrases in the sentence having a taxonomic relationship. If yes, we extract the hypernym, hyponym and all words between them from the sen-

tence as a training triple. In total, we have extracted 15,499,173 training triples from Wikipedia.

Here, we apply the Stanford parser rather than matching the terms directly in the sentence in order to avoid term ambiguity as a term can serve for different grammatical functions such as noun or verb. For example, consider the following sentence:

- *Many supporters book tickets for the premiere of his new publication.*

The triple (*'publication', 'book', 'tickets for the premiere of his new'*) may be incorrectly added to the training set due to the occurrence of the taxonomic pair (*'publication'*, *'book'*), even though the meaning of *'book'* in this sentence is not about the *'publication'*.

3.1.3 Training neural network

Contextual information is an important indicator for detecting taxonomic relations. For example, in the following two sentences:

- *Dog is a type of animal which you can have as a pet.*
- *Animal such as dog is more sensitive to sound than human.*

The occurrence of contextual words *'is a type of'* and *'such as'* can be used to identify the taxonomic relation between *'dog'* and *'animal'* in the sentences. Many works in the literature (Kozareva and Hovy, 2010; Navigli et al., 2011; Wentao et al., 2012) attempted to manually find these contextual patterns, or automatically learn them. However, due to the wide range of complex linguistic structures, it is difficult to discover all possible contextual patterns between hypernyms and hyponyms in order to detect taxonomic relations effectively.

In this paper, instead of explicitly discovering the contextual patterns of taxonomic relations, we propose a *dynamic weighting neural network* to encode this information, together with the hypernym and hyponym, for learning term embeddings. Specifically, the target of the neural network is to predict the hypernym term from the given hyponym term and contextual words. The architecture of the proposed neural network is shown in Figure 2, which consists of three layers: input layer, hidden layer and output layer.

In our setting, the vocabulary size is V, and the hidden layer size is N. The nodes on adjacent layers are fully connected. Given a term/word t in the vocabulary, the input vector of t is encoded as a one-hot V-dimensional vector x_t, i.e. x_t consists of 0s in all elements except the element used to uniquely identify t which is set as 1. The weights between the input layer and output layer are represented by a $V \times N$ matrix W. Each row of W is a N-dimensional vector representation v_t of the associated word/term t of the input layer.

Given a hyponym term $hypo$ and k context words c_1, c_2, .., c_k in the training triple, the output of hidden layer h is calculated as:

$$\begin{aligned} h &= W^\top \cdot \frac{1}{2k}(k \times x_{hypo} + x_{c_1} + x_{c_2} + ... + x_{c_k}) \\ &= \frac{1}{2k}(k \times v_{hypo} + v_{c_1} + v_{c_2} + ... + v_{c_k}) \end{aligned} \tag{1}$$

where v_t is the vector representation of the input word/term t.

The weight of h in Equation (1) is calculated as the average of the vector representation of hyponym term and contextual words. Therefore, this weight is not based on a fixed number of inputs. Instead, it is dynamically updated based on the number of contextual words k in the current training triple, and the hyponym term. This model is called *dynamic weighting neural network* to reflect its dynamic nature. Note that to calculate h, we also multiply the vector representation of hyponym by k to reduce the bias problem of high number of contextual words, so that the weight of the input vector of hyponym is balanced with the total weight of contextual words.

From the hidden layer to the output layer, there is another weight $N \times V$ for the output matrix W'. Each column of W' is a N-dimensional vector v'_t representing the output vector of t. Using these weights, we can compute an output score u_t for each term/word t in the vocabulary:

$$u_t = {v'_t}^\top \cdot h \tag{2}$$

where v'_t is the output vector of t.

We then use soft-max, a log-linear classification model, to obtain the posterior distribution of hypernym terms as follows:

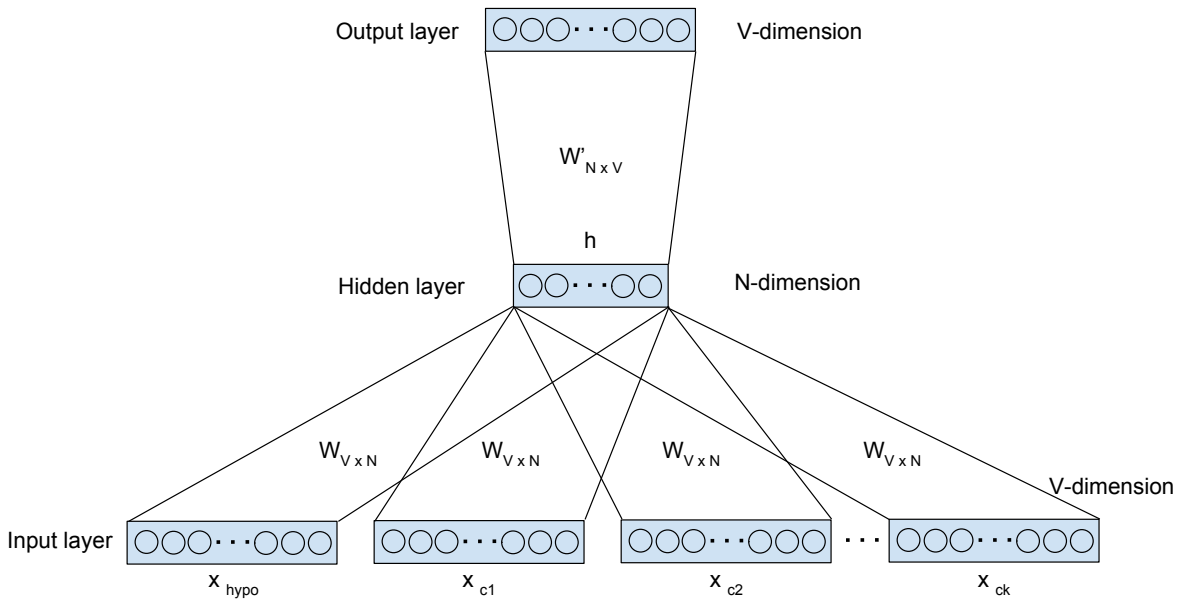

Figure 2: The architecture of the proposed dynamic weighting neural network model.

$$
\begin{aligned}
&p(hype|hypo, c_1, c_2, .., c_k) \\
&= \frac{e^{u_{hype}}}{\sum_{i=1}^{V} e^{u_i}} \\
&= \frac{e^{v'^{\top}_{hype} \cdot \frac{1}{2k}(k \times v_{hypo} + \sum_{j=1}^{k} v_{c_j})}}{\sum_{i=1}^{V} e^{v'^{\top}_{i} \cdot \frac{1}{2k}(k \times v_{hypo} + \sum_{j=1}^{k} v_{c_j})}}
\end{aligned} \tag{3}
$$

The objective function is then defined as:

$$
O = \frac{1}{T} \sum_{t=1}^{T} log(p(hype_t|hypo_t, c_{1t}, c_{2t}, .., c_{kt})) \tag{4}
$$

where T is the number of training triples; $hype_t$, $hypo_t$ and c_{it} are hypernym term, hyponym term and contextual words respectively in the training triple t.

After maximizing the log-likelihood objective function in Equation (4) over the entire training set using stochastic gradient descent, the term embeddings are learned accordingly.

3.2 Supervised taxonomic relation identification

To decide whether a term x is a hypernym of term y, we build a classifier that uses embedding vectors as features for taxonomic relation identification. Specifically, we use Support Vector Machine (SVM) (Cortes and Vapnik, 1995) for this purpose. Given an ordered pair (x, y), the input feature is the concatenation of embedding vectors (v_x,v_y) of x and y. In addition, our term embedding learning approach has the property that the embedding of hypernym is encoded based on not only the information of hyponym but also the information of contextual words. Therefore, we add one more feature to the input of SVM, i.e. the offset vector $(v_x - v_y)$, to contain the information of all contextual words between x and y. In summary, the feature vector is a $3d$ dimensional vector $\langle v_x, v_y, v_x - v_y \rangle$, where d is the dimension of term embeddings. As will be shown later in the experimental results, the offset vector plays an important role in the task of taxonomic relation identification of our approach.

4 Experiments

We conduct experiments to evaluate the performance of our term embedding learning approach on the general domain areas as well as the specific domain areas. In performance evaluation, we compare our approach with two other state-of-the-art supervised term embedding learning methods in Yu et al. (2015) and the Word2Vec model (Mikolov et al., 2013a).

4.1 Datasets

There are five datasets used in the experiments. Two datasets, namely BLESS and ENTAILMENT, are general domain datasets. The other three datasets, namely Animal, Plant and Vehicle, are specific domain datasets.

- BLESS (Baroni and Lenci, 2011) dataset: It covers 200 distinct, unambiguous concepts (terms); each of which is involved with other terms, called *relata*, in some relations. We extract from BLESS 14,547 pairs of terms for the following four types of relations: taxonomic relation, meronymy relation (a.k.a. part-of relation), coordinate relation (i.e. two terms having the same hypernym), and random relation. From these pairs, we set taxonomic relations as positive examples, while other relations form the negative examples.
- ENTAILMENT dataset (Baroni et al., 2012): It consists of 2,770 pairs of terms, with equal number of positive and negative examples of taxonomic relations. Altogether, there are 1,376 unique hyponyms and 1,016 unique hypernyms.
- Animal, Plant and Vehicle datasets (Velardi et al., 2013): They are taxonomies constructed based on the dictionaries and data crawled from the Web for the corresponding domains. The positive examples are created by extracting all possible (direct and indirect) taxonomic relations from the taxonomies. The negative examples are generated by randomly pairing two terms which are not involved in any taxonomic relation.

The number of terms, positive examples and negative examples extracted from the five datasets are summarized in Table 1.

Dataset	# terms	# positive	# negative
BLESS	5229	1337	13210
ENTAILMENT	2392	1385	1385
Animal	659	4164	8471
Plant	520	2266	4520
Vehicle	117	283	586

Table 1: Datasets used in the experiments.

4.2 Comparison models

In the experiments, we use the following supervised models for comparison:

- SVM+Our: This model uses SVM and the term embeddings obtained by our learning approach. The input is a 3d-dimensional vector $\langle v_x, v_y, v_x - v_y \rangle$, where d is the dimension of term embeddings, x and y are two terms used to check whether x is a hypernym of y or not, and v_x, v_y are the term embeddings of x and y respectively.
- SVM+Word2Vec: This model uses SVM and the term embeddings obtained by applying the Skip-gram model (Mikolov et al., 2013a) on the entire English Wikipedia corpus. The input is also a 3d-dimensional vector as in the SVM+Our model. Note that the results of the Skip-gram model are word embeddings. So if a term is a multiword term, its embedding is calculated as the average of all words in the term.
- SVM+Yu: This model uses SVM and the term embeddings obtained by using Yu et al.'s method (2015). According to the best setting stated in (Yu et al., 2015), the input is a 2d+1 dimensional vector $\langle O(x), E(y), \|O(x)\text{-}E(y)\|_1 \rangle$, where $O(x)$, $E(y)$ and $\|\text{O(x)-E(y)}\|_1$ are hyponym embedding of x, hypernym embedding of y and 1-norm distance of the vector ($O(x)$-$E(y)$) respectively.

Parameter settings. The SVM in the three models is trained using a RBF kernel with λ= 0.03125 and penalty term C = 8.0. For term embedding learning, the vector's dimension is set to 100. The tuning of the dimension will be discussed in Section 4.6.

4.3 Performance on general domain datasets

For the general domain datasets, we have conducted two experiments to evaluate the performance of our proposed approach.

Experiment 1. For the BLESS dataset, we hold out one concept for testing and train on the remaining 199 concepts. The hold-out concept and its relatum constitute the testing set, while the remaining 199 concepts and their relatum constitute the training set. To further separate the training and testing sets, we exclude from the training set any pair

of terms that has one term appearing in the testing set. We report the average accuracy across all concepts. For the ENTAILMENT dataset, we use the same evaluation method: hold out one hypernym for testing and train on the remaining hypernyms, and we also report the average accuracy across all hypernyms. Furthermore, to evaluate the effect of the offset vector to taxonomic relation identification, we deploy a setting that removes the offset vector in the feature vectors of SVM. Specifically, for SVM+Our and SVM+Word2Vec, the input vector is changed from $\langle v_x, v_y, v_x - v_y \rangle$ to $\langle v_x, v_y \rangle$. We use the subscript $short$ to denote this setting.

Model	Dataset	Accuracy
SVM+Yu	BLESS	90.4%
SVM+Word2Vec$_{short}$	BLESS	83.8%
SVM+Word2Vec	BLESS	84.0%
SVM+Our$_{short}$	BLESS	91.1%
SVM+Our	BLESS	**93.6%**
SVM+Yu	ENTAIL	87.5%
SVM+Word2Vec$_{short}$	ENTAIL	82.8%
SVM+Word2Vec	ENTAIL	83.3%
SVM+Our$_{short}$	ENTAIL	88.2%
SVM+Our	ENTAIL	**91.7%**

Table 2: Performance results for the BLESS and ENTAILMENT datasets.

Table 2 shows the performance of the three supervised models in Experiment 1. Our approach achieves significantly better performance than Yu's method and Word2Vec method in terms of accuracy (t-test, p-value < 0.05) for both BLESS and ENTAILMENT datasets. Specifically, our approach improves the average accuracy by 4% compared to Yu's method, and by 9% compared to the Word2Vec method. The Word2Vec embeddings have the worst result because it is based only on co-occurrence based similarity, which is not effective for the classifier to accurately recognize all the taxonomic relations. Our approach performs better than Yu's method and it shows that our approach can learn embeddings more effectively. Our approach encodes not only hypernym and hyponym terms but also the contextual information between them, while Yu's method ignores the contextual information for taxonomic relation identification.

Moreover, from the experimental results of SVM+Our and SVM+Our$_{short}$, we can observe that the offset vector between hypernym and hyponym, which captures the contextual information, plays an important role in our approach as it helps to improve the performance in both datasets. However, the offset feature is not so important for the Word2Vec model. The reason is that the Word2Vec model is targeted for the analogy task rather than taxonomic relation identification.

Experiment 2. This experiment aims to evaluate the generalization capability of our extracted term embeddings. In the experiment, we train the classifier on the BLESS dataset, test it on the ENTAILMENT dataset and vice versa. Similarly, we exclude from the training set any pair of terms that has one term appearing in the testing set. The experimental results in Table 3 show that our term embedding learning approach performs better than other methods in accuracy. It also shows that the taxonomic properties identified by our term embedding learning approach have great generalization capability (i.e. less dependent on the training set), and can be used generically for representing taxonomic relations.

Model	Training	Testing	Accuracy
SVM+Yu	BLESS	ENTAIL	83.7%
SVM+Word2Vec$_{short}$	BLESS	ENTAIL	76.5%
SVM+Word2Vec	BLESS	ENTAIL	77.1%
SVM+Our$_{short}$	BLESS	ENTAIL	85.8%
SVM+Our	BLESS	ENTAIL	**89.4%**
SVM+Yu	ENTAIL	BLESS	87.1%
SVM+Word2Vec$_{short}$	ENTAIL	BLESS	78.0%
SVM+Word2Vec	ENTAIL	BLESS	78.9%
SVM+Our$_{short}$	ENTAIL	BLESS	87.1%
SVM+Our	ENTAIL	BLESS	**90.6%**

Table 3: Performance results for the general domain datasets when using one domain for training and another domain for testing.

4.4 Performance on specific domain datasets

Similarly, for the specific domain datasets, we have conducted two experiments to evaluate the performance of our proposed approach.

Experiment 3. For each of the Animal, Plant and Vehicle datasets, we also hold out one term for testing and train on the remaining terms. The positive and negative examples which contain the hold-out term constitute the testing set, while other positive and negative examples constitute the training

set. We also exclude from the training set any pair of terms that has one term appearing in the testing set. The experimental results are given in Table 4. We can observe that not only for general domain datasets but also for specific domain datasets, our term embedding learning approach has achieved significantly better performance than Yu's method and the Word2Vec method in terms of accuracy (t-test, p-value < 0.05). Specifically, our approach improves the average accuracy by 22% compared to Yu's method, and by 9% compared to the Word2Vec method.

Model	Dataset	Accuracy
SVM+Yu	Animal	67.8%
SVM+Word2Vec	Animal	80.2%
SVM+Our	Animal	**89.3%**
SVM+Yu	Plant	65.7%
SVM+Word2Vec	Plant	81.5%
SVM+Our	Plant	**92.1%**
SVM+Yu	Vehicle	70.5%
SVM+Word2Vec	Vehicle	82.1%
SVM+Our	Vehicle	**89.6%**

Table 4: Performance results for the Animal, Plant and Vehicle datasets.

Another interesting point to observe is that the accuracy of Yu's method drops significantly in specific domain datasets (as shown in Table 4) when compared to the general domain datasets (as shown in Table 2). One possible explanation is the accuracy of Yu's method depends on the training data. As Yu's method learns the embeddings using pre-extracted taxonomic relations from Probase, and if a relation does not exist in Probase, there is high possibility that it becomes a negative example and be recognized as a non-taxonomic relation by the classifier. Therefore, the training data extracted from Probase plays an important role in Yu's method. For general domain datasets (BLESS and ENTAILMENT), there are about 75%-85% of taxonomic relations in these datasets found in Probase, while there are only about 25%-45% of relations in the specific domains (i.e. Animal, Plant and Vehicle) found in Probase. Therefore, Yu's method achieves better performance in general domain datasets than the specific ones. Our approach, in contrast, less depends on the training relations. Therefore, it can achieve high accuracy in both the general and specific domain datasets.

Experiment 4. Similar to experiment 2, this experiment aims to evaluate the generalization capability of our term embeddings. In this experiment, for each of the Animal, Plant and Vehicle domains, we train the classifier using the positive and negative examples in each domain and test the classifier in other domains. The experimental results in Table 5 show that our approach achieves the best performance compared to other state-of-the-art methods for all the datasets. As also shown in Table 3, our approach has achieved high accuracy for both general and specific domain datasets, while in Yu's method, there is a huge difference in accuracy between these domain datasets.

Model	Training	Testing	Accuracy
SVM+Yu	Animal	Plant	65.5%
SVM+Word2Vec	Animal	Plant	82.4%
SVM+Our	Animal	Plant	**91.9%**
SVM+Yu	Animal	Vehicle	66.2%
SVM+Word2Vec	Animal	Vehicle	81.3%
SVM+Our	Animal	Vehicle	**89.5%**
SVM+Yu	Plant	Animal	68.4%
SVM+Word2Vec	Plant	Animal	81.8%
SVM+Our	Plant	Animal	**91.5%**
SVM+Yu	Plant	Vehicle	65.2%
SVM+Word2Vec	Plant	Vehicle	81.0%
SVM+Our	Plant	Vehicle	**88.5%**
SVM+Yu	Vehicle	Animal	70.9%
SVM+Word2Vec	Vehicle	Animal	79.7%
SVM+Our	Vehicle	Animal	**87.6%**
SVM+Yu	Vehicle	Plant	66.2%
SVM+Word2Vec	Vehicle	Plant	78.7%
SVM+Our	Vehicle	Plant	**87.7%**

Table 5: Performance results for the specific domain datasets when using one domain for training and another domain for testing.

4.5 Empirical comparison with WordNet

By error analysis, we found that our results may complement WordNet. For example, in the Animal domain, our approach identifies *'wild sheep'* as a hyponym of *'sheep'*, but in WordNet, they are siblings. However, many references [1, 2] consider *'wild sheep'* as a species of *'sheep'*. Another such example is shown in the Plant domain, where our ap-

[1] http://en.wikipedia.org/wiki/Ovis

[2] http://www.bjornefabrikken.no/side/norwegian-sheep/

proach recognizes *'lily'* as a hyponym of *'flowering plant'*, but WordNet places them in different subtrees incorrectly [3]. Therefore, our results may help restructure and even extend WordNet.

Note that these taxonomic relations are not in our training set. They are also not recognized by the term embeddings obtained from the Word2Vec method and Yu et al.'s method. It again shows that our term embedding learning approach has the capability to identify taxonomic relations which are not even defined in dictionary or training data.

4.6 Tuning vector dimensions

We also conduct experiments to learn term embeddings from the general domain datasets with different dimensions (i.e. 50, 100, 150 and 300) using our proposed approach. We then use these embeddings to evaluate the performance of taxonomic relation identification based on training time and accuracy, and show the results in Table 6. The experiments are carried out on a PC with Intel(R) Xeon(R) CPU at 3.7GHz and 16GB RAM.

Dimension	Dataset	Training time	Accuracy
50	BLESS	1825s	87.7%
100	BLESS	2991s	89.4%
150	BLESS	4025s	89.9%
300	BLESS	7113s	90.0%
50	ENTAIL	1825s	88.5%
100	ENTAIL	2991s	90.6%
150	ENTAIL	4025s	90.9%
300	ENTAIL	7113s	90.9%

Table 6: Performance results based on training time and accuracy of the SVM+Our model using different vector dimensions.

In general, when increasing the vector dimension, the accuracy of our term embedding learning approach will be increased gradually. More specifically, the accuracy improves slightly when the dimension is increased from 50 to 150. But after that, increasing the dimension has very little effect on the accuracy. We observe that the vector dimension for learning term embeddings can be set between 100 to 150 to achieve the best performance, based on the trade-off between accuracy and training time.

[3] https://en.wikipedia.org/wiki/Lilium

5 Conclusion

In this paper, we proposed a novel approach to learn term embeddings using dynamic weighting neural network. This model encodes not only the hypernym and hyponym terms, but also the contextual information between them. Therefore, the extracted term embeddings have good generalization capability to identify unseen taxonomic relations which are not even defined in dictionary and training data. The experimental results show that our approach significantly outperforms other state-of-the-art methods in terms of accuracy in identifying taxonomic relation identification.

Abstract

Given a set of documents from a specific domain (e.g., medical research journals), how do we automatically build a Knowledge Graph (KG) for that domain? Automatic identification of relations and their schemas, i.e., type signature of arguments of relations (e.g., *undergo(Patient, Surgery)*), is an important first step towards this goal. We refer to this problem as *Relation Schema Induction (RSI)*. In this paper, we propose Schema Induction using Coupled Tensor Factorization (SICTF), a novel tensor factorization method for relation schema induction. SICTF factorizes Open Information Extraction (OpenIE) triples extracted from a domain corpus along with additional side information in a principled way to induce relation schemas. To the best of our knowledge, this is the first application of tensor factorization for the RSI problem. Through extensive experiments on multiple real-world datasets, we find that SICTF is not only more accurate than state-of-the-art baselines, but also significantly faster (about 14x faster).

1 Introduction

Over the last few years, several techniques to build Knowledge Graphs (KGs) from large unstructured text corpus have been proposed, examples include NELL (Mitchell et al., 2015) and Google Knowledge Vault (Dong et al., 2014). Such KGs consist of millions of entities (e.g., *Oslo, Norway*, etc.), their types (e.g., *isA(Oslo, City)*, *isA(Norway, Country)*), and relationships among them (e.g., *cityLocatedInCountry(Oslo, Norway)*). These KG construction techniques are called ontology-guided as they require as input list of relations, their schemas (i.e., their type signatures, e.g., *cityLocatedInCountry(City, Country)*), and seed instances of each such relation. Listing of such relations and their schemas are usually prepared by human domain experts.

The reliance on domain expertise poses significant challenges when such ontology-guided KG construction techniques are applied to domains where domain experts are either not available or are too expensive to employ. Even when such a domain expert may be available for a limited time, she may be able to provide only a partial listing of relations and their schemas relevant to that particular domain. Moreover, this expert-mediated model is not scalable when new data in the domain becomes available, bringing with it potential new relations of interest. In order to overcome these challenges, we need automatic techniques which can discover relations and their schemas from unstructured text data itself, without requiring extensive human input. We refer to this problem as *Relation Schema Induction (RSI)*.

In contrast to ontology-guided KG construction techniques mentioned above, Open Information Extraction (OpenIE) techniques (Etzioni et al., 2011) aim to extract surface-level triples from unstructured text. Such OpenIE triples may provide a suitable starting point for the RSI problem. In fact, KB-LDA,

Austin, Texas, November 1-5, 2016.

	Target task	Interpretable latent factors?	Can induce relation schema?	Can use NP side info?	Can use relation side info?
Typed RESCAL (Chang et al., 2014a)	Embedding	No	No	Yes	No
Universal Schema (Singh et al., 2015)	Link Prediction	No	No	No	No
KB-LDA (Movshovitz-Attias and Cohen, 2015)	Ontology Induction	Yes	Yes	Yes	No
SICTF (this paper)	Schema Induction	Yes	Yes	Yes	Yes

Table 1: Comparison among SICTF (this paper) and other related methods. KB-LDA is the most related prior method which is extensively compared against SICTF in Section 4

a topic modeling-based method for inducing an ontology from SVO (Subject-Verb-Object) triples was recently proposed in (Movshovitz-Attias and Cohen, 2015). We note that ontology induction (Velardi et al., 2013) is a more general problem than RSI, as we are primarily interested in identifying categories and relations from a domain corpus, and not necessarily any hierarchy over them. Nonetheless, KB-LDA maybe used for the RSI problem and we use it as a representative of the state-of-the-art of this area.

Instead of a topic modeling approach, we take a tensor factorization-based approach for RSI in this paper. Tensors are a higher order generalization of matrices and they provide a natural way to represent OpenIE triples. Applying tensor factorization methods over OpenIE triples to identify relation schemas is a natural approach, but one that has not been explored so far. Also, a tensor factorization-based approach presents a flexible and principled way to incorporate various types of side information. Moreover, as we shall see in Section 4, compared to state-of-the-art baselines such as KB-LDA, tensor factorization-based approach results in better and faster solution for the RSI problem. In this paper, we make the following contributions:

- We present Schema Induction using Coupled Tensor Factorization (SICTF), a novel and principled tensor factorization method which jointly factorizes a tensor constructed out of OpenIE triples extracted from a domain corpus, along with various types of additional side information for relation schema induction.

- We compare SICTF against state-of-the-art baseline on various real-world datasets from diverse domains. We observe that SICTF is not only significantly more accurate than such baselines, but also much faster. For example, SICTF achieves 14x speedup over KB-LDA (Movshovitz-Attias and Cohen, 2015).

- We have made the data and code available [1].

2 Related Work

Schema Induction: Properties of SICTF and other related methods are summarized in Table 1[2]. A method for inducing (binary) relations and the categories they connect was proposed by (Mohamed et al., 2011). However, in that work, categories and their instances were known a-priori. In contrast, in case of SICTF, both categories and relations are to be induced. A method for event schema induction, the task of learning high-level representations of complex events and their entity roles from unlabeled text, was proposed in (Chambers, 2013). This gives the schemas of slots per event, but our goal is to find schemas of relations. (Chen et al., 2013) and (Chen et al., 2015) deal with the problem of finding semantic slots for unsupervised spoken language understanding, but we are interested in finding schemas of relations relevant for a given domain. Methods for link prediction in the Universal Schema setting using matrix and a combination of matrix and tensor factorization are proposed in (Riedel et al., 2013) and (Singh et al., 2015), respectively. Instead of link prediction where relation schemas are assumed to be given, SICTF focuses on discovering such relation schemas. Moreover, in contrast to such

[1] https://github.com/malllabiisc/sictf

[2] Please note that not all methods mentioned in the table are directly comparable with SICTF, the table only illustrates the differences. KB-LDA is the only method which is directly comparable.

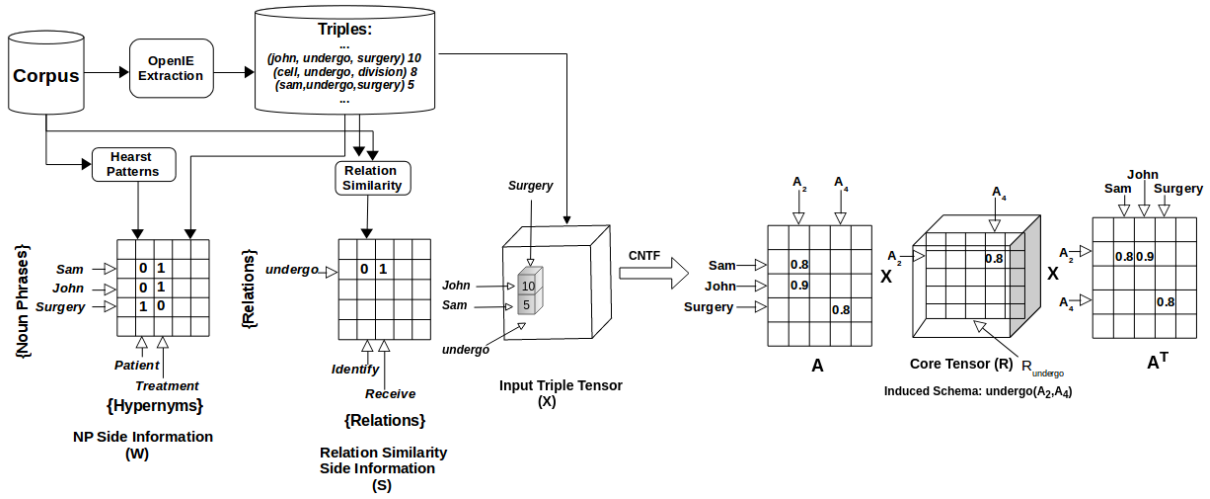

Figure 1: Relation Schema Induction (RSI) by SICTF, the proposed method. First, a tensor (X) is constructed to represent OpenIE triples extracted from a domain corpus. Noun phrase side information in the form of (noun phrase, hypernym), and relation-relation similarity side information are separately calculated and stored in two separate matrices (W and S, respectively). SICTF then performs coupled factorization of the tensor and the two side information matrices to identify relation schemas which are stored in the core tensor (R) in the output. Please see Section 3 for details.

methods which assume access to existing KGs, the setting in this paper is unsupervised.

Tensor Factorization: Due to their flexibility of representation and effectiveness, tensor factorization methods have seen increased application in Knowledge Graph (KG) related problems over the last few years. Methods for decomposing ontological KGs such as YAGO (Suchanek et al., 2007) were proposed in (Nickel et al., 2012; Chang et al., 2014b; Chang et al., 2014a). In these cases, relation schemas are known in advance, while we are interested in inducing such relation schemas from unstructured text. A PARAFAC (Harshman, 1970) based method for jointly factorizing a matrix and tensor for data fusion was proposed in (Acar et al., 2013). In such cases, the matrix is used to provide auxiliary information (Narita et al., 2012; Erdos and Miettinen, 2013). Similar PARAFAC-based ideas are explored in Rubik (Wang et al., 2015) to factorize structured electronic health records. In contrast to such structured data sources, SICTF aims at inducing relation schemas from unstructured text data. Propstore, a tensor-based model for distributional semantics, a problem different from RSI, was presented in (Goyal et al., 2013). Even though coupled factorization of tensor and matrices constructed out of unstructured text corpus provide a natural and plausible approach for the RSI problem, they have not yet been explored – we fill this gap in this paper.

Ontology Induction: Relation Schema Induction can be considered a sub problem of Ontology Induction (Velardi et al., 2013). Instead of building a full-fledged hierarchy over categories and relations as in ontology induction, we are particularly interested in finding relations and their schemas from unstructured text corpus. We consider KB-LDA[3] (Movshovitz-Attias and Cohen, 2015), a topic-modeling based approach for ontology induction, as a representative of this area. Among all prior work, KB-LDA is most related to SICTF. While both KB-LDA and SICTF make use of noun phrase side information, SICTF is also able to exploit relational side information in a principled manner. In Section 4, through experiments on multiple real-world datasets, we observe that SICTF is not only more accurate than KB-LDA but also significantly faster with a speedup of 14x.

A method for canonicalizing noun and relation phrases in OpenIE triples was recently proposed in (Galárraga et al., 2014). The main focus of this approach is to cluster lexical variants of a *single* entity or relation. This is not directly relevant for RSI, as

[3]In this paper, whenever we refer to KB-LDA, we only refer to the part of it that learns relations from unstructured data.

we are interested in grouping *multiple* entities of the same type into one cluster, and use that to induce relation schema.

3 Our Approach: Schema Induction using Coupled Tensor Factorization (SICTF)

3.1 Overview

SICTF poses the relation schema induction problem as a coupled factorization of a tensor along with matrices containing relevant side information. Overall architecture of the SICTF system is presented in Figure 1. First, a tensor $X \in \mathbb{R}_+^{n \times n \times m}$ is constructed to store OpenIE triples and their scores extracted from the text corpus[4]. Here, n and m represent the number of NPs and relation phrases, respectively. Following (Movshovitz-Attias and Cohen, 2015), SICTF makes use of noun phrase (NP) side information in the form of (noun phrase, hypernym). Additionally, SICTF also exploits relation-relation similarity side information. These two side information are stored in matrices $W \in \{0,1\}^{n \times h}$ and $S \in \{0,1\}^{m \times m}$, where h is the number of hypernyms extracted from the corpus. SICTF then performs collective non-negative factorization over X, W, and S to output matrix $A \in \mathbb{R}_+^{n \times c}$ and the core tensor $R \in \mathbb{R}_+^{c \times c \times m}$. Each row in A corresponds to an NP, while each column corresponds to an induced category (latent factor). For brevity, we shall refer to the induced category corresponding to the q^{th} column of A as A_q. Each entry A_{pq} in the output matrix provides a membership score for NP p in induced category A_q. Please note that each induced category is represented using the NPs participating in it, with the NPs ranked by their membership scores in the induced category. In Figure 1, $A_2 = [(John, 0.9), (Sam, 0.8), \ldots]$ is an induced category.

Each slice of the core tensor R is a matrix which corresponds to a specific relation, e.g., the matrix $R_{undergo}$ highlighted in Figure 1 corresponds to the relation *undergo*. Each cell in this matrix corresponds to an induced schema connecting two induced categories (two columns of the A matrix), with the cell value representing model's score of the induced schema. For example, in Figure 1, *undergo*(A_2, A_4) is an induced relation schema with score 0.8 involving relation *undergo* and induced categories A_2 and A_4.

In Section 3.2, we present details of the side information used by SICTF, and then in Section 3.3 present details of the optimization problem solved by SICTF.

[4] $\mathbb{R}_+$ is the set of non-negative reals.

3.2 Side Information

- **Noun Phrase Side Information**: Through this type of side information, we would like to capture type information of as many noun phrases (NPs) as possible. We apply Hearst patterns (Hearst, 1992), e.g., *"<Hypernym> such as <NP>"*, over the corpus to extract such *(NP, Hypernym)* pairs. Please note that neither hypernyms nor NPs are pre-specified, and they are all extracted from the data by the patterns. Examples of a few such pairs extracted from two different datasets are shown in Table 2. These extracted tuples are stored in a matrix $W_{n \times h}$ whose rows correspond to NPs and columns correspond to extracted hypernyms. We define,

$$W_{ij} = \begin{cases} 1, & \text{if NP}_\text{i} \text{ belongs to Hypernym}_\text{j} \\ 0, & \text{otherwise} \end{cases}.$$

  Please note that we don't expect W to be a fully specified matrix, i.e., we don't assume that we know all possible hypernyms for a given NP.

- **Relation Side Information**: In addition to the side information involving NPs, we would also

like to take prior knowledge about textual relations into account during factorization. For example, if we know two relations to be similar to one another, then we also expect their induced schemas to be similar as well. Consider the following sentences *"Mary purchased a stuffed animal toy."* and *"Janet bought a toy car for her son."*. From these we can say that both relations *purchase* and *buy* have the schema (Person, Item). Even if one of these relations is more abundant than the other in the corpus, we still want to learn similar schemata for both the relations. As mentioned before, $S \in \mathbb{R}_{+}^{m \times m}$ is the relation similarity matrix, where m is the number of textual relations. We define,

$$S_{ij} = \begin{cases} 1, & \text{if Similarity(Rel}_\text{i}\text{, Rel}_\text{j}\text{)} \geq \gamma \\ 0, & \text{otherwise} \end{cases}$$

where γ is a threshold[5]. For the experiments in this paper, we use cosine similarity over word2vec (Mikolov et al., 2013) vector representations of the relational phrases. Examples of a few similar relation pairs are shown in Table 3.

3.3 SICTF Model Details

SICTF performs coupled non-negative factorization of the input triple tensor $X_{n \times n \times m}$ along with the two side information matrices $W_{n \times h}$ and $S_{m \times m}$ by solving the following optimization problem.

$$\min_{A,V,R} \sum_{k=1}^{m} f(X_k, A, R_k) + f_{np}(W, A, V) + f_{rel}(S, R) \tag{1}$$

where,

$$f(X_k, A, R_k) = \| X_{:,:,k} - A R_{:,:,k} A^T \|_F^2 + \lambda_R \| R_{:,:,k} \|_F^2$$

$$f_{np}(W, A, V) = \lambda_{np} \| W - AV \|_F^2 + \lambda_A \| A \|_F^2 + \lambda_V \| V \|_F^2$$

$$f_{rel}(S, R) = \lambda_{rel} \sum_{i=1}^{m} \sum_{j=1}^{m} S_{ij} \| R_{:,:,i} - R_{:,:,j} \|_F^2$$

$$A_{i,j} \geq 0, V_{j,r} \geq 0, R_{p,q,k} \geq 0 \quad \text{(non negative)}$$
$$\forall\, 1 \leq i \leq n, 1 \leq r \leq h,$$
$$1 \leq j, p, q \leq c, 1 \leq k \leq m$$

In the objective above, the first term $f(X_k, A, R_k)$ minimizes reconstruction error for the k^{th} relation, with additional regularization on the $R_{:,:,k}$ matrix[6]. The second term, $f_{np}(W, A, V)$, factorizes the NP side information matrix $W_{n \times h}$ into two matrices $A_{n \times c}$ and $V_{c \times h}$, where c is the number of induced categories. We also enforce A to be non-negative. Typically, we require $c \ll h$ to get a lower dimensional embedding of each NP (rows of A). Finally, the third term $f_{rel}(S, R)$ enforces the requirement that two similar relations as given by the matrix S should have similar signatures (given by the corresponding R matrix). Additionally, we require V and R to be non-negative, as marked by the (non-negative) constraints. In this objective, λ_R, λ_{np}, λ_A, λ_V, and λ_{rel} are all hyper-parameters.

We derive non-negative multiplicative updates for A, R_k and V following the rules proposed in (Lee and Seung, 2000), which has the following general form:

$$\theta_i = \theta_i \left(\frac{\frac{\partial C(\theta)^-}{\partial \theta_i}}{\frac{\partial C(\theta)^+}{\partial \theta_i}} \right)^{\alpha}$$

Here $C(\theta)$ represents the cost function of the non-negative variables θ and $\frac{\partial C(\theta)^-}{\partial \theta_i}$ and $\frac{\partial C(\theta)^-}{\partial \theta_i}$ are the negative and positive parts of the derivative of $C(\theta)$ (Mørup et al., 2008). (Lee and Seung, 2000) proved that for $\alpha = 1$, the cost function $C(\theta)$ monotonically decreases with the multiplicative updates [7]. $C(\theta)$ for SICTF is given in equation (1). The above procedure will give the following updates:

$$A \leftarrow A * \frac{\sum_k (X_k A R_k^T + X_k^T A R_k) + \lambda_{np} W V^T}{A(\tilde{B} + \lambda_A I + \lambda_{np} V V^T)}$$

$$\tilde{B} = \sum_k (R_k A^T A R_k^T + R_k^T A^T A R_k)$$

$$R_k \leftarrow R_k * \frac{A^T X_k A + 2\, \lambda_{rel} \sum_{j=1}^{m} R_j S_{kj}}{A^T A R_k A^T A + \tilde{D}}$$

$$\tilde{D} = 2\, \lambda_{rel}\, R_k \sum_{j=1}^{m} S_{kj} + \lambda_R R_k$$

$$V \leftarrow V * \frac{\lambda_{np} A^T W}{\lambda_{np} A^T A V + \lambda_V V}$$

[5] For the experiments in this paper, we set $\gamma = 0.7$, a relatively high value, to focus on highly similar relations and thereby justifying the binary S matrix.

[6] For brevity, we also refer to $R_{:,:,k}$ as R_k, and similarly $X_{:,:,k}$ as X_k

[7] We also use $\alpha = 1$.

4 Experiments

In this section, we evaluate performance of different methods on the Relation Schema Induction (RSI) task. Specifically, we address the following questions.

- Which method is most effective on the RSI task? (Section 4.3.1)
- How important are the additional side information for RSI? (Section 4.3.2)
- What is the importance of non-negativity in RSI with tensor factorization? (Section 4.3.3)

4.1 Experimental Setup

Datasets: We used two datasets for the experiments in this paper, they are summarized in Table 4. For MEDLINE dataset, we used Stanford CoreNLP (Manning et al., 2014) for coreference resolution and Open IE v4.0[9] for triple extraction. Triples with Noun Phrases that have Hypernym information were retained. We obtained the StackOverflow triples directly from the authors of (Movshovitz-Attias and Cohen, 2015), which were also prepared using a very similar process. In both datasets, we use corpus frequency of triples for constructing the tensor.

Side Information: Seven Hearst patterns such as *"<hypernym> such as <NP>", "<NP> or other <hypernym>"* etc., given in (Hearst, 1992) were used to extract NP side information from the MEDLINE documents. NP side information for the StackOverflow dataset was obtained from the authors of (Movshovitz-Attias and Cohen, 2015).

As described in Section 3, word2vec embeddings of the relation phrases were used to extract relation-similarity based side-information. This was done for both datasets. Cosine similarity threshold of $\gamma = 0.7$ was used for the experiments in the paper.

Samples of side information used in the experiments are shown in Table 2 and Table 3. A total of 2067 unique NP-hypernym pairs were extracted from MEDLINE data and 16,639 were from StackOverflow data. 25 unique pairs of relation phrases out of 1172 were found to be similar in MEDLINE data, whereas 280 unique pairs of relation phrases out of approximately 3200 were found similar in StackOverflow data.

Hyperparameters were tuned using grid search and the set which gives minimum reconstruction error for both X and W was chosen. We set $\lambda_{np} = \lambda_{rel} = 100$ for StackOverflow, and $\lambda_{np} = 0.05$ and $\lambda_{rel} = 0.001$ for Medline and we use $c = 50$ for our experiments. Please note that our setting is unsupervised, and hence there is no separate train, dev and test sets.

4.2 Evaluation Protocol

In this section, we shall describe how the induced schemas are presented to human annotators and how final accuracies are calculated. In factorizations produced by SICTF and other ablated versions of SICTF, we first select a few top relations with best reconstruction score. The schemas induced for each selected relation k is represented by the matrix slice R_k of the core tensor obtained after factorization (see Section 3). From each such matrix, we identify the indices (i, j) with highest values. The indices i and j select columns of the matrix A. A few top ranking NPs from the columns A_i and A_j along with the relation k are presented to the human annotator, who then evaluates whether the tuple $\text{Relation}_k(A_i, A_j)$ constitutes a valid schema for relation k. Examples of a few relation schemas induced by SICTF are presented in Table 5. A human annotator would see the first and second columns of this table and then offer judgment as indicated in the third column of the table. All such judgments across all top-reconstructed relations are aggregated to get the final accuracy score. This evaluation protocol was also used in (Movshovitz-Attias and Cohen, 2015) to measure learned relation accuracy.

All evaluations were blind, i.e., the annotators were not aware of the method that generated the output they were evaluating. Moreover, the anno-

[8] $(A * B)_{i,j} = A_{i,j} \times B_{i,j}$

(a) (b)

Figure 2: (a) Relation Schema Induction (RSI) accuracies of different methods on the two datasets. SICTF, our proposed method, significantly outperforms state-of-the-art method KBLDA. This is the main result of the paper. Results for KB-LDA on StackOveflow are directly taken from the paper. Please see Section 4.3.1 for details. (b) Runtime comparison between KB-LDA and SICTF. We observe that SICTF results in 14x speedup over KB-LDA. Please see Section 4.3.1 (Runtime Comparison) for details.

tators are experts in software domain and has high-school level knowledge in medical domain. Though recall is a desirable statistic to measure, it is very challenging to calculate it in our setting due to the non-availability of relation schema annotated text on large scale.

4.3 Results

4.3.1 Effectiveness of SICTF

Experimental results comparing performance of various methods on the RSI task in the two datasets are presented in Figure 2(a). RSI accuracy is calculated based on the evaluation protocol described in Section 4.2. Performance number of KB-LDA for StackOveflow dataset is taken directly from the (Movshovitz-Attias and Cohen, 2015) paper, we used our implementation of KB-LDA for the MEDLINE dataset. Annotation accuracies from two annotators were averaged to get the final accuracy. From Figure 2(a), we observe that SICTF outperforms KB-LDA on the RSI task. Please note that the inter-annotator agreement for SICTF is 88% and 97% for MEDLINE and StackOverflow datasets respectively. This is the main result of the paper.

In addition to KB-LDA, we also compared SICTF with PARAFAC, a standard tensor factorization method. PARAFAC induced extremely poor and small number of relation schemas, and hence we didn't consider it any further.

Runtime comparison: Runtimes of SICTF and KB-LDA over both datasets are compared in Figure 2(b). From this figure, we find that SICTF is able to achieve a 14x speedup on average over KB-LDA[10]. In other words, SICTF is not only able to

[10]Runtime of KB-LDA over the StackOverflow dataset was obtained from the authors of (Movshovitz-Attias and Cohen, 2015) through personal communication. Our own implementation also resulted in similar runtime over this dataset.

SICTF (λ_{rel}=0, λ_{np} = 0, and no non-negativity constraints)	0.14	0.10	0.12	0.20	0.14	0.17

Table 6: RSI accuracy comparison of SICTF with its ablated versions when no relation side information is used (λ_{rel} = 0), when no NP side information is used (λ_{np} = 0), when no side information of any kind is used (λ_{rel} = 0, λ_{np} = 0), and when additionally there are no non-negative constraints. From this, we observe that additional side information improves performance, validating one of the central thesis of this paper. Please see Section 4.3.2 and Section 4.3.3 for details.

induce better relation schemas, but also do so at a significantly faster speed.

4.3.2 Importance of Side Information

One of the central hypothesis of our approach is that coupled factorization through additional side information should result in better relation schema induction. In order to evaluate this thesis further, we compare performance of SICTF with its ablated versions: (1) SICTF (λ_{rel} = 0), which corresponds to the setting when no relation side information is used, (2) SICTF ($\lambda_{np} = 0$), which corresponds to the setting when no noun phrases side information is used, and (3) SICTF (λ_{rel} = 0, $\lambda_{np} = 0$), which corresponds to the setting when no side information of any kind is used. Hyperparameters are separately tuned for the variants of SICTF. Results are presented in the first four rows of Table 6. From this, we observe that additional coupling through the side information significantly helps improve SICTF performance. This further validates the central thesis of our paper.

4.3.3 Importance of Non-Negativity on Relation Schema Induction

In the last row of Table 6, we also present an ablated version of SICTF when no side information no non-negativity constraints are used. Comparing the last two rows of this table, we observe that non-negativity constraints over the A matrix and core tensor R result in significant improvement in performance. We note that the last row in Table 6 is equivalent to RESCAL (Nickel et al., 2011) and the fourth row is equivalent to Non-Negative RESCAL (Krompaß et al., 2013), two tensor factorization techniques. We also note that none of these tensor factorization techniques have been previously used for the relation schema induction problem.

The reason for this improved performance may be explained by the fact that absence of non-negativity constraint results in an under constrained factorization problem where the model often overgenerates incorrect triples, and then compensates for this overgeneration by using negative latent factor weights. In contrast, imposition of non-negativity constraints restricts the model further forcing it to commit to specific semantics of the latent factors in A. This improved interpretability also results in better RSI accuracy as we have seen above. Similar benefits of non-negativity on interpretability have also been observed in matrix factorization (Murphy et al., 2012).

5 Conclusion

Relation Schema Induction (RSI) is an important first step towards building a Knowledge Graph (KG) out of text corpus from a given domain. While human domain experts have traditionally prepared listing of relations and their schemas, this expert-mediated model poses significant challenges in terms of scalability and coverage. In order to overcome these challenges, in this paper, we present SICTF, a novel non-negative coupled tensor factorization method for relation schema induction. SICTF is flexible enough to incorporate various types of side information during factorization. Through extensive experiments on real-world datasets, we find that SICTF is not only more accurate but also significantly faster (about 14x speedup) compared to state-of-the-art baselines. As part of future work, we hope to analyze SICTF further, as-

sign labels to induced categories, and also apply the model to more domains.

Abstract

Lexical taxonomies are graph-like hierarchical structures that provide a formal representation of knowledge. Most knowledge graphs to date rely on *is-a* (hypernymic) relations as the backbone of their semantic structure. In this paper, we propose a supervised distributional framework for hypernym discovery which operates at the sense level, enabling large-scale automatic acquisition of disambiguated taxonomies. By exploiting semantic regularities between hyponyms and hypernyms in embeddings spaces, and integrating a domain clustering algorithm, our model becomes sensitive to the target data. We evaluate several configurations of our approach, training with information derived from a manually created knowledge base, along with hypernymic relations obtained from Open Information Extraction systems. The integration of both sources of knowledge yields the best overall results according to both automatic and manual evaluation on ten different domains.

1 Introduction

Lexical taxonomies (taxonomies henceforth) are graph-like hierarchical structures where terms are nodes, and are typically organized over a predefined merging or splitting criterion (Hwang et al., 2012). By embedding cues about how we perceive concepts, and how these concepts generalize in a domain of knowledge, these resources bear a capacity for generalization that lies at the core of human cognition (Yu et al., 2015) and have become key in Natural Language Processing (NLP) tasks where inference and reasoning have proved to be essential. In fact, taxonomies have enabled a remarkable number of novel NLP techniques, e.g. the contribution of WordNet (Miller, 1995) to lexical semantics (Pilehvar et al., 2013; Yu and Dredze, 2014) as well as various tasks, from word sense disambiguation (Agirre et al., 2014) to information retrieval (Varelas et al., 2005), question answering (Harabagiu et al., 2003) and textual entailment (Glickman et al., 2005). To date, the application of taxonomies in NLP has consisted mainly of, on one hand, formally representing a domain of knowledge (e.g. `Food`), and, on the other hand, constituting the semantic backbone of large-scale knowledge repositories such as ontologies or Knowledge Bases (KBs).

In domain knowledge formalization, prominent work has made use of the web (Kozareva and Hovy, 2010), lexico-syntactic patterns (Navigli and Velardi, 2010), syntactic evidence (Luu Anh et al., 2014), graph-based algorithms (Fountain and Lapata, 2012; Velardi et al., 2013; Bansal et al., 2014) or popularity of web sources (Luu Anh et al., 2015). As for enabling large-scale knowledge repositories, this task often tackles the additional problem of disambiguating word senses and entity mentions. Notable approaches of this kind include Yago (Suchanek et al., 2007), WikiTaxonomy (Ponzetto and Strube, 2008), and the Wikipedia Bitaxonomy (Flati et al., 2014). In addition, while not being taxonomy learning systems *per se*, semi-supervised systems for Information Extraction such as NELL (Carlson et al., 2010) rely crucially on taxonomized concepts and their relations within their learning process.

Taxonomy learning is roughly based on a two-step process, namely *is-a* (hypernymic) *relation de-*

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 424–435,
Austin, Texas, November 1-5, 2016.

tection, and *graph induction*. The hypernym detection phase has gathered much interest not only for taxonomy learning but also for lexical semantics. It has been addressed by means of pattern-based methods[1] (Hearst, 1992; Snow et al., 2004; Kozareva and Hovy, 2010; Carlson et al., 2010; Boella and Di Caro, 2013; Espinosa-Anke et al., 2016), clustering (Yang and Callan, 2009) and graph-based approaches (Fountain and Lapata, 2012; Velardi et al., 2013). Moreover, work stemming from distributional semantics introduced notions of linguistic regularities found in vector representations such as word embeddings (Mikolov et al., 2013d). In this area, supervised approaches, arguably the most popular nowadays, learn a feature vector between term-hypernym vector pairs and train classifiers to predict hypernymic relations. These pairs may be represented either as a concatenation of both vectors (Baroni et al., 2012), difference (Roller et al., 2014), dot-product (Mikolov et al., 2013c), or including additional linguistic information for LSTM-based learning (Shwartz et al., 2016).

In this paper we propose TAXOEMBED[2], a hypernym detection algorithm based on sense embeddings, which can be easily applied to the construction of lexical taxonomies. It is designed to discover hypernymic relations by exploiting linear transformations in embedding spaces (Mikolov et al., 2013b) and, unlike previous approaches, leverages this intuition to learn a specific *semantically-aware transformation matrix* for each domain of knowledge. Our best configuration (ranking first in two thirds of the experiments conducted) considers two training sources: (1) Manually curated pairs from Wikidata (Vrandečić and Krötzsch, 2014); and (2) Hypernymy relations from a KB which integrates several Open Information Extraction (OIE) systems (Delli Bovi et al., 2015a). Since our method uses a very large semantic network as reference sense inventory, we are able to perform jointly hypernym extraction and disambiguation, from which expanding existing ontologies becomes a trivial task. Compared to word-level taxonomy learning, TAXOEMBED results in more refined and unambiguous hypernymic relations at the sense level, with a direct application in tasks such as semantic search. Evaluation (both manual and automatic) shows that we can effectively replicate the Wikidata *is-a* branch, and capture previously unseen relations in other reference taxonomies (YAGO or WIBI).

2 Related Work

Pattern-based methods for hypernym identification exploit the joint co-ocurrence of term and hypernym in text corpora. Building up on Hearst's patterns (Hearst, 1992), these approaches have focused on, for instance, exploiting templates for harvesting candidate instances which are ranked via mutual information (Etzioni et al., 2005), training a classifier with WordNet hypernymic relations combined with syntactic dependencies (Snow et al., 2006), or applying a doubly-anchored method (Kozareva and Hovy, 2010), which queries the web with two semantically related terms for collecting domain-specific corpora. Syntactic information is also used for supervised definition and hypernym extraction (Navigli and Velardi, 2010; Boella and Di Caro, 2013), or together with Wikipedia-specific heuristics (Flati et al., 2014). One of the main drawbacks of these methods is that they require both term and hypernym to co-occur in text within a certain window, which strongly hinders their recall. Higher recall can be achieved thanks to distributional methods, as they do not have co-occurrence requirements. In addition, they can be tailored to cover any number of predefined semantic relations such as co-hyponymy or meronymy (Baroni and Lenci, 2011), but also cause-effect or entity-origin (Hendrickx et al., 2009). However, they are often more imprecise and seem to perform best in discovering broader semantic relations (Shwartz et al., 2016).

One way to surmount the issue of generality was proposed by Fu et al. (2014), who explored the possibility to learn a *hypernymic* transformation matrix over a word embeddings space. As shown empirically in Fu et al.'s original work, the hypernymic relation that holds for the pair (*dragonfly*, *insect*) differs from the one of e.g. (*carpenter*, *man*). Prior to

[1]The terminology is not entirely unified in this respect. In addition to *pattern-based* (Fountain and Lapata, 2012; Bansal et al., 2014; Yu et al., 2015), other terms like *path-based* (Shwartz et al., 2016) or *rule-based* (Navigli and Velardi, 2010) are also used.

[2]Data and source code available from the following link: `www.taln.upf.edu/taxoembed`.

training, their system addresses this discrepancy via k-means clustering using a held-out development set for tuning.

The previously described methods for hypernym and taxonomy learning operate inherently at the surface level. This is partly due to the way evaluation is conducted, which is often limited to very specific domains with no integrative potential (e.g. taxonomies in `food`, `science` or `equipment` from Bordea et al. (2015)), or restricted to lists of word pairs. Hence, a drawback of surface-level taxonomy learning, apart from ambiguity issues, is that they require additional and error-prone steps to identify semantic clusters (Fu et al., 2014).

Alternatively, recent advances in OIE based on disambiguation and deeper semantic analysis (Nakashole et al., 2012; Grycner and Weikum, 2014; Delli Bovi et al., 2015b) have shown their potential to construct taxonomized disambiguated resources both at node and at relation level. However, in addition to their inherently broader scope, OIE approaches are designed to achieve high coverage, and hence they tend to produce noisier data compared to taxonomy learning systems.

In our sense-based approach, instead, not only do we leverage an unambiguous vector representation for hypernym discovery, but we also take advantage of a domain-wise clustering strategy to directly obtain specific term-hypernym training pairs, thereby substantially refining this step. Additionally, we exploit the complementary knowledge of OIE systems by incorporating high-confidence relation triples drawn from OIE-derived resources, yielding the best average configuration as evaluated on ten different domains of knowledge.

3 Preliminaries

TAXOEMBED leverages the vast amounts of training data available from structured and unstructured knowledge resources, along with the mapping among these resources and a state-of-the-art vector representation of word senses.

BabelNet[3] (Navigli and Ponzetto, 2012) constitutes our sense inventory, as it is currently the largest single multilingual repository of named entities and concepts, integrating various resources such as WordNet, Wikipedia or Wikidata. As in WordNet, BabelNet is structured in synsets. Each synset is composed of a set of words (*lexicalizations* or *senses*) representing the same meaning. For instance, the synset referring to *the members of a business organization* is represented by the set of senses *firm, house, business firm*. BabelNet contains around 14M synsets in total. We exploit BabelNet[4] as (1) A repository for the manually-curated hypernymic relations included in **Wikidata**; (2) A semantic pivot of the integration of several OIE systems into one single resource, namely **KB-UNIFY**; and (3) A sense inventory for the **SENSEMBED** vector representations. In the following we provide further details about each of these resources.

3.1 Training Data

Wikidata[5] (Vrandečić and Krötzsch, 2014) is a document-oriented semantic database operated by the Wikimedia Foundation with the goal of providing a common source of data that can be used by other Wikimedia projects. Our initial training set $\mathcal{W}$ consists of the hypernym branch of Wikidata, specifically the version included in BabelNet. Each term-hypernym $\in \mathcal{W}$ is in fact a pair of BabelNet synsets, e.g. the synset for *Apple* (with the company sense), and the concept *company*.

KB-UNIFY[6] (Delli Bovi et al., 2015a) (KB-U) is a knowledge-based approach, based on BabelNet, for integrating the output of different OIE systems into a single unified and disambiguated knowledge repository. The unification algorithm takes as input a set **K** of OIE-derived resources, each of which is modeled as a set of ⟨entity, relation, entity⟩ triples, and comprises two subsequent stages: in the first *disambiguation* stage, each KB in **K** is linked to the sense inventory of BabelNet by disambiguating its relation argument pairs; in the following *alignment* stage, equivalent relations across different KB in **K** are merged together. As a result, KB-U generates a KB of triples where arguments are linked to the corresponding BabelNet synsets, and relations are replaced by *relation synsets* of semantically

[3] `http://babelnet.org`

[4] We use BabelNet 3.0 release version in our experiments.

[5] `https://www.wikidata.org`

[6] `http://lcl.uniroma1.it/kb-unify`

similar OIE-derived relation patterns. The original experimental setup of KB-UNIFY included NELL (Carlson et al., 2010) as one of its input resources: since NELL features its own manually-built taxonomic structure and relation type inventory (hence its own *is-a* relation type), we identified the relation synset containing NELL's *is-a*[7] and then drew from the unified KB all the corresponding triples, which we denote as $\mathcal{K}$. These triples constitute, similarly as in the previous case, a set of term-hypernym pairs automatically extracted from OIE-derived resources, with a disambiguation confidence of above 0.9 according to the disambiguation strategy described in the original paper.

Initially, $|\mathcal{W}|$ = 5,301,867 and $|\mathcal{K}|$ = 1,358,949.

3.2 Sense vectors

SENSEMBED (Iacobacci et al., 2015)[8] constitutes the sense embeddings space that we use for training our hypernym detection algorithm. Vectors in the SENSEMBED space, denoted as $\mathcal{S}$, are latent continuous representations of word senses based on the Word2Vec architecture (Mikolov et al., 2013a), which was applied on a disambiguated Wikipedia corpus. Each vector $\vec{v} \in \mathcal{S}$ represents a BabelNet sense, i.e. a synset along with one of its lexicalizations (e.g. *album_chart_bn:00002488n*). This differs from unsupervised approaches (Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014) that learn sense representations from text corpora only and are not mapped to any lexical resource, limiting their application in our task.

4 Methodology

Our approach can be summarized as follows. First, we take advantage of a clustering algorithm for allocating each BabelNet synset of the training set into a domain cluster C (Section 4.1). Then, we expand the training set by exploiting the different lexicalizations available for each BabelNet synset (Section 4.2). Finally, we learn a cluster-wise linear projection (a *hypernym transformation matrix*) over all pairs (term-hypernym) of the expanded training set (Section 4.3).

[7] represented by the relation `generalizations`.

[8] `http://lcl.uniroma1.it/sensembed`

4.1 Domain Clustering

Fu et al. (2014) induced semantic clusters via k-means, where k was tuned on a development set. Instead, we aim at learning a function sensitive to a predefined knowledge domain, under the assumption that vectors clustered with this criterion are likely to exhibit similar semantic properties (e.g. similarity). First, we allocate each synset into its most representative domain, which is achieved by exploiting the set of thirty four domains available in the Wikipedia featured articles page[9]. `Warfare`, `transport`, or `music` are some of these domains. In the Wikipedia featured articles page each domain is composed of 128 Wikipedia pages on average. Then, in order to expand the set of concepts associated with each domain, we leverage NASARI[10] (Camacho-Collados et al., 2015), a distributional approach that has been used to construct explicit vector representations of BabelNet synsets.

Our goal is to associate BabelNet synsets with domains. To this end, we follow Camacho-Collados et al. (2016) and build a lexical vector for each Wikipedia domain by concatenating all Wikipedia pages representing the given domain into a single text. Finally, given a BabelNet synset b, we calculate the similarity between its corresponding NASARI lexical vector and all the domain vectors, selecting the domain leading to the highest similarity score:

$$\hat{d}(b) = \max_{d \in D} WO(\vec{d}, \vec{b}) \quad (1)$$

where D is the set of all thirty-three domains, $\vec{d}$ is the vector of the domain $d \in D$, $\vec{b}$ is the vector of the BabelNet synset b, and WO refers to the *Weighted Overlap* comparison measure (Pilehvar et al., 2013), which is defined as follows:

$$WO(\vec{v_1}, \vec{v_2}) = \sqrt{\frac{\sum_{w \in O} \left(rank_{w,\vec{v_1}} + rank_{w,\vec{v_2}}\right)^{-1}}{\sum_{i=1}^{|O|}(2i)^{-1}}} \quad (2)$$

where $rank_{w,\vec{v_i}}$ is the rank of the word w in the vector $\vec{v_i}$ according to its weight, and O is the set of overlapping words between the two vectors. In order to have a highly reliable set of domain labels, those

[9] `https://en.wikipedia.org/wiki/Wikipedia:Featured_articles`

[10] `http://lcl.uniroma1.it/nasari`

synsets whose maximum similarity score is below a certain threshold are not annotated with any domain. We fixed the threshold to 0.35, which provided a fine balance between precision (estimated in around 85%) and recall in our development set. By following this approach almost 2 million synsets are labelled with a domain.

4.2 Training Data Expansion

Prior to training our model, we benefit from the fact that a given BabelNet synset may be associated with a fixed number of lexicalizations or senses, i.e. different ways of referring to the same concept, to expand our set of training pairs. For instance, the synset b associated with the concept *music_album* is represented by the set of lexicalizations $\mathcal{L}_b = \{$album, music_album ... album_project$\}$. We take advantage of this synset representation to expand each term-hypernym synset pair. For each term-hypernym pair, both concepts are expanded to their given lexicalizations and thus, each synset pair term-hypernym in the training data is expanded to a set of $|\mathcal{L}_t|.|\mathcal{L}_h|$ sense training pairs.

This expansion step results in much larger sets $\mathcal{W}^*$ and $\mathcal{K}^*$, where $|\mathcal{W}^*| = 18{,}291{,}330$ and $|\mathcal{K}^*| = 15{,}362{,}268$. Specifically, they are 3 and 11 times bigger than the original training sets described in Section 3.1. These numbers are higher than those reported in recent approaches for hypernym detection, which exploited Chinese semantic thesauri along with manual validation of hypernym pairs (Fu et al., 2014) (obtaining a total of 1,391 instances), or pairs from knowledge resources such as Wikidata, Yago, WordNet and DBpedia (Shwartz et al., 2016), where the maximum reported split for training data (70%) amounted to 49,475 pairs.

4.3 Learning a Hypernym Detection Matrix

The gist of our approach lies on the property of current semantic vector space models to capture relations between vectors, in our case hypernymy. This can be found even in disjoint spaces, where this property has been exploited for machine translation (Mikolov et al., 2013b) or language normalization (Tan et al., 2015). For our purposes, however, instead of learning a global linear transformation function in two spaces over a broad relation like hypernymy, we learn a function sensitive to a given domain of knowledge. Thus, our training data becomes restricted to those term-hypernym BabelNet sense pairs $\left(x^d, y^d\right) \in C_d \times C_d$, where C_d is the cluster of BabelNet synsets labelled with the domain d.

For each domain-wise expanded training set T^d, we construct a hyponym matrix $\mathbf{X}^d = [\vec{x}_1^d \dots \vec{x}_n^d]$ and a hypernym matrix $\mathbf{Y}^d = [\vec{y}_i^d \dots \vec{y}_n^d]$, which are composed by the corresponding SENSEMBED vectors of the training pairs $\left(x_i^d, y_i^d\right) \in C_d \times C_d, 0 \leq i \leq n$.

Under the intuition that there exists a matrix Ψ so that $\vec{y}^d = \Psi\vec{x}^d$, we learn a transformation matrix for each domain cluster C_d by minimizing:

$$\min_{\Psi^C} \sum_{i=1}^{|T^d|} \|\Psi^C \vec{x}_i^d - \vec{y}_i^d\|^2 \tag{3}$$

Then, for any unseen term x^d, we obtain a ranked list of the most likely hypernyms of its lexicalization vectors $\vec{x_j}^d$, using as measure cosine similarity:

$$\text{argmax}_{\vec{v}\in\mathcal{S}} \frac{\vec{v} \cdot \Psi^C \vec{x_j}^d}{||\vec{v}||||\Psi^C \vec{x_j}^d||} \tag{4}$$

At this point, we have associated with each sense vector a ranked list of candidate hypernym vectors. However, in the (frequent) cases in which one synset has more than one lexicalization, we need to condense the results into one single list of candidates, which we achieve with a simple ranking function $\lambda(\cdot)$, which we compute as $\lambda(\vec{v}) = \frac{cos(\vec{v}, \Psi^C \vec{x}^d)}{rank(\vec{v})}$, where $rank(\vec{v})$ is the rank of $\vec{v}$ according to its cosine similarity with $\Psi^C \vec{x}^d$.

The above operations allow us to cast the hypernym detection task as a ranking problem. This is also particularly interesting to enable a flexible evaluation framework where we can combine highly demanding metrics for the quality of the candidate given at a certain rank, as well as other measures which consider the rank of the first valid retrieved candidate.

5 Evaluation

The performance of TAXOEMBED is evaluated by conducting several experiments, both automatic and manual. Specifically, we assess its ability to return valid hypernyms for a given unseen term with

a held-out evaluation dataset of 250 Wikidata term-hypernym pairs (Section 5.1). In addition, we assess the extent to which TAXOEMBED is able to correctly identify hypernyms *outside of Wikidata* (Section 5.2).

5.1 Experiment 1: Automatic Evaluation

5.1.1 Experimental setting

For each domain, we retain 5k, 10k, 15k, 20k and 25k Wikidata term-hypernym training pairs for different experiments, and evaluate on 250 test pairs for each of the 10 domains. Moreover, we aim at improving TAXOEMBED by including 1k and 25k extra OIE-derived training pairs per domain (generating two more systems, namely 25k+K^d_{1k} and 25k+K^d_{25k}). These OIE-derived instances are those contained in KB-U (see Section 3.1). Moreover, in order to quantify the empirically grounded intuition of the need to train a cluster-wise transformation matrix (Fu et al., 2014), we also introduce an additional configuration at 25k (25k+K^r_{50k}), where we include 50k additional pairs randomly from KB-U, and two more settings with only random pairs coming from Wikidata (100k$^r_{wd}$) and KB-U (100k+$^r_{kbu}$).

We also include a distributional supervised baseline[11] based on word analogies (Mikolov et al., 2013a), computed as follows. First, we calculate the difference vector of each training SENSEMBED vector pair ($\vec{x}^d$,$\vec{y}^d$) of a given domain d. Then, we average all the difference vectors of all training pairs to obtain a global vector $\vec{V}_d$ for the domain d. Finally, given a test term t we calculate the closest vector of the sum of the corresponding term vector and $\vec{V}_d$:

$$\hat{t} = \text{argmax}_{\vec{v} \in \mathcal{S}} \vec{V}_d + \vec{t} \quad (5)$$

This baseline has shown to capture different semantic relations and to improve as training data increases (Mikolov et al., 2013a).

Evaluation metrics. We computed, for each domain and for the above configurations, the following metrics: Mean Reciprocal Rank (MRR), Mean Average Precision (MAP), and R-Precision (R-P). These measures provide insights on different aspects of the outcome of the task, e.g. how often valid hypernyms were retrieved in the first positions of the rank (MRR), and if there were more than one valid hypernym, whether this set was correctly retrieved, (MAP and R-P)[12].

5.1.2 Results and discussion

We summarize the main outcome of our experiments in Table 1. Results suggest that the performance of TAXOEMBED increases as training data expands. This is consistent with the findings shown in Mikolov et al. (2013b), who showed a substantial improvement in accuracy in the machine translation task by gradually increasing the training set. Additionally, the improvement of TAXOEMBED over the baseline is consistent across most evaluation domain clusters and metrics, with domain-filtered data from KB-U contributing to the learning process in about two thirds of the evaluated configurations. These are very encouraging results considering the noisy nature of OIE systems, and that the resource we obtained from KB-U is the result of error-prone steps such as Word Sense Disambiguation and Entity Linking, as well as relation clustering.

As far as the individual domains are concerned, the `biology` domain seems to be easier to model than the rest, likely due to the fact that fauna and flora are areas where hierarchical division of species is a field of study in itself, which traces back to Aristotelian times (Mayr, 1982), and therefore has been constantly refined over the years. Also, it is notable how well the 100k$^r_{wd}$ configuration performs on this domain. This is the only domain in which training with no semantic awareness gives good results. We argue that this is highly likely due to the fact that a vast amount of synsets are allocated into the `biology` cluster (60% of them, and up to 80% in hypernym position). This produces the so-called lexical memorization phenomenon (Levy et al., 2015), as the system memorizes prototypical biology-related hypernyms like *taxon* as valid hypernyms for many concepts. This contrasts with the lower presence of other domains, e.g. 5% in `media`, 4% in `music`, or 2% in `transport`.

Another remarkable case involves the `education` and `media` domains, which experience the highest improvement when training with KB-U (5 and 6 MRR points, respectively).

[11] Using the 25k domain-filtered expanded Wikidata pairs as training set.

[12] See Bian et al. (2008) for an in-depth analysis of these metrics.

Table 1: Overview of the performance of TAXOEMBED using different training data samples.

One of the main sources for *is-a* relations in KB-U is NELL, which contains a vast amount of relation triples between North American academic entities (professors, sports teams, alumni, donators; as well as media celebrities). Many of these entities are missing in Wikidata, and relations among them encoded in NELL are likely to be correct because in most cases these are unambiguous entities which occur in the same communicative contexts. For example, leveraging KB-U we were able to include the pair (*university_of_north_wales*, *four_year_college*), which is absent in Wikidata. In fact, many high quality *is-a* pairs like this can be found in KB-U for these two domains.

We also computed P@k (number of valid hypernyms on the first k returned candidates), where k ranges from 1 to 5. Numbers are on the line of the results shown in Table 1 and therefore are not provided in detail. The main trend we found is showcased in Figure 1, which shows an illustrative example from the `transport` domain. As we can see, all values of k exhibit a similar performance curve, with a gradual increase of performance as the training set becomes larger.

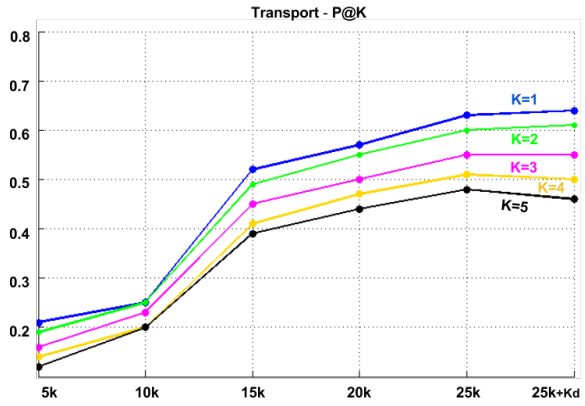

Figure 1: P@k scores for the `transport` domain.

False positives. We complement this experiment with a manual evaluation of *theoretical* false positives. Our intuition is that due to the nature of the task, some domains may be more flexible in allow-

ing two terms to encode an *is-a* relation, while others may be more restrictive. We asked human judges to manually validate a sample of 200 *wrong pairs* from our best run in each domain, and estimated precision over them. As expected, *hard science* domains like `physics` obtain very low results (about 1% precision). In contrast, other domains like `education` (12% precision), or `transport` (16% precision), probably due to their multidisciplinary nature, allow more valid hypernyms for a given term than what is currently encoded in Wikidata.

5.2 Experiment 2: Extra-Coverage

In this experiment we evaluate the performance of TAXOEMBED on instances not included in Wikidata. We describe the experimental setting in Section 5.2.1 and present the results in Section 5.2.2.

5.2.1 Experimental setting

For this experiment we use two configurations of TAXOEMBED: the first one includes 25k domain-wise expanded training pairs (TaxE_{25k}), whereas the second one adds 1k pairs from KB-U (TaxE_{25k+K^d}). We randomly extract 200 test BabelNet synsets (20 per domain) whose hypernyms are missing in Wikidata. We compare against a number of taxonomy learning and Information Extraction systems, namely Yago (Suchanek et al., 2007), WiBi (Flati et al., 2014) and DefIE (Delli Bovi et al., 2015b). Yago and WiBi are used as *upper bounds* due to the nature of their hypernymic relations. They include a great number of manually-encoded taxonomies (e.g. exploiting WordNet and Wikipedia categories). Yago derives its taxonomic relations from an automatic mapping between WordNet and Wikipedia categories. WiBi, on the other hand, exploits, among a number of different Wikipedia-specific heuristics, categories and the syntactic structure of the introductory sentence of Wikipedia pages. Finally, DefIE is an automaic OIE system relying on the syntactic structure of pre-disambiguated definitions[13]. Three annotators manually evaluated the validity of the hypernyms extracted by each system (one per test instance).

5.2.2 Results and discussion

Table 2 shows the results of TAXOEMBED and all comparison systems. As expected, Yago and WiBi achieve the best overall results. However, TAXOEMBED, based solely on distributional information, performed competitively in detecting new hypernyms when compared to DefIE, improving its recall in most domains, and even surpassing Yago in technical areas like `biology` or `health`. However, our model does not perform particularly well on `media` and `physics`. In most domains our model is able to discover novel hypernym relations that are not captured by any other system (e.g. *therapy* for *radiation treatment planning* in the `health` domain or *decoration* for *molding* in the `art` domain)[14].

In fact, the overlap between our approach and the remaining systems is actually quite small (on average less than 25% with all of them on the Extra-Coverage experiment). This is mainly due to the fact that TAXOEMBED only exploits distributional information and does not make use of predefined syntactic heuristics, suggesting that the information it provides and the rule-based comparison systems may be complementary. We foresee a potential avenue focused on combining a supervised distributional approach such as TAXOEMBED with syntactically-motivated systems such as Wibi or Yago. This combination of a distributional system and manual patterns was already introduced by Shwartz et al. (2016) on the hypernym detection task with highly encouraging results.

6 Conclusion

We have presented TAXOEMBED, a supervised taxonomy learning framework exploiting the property that was observed in Fu et al. (2014), namely that there exists, for a given domain-specific terminology, a shared linear projection among term-hypernym pairs. We showed how this can be used to learn a hypernym transformation matrix for discovering novel *is-a* relations, which are the backbone of lexical taxonomies. First, we allocate almost 2M BabelNet synsets into a predefined domain of knowledge. Then, we collect training data both from a manually constructed knowledge base (Wiki-

[13]For this experiment, we included DefIE's *is-a* relations only.

[14]For simplicity, we use the word surface form to refer to BabelNet synsets.

data), and from OIE systems. We substantially expand our initial training set by expanding both terms and hypernyms to all their available senses, and in a last step, to their corresponding disambiguated vector representations.

Evaluation shows that the general trend is that our hypernym matrix improves as we increase training data. Our best domain-wise configuration combines 25k training pairs from Wikidata and additional pairs from an OIE-derived KB, achieving promising results. The domains in which the addition of the OIE-based information contributed the most are `education`, `transport` and `media`. For instance, in the case of `education`, this may be due to the over representation of the North American educational system in IE systems like NELL. We accompany this quantitative evaluation with manual assessment of precision of false positives, and an analysis of the potential coverage comparing it with knowledge taxonomies like Yago or WiBi, and with DefIE, a *quasi*-OIE system.

7 Future Work

For future work we are planning to apply this strategy to learn large-scale semantic relations beyond hypernymy. This may constitute a first step towards a global and fully automatic ontology learning system. In the context of semantic web, we would like to include semantic parsers and distant supervision to our algorithm in order to capture n-ary relations between pairs of concepts to further create and improve existing KBs.

As mentioned in Section 5.2.2, we are also planning to combine our distributional approach with rule-based heuristics, following the line of work introduced by Shwartz et al. (2016). Finally, we see potential in the domain clustering approach for improving graph-based taxonomy learning systems, as it can serve as a weighting measure as to how pertinent a given set of concepts in a taxonomy are for a specific domain.

Acknowledgments

This work is partially funded by the Spanish Ministry of Economy and Competitiveness under the Maria de Maeztu Units of Excellence Programme (MDM-2015-0502) and under the TUNER project (TIN2015-65308-C5-5-R, MINECO/FEDER, UE). The authors also acknowledge support from Dr. Inventor (FP7-ICT-2013.8.1611383). José Camacho-Collados is supported by a Google Doctoral Fellowship in Natural Language Processing. We would also like to thank Tommaso Pasini for helping us to compute the Wibi and Yago baselines in our second experiment.

Abstract

In this paper we introduce Latent Tree Language Model (LTLM), a novel approach to language modeling that encodes syntax and semantics of a given sentence as a tree of word roles.

The learning phase iteratively updates the trees by moving nodes according to Gibbs sampling. We introduce two algorithms to infer a tree for a given sentence. The first one is based on Gibbs sampling. It is fast, but does not guarantee to find the most probable tree. The second one is based on dynamic programming. It is slower, but guarantees to find the most probable tree. We provide comparison of both algorithms.

We combine LTLM with 4-gram Modified Kneser-Ney language model via linear interpolation. Our experiments with English and Czech corpora show significant perplexity reductions (up to 46% for English and 49% for Czech) compared with standalone 4-gram Modified Kneser-Ney language model.

1 Introduction

Language modeling is one of the core disciplines in natural language processing (NLP). Automatic speech recognition, machine translation, optical character recognition, and other tasks strongly depend on the language model (LM). An improvement in language modeling often leads to better performance of the whole task. The goal of language modeling is to determine the joint probability of a sentence. Currently, the dominant approach is n-gram language modeling, which decomposes the joint probability into the product of conditional probabilities by using the *chain rule*. In traditional n-gram LMs the words are represented as distinct symbols. This leads to an enormous number of word combinations.

In the last years many researchers have tried to capture words contextual meaning and incorporate it into the LMs. Word sequences that have never been seen before receive high probability when they are made of words that are semantically similar to words forming sentences seen in training data. This ability can increase the LM performance because it reduces the *data sparsity* problem. In NLP a very common paradigm for word meaning representation is the use of the *Distributional hypothesis*. It suggests that two words are expected to be semantically similar if they occur in similar contexts (they are similarly distributed in the text) (Harris, 1954). Models based on this assumption are denoted as distributional semantic models (DSMs).

Recently, semantically motivated LMs have begun to surpass the ordinary n-gram LMs. The most commonly used architectures are *neural network LMs* (Bengio et al., 2003; Mikolov et al., 2010; Mikolov et al., 2011) and *class-based LMs*. Class-based LMs are more related to this work thus we investigate them deeper.

Brown et al. (1992) introduced class-based LMs of English. Their unsupervised algorithm searches classes consisting of words that are most probable in the given context (one word window in both directions). However, the computational complexity of this algorithm is very high. This approach was later extended by (Martin et al., 1998; Whit-

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 436–446,
Austin, Texas, November 1-5, 2016.

taker and Woodland, 2003) to improve the complexity and to work with wider context. Deschacht et al. (2012) used the same idea and introduced Latent Words Language Model (LWLM), where word classes are latent variables in a graphical model. They apply Gibbs sampling or the expectation maximization algorithm to discover the word classes that are most probable in the context of surrounding word classes. A similar approach was presented in (Brychcín and Konopík, 2014; Brychcín and Konopík, 2015), where the word clusters derived from various semantic spaces were used to improve LMs.

In above mentioned approaches, the meaning of a word is inferred from the surrounding words independently of their relation. An alternative approach is to derive contexts based on the syntactic relations the word participates in. Such syntactic contexts are automatically produced by dependency parse-trees. Resulting word representations are usually less topical and exhibit more functional similarity (they are more syntactically oriented) as shown in (Padó and Lapata, 2007; Levy and Goldberg, 2014).

Dependency-based methods for syntactic parsing have become increasingly popular in NLP in the last years (Kübler et al., 2009). Popel and Mareček (2010) showed that these methods are promising direction of improving LMs. Recently, unsupervised algorithms for dependency parsing appeared in (Headden III et al., 2009; Cohen et al., 2009; Spitkovsky et al., 2010; Spitkovsky et al., 2011; Mareček and Straka, 2013) offering new possibilities even for poorly-resourced languages.

In this work we introduce a new DSM that uses tree-based context to create word roles. The word role contains the words that are similarly distributed over similar tree-based contexts. The word role encodes the semantic and syntactic properties of a word. We do not rely on parse trees as a prior knowledge, but we jointly learn the tree structures and word roles. Our model is a soft clustering, i.e. one word may be present in several roles. Thus it is theoretically able to capture the word polysemy. The learned structure is used as a LM, where each word role is conditioned on its parent role. We present the unsupervised algorithm that discovers the tree structures only from the distribution of words in a training corpus (i.e. no labeled data or external sources of information are needed). In our work we were inspired by class-based LMs (Deschacht et al., 2012), unsupervised dependency parsing (Mareček and Straka, 2013), and tree-based DSMs (Levy and Goldberg, 2014).

This paper is organized as follows. We start with the definition of our model (Section 2). The process of learning the hidden sentence structures is explained in Section 3. We introduce two algorithms for searching the most probable tree for a given sentence (Section 4). The experimental results on English and Czech corpora are presented in Section 6. We conclude in Section 7 and offer some directions for future work.

2 Latent Tree Language Model

In this section we describe Latent Tree Language Model (LTLM). LTLM is a generative statistical model that discovers the tree structures hidden in the text corpus.

Let $\boldsymbol{L}$ be a word vocabulary with total of $|\boldsymbol{L}|$ distinct words. Assume we have a training corpus $\boldsymbol{w}$ divided into S sentences. The goal of LTLM or other LMs is to estimate the probability of a text $P(\boldsymbol{w})$. Let N_s denote the number of words in the s-th sentence. The s-th sentence is a sequence of words $\boldsymbol{w}_s = \{w_{s,i}\}_{i=0}^{N_s}$, where $w_{s,i} \in \boldsymbol{L}$ is a word at position i in this sentence and $w_{s,0} = <\mathrm{s}>$ is an artificial symbol that is added at the beginning of each sentence.

Each sentence s is associated with the dependency graph $\boldsymbol{G}_s$. We define the dependency graph as a labeled directed graph, where nodes correspond to the words in the sentence and there is a label for each node that we call *role*. Formally, it is a triple $\boldsymbol{G}_s = (\boldsymbol{V}_s, \boldsymbol{E}_s, \boldsymbol{r}_s)$ consisting of:

- The set of nodes $\boldsymbol{V}_s = \{0, 1, ..., N_s\}$. Each token $w_{s,i}$ is associated with node $i \in \boldsymbol{V}_s$.
- The set of edges $\boldsymbol{E}_s \subseteq \boldsymbol{V}_s \times \boldsymbol{V}_s$.
- The sequence of roles $\boldsymbol{r}_s = \{r_{s,i}\}_{i=0}^{N_s}$, where $1 \leq r_{s,i} \leq K$ for $i \in \boldsymbol{V}_s$. K is the number of roles.

The artificial word $w_{s,0} = <\mathrm{s}>$ at the beginning of the sentence has always role 1 ($r_{s,0} = 1$). Analogously to $\boldsymbol{w}$, the sequence of all $\boldsymbol{r}_s$ is denoted as $\boldsymbol{r}$ and sequence of all $\boldsymbol{G}_s$ as $\boldsymbol{G}$.

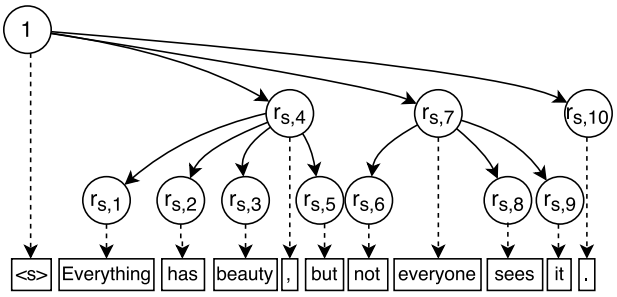

Figure 1: Example of LTLM for the sentence "*Everything has beauty, but not everyone sees it.*"

Edge $e \in \boldsymbol{E}_s$ is an ordered pair of nodes (i, j). We say that i is the *head* or the *parent* and j is the *dependent* or the *child*. We use the notation $i \rightarrow j$ for such edge. The directed path from node i to node j is denoted as $i \overset{*}{\rightarrow} j$.

We place a few constraints on the graph $\boldsymbol{G}_s$.

- The graph $\boldsymbol{G}_s$ is a *tree*. It means it is the acyclic graph (if $i \rightarrow j$ then not $j \overset{*}{\rightarrow} i$), where each node has one parent (if $i \rightarrow j$ then not $k \rightarrow j$ for every $k \neq i$).
- The graph $\boldsymbol{G}_s$ is *projective* (there are no cross edges). For each edge (i, j) and for each k between i and j (i.e. $i < k < j$ or $i > k > j$) there must exist the directed path $i \overset{*}{\rightarrow} k$.
- The graph $\boldsymbol{G}_s$ is always rooted in the node 0.

We denote these graphs as the *projective dependency trees*. Example of such a tree is on Figure 1. For the tree $\boldsymbol{G}_s$ we define a function

$$h_s(j) = i, \quad \text{when } (i, j) \in \boldsymbol{E}_s \tag{1}$$

that returns the parent for each node except the root.

We use graph $\boldsymbol{G}_s$ as a representation of the *Bayesian network* with random variables $\boldsymbol{E}_s$ and $\boldsymbol{r}_s$. The roles $r_{s,i}$ represent the node labels and the edges express the dependences between the roles. The conditional probability of the role at position i given its parent role is denoted as $P(r_{s,i}|r_{s,h_s(i)})$. The conditional probability of the word at position i in the sentence given its role $r_{s,i}$ is denoted as $P(w_{s,i}|r_{s,i})$.

We model the distribution over words in the sentence s as the mixture

$$P(\boldsymbol{w}_s) = P(\boldsymbol{w}_s|r_{s,0}) = \prod_{i=1}^{N_s} \sum_{k=1}^{K} P(w_{s,i}|r_{s,i} = k) P(r_{s,i} = k|r_{s,h_s(i)}). \tag{2}$$

The root role is kept fixed for each sentence ($r_{s,0}$ = 1) so $P(\boldsymbol{w}_s) = P(\boldsymbol{w}_s|r_{s,0})$.

We look at the roles as mixtures over child roles and simultaneously as mixtures over words. We can represent dependency between roles with a set of K multinomial distributions $\boldsymbol{\theta}$ over K roles, such that $P(r_{s,i}|r_{s,h_s(i)} = k) = \theta^{(k)}_{r_{s,i}}$. Simultaneously, dependency of words on their roles can be represented as a set of K multinomial distributions $\boldsymbol{\phi}$ over $|\boldsymbol{L}|$ words, such that $P(w_{s,i}|r_{s,i} = k) = \phi^{(k)}_{w_{s,i}}$. To make predictions about new sentences, we need to assume a prior distribution on the parameters $\boldsymbol{\theta}^{(k)}$ and $\boldsymbol{\phi}^{(k)}$.

We place a Dirichlet prior D with the vector of K hyper-parameters $\boldsymbol{\alpha}$ on a multinomial distribution $\boldsymbol{\theta}^{(k)} \sim D(\boldsymbol{\alpha})$ and with the vector of $|\boldsymbol{L}|$ hyper-parameters $\boldsymbol{\beta}$ on a multinomial distribution $\boldsymbol{\phi}^{(k)} \sim D(\boldsymbol{\beta})$. In general, D is not restricted to be Dirichlet distribution. It could be any distribution over discrete children, such as logistic normal. In this paper, we focus only on Dirichlet as a conjugate prior to the multinomial distribution and derive the learning algorithm under this assumption.

The choice of the child role depends only on its parent role, i.e. child roles with the same parent are mutually independent. This property is especially important for the learning algorithm (Section 3) and also for searching the most probable trees (Section 4). We do not place any assumption on the length of the sentence N_s or on how many children the parent node is expected to have.

3 Parameter Estimation

In this section we present the learning algorithm for LTLM. The goal is to estimate $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ in a way that maximizes the predictive ability of the model (generates the corpus with maximal joint probability $P(\boldsymbol{w})$).

Let $\chi^k_{(i,j)}$ be an operation that changes the tree $\boldsymbol{G}_s$ to $\boldsymbol{G}'_s$

$$\chi^k_{(i,j)} : \boldsymbol{G}_s \rightarrow \boldsymbol{G}'_s, \tag{3}$$

such that the newly created tree $\boldsymbol{G}'(\boldsymbol{V}'_s, \boldsymbol{E}'_s, \boldsymbol{r}'_s)$ consists of:

- $\boldsymbol{V}'_s = \boldsymbol{V}_s$.
- $\boldsymbol{E}'_s = (\boldsymbol{E}_s \setminus \{(h_s(i), i)\}) \cup \{(j, i)\}$.
- $r'_{s,a} = \begin{cases} r_{s,a} & \text{for } a \neq i \\ k & \text{for } a = i \end{cases}$, where $0 \leq a \leq N_s$.

It means that we change the role of the selected node i so that $r_{s,i} = k$ and simultaneously we change the parent of this node to be j. We call this operation a *partial change*.

The newly created graph $\boldsymbol{G}'$ must satisfy all conditions presented in Section 2, i.e. it is a projective dependency tree rooted in the node 0. Thus not all partial changes $\chi^k_{(i,j)}$ are possible to perform on graph $\boldsymbol{G}_s$.

Clearly, for the sentence s there is at most $\frac{N_s(1+N_s)}{2}$ parent changes[1].

To estimate the parameters of LTLM we apply Gibbs sampling and gradually sample $\chi^k_{(i,j)}$ for trees $\boldsymbol{G}_s$. For doing so we need to determine the posterior predictive distribution[2]

$$\boldsymbol{G}'_s \sim P(\chi^k_{(i,j)}(\boldsymbol{G}_s)|\boldsymbol{w}, \boldsymbol{G}), \tag{4}$$

from which we will sample partial changes to update the trees. In the equation, $\boldsymbol{G}$ denote the sequence of all trees for given sentences $\boldsymbol{w}$ and $\boldsymbol{G}'_s$ is a result of one sampling. In the following text we derive this equation under assumptions from Section 2.

The posterior predictive distribution of Dirichlet multinomial has the form of additive smoothing that is well known in the context of language modeling. The hyper-parameters of Dirichlet prior determine how much is the predictive distribution smoothed. Thus the predictive distribution for the word-in-role distribution can be expressed as

$$P(w_{s,i}|r_{s,i}, \boldsymbol{w}_{\setminus s,i}, \boldsymbol{r}_{\setminus s,i}) = \frac{n^{(w_{s,i}|r_{s,i})}_{\setminus s,i} + \beta}{n^{(\bullet|r_{s,i})}_{\setminus s,i} + |\boldsymbol{L}|\,\beta}, \tag{5}$$

where $n^{(w_{s,i}|r_{s,i})}_{\setminus s,i}$ is the number of times the role $r_{s,i}$ has been assigned to the word $w_{s,i}$, excluding the position i in the s-th sentence. The symbol $\bullet$ represents any word in the vocabulary so that $n^{(\bullet|r_{s,i})}_{\setminus s,i} = \sum_{l \in \boldsymbol{L}} n^{(l|r_{s,i})}_{\setminus s,i}$. We use the symmetric Dirichlet distribution for the word-in-role probabilities as it could be difficult to estimate the vector of hyper-parameters $\boldsymbol{\beta}$ for large word vocabulary. In the above mentioned equation, β is a scalar.

The predictive distribution for the role-by-role distribution is

$$P\left(r_{s,i}|r_{s,h_s(i)}, \boldsymbol{r}_{\setminus s,i}\right) = \frac{n^{(r_{s,i}|r_{s,h_s(i)})}_{\setminus s,i} + \alpha_{r_{s,i}}}{n^{(\bullet|r_{s,h_s(i)})}_{\setminus s,i} + \sum_{k=1}^{K} \alpha_k}. \tag{6}$$

Analogously to the previous equation, $n^{(r_{s,i}|r_{s,h_s(i)})}_{\setminus s,i}$ denote the number of times the role $r_{s,i}$ has the parent role $r_{s,h_s(i)}$, excluding the position i in the s-th sentence. The symbol $\bullet$ represents any possible role to make the probability distribution summing up to 1. We assume an asymmetric Dirichlet distribution.

We can use predictive distributions of above mentioned Dirichlet multinomials to express the joint probability that the role at position i is k ($r_{s,i} = k$) with parent at position j conditioned on current values of all variables, except those in position i in the sentence s

$$\begin{aligned} P(r_{s,i} = k, j|\boldsymbol{w}, \boldsymbol{r}_{\setminus s,i}) \propto \\ & P(w_{s,i}|r_{s,i} = k, \boldsymbol{w}_{\setminus s,i}, \boldsymbol{r}_{\setminus s,i}) \\ \times \quad & P(r_{s,i} = k|r_{s,j}, \boldsymbol{r}_{\setminus s,i}) \\ \times \quad & \prod_{a:h_s(a)=i} P(r_{s,a}|r_{s,i} = k, \boldsymbol{r}_{\setminus s,i}). \end{aligned} \tag{7}$$

The choice of the node i role affects the word that is produced by this role and also all the child roles of the node i. Simultaneously, the role of the node i depends on its parent j role. Formula 7 is derived from the joint probability of a sentence s and a tree $\boldsymbol{G}_s$, where all probabilities which do not depend on the choice of the role at position i are removed and equality is replaced by proportionality ($\propto$).

We express the final predictive distribution for sampling partial changes $\chi^k_{(i,j)}$ as

[1]The most parent changes are possible for the special case of the tree, where each node i has parent $i-1$. Thus for each node i we can change its parent to any node $j < i$ and keep the projectivity of the tree. That is $\frac{N_s(1+N_s)}{2}$ possibilities.

[2]The posterior predictive distribution is the distribution of an unobserved variable conditioned by the observed data, i.e. $P(X_{n+1}|X_1, ..., X_n)$, where X_i are i.i.d. (independent and identically distributed random variables).

$$P(\chi^k_{(i,j)}(\boldsymbol{G}_s)|\boldsymbol{w},\boldsymbol{G}) \propto \frac{P(r_{s,i}=k,j|\boldsymbol{w},\boldsymbol{r}_{\setminus s,i})}{P(r_{s,i},h_s(i)|\boldsymbol{w},\boldsymbol{r}_{\setminus s,i})} \tag{8}$$

that is essentially the fraction between the joint probability of $r_{s,i}$ and its parent after the partial change and before the partial change (conditioned on all other variables). This fraction can be interpreted as the necessity to perform this partial change.

We investigate two strategies of sampling partial changes:

- **Per sentence**: We sample a single partial change according to Equation 8 for each sentence in the training corpus. It means during one pass through the corpus (one iteration) we perform S partial changes.
- **Per position**: We sample a partial change for each position in each sentence. We perform in total $N = \sum_{s=1}^{S} N_s$ partial changes during one pass. Note that the denominator in Equation 8 is constant for this strategy and can be removed.

We compare both training strategies in Section 6. After enough training iterations, we can estimate the conditional probabilities $\phi_l^{(k)}$ and $\theta_k^{(p)}$ from actual samples as

$$\phi_l^{(k)} \approx \frac{n^{(w_{s,i}=l|r_{s,i}=k)} + \beta}{n^{(\bullet|r_{s,i}=k)} + |\boldsymbol{L}|\,\beta} \tag{9}$$

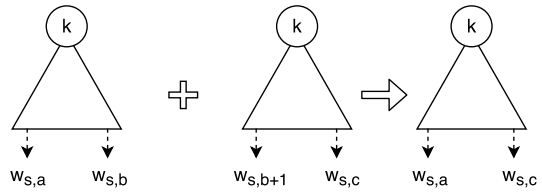
$$\theta_k^{(p)} \approx \frac{n^{(r_{s,i}=k|r_{s,h_s(i)}=p)} + \alpha_k}{n^{(\bullet|r_{s,h_s(i)}=p)} + \sum_{m=1}^{K} \alpha_m}. \tag{10}$$

These equations are similar to equations 5 and 6, but here the counts n do not exclude any position in a corpus.

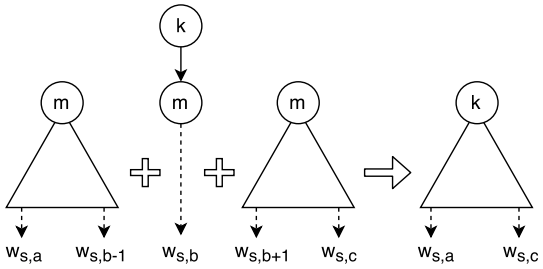
Note that in the Gibbs sampling equation, we assume that the Dirichlet parameters $\boldsymbol{\alpha}$ and β are given. We use a fixed point iteration technique described in (Minka, 2003) to estimate them.

4 Inference

In this section we present two approaches for searching the most probable tree for a given sentence assuming we have already estimated the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$.



(a) The root has two or more children.



(b) The root has only one child.

Figure 2: Searching the most probable subtrees.

4.1 Non-deterministic Inference

We use the same sampling technique as for estimating parameters (Equation 8), i.e. we iteratively sample the partial changes $\chi^k_{(i,j)}$. However, we use equations 9 and 10 for predictive distributions of Dirichlet multinomials instead of 5 and 6. In fact, these equations correspond to the predictive distributions over the newly added word $w_{s,i}$ with the role $r_{s,i}$ into the corpus, conditioned on $\boldsymbol{w}$ and $\boldsymbol{r}$. This sampling technique rarely finds the best solution, but often it is very near.

4.2 Deterministic Inference

Here we present the deterministic algorithm that guarantees to find the most probable tree for a given sentence. We were inspired by Cocke-Younger-Kasami (CYK) algorithm (Lange and Leiß, 2009).

Let $\boldsymbol{T}^n_{s,a,c}$ denote the subtree of $\boldsymbol{G}_s$ (subgraph of $\boldsymbol{G}_s$ that is also a tree) containing subsequence of nodes $\{a, a+1, ..., c\}$. The superscript n denotes the number of children the root of this subtree has. We denote the joint probability of a subtree from position a to position c with the corresponding words conditioned by the root role k as $P^n(\{w_{s,i}\}_{i=a}^c, \boldsymbol{T}^n_{s,a,c}|k)$. Our goal is to find the tree $\boldsymbol{G}_s = \boldsymbol{T}^{1+}_{s,0,N_s}$ that maximizes probability $P(\boldsymbol{w}_s, \boldsymbol{G}_s) = P^{1+}(\{w_{s,i}\}_{i=0}^{N_s}, \boldsymbol{T}^{1+}_{s,0,N_s}|0)$.

Similarly to CYK algorithm, our approach fol-

lows bottom-up direction and goes through all possible subsequences for a sentence (sequence of words). At the beginning, the probabilities for subsequences of length 1 (i.e. single words) are calculated as $P^{1+}(\{w_{s,a}\}, \boldsymbol{T}^{1+}_{s,a,a}|k) = P(w_{s,a}|r_{s,a} = k)$. Once it has considered subsequences of length 1, it goes on to subsequences of length 2, and so on.

Thanks to mutual independence of roles under the same parent, we can find the most probable subtree with the root role k and with at least two root children according to

$$P^{2+}(\{w_{s,i}\}_{i=a}^{c}, \boldsymbol{T}^{2+}_{s,a,c}|k) = \max_{b:a<b<c} [P^{1+}(\{w_{s,i}\}_{i=a}^{b}, \boldsymbol{T}^{1+}_{s,a,b}|k) \times P^{1+}(\{w_{s,i}\}_{i=b+1}^{c}, \boldsymbol{T}^{1+}_{s,b+1,c}|k)]. \quad (11)$$

It means we merge two neighboring subtrees with the same root role k. This is the reason why the new subtree has at least two root children. This formula is visualized on Figure 2a. Unfortunately, this does not cover all subtree cases. We find the most probable tree with only root child as follows

$$P^{1}(\{w_{s,i}\}_{i=a}^{c}, \boldsymbol{T}^{1}_{s,a,c}|k) = \max_{b,m:a\le b\le c, 1\le m\le K} [P(w_{s,b}|r_{s,b} = m) \times P(r_{s,b} = m|k) \times P^{1+}(\{w_{s,i}\}_{i=a}^{b-1}, \boldsymbol{T}^{1+}_{s,a,b-1}|m) \times P^{1+}(\{w_{s,i}\}_{i=b+1}^{c}, \boldsymbol{T}^{1+}_{s,b+1,c}|m)]. \quad (12)$$

This formula is visualized on Figure 2b.

To find the most probable subtree no matter how many children the root has, we need to take the maximum from both mentioned equations $P^{1+} = max(P^{2+}, P^{1})$.

The algorithm has complexity $\mathcal{O}(N_s^3 K^2)$, i.e. it has cubic dependence on the length of the sentence N_s.

5 Side-dependent LTLM

Until now, we presented LTLM in its simplified version. In role-by-role probabilities (role conditioned on its parent role) we did not distinguish whether the role is on the left side or the right side of the parent. However, this position keeps important information about the syntax of words (and their roles).

We assume separate multinomial distributions $\dot{\boldsymbol{\theta}}$ for roles that are on the left and $\ddot{\boldsymbol{\theta}}$ for roles on the right. Each of them has its own Dirichlet prior with hyper-parameters $\dot{\boldsymbol{\alpha}}$ and $\ddot{\boldsymbol{\alpha}}$, respectively. The process of estimating LTLM parameters is almost the same. The only difference is that we need to redefine the predictive distribution for the role-by-role distribution (Equation 6) to include only counts of roles on the appropriate side. Also, every time the role-by-role probability is used we need to distinguish sides:

$$P(r_{s,i}|r_{s,h_s(i)}) = \begin{cases} \dot{\theta}^{(r_{s,h_s(i)})}_{r_{s,i}} & \text{for } i < h_s(i)) \\ \ddot{\theta}^{(r_{s,h_s(i)})}_{r_{s,i}} & \text{for } i > h_s(i)) \end{cases}. \quad (13)$$

In the following text we always assume the side-dependent LTLM.

6 Experimental Results and Discussion

In this section we present experiments with LTLM on two languages, English (EN) and Czech (CS).

As a training corpus we use CzEng 1.0 (Bojar et al., 2012) of the sentence-parallel Czech-English corpus. We choose this corpus because it contains multiple domains, it is of reasonable length, and it is parallel so we can easily provide comparison between both languages. The corpus is divided into 100 similarly-sized sections. We use parts 0–97 for training, the part 98 as a development set, and the last part 99 for testing.

We have removed all sentences longer than 30 words. The reason was that the complexity of the learning phase and the process of searching most probable trees depends on the length of sentences. It has led to removing approximately a quarter of all sentences. The corpus is available in a tokenized form so the only preprocessing step we use is lowercasing. We keep the vocabulary of 100,000 most frequent words in the corpus for both languages. The less frequent words were replaced by the symbol <unk>. Statistics for the final corpora are shown in Table 1.

We measure the quality of LTLM by *perplexity* that is the standard measure used for LMs. Perplexity is a measure of uncertainty. The lower perplexity means the better predictive ability of the LM.

Corpora	Sentences	Tokens	OOV rate
EN train	11,530,604	138,034,779	1.30%
EN develop.	117,735	1,407,210	1.28%
EN test	117,360	1,405,106	1.33%
CS train	11,832,388	133,022,572	3.98%
CS develop.	120,754	1,353,015	4.00%
CS test	120,573	1,357,717	4.03%

Table 1: Corpora statistics. *OOV rate* denotes the out-of-vocabulary rate.

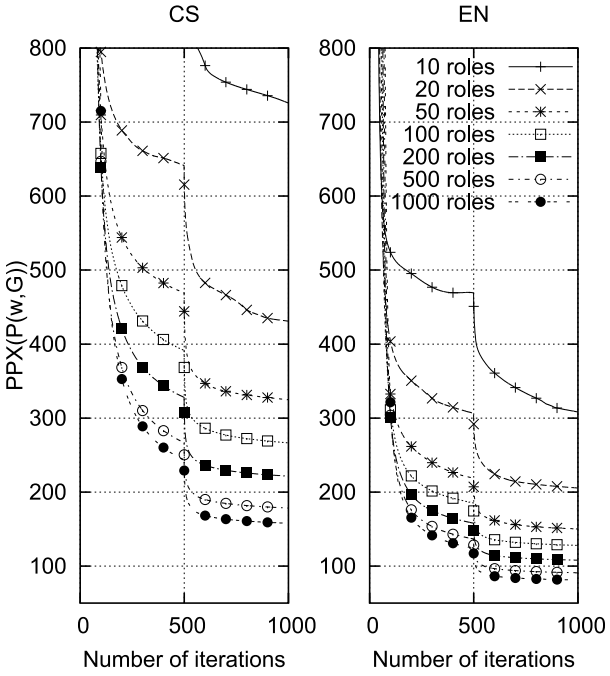


Figure 3: Learning curves of LTLM for both English and Czech. The points in the graphs represent the perplexities in every 100th iteration.

During the process of parameter estimation we measure the perplexity of joint probability of sentences and their trees defined as $\mathrm{PPX}(P(\boldsymbol{w}, \boldsymbol{G})) = \sqrt[N]{\frac{1}{P(\boldsymbol{w},\boldsymbol{G})}}$, where N is the number of all words in the training data $\boldsymbol{w}$.

As we describe in Section 3, there are two approaches for the parameter estimation of LTLM. During our experiments, we found that the per-position strategy of training has the ability to converge faster, but to a worse solution compared to the per-sentence strategy which converges slower, but to a better solution.

We train LTLM by 500 iterations of the per-position sampling followed by another 500 iterations of the per-sentence sampling. This proves to be efficient in both aspects, the reasonable speed of convergence and the satisfactory predictive ability of the model. The learning curves are showed on Figure 3. We present the models with 10, 20, 50, 100, 200, 500, and 1000 roles. The higher role cardinality models were not possible to create because of the very high computational requirements. Similarly to the training of LTLM, the non-deterministic inference uses 100 iterations of per-position sampling followed by 100 iterations of per-sentence sampling.

4-gram MKN + 1000r det. LTLM	**24.9 (-43.1%)**	**37.2 (-49.4%)**

Table 2: Perplexity results on the test data. The numbers in brackets are the relative improvements compared with standalone 4-gram MKN LM.

In the following experiments we measure how well LTLM generalizes the learned patterns, i.e. how well it works on the previously unseen data. Again, we measure the perplexity, but of probability $P(\boldsymbol{w})$ for mutual comparison with different LMs that are based on different architectures ($\mathrm{PPX}(P(\boldsymbol{w})) = \sqrt[N]{\frac{1}{P(\boldsymbol{w})}}$).

To show the strengths of LTLM we compare it with several state-of-the-art LMs. We experiment with Modified Kneser-Ney (MKN) interpolation (Chen and Goodman, 1998), with Recurrent Neural Network LM (RNNLM) (Mikolov et al., 2010; Mikolov et al., 2011)[3], and with LWLM (Deschacht et al., 2012)[4]. We have also created syntactic dependency tree based LM (denoted as STLM). Syntactic dependency trees for both languages are provided within CzEng corpus and are based on

[3]Implementation is available at `http://rnnlm.org/`. Size of the hidden layer was set to 300 in our experiments. It was computationally intractable to use more neurons.

[4]Implementation is available at `http://liir.cs.kuleuven.be/software.php`.

Table 3: Perplexity results on the test data for LTLMs and STLMs with different number of roles. Deterministic inference is denoted as *det.* and non-deterministic inference as *non-det.*

MST parser (McDonald et al., 2005). We use the same architecture as for LTLM and experiment with two approaches to represent the roles. Firstly, the roles are given by the part-of-speech tag (denoted as PoS STLM). No training is required, all information come from CzEng corpus. Secondly, we learn the roles using the same algorithm as for LTLM. The only difference is that the trees are kept unchanged. Note that both deterministic and non-deterministic inference perform almost the same in this model so we do not distinguish between them.

We combine baseline 4-gram MKN model with other models via linear combination (in the tables denoted by the symbol $+$) that is simple but very efficient technique to combine LMs. Final probability is then expressed as

$$P(\boldsymbol{w}) = \prod_{s=1}^{S} \prod_{i=1}^{N_s} \left[\lambda P^{\text{LM1}} + (\lambda - 1)\, P^{\text{LM2}}\right]. \quad (14)$$

In the case of MKN the probability P^{MKN} is the probability of a word $w_{s,i}$ conditioned by 3 previous words with MKN smoothing. For LTLM or STLM this probability is defined as

$$P^{\text{LTLM}}(w_{s,i}|r_{s,h_s(i)}) = \sum_{k=1}^{K} P(w_{s,i}|r_{s,i}=k) P(r_{s,i}=k|r_{s,h_s(i)}). \quad (15)$$

We use the *expectation maximization* algorithm (Dempster et al., 1977) for the maximum likelihood estimate of λ parameter on the development part of the corpus. The influence of the number of roles on the perplexity is shown in Table 3 and the final

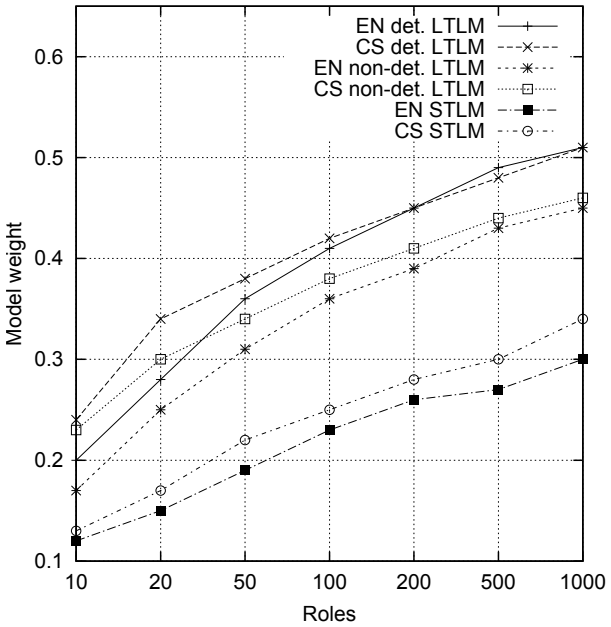

Figure 4: Model weights optimized on development data when interpolated with 4-gram MKN LM.

results are shown in Table 2. Note that these perplexities are not comparable with those on Figure 3 ($\text{PPX}(P(\boldsymbol{w}))$ vs. $\text{PPX}(P(\boldsymbol{w}, \boldsymbol{G}))$). Weights of LTLM and STLM when interpolated with MKN LM are shown on Figure 4.

From the tables we can see several important findings. Standalone LTLM performs worse than MKN on both languages, however their combination leads to dramatic improvements compared with other LMs. Best results are achieved by 4-gram MKN interpolated with 1000 roles LTLM and the deterministic inference. The perplexity was improved by approximately 46% on English and 49% on Czech compared with standalone MKN. The deterministic inference outperformed the non-deterministic one in all cases. LTLM also signifi-

cantly outperformed STLM where the syntactic dependency trees were provided as a prior knowledge. The joint learning of syntax and semantics of a sentence proved to be more suitable for predicting the words.

An in-depth analysis of semantic and syntactic properties of LTLM is beyond the scope of this paper. For better insight into the behavior of LTLM, we show the most probable word substitutions for one selected sentence (see Table 4). We can see that the original words are often on the front positions. Also it seems that LTLM is more syntactically oriented, which confirms claims from (Levy and Goldberg, 2014; Padó and Lapata, 2007), but to draw such conclusions a deeper analysis is required. The properties of the model strongly depends on the number of distinct roles. We experimented with maximally 1000 roles. To catch the meaning of various words in natural language, more roles may be needed. However, with our current implementation, it was intractable to train LTLM with more roles in a reasonable time. Training 1000 roles LTLM took up to two weeks on a powerful computational unit.

7 Conclusion and Future Work

In this paper we introduced the Latent Tree Language Model. Our model discovers the latent tree structures hidden in natural text and uses them to predict the words in a sentence. Our experiments with English and Czech corpora showed dramatic improvements in the predictive ability compared with standalone Modified Kneser-Ney LM. Our Java implementation is available for research purposes at `https://github.com/brychcin/LTLM`.

It was beyond the scope of this paper to explicitly test the semantic and syntactic properties of the model. As the main direction for future work we plan to investigate these properties for example by comparison with human-assigned judgments. Also, we want to test our model in different NLP tasks (e.g. speech recognition, machine translation, etc.).

We think that the role-by-role distribution should depend on the distance between the parent and the child, but our preliminary experiments were not met with success. We plan to elaborate on this assumption. Another idea we want to explore is to use different distributions as a prior to multinomials. For example, Blei and Lafferty (2006) showed that the logistic-normal distribution works well for topic modeling because it captures the correlations between topics. The same idea might work for roles.

Comparing Data Sources and Architectures for Deep Visual Representation Learning in Semantics

Abstract

Multi-modal distributional models learn grounded representations for improved performance in semantics. Deep visual representations, learned using convolutional neural networks, have been shown to achieve particularly high performance. In this study, we systematically compare deep visual representation learning techniques, experimenting with three well-known network architectures. In addition, we explore the various data sources that can be used for retrieving relevant images, showing that images from search engines perform as well as, or better than, those from manually crafted resources such as ImageNet. Furthermore, we explore the optimal number of images and the multi-lingual applicability of multi-modal semantics. We hope that these findings can serve as a guide for future research in the field.

1 Introduction

Multi-modal distributional semantics addresses the fact that text-based semantic models, which represent word meanings as a distribution over other words (Turney and Pantel, 2010; Clark, 2015), suffer from the grounding problem (Harnad, 1990). Recent work has shown that this theoretical motivation can be successfully exploited for practical gain. Indeed, multi-modal representation learning leads to improvements over language-only models in a range of tasks, including modelling semantic similarity and relatedness (Bruni et al., 2014; Silberer and Lapata, 2014; Kiela and Bottou, 2014; Lazaridou et al., 2015), improving lexical entailment (Kiela et al., 2015a), predicting compositionality (Roller and Schulte im Walde, 2013), bilingual lexicon induction (Bergsma and Van Durme, 2011), selectional preference prediction (Bergsma and Goebel, 2011), linguistic ambiguity resolution (Berzak et al., 2015), visual information retrieval (Bulat et al., 2016) and metaphor identification (Shutova et al., 2016).

Most multi-modal semantic models tend to rely on raw images as the source of perceptual input. Many data sources have been tried, ranging from image search engines to photo sharing websites to manually crafted resources. Images are retrieved for a given target word if they are ranked highly, have been tagged, or are otherwise associated with the target word(s) in the data source.

Traditionally, representations for images were learned through bag-of-visual words (Sivic and Zisserman, 2003), using SIFT-based local feature descriptors (Lowe, 2004). Kiela and Bottou (2014) showed that transferring representations from deep convolutional neural networks (ConvNets) yield much better performance than bag-of-visual-words in multi-modal semantics. ConvNets (LeCun et al., 1998) have become very popular in recent years: they are now the dominant approach for almost all recognition and detection tasks in the computer vision community (LeCun et al., 2015), approaching or even exceeding human performance in some cases (Weyand et al., 2016). The work by Alex Krizhevsky et al. (2012), which won the ImageNet Large Scale Visual Recognition Challenge (ILSVRC) (Russakovsky et al., 2015) in 2012, has played an important role in bringing convolutional

networks (back) to prominence. A similar network was used by Kiela and Bottou (2014) to obtain high quality image embeddings for semantics.

This work aims to provide a systematic comparison of such deep visual representation learning techniques and data sources; i.e. we aim to answer the following open questions in multi-modal semantics:

- Does the improved performance over bag-of-visual-words extend to different convolutional network architectures, or is it specific to Krizhevsky's AlexNet? Do others work even better?
- How important is the source of images? Is there a difference between search engines and manually annotated data sources? Does the number of images obtained for each word matter?
- Do these findings extend to different languages beyond English?

We evaluate semantic representation quality through examining how well a system's similarity scores correlate with human similarity and relatedness judgments. We examine both the visual representations themselves as well as the multi-modal representations that fuse visual representations with linguistic input, in this case using middle fusion (i.e., concatenation). To the best of our knowledge, this work is the first to systematically compare these aspects of visual representation learning.

2 Architectures

We use the MMFeat toolkit[1] (Kiela, 2016) to obtain image representations for three different convolutional network architectures: AlexNet (Krizhevsky et al., 2012), GoogLeNet (Szegedy et al., 2015) and VGGNet (Simonyan and Zisserman, 2014). Image representations are turned into an overall word-level visual representation by either taking the mean or the elementwise maximum of the relevant image representations. All three networks are trained to maximize the multinomial logistic regression objective using mini-batch gradient descent with momentum:

$$-\sum_{i=1}^{D}\sum_{k=1}^{K}\mathbf{1}\{y^{(i)}=k\}\log\frac{\exp(\theta^{(k)\top}x^{(i)})}{\sum_{j=1}^{K}\exp(\theta^{(j)\top}x^{(i)})}$$

where $\mathbf{1}\{\cdot\}$ is the indicator function, $x^{(i)}$ and $y^{(i)}$ are the input and output, respectively. D is the number of training examples and K is the number of classes. The networks are trained on the ImageNet classification task and we transfer layers from the pre-trained network. See Table 1 for an overview. In this section, we describe the network architectures and their properties.

AlexNet The network by Krizhevsky (2012) introduces the following network architecture: first, there are five convolutional layers, followed by two fully-connected layers, where the final layer is fed into a softmax which produces a distribution over the class labels. All layers apply rectified linear units (ReLUs) (Nair and Hinton, 2010) and use dropout for regularization (Hinton et al., 2012). This network won the ILSVRC 2012 ImageNet classification challenge. In our case, we actually use the CaffeNet reference model, which is a replication of AlexNet, with the difference that it is not trained with relighting data-augmentation, and that the order of pooling and normalization layers is switched (in CaffeNet, pooling is done before normalization,

instead of the other way around). While it uses an almost identical architecture, performance of CaffeNet is slightly better than the original AlexNet.

GoogLeNet The ILSVRC 2014 challenge winning GoogLeNet (Szegedy et al., 2015) uses "inception modules" as a network-in-network method (Lin et al., 2013) for enhancing model discriminability for local patches within the receptive field. It uses much smaller receptive fields and explicitly focuses on efficiency: while it is much deeper than AlexNet, it has fewer parameters. Its architecture consists of two convolutional layers, followed by inception layers that culminate into an average pooling layer that feeds into the softmax decision (so it has no fully connected layers). Dropout is only applied on the final layer. All connections use rectifiers.

VGGNet The ILSVRC 2015 ImageNet classification challenge was won by VGGNet (Simonyan and Zisserman, 2014). Like GoogLeNet, it is much deeper than AlexNet and uses smaller receptive fields. It has many more parameters than the other networks. It consists of a series of convolutional layers followed by the fully connected ones. All layers are rectified and dropout is applied to the first two fully connected layers.

These networks were selected because they are very well-known in the computer vision community. They exhibit interesting qualitative differences in terms of their depth (i.e., the number of layers), the number of parameters, regularization methods and the use of fully connected layers. They have all been winning network architectures in the ILSVRC ImageNet classification challenges.

3 Sources of Image Data

Some systematic studies of parameters for text-based distributional methods have found that the source corpus has a large impact on representational quality (Bullinaria and Levy, 2007; Kiela and Clark, 2014). The same is likely to hold in the case of

Table 2: Sources of image data.

visual representations. Various sources of image data have been used in multi-modal semantics, but there have not been many comparisons: Bergsma and Goebel (2011) compare Google and Flickr, and Kiela and Bottou (2014) compare ImageNet (Deng et al., 2009) and the ESP Game dataset (von Ahn and Dabbish, 2004), but most works use a single data source. In this study, one of our objectives is to asses the quality of various sources of image data. Table 2 provides an overview of the data sources, and Figure 1 shows some example images. We examine the following corpora:

Google Images Google's image search[2] results have been found to be comparable to hand-crafted image datasets (Fergus et al., 2005).

Bing Images An alternative image search engine is Bing Images[3]. It uses different underlying technology from Google Images, but offers the same functionality as an image search engine.

Flickr Although Bergsma and Goebel (2011) have found that Google Images works better in one experiment, the photo sharing service Flickr[4] is an interesting data source because its images are tagged by human annotators.

ImageNet ImageNet (Deng et al., 2009) is a large ontology of images developed for a variety of computer vision applications. It serves as a benchmarking standard for various image processing and computer vision tasks. ImageNet is constructed along the same hierarchical structure as WordNet (Miller, 1995), by attaching images to the corresponding synset (synonym set).

	MEN (3000)	SimLex (999)
Google	3000	999
Bing	3000	999
Flickr	3000	999
ImageNet	1326	373
ESPGame	2927	833
Common subset	1310	360

Table 3: Coverage on MEN and SimLex for our data sources.

ESP Game The ESP Game dataset (von Ahn and Dabbish, 2004) was constructed through a so-called "game with a purpose". Players were matched online and had to agree on an appropriate word label for a randomly selected image within a time limit. Once a word has been mentioned a certain number of times, that word becomes a taboo word and can no longer be used as a label.

These data sources have interesting qualitative differences. Online services return images for almost any query, with much better coverage than the fixed-size ImageNet and ESP Game datasets. Search engines annotate automatically, while the others are human-annotated, either through a strict annotation procedure in the case of ImageNet, or by letting users tag images, as in the case of Flickr and ESP. Automatic systems sort images by relevance, while the others are unsorted. The relevance ranking method is not accessible, however, and so has to be treated as a black box. Search results can be

Table 4: Performance on maximally covered datasets.

language-specific, while the human annotated data sources are restricted to English. Google and Bing will return images that were ranked highly, while Flickr contains photos rather than just any kind of image. ImageNet contains high-quality images descriptive of a given synset, meaning that the tagged object is likely to be centered in the image, while the ESP Game and Flickr images may have tags describing events happening in the background also.

3.1 Selecting and processing images

Selecting images for Google, Bing and Flickr is straightforward: using their respective APIs, the desired word is given as the search query and we obtain the top N returned images (unless otherwise indicated, we use N=10). In the case of ImageNet and ESP, images are not ranked and vary greatly in number: for some words there is only a single image, while others have thousands. With ImageNet, we are faced with the additional problem that images tend to be associated only with leaf nodes in the hierarchy. For example, *dog* has no directly associated images, while its hyponyms (e.g. *golden retriever*, *labrador*) have many. If a word has no associated images in its subtree, we try going up one level and seeing if the parent node's tree yields any images. We subsequently randomly sample 100 images associated with the word and obtain semi-ranked results by selecting the 10 images closest to the median representation as the sampled image representations. We use the same method for the ESP Game dataset. In all cases, images are resized and center-cropped to ensure that they are the correct size input.

4 Evaluation

Representation quality in semantics is usually evaluated using intrinsic datasets of human similarity and relatedness judgments. Model performance is assessed through the Spearman ρ_s rank correlation between the system's similarity scores for a given pair of words, together with human judgments. Here, we evaluate on two well-known similarity and relatedness judgment datasets: MEN (Bruni et al., 2012) and SimLex-999 (Hill et al., 2015). MEN focuses explicitly on relatedness (i.e. *coffee-tea* and *coffee-mug* get high scores, while *bakery-zebra* gets a low score), while SimLex-999 focuses on what it calls "genuine" similarity (i.e., *coffee-tea* gets a high score, while both *coffee-mug* and *bakery-zebra* get low scores). They are standard evaluations for evaluating representational quality in semantics.

In each experiment, we examine performance of the visual representations compared to text-based representations, as well as performance of the multimodal representation that fuses the two. In this

Table 5: Performance on common coverage subsets of the datasets (MEN* and SimLex*).

case, we apply mid-level fusion, concatenating the L2-normalized representations (Bruni et al., 2014). Middle fusion is a popular technique in multi-modal semantics that has several benefits: 1) it allows for drawing from different data sources for each modality, that is, it does not require joint data; 2) concatenation is less susceptible to noise, since it preserves the information in the individual modalities; and 3) it is straightforward to apply and computationally inexpensive. Linguistic representations are 300-dimensional and are obtained by applying skip-gram with negative sampling (Mikolov et al., 2013) to a recent dump of Wikipedia. The normalization step that is performed before applying fusion ensures that both modalities contribute equally to the overall multi-modal representation.

5 Results

As Table 3 shows, the data sources vary in coverage: it would be unfair to compare data sources on the different subsets of the evaluation datasets that they have coverage for. That is, when comparing data sources we want to make sure we evaluate on images for the exact same word pairs. When comparing network architectures, however, we are less interested in the relative coverage between datasets and more interested in overall performance, in such a way that it can be compared to other work that was evaluated on the fully covered datasets. Hence, we report results on the maximally covered subsets per data source, which we refer to as MEN and SimLex, as well as for the overlapping common subset of word pairs that have images in each of the sources, which we refer to as MEN* and SimLex*.

5.1 Maximum coverage comparison

Table 4 shows the results on the maximally covered datasets. This means we cannot directly compare between data sources, because they have different coverage, but we can look at absolute performance and compare network architectures. The first row reports results for the text-based linguistic representations that were obtained from Wikipedia (repeated across columns for convenience). For each of the three architectures, we evaluate on SimLex (SL) and MEN, using either the mean (Mean) or elementwise maximum (Max) method for aggregating image representations into visual ones (see Section 2). For each data source, we report results for the visual representations, as well as for the multi-modal representations that fuse the visual and textual ones together. Performance across architectures is remarkably stable: we have had to report results up to three decimal points to show the difference in performance in some cases.

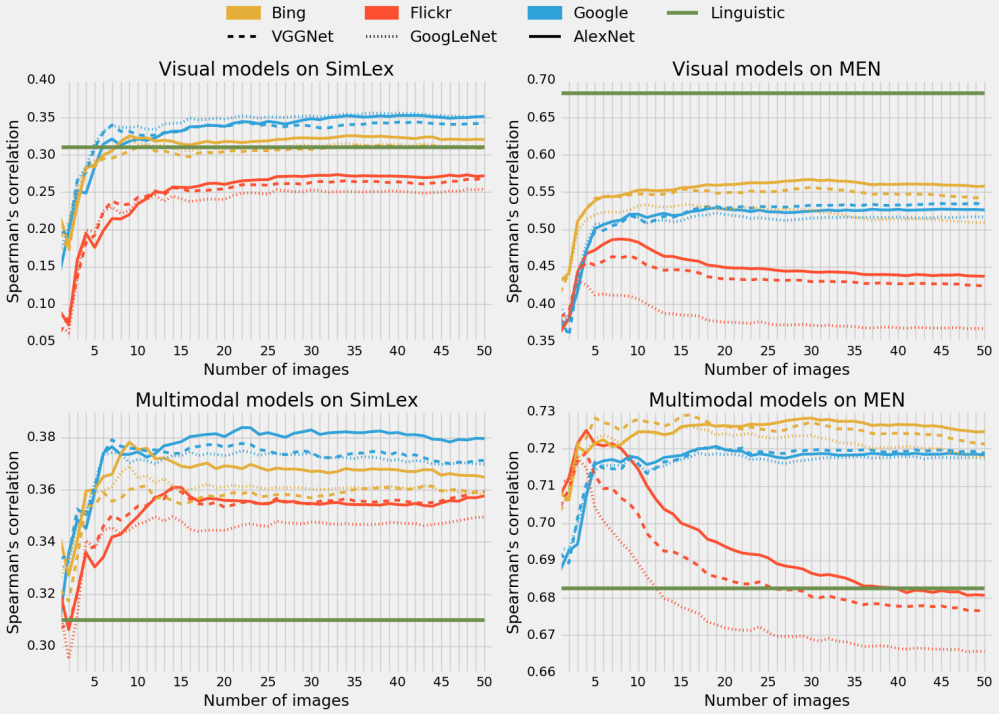

Figure 2: The effect of the number of images on representation quality.

For each of the network architectures, we see a marked improvement of multi-modal representations over uni-modal linguistic representations. In many cases, we also see visual representations outperforming linguistic ones, especially on SimLex. This is interesting, because e.g. Google and Bing have full coverage over the datasets, so their visual representations include highly abstract words, which does not appear to have an adverse impact on the method's performance. For the ESP Game dataset (on which performance is quite low) and ImageNet, we observe an increase in performance as we move to the right in the table. Interestingly, VGGNet on ImageNet scores very highly, which seems to indicate that VGGNet is somehow more "specialized" on ImageNet than the others. The difference between mean and max aggregation is relatively small, although the former seems to work better for SimLex while the latter does slightly better for MEN.

5.2 Common subset comparison

Table 5 shows the results on the common subset of the evaluation datasets, where all word pairs have images in each of the data sources. First, note the same patterns as before: multi-modal representations perform better than linguistic ones. Even for the poorly performing ESP Game dataset, the VGGNet representations perform better on both SimLex and MEN (bottom right of the table). Visual representations from Google, Bing, Flickr and ImageNet all perform much better than ESP Game on this common covered subset. In a sense, the full-coverage datasets were "punished" for their ability to return images for abstract words in the previous experiment: on this subset, which is more concrete, the search engines do much better. To a certain extent, including linguistic information is actually detrimental to performance, with multi-modal performing worse than purely visual. Again, we see the marked improvement with VGGNet for ImageNet, while Google, Bing and Flickr all do very well, regardless of the architecture.

These numbers indicate the robustness of the approach: we find that multi-modal representation learning yields better performance across the board: for different network architectures, different data sources and different aggregation methods. If computational efficiency or memory usage are issues, then GoogLeNet or AlexNet are the best choices. The ESP Game dataset does not appear to work very

well, and is best avoided. If we have the right coverage, then ImageNet gives good results, especially if we can use VGGNet. However, coverage is often the main issue, in which case Google and Bing yield images that are comparable or even better than images from the carefully annotated ImageNet.

5.3 Number of images

Another question is the number of images we want to use: does performance increase with more images? Is it always better to have seen 100 cats instead of only 10, or do we have enough information after having seen one or two already? There is an obvious trade-off here, since downloading and processing images takes time (and may incur financial costs). This experiment only applies to relevance-sorted data sources: the image selection procedure for ImageNet and ESPGame is more about removing outliers than about finding the best possible images.

As Figure 2 shows, it turns out that the optimal number of images stabilizes surprisingly quickly: around 10-20 images appears to be enough, and in some cases already too many. Performance across networks does not vary dramatically when using more images, but in the case of Flickr images on the MEN dataset, performance drops significantly as the number of images increases.

5.4 Multi- and cross-lingual applicability

Although there are some indicators that visual representation learning extends to other languages, particularly in the case of bilingual lexicon learning (Bergsma and Van Durme, 2011; Kiela et al., 2015b; Vulić et al., 2016), this has not been shown directly on the same set of human similarity and relatedness judgments. In order to examine the multi-lingual applicability of our findings, we train linguistic representations on recent dumps of the English and Italian Wikipedia. We then search for 10 images per word on Google and Bing, while setting the language to English or Italian. We compare the results on the original SimLex, and the Italian version from Leviant and Reichart (2015).

Similarly, we examine a cross-lingual scenario, where we translate Italian words into English using Google Translate. We then obtain images for the translated words and extract visual representations. These cross-lingual visual representations are subsequently evaluated on the Italian version of SimLex. Since we know that performance across architectures is similar, we use AlexNet representations.

		SimLex		
		EN	IT (M)	IT (C)
Wikipedia	Linguistic	.310	.179	.179
Google	Visual	.340	.231	.238
	Multi-modal	.380	.231	.227
Bing	Visual	.325	.212	.194
	Multi-modal	.373	.227	.207

Table 6: Performance on English and Italian SimLex, either in the multi-lingual setting (M) or the cross-lingual settting (C) where we first map to English.

The results can be found in Table 6. We find the same pattern: in all cases, visual and multi-modal representations outperform linguistic ones. The Italian version of SimLex appears to be more difficult than the English version. Google performs better than Bing, especially on the Italian evaluations. For Google, the cross-lingual scenario works better, while Bing yields better results in the multi-lingual setting where we use the language itself instead of mapping to English. Although somewhat preliminary, these results clearly indicate that multi-modal semantics can fruitfully be applied to languages other than English.

6 Conclusion and future work

The objective of this study has been to systematically compare network architectures and data sources for multi-modal systems. In particular, we focused on the capabilities of deep visual representations in capturing semantics, as measured by correlation with human similarity and relatedness judgments. Our findings can be summarized as follows:

- We examined AlexNet, GoogLeNet and VGGNet, all three recent winners of the ILSVRC ImageNet classification challenge (Russakovsky et al., 2015), and found that they perform very similarly. If efficiency or memory are issues, AlexNet or GoogLeNet are the most suitable architectures. For overall

best performance, AlexNet and VGGNet are the best choices.

- The choice of data sources appeared to have a bigger impact: Google, Bing, Flickr and ImageNet were much better than the ESP Game dataset. Google, Flickr and Bing have the advantage that they have potentially unlimited coverage. Google and Bing are particularly suited to full-coverage experiments, even when these include abstract words.

- We found that the number of images has an impact on performance, but that it stabilizes at around 10-20 images, indicating that it is usually not necessary to obtain more than 10 images per word. For Flickr, obtaining more images is detrimental to performance.

- Lastly, we established that these findings extend to other languages beyond English, obtaining the same findings on an Italian version of SimLex using the Italian Wikipedia. We examined both the multi-lingual setting where we obtain search results using the Italian language and a cross-lingual setting where we mapped Italian words to English and retrieved images for those.

This work answers several open questions in multi-modal semantics and we hope that it will serve as a guide for future research in the field. It is important to note that the multi-modal results only apply to the mid-level fusion method of concatenating normalized vectors: although these findings are indicative of performance for other fusion methods, different architectures or data sources may be more suitable for different fusion methods.

In future work, downstream tasks should be addressed: it is good that multi-modal semantics improves performance on intrinsic evaluations, but it is important to show its practical benefits in more applied tasks as well. Understanding what it is that makes these representations perform so well is another important and yet unanswered question. We hope that this work may be used as a reference in determining some of the choices that can be made when developing multi-modal models.

Abstract

Modeling textual or visual information with vector representations trained from large language or visual datasets has been successfully explored in recent years. However, tasks such as visual question answering require combining these vector representations with each other. Approaches to multimodal pooling include element-wise product or sum, as well as concatenation of the visual and textual representations. We hypothesize that these methods are not as expressive as an outer product of the visual and textual vectors. As the outer product is typically infeasible due to its high dimensionality, we instead propose utilizing Multimodal Compact Bilinear pooling (MCB) to efficiently and expressively combine multimodal features. We extensively evaluate MCB on the visual question answering and grounding tasks. We consistently show the benefit of MCB over ablations without MCB. For visual question answering, we present an architecture which uses MCB twice, once for predicting attention over spatial features and again to combine the attended representation with the question representation. This model outperforms the state-of-the-art on the Visual7W dataset and the VQA challenge.

1 Introduction

Representation learning for text and images has been extensively studied in recent years. Recurrent neural networks (RNNs) are often used to represent sentences or phrases (Sutskever et al., 2014; Kiros et al., 2015), and convolutional neural networks (CNNs) have shown to work best to represent images (Donahue et al., 2013; He et al., 2015). For tasks such as visual question answering (VQA) and visual grounding, most approaches require joining the representation of both modalities. For combining the two vector representations (multimodal pooling), current approaches in VQA or grounding rely on concatenating vectors or applying element-wise sum or product. While this generates a joint representation, it might not be expressive enough to fully capture the complex associations between the two different modalities.

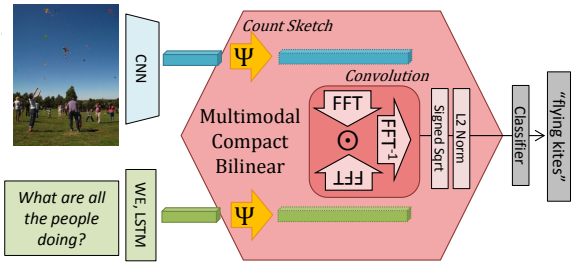

Figure 1: Multimodal Compact Bilinear Pooling for visual question answering.

In this paper, we propose to rely on Multimodal Compact Bilinear pooling (MCB) to get a joint representation. Bilinear pooling computes the outer product between two vectors, which allows, in contrast to element-wise product, a multiplicative interaction between all elements of both vectors. Bilinear pooling models (Tenenbaum and Freeman, 2000) have recently been shown to be beneficial for fine-grained classification for vision only tasks (Lin et al., 2015). However, given their high dimensionality (n^2), bilinear pooling has so far not been widely used. In

Austin, Texas, November 1-5, 2016.

this paper, we adopt the idea from Gao et al. (2016) which shows how to efficiently compress bilinear pooling for a single modality. In this work, we discuss and extensively evaluate the extension to the multimodal case for text and visual modalities. As shown in Figure 1, Multimodal Compact Bilinear pooling (MCB) is approximated by randomly projecting the image and text representations to a higher dimensional space (using Count Sketch (Charikar et al., 2002)) and then convolving both vectors efficiently by using element-wise product in Fast Fourier Transform (FFT) space. We use MCB to predict answers for the VQA task and locations for the visual grounding task. For open-ended question answering, we present an architecture for VQA which uses MCB twice, once to predict spatial attention and the second time to predict the answer. For multiple-choice question answering we introduce a third MCB to relate the encoded answer to the question-image space. Additionally, we discuss the benefit of attention maps and additional training data for the VQA task. To summarize, MCB is evaluated on two tasks, four datasets, and with a diverse set of ablations and comparisons to the state-of-the-art.

2 Related Work

Multimodal pooling. Current approaches to multimodal pooling involve element-wise operations or vector concatenation. In the visual question answering domain, a number of models have been proposed. Simpler models such as iBOWIMG baseline (Zhou et al., 2015) use concatenation and fully connected layers to combine the image and question modalities. Stacked Attention Networks (Yang et al., 2015) and Spatial Memory Networks (Xu et al., 2015) use LSTMs or extract soft-attention on the image features, but ultimately use element-wise product or element-wise sum to merge modalities. D-NMN (Andreas et al., 2016a) introduced REINFORCE to dynamically create a network and use element-wise product to join attentions and element-wise sum predict answers. Dynamic Memory Networks (DMN) (Xiong et al., 2016) pool the image and question with element-wise product and sum, attending to part of the image and question with an Episodic Memory Module (Kumar et al., 2016). DPPnet (Noh et al., 2015) creates a Parameter Prediction Network which learns to predict the parameters of the second to last visual recognition layer dynamically from the question. Similar to this work, DPPnet allows multiplicative interactions between the visual and question encodings. Lu et al. (2016) recently proposed a model that extracts multiple co-attentions on the image and question and combines the co-attentions in a hierarchical manner using element-wise sum, concatenation, and fully connected layers.

For the visual grounding task, Rohrbach et al. (2016) propose an approach where the language phrase embedding is concatenated with the visual features in order to predict the attention weights over multiple bounding box proposals. Similarly, Hu et al. (2016a) concatenate phrase embeddings with visual features at different spatial locations to obtain a segmentation.

Bilinear pooling. Bilinear pooling has been applied to the fine-grained visual recognition task. Lin et al. (2015) use two CNNs to extract features from an image and combine the resulting vectors using an outer product, which is fully connected to an output layer. Gao et al. (2016) address the space and time complexity of bilinear features by viewing the bilinear transformation as a polynomial kernel. Pham and Pagh (2013) describe a method to approximate the polynomial kernel using Count Sketches and convolutions.

Joint multimodal embeddings. In order to model similarities between two modalities, many prior works have learned joint multimodal spaces, or embeddings. Some of such embeddings are based on Canonical Correlation Analysis (Hardoon et al., 2004) e.g. (Gong et al., 2014; Klein et al., 2015; Plummer et al., 2015), linear models with ranking loss (Frome et al., 2013; Karpathy and Fei-Fei, 2015; Socher et al., 2014; Weston et al., 2011) or non-linear deep learning models (Kiros et al., 2014; Mao et al., 2015; Ngiam et al., 2011). Our multimodal compact bilinear pooling can be seen as a complementary operation that allows us to capture different interactions between two modalities more expressively than e.g. concatenation. Consequently, many embedding learning approaches could benefit from incorporating such interactions.

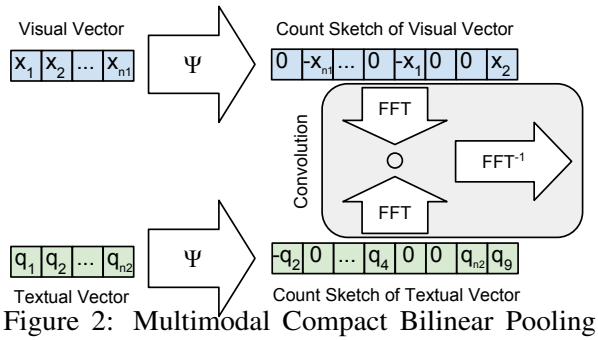

Figure 2: Multimodal Compact Bilinear Pooling (MCB)

3 Multimodal Compact Bilinear Pooling for Visual and Textual Embeddings

For the task of visual question answering (VQA) or visual grounding, we have to predict the most likely answer or location $\hat{a}$ for a given image $\mathbf{x}$ and question or phrase $\mathbf{q}$. This can be formulated as

$$\hat{a} = \underset{a \in A}{\operatorname{argmax}}\, p(a|\mathbf{x}, \mathbf{q}; \theta) \tag{1}$$

with parameters θ and the set of answers or locations A. For an image embedding $x = \Xi(\mathbf{x})$ (i.e. a CNN) and question embedding $q = \Omega(\mathbf{q})$ (i.e. an LSTM), we are interested in getting a good joint representation by pooling both representations. With a multimodal pooling $\Phi(x, q)$ that encodes the relationship between x and q well, it becomes easier to learn a classifier for Equation (1).

In this section, we first discuss our multimodal pooling Φ for combining representations from different modalities into a single representation (Sec. 3.1) and then detail our architectures for VQA (Sec. 3.2) and visual grounding (Sec. 3.3), further explaining how we predict $\hat{a}$ with the given image representation Ξ and text representation Ω.

3.1 Multimodal Compact Bilinear Pooling (MCB)

Bilinear models (Tenenbaum and Freeman, 2000) take the outer product of two vectors $x \in \mathbb{R}^{n_1}$ and $q \in \mathbb{R}^{n_2}$ and learn a model W (here linear), i.e. $z = W\,[x \otimes q]$, where $\otimes$ denotes the outer product (xq^T) and $[\,]$ denotes linearizing the matrix in a vector. As discussed in the introduction, bilinear pooling is interesting because it allows all elements of both vectors to interact with each other in a multiplicative way. However, the high dimensional representation (i.e. when n_1 and n_2 are large) leads to an infeasible number of parameters to learn in W. For example, we use $n_1 = n_2 = 2048$ and $z \in \mathbb{R}^{3000}$ for VQA. W thus would have 12.5 billion parameters, which leads to very high memory consumption and high computation times.

Algorithm 1 Multimodal Compact Bilinear

1: input: $v_1 \in \mathbb{R}^{n_1}, v_2 \in \mathbb{R}^{n_2}$
2: output: $\Phi(v_1, v_2) \in \mathbb{R}^d$
3: **procedure** MCB(v_1, v_2, n_1, n_2, d)
4: **for** $k \leftarrow 1 \ldots 2$ **do**
5: **if** h_k, s_k not initialized **then**
6: **for** $i \leftarrow 1 \ldots n_k$ **do**
7: sample $h_k[i]$ from $\{1, \ldots, d\}$
8: sample $s_k[i]$ from $\{-1, 1\}$
9: $v'_k = \Psi(v_k, h_k, s_k, n_k)$
10: $\Phi = \text{FFT}^{-1}(\text{FFT}(v'_1) \odot \text{FFT}(v'_2))$
11: **return** Φ
12: **procedure** $\Psi(v, h, s, n)$
13: $y = [0, \ldots, 0]$
14: **for** $i \leftarrow 1 \ldots n$ **do**
15: $y[h[i]] = y[h[i]] + s[i] \cdot v[i]$
16: **return** y

We thus need a method that projects the outer product to a lower dimensional space and also avoids computing the outer product directly. As suggested by Gao et al. (2016) for a single modality, we rely on the Count Sketch projection function Ψ (Charikar et al., 2002), which projects a vector $v \in \mathbb{R}^n$ to $y \in \mathbb{R}^d$. We initialize two vectors $s \in \{-1, 1\}^n$ and $h \in \{1, ..., d\}^n$: s contains either 1 or -1 for each index, and h maps each index i in the input v to an index j in the output y. Both s and h are initialized randomly from a uniform distribution and remain constant for future invocations of count sketch. y is initialized as a zero vector. For every element $v[i]$ its destination index $j = h[i]$ is looked up using h, and $s[i] \cdot v[i]$ is added to $y[j]$. See lines 1-9 and 12-16 in Algorithm 1.

This allows us to project the outer product to a lower dimensional space, which reduces the number of parameters in W. To avoid computing the outer product explicitly, Pham and Pagh (2013) showed that the count sketch of the outer product of two vectors can be expressed as convolution of both count sketches: $\Psi(x \otimes q, h, s) = \Psi(x, h, s) * \Psi(q, h, s)$,

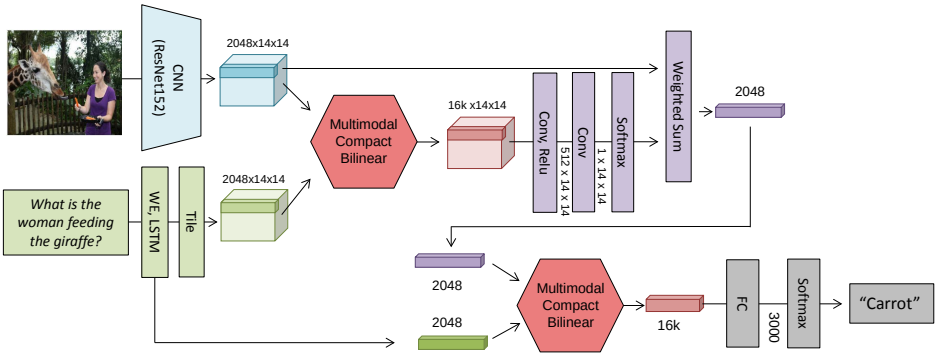

Figure 3: Our architecture for VQA: Multimodal Compact Bilinear (MCB) with Attention. Conv implies convolutional layers and FC implies fully connected layers. For details see Sec. 3.2.

where $*$ is the convolution operator. Additionally, the convolution theorem states that convolution in the time domain is equivalent to element-wise product in the frequency domain. The convolution $x' * q'$ can be rewritten as $\text{FFT}^{-1}(\text{FFT}(x') \odot \text{FFT}(q'))$, where $\odot$ refers to element-wise product. These ideas are summarized in Figure 2 and formalized in Algorithm 1, which is based on the Tensor Sketch algorithm of Pham and Pagh (2013). We invoke the algorithm with $v_1 = x$ and $v_2 = q$. We note that this easily extends and remains efficient for more than two multi-modal inputs as the combination happens as element-wise product.

3.2 Architectures for VQA

In VQA, the input to the model is an image and a question, and the goal is to answer the question. Our model extracts representations for the image and the question, pools the vectors using MCB, and arrives at the answer by treating the problem as a multi-class classification problem with 3,000 possible classes.

We extract image features using a 152-layer Residual Network (He et al., 2015) that is pretrained on ImageNet data (Deng et al., 2009). Images are resized to 448×448, and we use the output of the layer ("pool5") before the 1000-way classifier. We then perform L_2 normalization on the 2048-D vector.

Input questions are first tokenized into words, and the words are one-hot encoded and passed through a learned embedding layer. The tanh nonlinearity is used after the embedding. The embedding layer is followed by a 2-layer LSTM with 1024 units in each layer. The outputs of each LSTM layer are concatenated to form a 2048-D vector.

The two vectors are then passed through MCB. The MCB is followed by an element-wise signed square-root and L_2 normalization. After MCB pooling, a fully connected layer connects the resulting 16,000-D multimodal representation to the 3,000 top answers.

Attention. To incorporate spatial information, we use soft attention on our MCB pooling method. Explored by (Xu et al., 2015) for image captioning and by (Xu and Saenko, 2016) and (Yang et al., 2015) for VQA, the soft attention mechanism can be easily integrated in our model.

For each spatial grid location in the visual representation (i.e. last convolutional layer of ResNet [res5c], last convolutional layer of VGG [conv5]), we use MCB pooling to merge the slice of the visual feature with the language representation. As depicted in Figure 3, after the pooling we use two convolutional layers to predict the attention weight for each grid location. We apply softmax to produce a normalized soft attention map. We then take a weighted sum of the spatial vectors using the attention map to create the attended visual representation. We also experiment with generating multiple attention maps to allow the model to make multiple "glimpses" which are concatenated before being merged with the language representation through another MCB pooling for prediction. Predicting attention maps with MCB pooling allows the model to effectively learn how to attend to salient locations based on both the visual and language representations.

Answer Encoding. For VQA with multiple choices, we can additionally embed the answers. We

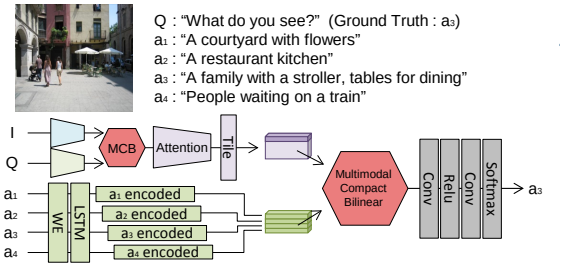

Figure 4: Our architecture for VQA: MCB with Attention and Answer Encoding

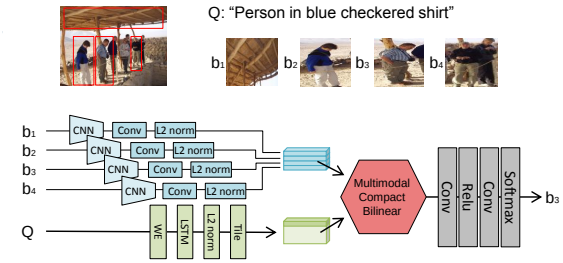

Figure 5: Our Architecture for Grounding with MCB (Sec. 3.3)

base our approach on the proposed MCB with attention. As can be seen from Figure 4, to deal with multiple variable-length answer choices, each choice is encoded using a word embedding and LSTM layers whose weights are shared across the candidates. In addition to using MCB with attention, we use an additional MCB pooling to merge the encoded answer choices with the multimodal representation of the original pipeline. The resulting embedding is projected to a classification vector with a dimension equal to the number of answers.

3.3 Architecture for Visual Grounding

We base our grounding approach on the fully-supervised version of GroundeR (Rohrbach et al., 2016). The overview of our model is shown in Figure 5. The input to the model is a query natural language phrase and an image along with multiple proposal bounding boxes. The goal is to predict a bounding box which corresponds to the query phrase. We replace the concatenation of the visual representation and the encoded phrase in GroundeR with MCB to combine both modalities. In contrast to Rohrbach et al. (2016), we include a linear embedding of the visual representation and L_2 normalization of both input modalities, instead of batch normalization (Ioffe and Szegedy, 2015), which we found to be beneficial when using MCB for the grounding task.

4 Evaluation on Visual Question Answering

We evaluate the benefit of MCB with a diverse set of ablations on two visual question answering datasets.

4.1 Datasets

The **Visual Question Answering (VQA)** real-image dataset (Antol et al., 2015) consists of approximately 200,000 MSCOCO images (Lin et al., 2014), with 3 questions per image and 10 answers per question. There are 3 data splits: train (80K images), validation (40K images), and test (80K images). Additionally, there is a 25% subset of test named test-dev. Accuracies for ablation experiments in this paper are reported on the test-dev data split. We use the VQA tool provided by Antol et al. (2015) for evaluation. We conducted most of our experiments on the open-ended real-image task. In Table 4, we also report our multiple-choice real-image scores.

The **Visual Genome** dataset (Krishna et al., 2016) uses 108,249 images from the intersection of YFCC100M (Thomee et al., 2015) and MSCOCO. For each image, an average of 17 question-answer pairs are collected. There are 1.7 million QA pairs of the 6W question types (*what, where, when, who, why*, and *how*). Compared to the VQA dataset, Visual Genome represents a more balanced distribution of the 6W question types. Moreover, the average question and answer lengths for Visual Genome are larger than the VQA dataset. To leverage the Visual Genome dataset as additional training data, we remove all the unnecessary words such as "a", "the", and "it is" from the answers to decrease the length of the answers and extract QA pairs whose answers are single-worded. The extracted data is filtered again based on the answer vocabulary space created from the VQA dataset, leaving us with additional 1M image-QA triplets.

The **Visual7W** dataset (Zhu et al., 2016) is a part of the Visual Genome. Visual7W adds a 7th *which* question category to accommodate visual answers,

Method	Accuracy
Element-wise Sum	56.50

Table 3: Multiple-choice QA tasks accuracy (%) on Visual7W test set.

but we only evaluate the models on the Telling task which involves 6W questions. The natural language answers in Visual7W are in a multiple-choice format and each question comes with four answer candidates, with only one being the correct answer. Visual7W is composed of 47,300 images from MSCOCO and there are a total of 139,868 QA pairs.

4.2 Experimental Setup

We use the Adam solver with $\epsilon = 0.0007$, $\beta_1 = 0.9$, $\beta_2 = 0.999$. We use dropout after the LSTM layers and in fully connected layers. For the experiments in Table 1 and 2, we train on the VQA train split, validate on the VQA validation split, and report results on the VQA test-dev split. We use early stopping: if the validation score does not improve for 50,000 iterations, we stop training and evaluate the best iteration on test-dev.

For the Visual7W task, we use the same hyperparameters and training settings as in the VQA experiments. We use the splits from (Zhu et al., 2016) to train, validate, and test our models. We also compute accuracies on this data using their evaluation code.

For VQA multiple choice, we train the open-ended models and take the argmax over the multiple choice answers at test time. For Visual7W, we use the answer encoding as described in Sec. 3.2.

4.3 Ablation Results

We compare the performance of non-bilinear and bilinear pooling methods in Table 1. We see that MCB pooling outperforms all non-bilinear pooling methods, such as eltwise sum, concatenation, and eltwise product.

One could argue that the compact bilinear method simply has more parameters than the non-bilinear pooling methods, which contributes to its performance. We compensated for this by stacking fully connected layers (with 4096 units per layer, ReLU activation, and dropout) after the non-bilinear pooling methods to increase their number of parameters. However, even with similar parameter budgets, non-bilinear methods could not achieve the same accuracy as the MCB method. For example, the "Concatenation + FC + FC" pooling method has approximately $4096^2 + 4096^2 + 4096 \times 3000 \approx 46$ million parameters, which matches the 48 million parameters available in MCB with $d = 16000$. However, the performance of the "Concatenation + FC + FC" method is only 57.10% compared to MCB's 59.83%.

Section 2 in Table 1 also shows that compact bi-

Table 4: Open-ended and multiple-choice (MC) results on VQA test set (trained on train+val set) compared with state-of-the-art: accuracy in %. See Sec. 4.4.

linear pooling has no impact on accuracy compared to full bilinear pooling. Section 3 in Table 1 demonstrates that the MCB brings improvements regardless of the image CNN used. We primarily use ResNet-152 in this paper, but MCB also improves performance if VGG-19 is used. Section 4 in Table 1 shows that our soft attention model works best with MCB pooling. In fact, attending to the Concatenation + FC layer has the same performance as not using attention at all, while attending to the MCB layer improves performance by 2.67 points.

Table 2 compares different values of d, the output dimensionality of the multimodal compact bilinear feature. Approximating the bilinear feature with a 16,000-D vector yields the highest accuracy.

We also evaluated models with multiple attention maps or channels. One attenion map achieves 64.67%, two 65.08% and four 64.24% accuracy (trained on train+val). Visual inspection of the generated attention maps reveals that an ensembling or smoothing effect occurs when using multiple maps.

Table 3 presents results for the Visual7W multiple-choice QA task. The MCB with attention model outperforms the previous state-of-the-art by 7.9 points overall and performs better in almost every category.

4.4 Comparison to State-of-the-Art

Table 4 compares our approach with the state-of-the-art on VQA test set. Our best single model uses MCB pooling with two attention maps. Additionally, we augment our training data with images and QA pairs from the Visual Genome dataset. We also concatenate the learned word embedding with pretrained GloVe vectors (Pennington et al., 2014).

Each model in our ensemble of 7 models uses MCB with attention. Some of the models were trained with data from Visual Genome, and some were trained with two attention maps. This ensem-

ble is 1.8 points above the next best approach on the VQA open-ended task and 0.8 points above the next best approach on the multiple-choice task (on Test-dev). Even without ensembles, our "MCB + Genome + Att. + GloVe" model still outperforms the next best result by 0.5 points, with an accuracy of 65.4% versus 64.9% on the open-ended task (on Test-dev).

5 Evaluation on Visual Grounding

5.1 Datasets

We evaluate our visual grounding approach on two datasets. The first is Flickr30k Entities (Plummer et al., 2015) which consists of 31K images from Flickr30k dataset (Hodosh et al., 2014) with 244K phrases localized with bounding boxes. We follow the experimental setup of Rohrbach et al. (2016), e.g. we use the same Selective Search (Uijlings et al., 2013) object proposals and the Fast R-CNN (Girshick, 2015) fine-tuned VGG16 features (Simonyan and Zisserman, 2014). The second dataset is ReferItGame (Kazemzadeh et al., 2014), which contains 20K images from IAPR TC-12 dataset (Grubinger et al., 2006) with segmented regions from SAIAPR-12 dataset (Escalante et al., 2010) and 120K associated natural language referring expressions. For ReferItGame we follow the experimental setup of Hu et al. (2016b) and rely on their ground-truth bounding boxes extracted around the segmentation masks. We use the Edge Box (Zitnick and Dollár, 2014) object proposals and visual features (VGG16 combined with the spatial features, which encode bounding box relative position) from Hu et al. (2016b).

5.2 Experimental Setup

In all experiments we use Adam solver (Kingma and Ba, 2014) with learning rate $\epsilon = 0.0001$. The embedding size is 500 both for visual and language embeddings. We use $d = 2048$ in the MCB pooling, which we found to work best for the visual grounding task. The accuracy is measured as percentage of query phrases which have been localized correctly. The phrase is localized correctly if the predicted bounding box overlaps with the ground-truth bounding box by more than 50% intersection over union (IOU).

5.3 Results

Tables 5 and 6 summarize our results in the visual grounding task. We present multiple ablations of our proposed architecture. First, we replace the MCB with simple concatenation of the embedded visual feature and the embedded phrase, resulting in 46.5% on the Flickr30k Entities and 25.48% on the ReferItGame datasets. The results can be improved by replacing the concatenation with the element-wise product of both embedded features (47.41% and 27.80%). We can further slightly increase the performance by introducing additional 2048-D convolution after the element-wise product (47.86% and 27.98%). However, even with fewer parameters, our MCB pooling significantly improves over this baseline on both datasets, reaching state-of-the-art accuracy of 48.69% on Flickr30k Entities and 28.91% on ReferItGame dataset. Figure 6 (bottom) shows examples of improved phrase localization.

[1]Plummer et al. (2016) achieve higher accuracy of 50.89% when taking into account box size and color. We believe our approach would also benefit from such additional features.

6 Conclusion

We propose the Multimodal Compact Bilinear Pooling (MCB) to combine visual and text representations. For visual question answering, our architecture with attention and multiple MCBs gives significant improvements on two VQA datasets compared to state-of-the-art. In the visual grounding task, introducing MCB pooling leads to improved phrase localization accuracy, indicating better interaction between query phrase representations and visual representations of proposal bounding boxes. The code to replicate our experiments is available at `https://github.com/akirafukui/vqa-mcb`.

Acknowledgments

We would like to thank Yang Gao and Oscar Beijbom for helpful discussions about Compact Bilinear Pooling. This work was supported by DARPA, AFRL, DoD MURI award N000141110688, NSF awards IIS-1427425 and IIS-1212798, and the Berkeley Artificial Intelligence Research (BAIR) Lab.

Abstract

We present the *Structured Weighted Violations Perceptron (SWVP)* algorithm, a new structured prediction algorithm that generalizes the Collins Structured Perceptron (CSP, (Collins, 2002)). Unlike CSP, the update rule of SWVP explicitly exploits the internal structure of the predicted labels. We prove the convergence of SWVP for linearly separable training sets, provide mistake and generalization bounds, and show that in the general case these bounds are tighter than those of the CSP special case. In synthetic data experiments with data drawn from an HMM, various variants of SWVP substantially outperform its CSP special case. SWVP also provides encouraging initial dependency parsing results.

1 Introduction

The structured perceptron ((Collins, 2002), henceforth denoted CSP) is a prominent training algorithm for structured prediction models in NLP, due to its effective parameter estimation and simple implementation. It has been utilized in numerous NLP applications including word segmentation and POS tagging (Zhang and Clark, 2008), dependency parsing (Koo and Collins, 2010; Goldberg and Elhadad, 2010; Martins et al., 2013), semantic parsing (Zettlemoyer and Collins, 2007) and information extraction (Hoffmann et al., 2011; Reichart and Barzilay, 2012), if to name just a few.

Like some training algorithms in structured prediction (e.g. structured SVM (Taskar et al., 2004; Tsochantaridis et al., 2005), MIRA (Crammer and Singer, 2003) and LaSo (Daumé III and Marcu, 2005)), CSP considers in its update rule the difference between *complete* predicted and gold standard labels (Sec. 2). Unlike others (e.g. factored MIRA (McDonald et al., 2005b; McDonald et al., 2005a) and dual-loss based methods (Meshi et al., 2010)) it does not exploit the structure of the predicted label. This may result in valuable information being lost.

Consider, for example, the gold and predicted dependency trees of Figure 1. The substantial difference between the trees may be mostly due to the difference in roots (*are* and *worse*, respectively). Parameter update w.r.t this mistake may thus be more useful than an update w.r.t the complete trees.

In this work we present a new perceptron algorithm with an update rule that exploits the structure of a predicted label when it differs from the gold label (Section 3). Our algorithm is called *The Structured Weighted Violations Perceptron (SWVP)* as its update rule is based on a weighted sum of updates w.r.t *violating assignments* and *non-violating assignments*: assignments to the input example, derived from the predicted label, that score higher (for violations) and lower (for non-violations) than the gold standard label according to the current model.

Our concept of *violating assignment* is based on Huang et al. (2012) that presented a variant of the CSP algorithm where the argmax inference problem is replaced with a violation finding function. Their update rule, however, is identical to that of the CSP algorithm. Importantly, although CSP and the above variant do not exploit the internal structure of the predicted label, they are special cases of SWVP.

In Section 4 we prove that for a linearly separable training set, SWVP converges to a linear separator of

Proceedings of the 2016 Conference on Empirical Methods in Natural Language Processing, pages 469–478,
Austin, Texas, November 1-5, 2016.

the data under certain conditions on the parameters of the algorithm, that are respected by the CSP special case. We further prove mistake and generalization bounds for SWVP, and show that in the general case the SWVP bounds are tighter than the CSP's.

In Section 5 we show that SWVP allows *aggressive* updates, that exploit only violating assignments derived from the predicted label, and more *balanced* updates, that exploit both violating and non-violating assignments. In experiments with synthetic data generated by an HMM, we demonstrate that various SWVP variants substantially outperform CSP training. We also provide initial encouraging dependency parsing results, indicating the potential of SWVP for real world NLP applications.

2 The Collins Structured Perceptron

In structured prediction the task is to find a mapping $f : \mathcal{X} \rightarrow \mathcal{Y}$, where $y \in \mathcal{Y}$ is a structured object rather than a scalar, and a feature mapping $\phi(x, y) : \mathcal{X} \times \mathcal{Y}(x) \rightarrow \mathbb{R}^d$ is given. In this work we denote $\mathcal{Y}(x) = \{y' | y' \in {D_Y}^{L_x}\}$, where L_x, a scalar, is the size of the allowed output sequence for an input x and D_Y is the domain of y'_i for every $i \in \{1, \ldots L_x\}$. [1] Our results, however, hold for the general case of an output space with variable size vectors as well.

The CSP algorithm (Algorithm 1) aims to learn a parameter (or weight) vector $\mathbf{w} \in \mathbb{R}^d$, that separates the training data, i.e. for each training example (x, y) it holds that: $y = \arg\max_{y' \in \mathcal{Y}(x)} \mathbf{w} \cdot \phi(x, y')$. To find such a vector the algorithm iterates over the training set examples and solves the above inference ($argmax$) problem. If the inferred label y^* differs from the gold label y the update $\mathbf{w} = \mathbf{w} + \Delta\phi(x, y, y^*)$ is performed. For linearly separable training data (see definition 4), CSP is proved to converge to a vector $\mathbf{w}$ separating the training data.

Collins and Roark (2004) and Huang et al. (2012) expanded the CSP algorithm by proposing various alternatives to the argmax *inference* problem which is often intractable in structured prediction problems (e.g. in high-order graph-based dependency parsing (McDonald and Pereira, 2006)). The basic idea is replacing the argmax problem with the search for a *violation*: an output label that the model scores higher than the gold standard label. The update rule in these CSP variants is, however, identical to the CSP's. We, in contrast, propose a novel update rule that exploits the internal structure of the model's prediction regardless of the way this prediction is generated.

[1] In the general case L_x is a set of output sizes, which may be finite or infinite (as in constituency parsing (Collins, 1997)).

Algorithm 1 The Structured Perceptron (CSP)

Input: data $D = \{x^i, y^i\}_{i=1}^n$, feature mapping ϕ
Output: parameter vector $\mathbf{w} \in \mathbb{R}^d$
Define: $\Delta\phi(x, y, z) \triangleq \phi(x, y) - \phi(x, z)$
Initialize $\mathbf{w} = 0$.
repeat
  for each $(x^i, y^i) \in D$ **do**
    $y^* = \arg\max_{y' \in \mathcal{Y}(x^i)} \mathbf{w} \cdot \phi(x^i, y')$
    if $y^* \neq y^i$ **then**
      $\mathbf{w} = \mathbf{w} + \Delta\phi(x^i, y^i, y^*)$
    end if
  end for
until Convergence

3 The Structured Weighted Violations Perceptron (SWVP)

SWVP exploits the internal structure of a predicted label $y^* \neq y$ for a training example $(x, y) \in D$, by updating the weight vector with respect to substructures of y^*. We start by presenting the fundamental concepts at the basis of our algorithm.

3.1 Basic Concepts

Sub-structure Sets We start with two fundamental definitions: **(1)** An individual *sub-structure* of a structured object (or label) $y \in {D_Y}^{L_x}$, denoted with J, is defined to be a subset of indexes $J \subseteq [L_x]$;[2] and **(2)** A *set of substructures* for a training example (x, y), denoted with JJ_x, is defined as $JJ_x \subseteq 2^{[L_x]}$.

Mixed Assignment We next define the concept of a *mixed assignment*:

Definition 1. *For a training pair (x, y) and a predicted label $y^* \in \mathcal{Y}(x)$, $y^* \neq y$, a **mixed assignment** (MA) vector denoted as $m^J(y^*, y)$ is defined with respect to $J \in JJ_x$ as follows:*

$$m_k^J(y^*, y) = \begin{cases} y_k^* & k \in J \\ y_k & else \end{cases}$$

That is, a mixed assignment is a new label, derived from the predicted label y^*, that is identical to y^* in all indexes in J and to y otherwise. For simplicity we denote $m^J(y^*, y) = m^J$ when the reference y^* and y labels are clear from the context.

[2] We use the notation $[n] = \{1, 2, \ldots n\}$.

Consider, for example, the trees of Figure 1, assuming that the top tree is y, the middle tree is y^* and $J = [2, 5]$.[3] In the $m^J(y^*, y)$ (bottom) tree the heads of all the words are identical to those of the top tree, except for the heads of *mistakes* and of *then*.

Violation The next central concept is that of a violation, originally presented by Huang et al. (2012):

Definition 2. *A triple (x, y, y^*) is said to be a **violation** with respect to a training example (x, y) and a parameter vector **w** if for $y^* \in \mathcal{Y}(x)$ it holds that $y^* \neq y$ and $\mathbf{w} \cdot \Delta\phi(x, y, y^*) \leq 0$.*

The SWVP algorithm distinguishes between MAs that are violations, and ones that are not. For a triplet (x, y, y^*) and a set of substructures $JJ_x \subseteq 2^{[L_x]}$ we provide the following notations:

$$I(y^*, y, JJ_x)^v = \{J \in JJ_x | m^J \neq y, \mathbf{w} \cdot \Delta\phi(x, y, m^J) \leq 0\}$$

$$I(y^*, y, JJ_x)^{nv} = \{J \in JJ_x | m^J \neq y, \mathbf{w} \cdot \Delta\phi(x, y, m^J) > 0\}$$

This notation divides the set of substructures into two subsets, one consisting of the substructures that yield violating MAs and one consisting of the substructures that yield non-violating MAs. Here again when the reference label y^* and the set JJ_x are known we denote: $I(y^*, y, JJ_x)^v = I^v$, $I(y^*, y, JJ_x)^{nv} = I^{nv}$ and $I = I^v \cup I^{nv}$.

Weighted Violations The key idea of SWVP is the exploitation of the internal structure of the predicted label in the update rule. For this aim at each iteration we define the set of substructures, JJ_x, and then, for each $J \in JJ_x$, update the parameter vector, **w**, with respect to the mixed assignments, MA^J's. This is a more flexible setup compared to CSP, as we can update with respect to the predicted output (if it is a violation, as is promised if inference is performed via argmax), if we wish to do so, as well as with respect to other mixed assignments.

Naturally, not all mixed assignments are equally important for the update rule. Hence, we weigh the different updates using a weight vector γ. This paper therefore extends the observation of Huang et al. (2012) that perceptron parameter update can be performed w.r.t violations (Section 2), by showing that **w** can actually be updated w.r.t linear combinations of mixed assignments, under certain conditions on the selected weights.

[3] We index the dependency tree words from 1 onwards.

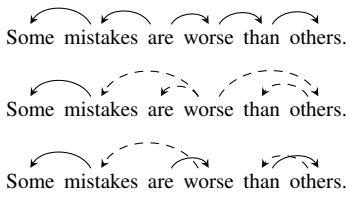

Figure 1: Example parse trees: gold tree (y, top), predicted tree (y^*, middle) with arcs differing from the gold's marked with a dashed line, and $m^J(y^*, y)$ for $J = [2, 5]$ (bottom tree).

3.2 Algorithm

With these definitions we can present the SWVP algorithm (Algorithm 2). SWVP is in fact a family of algorithms differing with respect to two decisions that can be made at each pass over each training example (x, y): the choice of the set JJ_x and the implementation of the SETGAMMA function.

SWVP is very similar to CSP except for in the update rule. Like in CSP, the algorithm iterates over the training data examples and for each example it first predicts a label according to the current parameter vector **w** (inference is discussed in Section 4.2, property 2). The main difference from CSP is in the update rule (lines 6-12). Here, for each substructure in the substructure set, $J \in JJ_x$, the algorithm generates a mixed assignment m^J (lines 7-9). Then, **w** is updated with a weighted sum of the mixed assignments (line 11), unlike in CSP where the update is held w.r.t the predicted assignment only.

The $\gamma(m^J)$ weights assigned to each of the $\Delta\phi(x, y, m^J)$ updates are defined by a SETGAMMA function (line 10). Intuitively, a $\gamma(m^J)$ weight should be higher the more the mixed assignment is assumed to convey useful information that can guide the update of **w** in the right direction. In Section 4 we detail the conditions on SETGAMMA under which SWVP converges, and in Section 5 we describe various SETGAMMA implementations.

Going back to the example of Figure 1, one would assume (Sec. 1) that the head word prediction for *worse* is pivotal to the substantial difference between the two top trees (UAS of 0.2). CSP does not directly exploit this observation as it only updates its parameter vector with respect to the differences between complete assignments: $\mathbf{w} = \mathbf{w} + \Delta\phi(x, y, z)$.

In contrast, SWVP can exploit this observation in various ways. For example, it can generate a mixed

assignment for each of the erroneous arcs where all other words are assigned their correct arc (according to the gold tree) except for that specific arc which is kept as in the bottom tree. Then, higher weights can be assigned to errors that seem more central than others. We elaborate on this in the next two sections.

Algorithm 2 The Structured Weighted Violations Perceptron

Input: data $D = \{x^i, y^i\}_{i=1}^n$, feature mapping ϕ
Output: parameter vector $\mathbf{w} \in \mathbb{R}^d$
Define: $\Delta\phi(x, y, z) \triangleq \phi(x, y) - \phi(x, z)$
1: Initialize $\mathbf{w} = 0$.
2: **repeat**
3: **for** each $(x^i, y^i) \in D$ **do**
4: $y^* = \arg\max_{y' \in \mathcal{Y}(x^i)} \mathbf{w} \cdot \phi(x^i, y')$
5: **if** $y^* \neq y^i$ **then**
6: **Define:** $JJ_{x^i} \subseteq 2^{[L_{x^i}]}$
7: **for** $J \in JJ_{x^i}$ **do**
8: **Define:** m^J s.t. $m_k^J = \begin{cases} y_k^* & k \in J \\ y_k^i & else \end{cases}$
9: **end for**
10: $\gamma = \text{SETGAMMA}()$
11: $\mathbf{w} = \mathbf{w} + \sum_{J \in I^v \cup I^{nv}} \gamma(m^J)\Delta\phi(x^i, y^i, m^J)$
12: **end if**
13: **end for**
14: **until** Convergence

4 Theory

We start this section with the convergence conditions on the γ vector which weighs the mixed assignment updates in the SWVP update rule (line 11). Then, using these conditions, we describe the relation between the SWVP and the CSP algorithms. After that, we prove the convergence of SWVP and analyse the derived properties of the algorithm.

γ Selection Conditions Our main observation in this section is that SWVP converges under two conditions: **(a)** the training set D is linearly separable; and **(b)** for any parameter vector $\mathbf{w}$ achievable by the algorithm, there exists $(x, y) \in D$ with $JJ_x \subseteq 2^{[L_x]}$, such that for the predicted output $y^* \neq y$, SETGAMMA returns a γ weight vector that respects the γ selection conditions defined as follows:

Definition 3. *The γ **selection conditions** for the SWVP algorithm are ($I = I^v \cup I^{nv}$):*

$$(1) \sum_{J \in I} \gamma(m^J) = 1. \quad \gamma(m^J) \geq 0, \quad \forall J \in I.$$

$$(2) \quad \boldsymbol{w} \cdot \sum_{J \in I} \gamma(m^J)\Delta\phi(x^i, y^i, m^J) \leq 0.$$

With this definition we are ready to prove the following property.

SWVP Generalizes the CSP Algorithm We now show that the CSP algorithm is a special case of SWVP. CSP can be derived from SWVP when taking: $JJ_x = \{[L_x]\}$, and $\gamma(m^{[L_x]}) = 1$ for every $(x, y) \in D$. With these parameters, the γ selection conditions hold for every $\mathbf{w}$ and y^*. Condition (1) holds trivially as there is only one γ coefficient and it is equal to 1. Condition (2) holds as $y^* = m^{[L_x]}$ and hence $I = \{[L_x]\}$ and $w \cdot \sum_{J \in I} \Delta\phi(x, y, m^J) \leq 0$.

4.1 Convergence for Linearly Separable Data

Here we give the theorem regarding the convergence of the SWVP in the separable case. We first define:

Definition 4. *A data set $D = \{x^i, y^i\}_{i=1}^n$ is **linearly separable with margin** $\delta > 0$ if there exists some vector $\boldsymbol{u}$ with $\|\boldsymbol{u}\|_2 = 1$ such that for all i:*

$$\boldsymbol{u} \cdot \Delta\phi(x^i, y^i, z) \geq \delta, \forall z \in \mathcal{Y}(x^i).$$

Definition 5. *The **radius** of a data set $D = \{x^i, y^i\}_{i=1}^n$ is the minimal scalar R s.t for all i:*

$$\|\Delta\phi(x^i, y^i, z)\| \leq R, \forall z \in \mathcal{Y}(x^i).$$

We next extend these definitions:

Definition 6. *Given a data set $D = \{x^i, y^i\}_{i=1}^n$ and a set $JJ = \{JJ_{x^i} \subseteq 2^{[L_{x^i}]} | (x^i, y^i) \in D\}$, D is **linearly separable w.r.t JJ, with margin** $\delta^{JJ} > 0$ if there exists a vector $\boldsymbol{u}$ with $\|\boldsymbol{u}\|_2 = 1$ such that: $\boldsymbol{u} \cdot \Delta\phi(x^i, y^i, m^J(z, y^i)) \geq \delta^{JJ}$ for all $i, z \in \mathcal{Y}(x^i), J \in JJ_{x^i}$.*

Definition 7. *The **mixed assignment radius w.r.t** JJ of a data set $D = \{x^i, y^i\}_{i=1}^n$ is a constant R^{JJ} s.t for all i it holds that:*

$$\|\Delta\phi(x^i, y^i, m^J(z, y^i))\| \leq R^{JJ}, \forall z \in \mathcal{Y}(x^i), J \in JJ_{x^i}.$$

With these definitions we can make the following observation (proof in A):

Observation 1. For linearly separable data D and a set JJ, every unit vector $\mathbf{u}$ that separates the data with margin δ, also separates the data with respect to mixed assignments with JJ, with margin $\delta^{JJ} \geq \delta$. Likewise, it holds that $R^{JJ} \leq R$.

We can now state our convergence theorem. While the proof of this theorem resembles that of the CSP (Collins, 2002), unlike the CSP proof the SWVP proof relies on the γ *selection conditions* presented above and on the *Jensen inequality*.

Theorem 1. *For any dataset D, linearly separable with respect to JJ with margin $\delta^{JJ} > 0$, the SWVP algorithm terminates after $t \leq \frac{(R^{JJ})^2}{(\delta^{JJ})^2}$ steps, where R^{JJ} is the mixed assignment radius of D w.r.t. JJ.*

Proof. Let $\mathbf{w}^t$ be the weight vector before the t^{th} update, thus $\mathbf{w}^1 = 0$. Suppose the t^{th} update occurs on example (x, y), i.e. for the predicted output y^* it holds that $y^* \neq y$. We will bound $\|\mathbf{w}^{t+1}\|^2$ from both sides.
First, it follows from the update rule of the algorithm that: $\mathbf{w}^{t+1} = \mathbf{w}^t + \sum_{J \in I^v \cup I^{nv}} \gamma(m^J) \Delta\phi(x, y, m^J)$. For simplicity, in this proof we will use the notation $I^v \cup I^{nv} = I$. Hence, multiplying each side of the equation by $\mathbf{u}$ yields:

$$\begin{aligned}
\mathbf{u} \cdot \mathbf{w}^{t+1} &= \mathbf{u} \cdot \mathbf{w}^t + \mathbf{u} \cdot \sum_{J \in I} \gamma(m^J) \Delta\phi(x, y, m^J) \\
&= \mathbf{u} \cdot \mathbf{w}^t + \sum_{J \in I} \gamma(m^J) \mathbf{u} \cdot \Delta\phi(x, y, m^J) \\
&\geq \mathbf{u} \cdot \mathbf{w}^t + \sum_{J \in I} \gamma(m^J) \delta^{JJ} \quad \text{(margin property)} \\
&\geq \mathbf{u} \cdot \mathbf{w}^t + \delta^{JJ} \geq \ldots \geq t\delta^{JJ}.
\end{aligned}$$

The last inequality holds because $\sum_{J \in I} \gamma(m^J) = 1$. From this we get that $\|w^{t+1}\|^2 \geq (\delta^{JJ})^2 t^2$ since $\|u\|$=1. Second,

$$\begin{aligned}
\|\mathbf{w}^{t+1}\|^2 &= \|\mathbf{w}^t + \sum_{J \in I} \gamma(m^J) \Delta\phi(x, y, m^J)\|^2 \\
&= \|\mathbf{w}^t\|^2 + \|\sum_{J \in I} \gamma(m^J) \Delta\Phi(x, y, m^J)\|^2 \\
&\quad + 2\mathbf{w}^t \cdot \sum_{J \in I} \gamma(m^J) \Delta\Phi(x, y, m^J).
\end{aligned}$$

From γ selection condition (2) we get that:

$$\begin{aligned}
\|\mathbf{w}^{t+1}\|^2 &\leq \|\mathbf{w}^t\|^2 + \|\sum_{J \in I} \gamma(m^J) \Delta\Phi(x, y, m^J)\|^2 \\
&\leq \|\mathbf{w}^t\|^2 + \sum_{J \in I} \gamma(m^J) \|\Delta\Phi(x, y, m^J)\|^2 \\
&\leq \|\mathbf{w}^t\|^2 + (R^{JJ})^2. \quad \text{(radius property)}
\end{aligned}$$

The inequality one before the last results from the *Jensen inequality* which holds due to **(a)** γ selection condition (1); and **(b)** the squared norm function being convex. From this we finally get:

$$\|\mathbf{w}^{t+1}\|^2 \leq \|\mathbf{w}^t\|^2 + (R^{JJ})^2 \leq \ldots \leq t(R^{JJ})^2.$$

Combining the two steps we get:

$$(\delta^{JJ})^2 t^2 \leq \|\mathbf{w}^{t+1}\|^2 \leq t(R^{JJ})^2.$$

From this it is easy to derive the upper bound in the theorem: $t \leq \frac{(R^{JJ})^2}{(\delta^{JJ})^2}$. □

4.2 Convergence Properties

We next point on three properties of the SWVP algorithm, derived from its convergence proof:

Property 1 (tighter iterations bound) The convergence proof of CSP (Collins, 2002) is given for a vector $\mathbf{u}$ that linearly separates the data, with margin δ and for a data radius R. Following observation 1, it holds that in our case, $\mathbf{u}$ also linearly separates the data with respect to mixed assignments with a set JJ and with margin $\delta^{JJ} \geq \delta$. Together with the definition of $R^{JJ} \leq R$ we get that: $\frac{(R^{JJ})^2}{(\delta^{JJ})^2} \leq \frac{R^2}{\delta^2}$. This means that the bound on the number of updates made by SWVP is tighter than the bound of CSP.

Property 2 (inference) From the γ selection conditions it holds that any label from which at least one violating MA can be derived through JJ_x is suitable for an update. This is because in such a case we can choose, for example, a SETGAMMA function that assigns the weight of 1 to that MA, and the weight of 0 to all other MAs.

Algorithm 2 employs the $argmax$ inference function, following the basic reasoning that it is a good choice to base the parameter update on. Importantly, if the inference function is argmax and the algorithm performs an update ($y^* \neq y$), this means that y^*, the output of the argmax function, is a violating MA by definition. However, it is obvious that solving the inference problem and the optimal γ assignment problems jointly may result in more informed parameter ($\mathbf{w}$) updates. We leave a deeper investigation of this issue to future research.

Property 3 (dynamic updates) The γ selection conditions paragraph states two conditions ((a) and (b)) under which the convergence proof holds. While it is trivial for SETGAMMA to generate a γ vector that respects condition (a), if there is a parameter vector **w'** achievable by the algorithm for which SETGAMMA cannot generate γ that respects condition (b), SWVP gets stuck when reaching **w'**.

This problem can be solved with *dynamic updates*. A deep look into the convergence proof reveals that the set JJ_x and the SETGAMMA function can actually differ between iterations. While this will change the bound on the number of iterations, it will not change the fact that the algorithm converges if the data is linearly separable. This makes SWVP highly flexible as it can always

back off to the CSP setup of $JJ_x = \{[L_x]\}$, and $\forall(x,y) \in D : \gamma(m^{[L_x]}) = 1$, update its parameters and continue with its original JJ and SETGAMMA when this option becomes feasible. If this does not happen, the algorithm can continue till convergence with the CSP setup.

4.3 Mistake and Generalization Bounds

The following bounds are proved: the number of updates in the separable case (see Theorem 1); the number of mistakes in the non-separable case (see Appendix B); and the probability to misclassify an unseen example (see supplementary material). It can be shown that in the general case these bounds are tighter than those of the CSP special case. We next discuss variants of SWVP.

5 Passive Aggressive SWVP

Here we present types of update rules that can be implemented within SWVP. Such rule types are defined by: (a) the selection of γ, which should respect the γ *selection conditions* (see Definition 3) and (b) the selection of $JJ = \{JJ_x \subseteq 2^{[L_x]} | (x,y) \in D\}$, the substructure sets for the training examples.

γ Selection A first approach we consider is the *aggressive approach*[4] where only mixed assignments that are violations $\{m^J : J \in I^v\}$ are exploited (i.e. for all $J \in I^{nv}, \gamma(m^J) = 0$). Note, that in this case condition (2) of the γ *selection conditions* trivially holds as: $\mathbf{w} \cdot \sum_{J \in I^v} \gamma(m^J)\Delta\phi(x,y,m^J) \leq 0$. The only remaining requirement is that condition (1) also holds, i.e. that $\sum_{J \in I^v} \gamma(m^J) = 1$.

The opposite, *passive approach*, exploits only non-violating MA's $\{m^J : J \in I^{nv}\}$. However, such γ assignments do not respect γ selection condition (2), as they yield: $\mathbf{w} \cdot \sum_{J \in I^{nv}} \gamma(m^J)\Delta\phi(x,y,m^J) \leq 0$ which holds if and only if for every $J \in I^{nv}$, $\gamma(m^J) = 0$ that in turn contradicts condition (1).

Finally, we can take a *balanced approach* which gives a positive γ coefficient for at least one violating MA and at least one positive γ coefficient for a non-violating MA. This approach is allowed by SWVP as long as both γ selection conditions hold.

[4]We borrow the term *passive-aggressive* from (Crammer et al., 2006), despite the substantial difference between the works.

We implemented two weighting methods, both based on the concept of margin:

(1) Weighted Margin (WM): $\gamma(m^J) = \frac{|\mathbf{w}\cdot\Delta\phi(x,y,m^J)|^\beta}{\sum_{J' \in JJ_x} |\mathbf{w}\cdot\Delta\phi(x,y,m^{J'})|^\beta}$

(2) Weighted Margin Rank (WMR): $\gamma(m^J) = \left(\frac{|JJ_x|-r}{|JJ_x|}\right)^\beta$. where r is the rank of $|\mathbf{w} \cdot \Delta\phi(x,y,m^J(y^*,y))|$ among the $|\mathbf{w} \cdot \Delta\phi(x,y,m^{J'}(y^*,y))|$ values for $J' \in JJ_x$.

Both schemes were implemented twice, within a balanced approach (denoted as B) and an aggressive approach (denoted as A).[5] The aggressive schemes respect both γ selection conditions. The balanced schemes, however, respect the first condition but not necessarily the second. Since all models that employ the balanced weighting schemes converged after at most 10 iterations, we did not impose this condition (which we could do by, e.g., excluding terms for $J \in I^{nv}$ till condition (2) holds).

JJ Selection Another choice that strongly affects the updates made by SWVP is that of JJ. A choice of $JJ_x = 2^{[L_x]}$, for every $(x,y) \in D$ results in an update rule which considers all possible mixing assignments derived from the predicted label y^* and the gold label y. Such an update rule, however, requires computing a sum over an exponential number of terms (2^{L_x}) and is therefore highly inefficient.

Among the wide range of alternative approaches, in this paper we exploit *single difference* mixed assignments. In this approach we define: $JJ = \{JJ_x = \{\{1\},\{2\},\ldots\{L_x\}\} | (x,y) \in D\}$. For a training pair $(x,y) \in D$, a predicted label y^* and $J = \{j\} \in JJ_x$, we will have:

$$m^J_k(y^*,y) = \begin{cases} y_k & k \neq j \\ y^*_k & k = j \end{cases}$$

Under this approach for the pair $(x,y) \in D$ only L_x terms are summed in the SWVP update rule. We leave a further investigation of JJ selection approaches to future research.

6 Experiments

Synthetic Data We experiment with synthetic data generated by a linear-chain, first-

[5]For the aggressive approach the equations for schemes (1) and (2) are changed such that JJ_x is replaced with $I(y^*,y,JJ_x)^v$.

order Hidden Markov Model (HMM, (Rabiner and Juang, 1986)). Our learning algorithm is a liner-chain conditional random field (CRF, (Lafferty et al., 2001)): $P(y|x) = \frac{1}{Z(x)} \prod_{i=1:L_x} exp(w \cdot \phi(y_{i-1}, y_i, x))$ (where $Z(x)$ is a normalization factor) with binary indicator features $\{x_i, y_i, y_{i-1}, (x_i, y_i), (y_i, y_{i-1}), (x_i, y_i, y_{i-1})\}$ for the triplet (y_i, y_{i-1}, x).

A dataset is generated by iteratively sampling K items, each is sampled as follows. We first sample a hidden state, y_1, from a uniform prior distribution. Then, iteratively, for $i = 1, 2, \ldots, L_x$ we sample an observed state from the emission probability and (for $i < L_x$) a hidden state from the transition probability. We experimented in 3 setups. In each setup we generated 10 datasets that were subsequently divided to a 7000 items training set, a 2000 items development set and a 1000 items test set. In all datasets, for each item, we set $L_x = 8$. We experiment in three conditions: (1) simple(++), learnable(+++), (2) simple(++), learnable(++) and (3) simple(+), learnable(+).[6]

For each dataset (3 setups, 10 datasets per setup) we train variants of the SWVP algorithm differing in the γ selection strategy (WM or WMR, Section 5), being aggressive (A) or passive (B), and in their β parameter ($\beta = \{0.5, 1, \ldots, 5\}$). Training is done on the training subset and the best performing variant on the development subset is applied to the test subset. For CSP no development set is employed as there is no hyper-parameter to tune. We report averaged accuracy (fraction of observed states for which the model successfully predicts the hidden state value) across the test sets, together with the standard deviation.

Dependency Parsing We also report initial dependency parsing results. We implemented our algorithms within the TurboParser (Martins et al., 2013). That is, every other aspect of the parser: feature set, probabilistic pruning algorithm, inference algorithm etc., is kept fixed but training is performed with SWVP. We compare our results to the parser performance with CSP training (which comes with the standard implementation of the parser).

We experiment with the datasets of the CoNLL 2007 shared task on multilingual dependency parsing (Nilsson et al., 2007), for a total of 9 languages. We followed the standard train/test split of these dataset. For SWVP, we randomly sampled 1000 sentences from each training set to serve as development sets and tuned the parameters as in the synthetic data experiments. CSP is trained on the training set and applied to the test set without any development set involved. We report the Unlabeled Attachment Score (UAS) for each language and model.

7 Results

Synthetic Data Table 1 presents our results. In all three setups an SWVP algorithm is superior. Averaged accuracy differences between the best performing algorithms and CSP are: 3.72 (B-WMR, (simple(++), learnable(+++))), 5.29 (B-WM, (simple(++), learnable(++))) and 5.18 (A-WM, (simple(+), learnable(+))). In all setups SWVP outperforms CSP in terms of averaged performance (except from B-WMR for (simple(+), learnable(+))). Moreover, the weighted models are more stable than CSP, as indicated by the lower standard deviation of their accuracy scores. Finally, for the more simple and learnable datasets the SWVP models outperform CSP in the majority of cases (7-10/10).

We measure generalization from development to test data in two ways. First, for each SWVP algorithm we count the number of times its β parameter results in an algorithm that outperforms the CSP on the development set but not on the test set (not shown in the table). Of the 120 comparisons reported in the table (4 SWVP models, 3 setups, 10 comparisons per model/setup combination) this happened once (A-MV, (simple(++), learnable(+++)).

Second, we count the number of times the best development set value of the β hyper-parameter is also the best value on the test set, or the test set accuracy with the best development set β is at most 0.5% lower than that with the best test set β. The *Gener-*

[6] Denoting $D_x = [C_x]$, $D_y = [C_y]$, and a permutation of a vector v with $perm(v)$, the parameters of the different setups are: (1) simple(++), learnable(+++): $C_x = 5$, $C_y = 3$, $P(y'|y) = perm(0.7, 0.2, 0.1)$, $P(x|y) = perm(0.75, 0.1, 0.05, 0.05, 0.05)$. (2) simple(++), learnable(++): $C_x = 5$, $C_y = 3$, $P(y'|y) = perm(0.5, 0.3, 0.2)$, $P(x|y) = perm(0.6, 0.15, 0.1, 0.1, 0.05)$. (3) simple(+), learnable(+): $C_x = 20$, $C_y = 7$, $P(y'|y) = perm(0.7, 0.2, 0.1, 0, \ldots, 0))$, $P(x|y) = perm(0.4, 0.2, 0.1, 0.1, 0.1, 0, \ldots, 0)$.

Table 2: First and second order dependency parsing UAS results for CSP trained models, as well as for models trained with SWVP with a balanced γ selection (B) and with a weighted margin (WM) strategy. For explanation of the B-WM, Top B-WM, and Test B-WM see text. For each language and parsing order we highlight the best result in bold font, but this do not include results from Test B-WM as it is provided only as an upper bound on the performance of SWVP.

alization column of the table shows that this has not happened in all of the 120 runs of SWVP.

Dependency Parsing Results are given in Table 2. For the SWVP trained models we report three numbers: (a) B-WM is the standard setup where the β hyper parameter is tuned on the development data; (b) For Top B-WM we first selected the models with a UAS score within 0.1% of the best development data result, and of these we report the UAS of the model that performs best on the test set; and (c) Test B-WM reports results when β is tuned on the test set. This measure provides an upper bound on SWVP with our simplistic JJ (Section 5).

Our results indicate the potential of SWVP. Despite our simple JJ set, Top B-WM and Test B-WM improve over CSP in 5/9 and 6/9 cases in first order parsing, respectively, and in 7/9 cases in second order parsing. In the latter case, Test B-WM improves the UAS over CSP in 0.22% on average across languages. Unfortunately, SWVP still does not generalize well from train to test data as indicated, e.g., by the modest improvements B-WM achieves over CSP in only 5 of 9 languages in second order parsing.

8 Conclusions

We presented the Structured Weighted Violations Perceptron (SWVP) algorithm, a generalization of the Structured Perceptron (CSP) algorithm that explicitly exploits the internal structure of the predicted label in its update rule. We proved the convergence of the algorithm for linearly separable training sets under certain conditions on its parameters, and provided generalization and mistake bounds.

In experiments we explored only very simple configurations of the SWVP parameters - γ and JJ. Nevertheless, several of our SWVP variants outperformed the CSP special case in synthetic data experiments. In dependency parsing experiments, SWVP demonstrated some improvements over CSP, but these do not generalize well. While we find these results somewhat encouraging, they emphasize the need to explore the much more flexible γ and JJ selection strategies allowed by SWVP (Sec. 4.2). In future work we will hence develop γ and JJ selection algorithms, where selection is ideally performed jointly with inference (property 2, Sec. 4.2), to make SWVP practically useful in NLP applications.

A Proof Observation 1.

Proof. For every training example $(x, y) \in D$, it holds that: $\cup_{z \in \mathcal{Y}(x)} m^J(z, y) \subseteq \mathcal{Y}(x)$. As $\mathbf{u}$ separates the data with margin δ, it holds that:

$$\mathbf{u} \cdot \Delta\phi(x, y, m^J(z, y)) \geq \delta^{JJ_x}, \quad \forall z \in \mathcal{Y}(x), J \in JJ_x.$$
$$\mathbf{u} \cdot \Delta\phi(x, y, z) \geq \delta, \quad \forall z \in \mathcal{Y}(x).$$

Therefore also $\delta^{JJ_x} \geq \delta$. As the last inequality holds for every $(x, y) \in D$ we get that $\delta^{JJ} = \min_{(x,y)\in D} \delta^{JJ_x} \geq \delta$.
From the same considerations it holds that $R^{JJ} \leq R$. This is because R^{JJ} is the radius of a subset of the dataset with radius R (proper subset if $\exists (x, y) \in D, [L_x] \notin JJ_x$, non-proper subset otherwise). □

B Mistake Bound - Non Separable Case

Here we provide a mistake bound for the algorithm in the non-separable case. We start with the following definition and observation:

Definition 8. *Given an example $(x^i, y^i) \in D$, for a $\boldsymbol{u}, \delta$ pair define:*

$$r^i = \boldsymbol{u} \cdot \phi(x^i, y^i) - \max_{z \in \mathcal{Y}(x^i)} \boldsymbol{u} \cdot \phi(x^i, z)$$
$$\epsilon_i = \max\{0, \delta - r^i\}$$
$$r^{iJJ} = \boldsymbol{u} \cdot \phi(x^i, y^i) - \max_{z \in \mathcal{Y}(x^i), J \in JJ_{x^i}} \boldsymbol{u} \cdot \phi(x^i, m^J(z, y^i))$$

Finally define: $D_{\boldsymbol{u},\delta} = \sqrt{\sum_{i=1}^{n} \epsilon_i^2}$

Observation 2. For all i: $r^i \leq r^{iJJ}$.
Observation 2 easily follows from Definition 8. Following this observation we denote: $r^{diff} = \min_i\{r^{iJJ} - r^i\} \geq 0$ and present the next theorem:

Theorem 2. *For any training sequence D, for the **first** pass over the training set of the CSP and the SWVP algorithms respectively, it holds that:*

$$\#mistakes - CSP \leq \min_{\boldsymbol{u}:\|\boldsymbol{u}\|=1,\delta>0} \frac{(R + D_{\boldsymbol{u},\delta})^2}{\delta^2}.$$
$$\#mistakes - SWVP \leq \min_{\boldsymbol{u}:\|\boldsymbol{u}\|=1,\delta>0} \frac{(R^{JJ} + D_{\boldsymbol{u},\delta})^2}{(\delta + r^{diff})^2}.$$

As $R^{JJ} \leq R$ (Observation 1) and $r^{diff} \geq 0$, we get a tighter bound for SWVP. The proof for #mistakes-CSP is given at (Collins, 2002). The proof for #mistakes-SWVP is given below.

Proof. We transform the representation $\phi(x, y) \in \mathbb{R}^d$ into a new representation $\psi(x, y) \in \mathbb{R}^{d+n}$ as follows: for $i = 1, ..., d : \psi_i(x, y) = \phi_i(x, y)$, for $j = 1, ..., n : \psi_{d+j}(x, y) = \Delta$ if $(x, y) = (x^j, y^j)$ and 0 otherwise, where $\Delta > 0$ is a parameter.
Given a $\mathbf{u}, \delta$ pair define $\mathbf{v} \in \mathbb{R}^{d+n}$ as follows: for $i = 1, ..., d : \mathbf{v}_i = \mathbf{u}_i$, for $j = 1, ..., n : \mathbf{v}_{d+j} = \frac{\epsilon_j}{\Delta}$.
Under these definitions we have:

$$\mathbf{v} \cdot \psi(x^i, y^i) - \mathbf{v} \cdot \psi(x^i, z) \geq \delta, \quad \forall i, z \in \mathcal{Y}(x^i).$$

For every $i, z \in \mathcal{Y}(x^i), J \in JJ_{x^i}$:

$$\mathbf{v} \cdot \psi(x^i, y^i) - \mathbf{v} \cdot \psi(x^i, m^J(z, y^i)) \geq \delta + r^{diff}.$$
$$\|\psi(x^i, y^i) - \psi(x^i, m^J(z, y^i))\|^2 \leq (R^{JJ})^2 + \Delta^2.$$

Last, we have,

$$\|\mathbf{v}\|^2 = \|\mathbf{u}\|^2 + \sum_{i=1}^{n} \frac{\epsilon_i^2}{\Delta^2} = 1 + \frac{D_{\mathbf{u},\delta}^2}{\Delta^2}.$$

We get that the vector $\frac{\mathbf{v}}{\|\mathbf{v}\|}$ linearly separates the data with respect to single decision assignments with margin $\frac{\delta}{\sqrt{1+\frac{D_{U,\delta}^2}{\Delta^2}}}$. Likewise, $\frac{\mathbf{v}}{\|\mathbf{v}\|}$ linearly separates the data with respect to mixed assignments with JJ, with margin $\frac{\delta + r^{diff}}{\sqrt{1+\frac{D_{\mathbf{u},\delta}}{\Delta^2}}}$. Notice that the **first** pass of SWVP with representation Ψ is identical to the first pass with representation Φ because the parameter weight for the additional features affects only a single example of the training data and do not affect the classification of test examples. By theorem 1 this means that the **first** pass of SWVP with representation Ψ makes at most $\frac{((R^{JJ})^2+\Delta^2)}{(\delta+r^{diff})^2} \cdot \left(1 + \frac{D_{\mathbf{u},\delta}^2}{\Delta^2}\right)$.
