## Preface: General Chair

Welcome to the 51st Annual Meeting of the Association for Computational Linguistics in Sofia, Bulgaria! The first ACL meeting was held in Denver in 1963 under the name AMTCL. This makes ACL one of the longest running conferences in computer science. This year we received a record total number of 1286 submissions, which is a testament to the continued and growing importance of computational linguistics and natural language processing.

The success of an ACL conference is made possible by the dedication and hard work of many people. I thank all of them for volunteering their time and energy in service to our community.

Priscilla Rasmussen, the ACL Business Manager, and Graeme Hirst, the treasurer, did most of the groundwork in selecting Sofia as the conference site, went through several iterations of planning and shouldered a significant part of the organizational work for the conference. It was my first exposure to the logistics of organizing a large event and I was surprised at how much expertise and experience is necessary to make ACL a successful meeting.

Thanks to Svetla Koeva and her team for their work on local arrangements, including social activities (Radka Vlahova, Tsvetana Dimitrova, Svetlozara Lesseva), local sponsorship (Stoyan Mihov, Rositsa Dekova), conference handbook (Nikolay Genov, Hristina Kukova), web site (Tinko Tinchev, Emil Stoyanov, Georgi Iliev), local exhibits (Maria Todorova, Ekaterina Tarpomanova), internet, wifi and equipment (Martin Yalamov, Angel Genov, Borislav Rizov) and student volunteer management (Kalina Boncheva). Perhaps most importantly, Svetla was the liaison to the professional conference organizer AIM Group, a relationship that is crucial for the success of the conference. Doing the local arrangements is a fulltime job for an extended period of time. We are lucky that we have people in our community who are willing to provide this service without compensation.

The program co-chairs Pascale Fung and Massimo Poesio selected a strong set of papers for the main conference and invited three great keynote speakers, Harald Baayen, Chantal Prat and Lars Rasmussen. Putting together the program of the top conference in our field is a difficult job and I thank Pascale and Massimo for taking on this important responsibility.

Thanks are also due to the other key members of the ACL organizing committees: Aoife Cahill and Qun Liu (workshop co-chairs); Johan Bos and Keith Hall (tutorial co-chairs); Miriam Butt and Sarmad Hussain (demo co-chairs); Steven Bethard, Preslav Nakov and Feiyu Xu (faculty advisors to the student research workshop); Anik Dey, Eva Vecchi, Sebastian Krause and Ivelina Nikolova (co-chairs of the student research workshop); Leo Wanner (mentoring chair); and Anisava Miltenova, Ivan Derzhanski and Anna Korhonen (publicity co-chairs).

I am particularly indebted to Roberto Navigli, Jing-Shin Chang and Stefano Faralli for producing the proceedings of the conference, a bigger job than usual because of the large number of submissions and the resulting large number of acceptances.

The ACL conference and the ACL organization benefit greatly from the financial support of our sponsors. We thank the platinum level sponsor, Baidu; the three gold level sponsors; the three silver level sponsors; and six bronze level sponsors. Three other sponsors took advantage of more creative options to assist us: Facebook sponsored the Student Volunteers; IBM sponsored the Best Student Paper Award; and SDL sponsored the conference bags. We are grateful for the financial support from these organizations.

Finally, I would like to express my appreciation to the area chairs, workshop organizers, tutorial presenters and reviewers for their participation and contribution.

Of course, the ACL conference is primarily held for the people who attend the conference, including the

authors. I would like to thank all of you for your participation and wish you a productive and enjoyable meeting in Sofia!

ACL 2013 General Chair  
Hinrich Schuetze, University of Munich

## Preface: Programme Committee Co-Chairs

Welcome to the 2013 Conference of the Association for Computational Linguistics! Our community continues to grow, and this year's conference has set a new record for paper submissions. We received 1286 submissions, which is 12% more than the previous record; we are particularly pleased to see a striking increase in the number of short papers submitted - 624, which is 21.8% higher than the previous record set in 2011.

Another encouraging trend in recent years is the increasing number of aspects of language processing, and forms of language, of interest to our community. In order to reflect this greater diversity, this year's conference has a much larger number of tracks than previous conferences, 26. Consequently, many more area chairs and reviewers were recruited than in the past, thus involving an even greater subset of the community in the selection of the program. We feel this, too, is a very positive development. We thank the area chairs and reviewers for their hard work.

A key innovation introduced this year is the presentation at the conference of sixteen papers accepted by the new ACL journal, Transactions of the Association for Computational Linguistics (TACL). We have otherwise maintained most of the innovations introduced in recent years, including accepting papers accompanied by supplemental materials such as corpora or software.

Another new practice this year is the presence of an industrial keynote speaker in addition to the two traditional keynote speakers. We are delighted to have as invited speakers two scholars as distinguished as Prof. Harald Baayen of Tuebingen and Alberta and Prof. Chantel Prat from the University of Wisconsin. Prof. Baayen will talk about using eye-tracking to study the semantics of compounds, an issue of great interest for work on distributional semantics. Prof. Prat will talk about research studying language in bilinguals using methods from neuroscience. The industrial keynote speaker, Dr. Lars Rasmussen from Facebook, will talk about the new graph search algorithm recently announced by the company. Last, but not least, the recipient of this year's ACL Lifetime Achievement Award will give a plenary lecture during the final day of the conference.

The list of people to thank for their contribution to this year's program is very long. First of all we wish to thank the authors who submitted top quality work to the conference; we would not have such a strong program without them, nor without the hard work of area chairs and reviewers, who enabled us to make often very difficult choices and to provide valuable feedback to the authors. As usual, Rich Gerber and the START team gave us crucial help with an amazing speed. The general conference chair Hinrich Schuetze provided valuable guidance and kept the timetable ticking along. We thank the local arrangements committee headed by Svetla Koeva, who played a key role in finalizing the program. We also thank the publication chairs, Jing-Shin Chang and Roberto Navigli, and their collaborator Stefano Faralli, who together produced this volume; and Priscilla Rasmussen, Drago Radev and Graeme Hirst, who provided enormously useful guidance and support. Finally, we wish to thank previous program chairs, and in particular John Carroll, Stephen Clark, and Jian Su, for their insight on the process.

We hope you will be as pleased as we are with the result and that you'll enjoy the conference in Sofia this Summer.

ACL 2013 Program Co-Chairs

Pascale Fung, Hong-Kong University of Science and Technology

Massimo Poesio, University of Essex

# Organizing Committee

## **General Chair:**

Hinrich Schuetze, University of Munich

## **Program Co-Chairs:**

Pascale Fung, The Hong Kong University of Science and Technology  
Massimo Poesio, University of Essex

## **Local Chair:**

Svetla Koeva, Bulgarian Academy of Sciences

## **Workshop Co-Chairs:**

Aoife Cahill, Educational Testing Service  
Qun Liu, Dublin City University & Chinese Academy of Sciences

## **Tutorial Co-Chairs:**

Johan Bos, University of Groningen  
Keith Hall, Google

## **Demo Co-Chairs:**

Miriam Butt, University of Konstanz  
Sarmad Hussain, Al-Khawarizmi Institute of Computer Science

## **Publication Chairs:**

Roberto Navigli, Sapienza University of Rome (Chair)  
Jing-Shin Chang, National Chi Nan University (Co-Chair)  
Stefano Faralli, Sapienza University of Rome

## **Faculty Advisors (Student Research Workshop):**

Steven Bethard, University of Colorado Boulder & KU Leuven  
Preslav I. Nakov, Qatar Computing Research Institute  
Feiyu Xu, DFKI, German Research Center for Artificial Intelligence

## **Student Chairs (Student Research Workshop):**

Anik Dey, The Hong Kong University of Science & Technology  
Eva Vecchi, Università di Trento

Sebastian Krause, DFKI, German Research Center for Artificial Intelligence  
Ivelina Nikolova, Bulgarian Academy of Sciences

**Mentoring Chair:**

Leo Wanner, Universitat Pompeu Fabra

**Publicity Co-Chairs:**

Anisava Miltenova, Bulgarian Academy of Sciences  
Ivan Derzhanski, Bulgarian Academy of Sciences  
Anna Korhonen, University of Cambridge

**Business Manager:**

Priscilla Rasmussen, ACL

**Area Chairs:**

Frank Keller, University of Edinburgh

## Invited Talk

### When parsing makes things worse: An eye-tracking study of English compounds

Harald Baayen

Seminar für Sprachwissenschaft, Eberhard Karls University, Tuebingen

### Abstract

Compounds differ in the degree to which they are semantically compositional (compare, e.g., "carwash", "handbag", "beefcake" and "humbug"). Since even relatively transparent compounds such as "carwash" may leave the uninitiated reader with uncertainty about the intended meaning (soap for washing cars? a place where you can get your car washed?), an efficient way of retrieving the meaning of a compound is to use the compound's form as an access key for its meaning.

However, in psychology, the view has become popular that at the earliest stage of lexical processing in reading, a morpho-orthographic decomposition into morphemes would necessarily take place. Theorists ascribing to obligatory decomposition appear to have some hash coding scheme in mind, with the constituents providing entry points to a form of table look-up (e.g., Taft & Forster, 1976).

Leaving aside the question of whether such a hash coding scheme would be computationally efficient as well as the question how the putative morpho-orthographic representations would be learned, my presentation focuses on the details of lexical processing as revealed by an eye-tracking study of the reading of English compounds in sentences.

A careful examination of the eye-tracking record with generalized additive modeling (Wood, 2006), combined with computational modeling using naive discrimination learning (Baayen, Milin, Filipovic, Hendrix, & Marelli, 2011) revealed that how far the eye moved into the compound is co-determined by the compound's lexical distributional properties, including the cosine similarity of the compound and its head in document vector space (as measured with latent semantic analysis, Landauer & Dumais, 1997). This indicates that compound processing is initiated already while the eye is fixating on the preceding word, and that even before the eye has landed on the compound, processes discriminating the meaning of the compound from the meaning of its head have already come into play.

Once the eye lands on the compound, two very different reading signatures emerge, which critically depend on the letter trigrams spanning the morpheme boundary (e.g., "ndb" and "dba" in "handbag"). From a discrimination learning perspective, these boundary trigrams provide the crucial (and only) orthographic cues for the compound's (idiosyncratic) meaning. If the boundary trigrams are sufficiently strongly associated with the compound's meaning, and if the eye lands early enough in the word, a single fixation suffices. Within 240 ms (of which 80 ms involve planning the next saccade) the compound's meaning is discriminated well enough to proceed to the next word.

However, when the boundary trigrams are only weakly associated with the compound's meaning, multiple fixations become necessary. In this case, without the availability of the critical orthographic cues, the eye-tracking record bears witness to the cognitive system engaging not only bottom-up processes from form to meaning, but also top-down guessing processes that are informed by the a-priori probability of the head and the cosine similarities of the compound and its constituents in semantic vector space.

These results challenge theories positing obligatory decomposition with hash coding, as hash coding predicts insensitivity to semantic transparency, contrary to fact. Our results also challenge theories positing blind look-up based on compounds' orthographic forms. Although this might be computationally efficient, the eye can't help seeing parts of the whole. In summary, reality is much more complex, with deep pre-arrival parafoveal processing followed by either efficient discrimination driven by the boundary

trigrams (within 140 ms), or by an inefficient decompositional process (requiring an additional 200 ms) that seeks to make sense of the conjunction of head and modifier.

## **Invited Talk**

### **The Natural Language Interface of Graph Search**

**Lars Rasmussen**

Facebook Inc

### **Abstract**

The backbone of the Facebook social network service is an enormous graph representing hundreds of types of nodes and thousands of types of edges. Among these nodes are over 1 billion users and 250 billion photos. The edges connecting these nodes have exceeded 1 trillion and continue to grow at an incredible rate. Retrieving information from such a graph has been a formidable and exciting task. Now it is possible for you to find, in an aggregated manner, restaurants in a city that your friends have visited, or photos of people who have attended college with you, and explore many other nuanced connections between the nodes and edges in our graph given that such information is visible to you.

Graph Search Beta, launched early this year, is a personalized semantic search engine that allows users to express their intent in natural language. It seeks answers through the traversal of relevant graph edges and ranks results by various signals extracted from our data. You can find “tv shows liked by people who study linguistics“ by issuing this query verbatim and, for the entertainment value, compare the results with “tv shows liked by people who study computer science“. Our system is built to be robust to many varied inputs, such as grammatically incorrect user queries or traditional keyword searches. Our query suggestions are always constructed in natural language, expressing the precise intention interpreted by our system. This means users would know in advance whether the system has correctly understood their intent before selecting any suggestion. The system also assists users with auto-completions, demonstrating what kinds of queries it can understand.

The development of the natural language interface encountered an array of challenging problems. The grammar structure needed to incorporate semantic information in order to translate an unstructured query into a structured semantic function, and also use syntactic information to return grammatically meaningful suggestions. The system required not only the recognition of entities in a query, but also the resolution of entities to database entries based on proximity of the entity and user nodes. Semantic parsing aimed to rank potential semantics including those that may match the immediate purpose of the query along with other refinements of the original intent. The ambiguous nature of natural language led us to consider how to interpret certain queries in the most sensible way. The need for speed demanded state-of-the-art parsing algorithms tailored for our system. In this talk, I will introduce the audience to Graph Search Beta, share our experience in developing the technical components of the natural language interface, and bring up topics that may be of interesting research value to the NLP community.

## **Invited Talk**

### **Individual Differences in Language and Executive Processes: How the Brain Keeps Track of Variables**

**Chantel S. Prat**

University of Washington

#### **Abstract**

Language comprehension is a complex cognitive process which requires tracking and integrating multiple variables. Thus, it is not surprising that language abilities (e.g., reading comprehension) vary widely even in the college population, and that language and general cognitive abilities (e.g., working memory capacity) co-vary. Although it has been widely accepted that improvements in general cognitive abilities enable (or give rise to) increased linguistic skills, the fact that individuals who develop bilingually outperform monolinguals in tests of executive functioning provides evidence of a situation in which a particular language experience gives rise to improvements in general cognitive processes. In this talk, I will describe two converging lines of research investigating individual differences in working memory capacity and reading ability in monolinguals and improved executive functioning in bilinguals. Results from these investigations suggest that the functioning of the fronto-striatal loops can explain the relation between language and non-linguistic executive functioning in both populations. I then discuss evidence suggesting that this system may function to track and route “variables” into prefrontal control structures.

## Table of Contents

<i>A Shift-Reduce Parsing Algorithm for Phrase-based String-to-Dependency Translation</i> Yang Liu .....	1
<i>Integrating Translation Memory into Phrase-Based Machine Translation during Decoding</i> Kun Wang, Chengqing Zong and Keh-Yih Su .....	11
<i>Training Nondeficient Variants of IBM-3 and IBM-4 for Word Alignment</i> Thomas Schoenemann .....	22
<i>Modelling Annotator Bias with Multi-task Gaussian Processes: An Application to Machine Translation Quality Estimation</i> Trevor Cohn and Lucia Specia .....	32
<i>Smoothed marginal distribution constraints for language modeling</i> Brian Roark, Cyril Allauzen and Michael Riley .....	43
<i>Grounded Language Learning from Video Described with Sentences</i> Haonan Yu and Jeffrey Mark Siskind .....	53
<i>Plurality, Negation, and Quantification: Towards Comprehensive Quantifier Scope Disambiguation</i> Mehdi Manshadi, Daniel Gildea and James Allen .....	64
<i>Joint Event Extraction via Structured Prediction with Global Features</i> Qi Li, Heng Ji and Liang Huang .....	73
<i>Language-Independent Discriminative Parsing of Temporal Expressions</i> Gabor Angeli and Jakob Uszkoreit .....	83
<i>Graph-based Local Coherence Modeling</i> Camille Guinaudeau and Michael Strube .....	93
<i>Recognizing Rare Social Phenomena in Conversation: Empowerment Detection in Support Group Chatrooms</i> Elijah Mayfield, David Adamson and Carolyn Penstein Rosé .....	104
<i>Decentralized Entity-Level Modeling for Coreference Resolution</i> Greg Durrett, David Hall and Dan Klein .....	114
<i>Chinese Parsing Exploiting Characters</i> Meishan Zhang, Yue Zhang, Wanxiang Che and Ting Liu .....	125
<i>A Transition-Based Dependency Parser Using a Dynamic Parsing Strategy</i> Francesco Sartorio, Giorgio Satta and Joakim Nivre .....	135
<i>General binarization for parsing and translation</i> Matthias Büchse, Alexander Koller and Heiko Vogler .....	145
<i>Distortion Model Considering Rich Context for Statistical Machine Translation</i> Isao Goto, Masao Utiyama, Eiichiro Sumita, Akihiro Tamura and Sadao Kurohashi .....	155
<i>Word Alignment Modeling with Context Dependent Deep Neural Network</i> Nan Yang, Shujie Liu, Mu Li, Ming Zhou and Nenghai Yu .....	166

<i>Microblogs as Parallel Corpora</i>	
Wang Ling, Guang Xiang, Chris Dyer, Alan Black and Isabel Trancoso .....	176
<i>Improved Bayesian Logistic Supervised Topic Models with Data Augmentation</i>	
Jun Zhu, Xun Zheng and Bo Zhang .....	187
<i>Fast and Robust Compressive Summarization with Dual Decomposition and Multi-Task Learning</i>	
Miguel Almeida and Andre Martins .....	196
<i>Unsupervised Transcription of Historical Documents</i>	
Taylor Berg-Kirkpatrick, Greg Durrett and Dan Klein .....	207
<i>Adapting Discriminative Reranking to Grounded Language Learning</i>	
Joohyun Kim and Raymond Mooney .....	218
<i>Universal Conceptual Cognitive Annotation (UCCA)</i>	
Omri Abend and Ari Rappoport .....	228
<i>Linking Tweets to News: A Framework to Enrich Short Text Data in Social Media</i>	
Weiwei Guo, Hao Li, Heng Ji and Mona Diab .....	239
<i>A computational approach to politeness with application to social factors</i>	
Cristian Danescu-Niculescu-Mizil, Moritz Sudhof, Dan Jurafsky, Jure Leskovec and Christopher Potts .....	250
<i>Modeling Thesis Clarity in Student Essays</i>	
Isaac Persing and Vincent Ng .....	260
<i>Translating Italian connectives into Italian Sign Language</i>	
Camillo Lugaresi and Barbara Di Eugenio .....	270
<i>Stop-probability estimates computed on a large corpus improve Unsupervised Dependency Parsing</i>	
David Mareček and Milan Straka .....	281
<i>Transfer Learning for Constituency-Based Grammars</i>	
Yuan Zhang, Regina Barzilay and Amir Globerson .....	291
<i>A Context Free TAG Variant</i>	
Ben Swanson, Elif Yamangil, Eugene Charniak and Stuart Shieber .....	302
<i>Fast and Adaptive Online Training of Feature-Rich Translation Models</i>	
Spence Green, Sida Wang, Daniel Cer and Christopher D. Manning .....	311
<i>Advancements in Reordering Models for Statistical Machine Translation</i>	
Minwei Feng, Jan-Thorsten Peter and Hermann Ney .....	322
<i>A Markov Model of Machine Translation using Non-parametric Bayesian Inference</i>	
Yang Feng and Trevor Cohn .....	333
<i>Scaling Semi-supervised Naive Bayes with Feature Marginals</i>	
Michael Lucas and Doug Downey .....	343
<i>Learning Latent Personas of Film Characters</i>	
David Bamman, Brendan O'Connor and Noah A. Smith .....	352

<i>Scalable Decipherment for Machine Translation via Hash Sampling</i> Sujith Ravi .....	362
<i>Automatic Interpretation of the English Possessive</i> Stephen Tratz and Eduard Hovy .....	372
<i>Is a 204 cm Man Tall or Small ? Acquisition of Numerical Common Sense from the Web</i> Katsuma Narisawa, Yotaro Watanabe, Junta Mizuno, Naoaki Okazaki and Kentaro Inui .....	382
<i>Probabilistic Domain Modelling With Contextualized Distributional Semantic Vectors</i> Jackie Chi Kit Cheung and Gerald Penn .....	392
<i>Extracting bilingual terminologies from comparable corpora</i> Ahmet Aker, Monica Paramita and Rob Gaizauskas .....	402
<i>The Haves and the Have-Nots: Leveraging Unlabelled Corpora for Sentiment Analysis</i> Kashyap Popat, Balamurali A.R, Pushpak Bhattacharyya and Gholamreza Haffari .....	412
<i>Large-scale Semantic Parsing via Schema Matching and Lexicon Extension</i> Qingqing Cai and Alexander Yates .....	423
<i>Fast and Accurate Shift-Reduce Constituent Parsing</i> Muhua Zhu, Yue Zhang, Wenliang Chen, Min Zhang and Jingbo Zhu .....	434
<i>Nonconvex Global Optimization for Latent-Variable Models</i> Matthew R. Gormley and Jason Eisner .....	444
<i>Parsing with Compositional Vector Grammars</i> Richard Socher, John Bauer, Christopher D. Manning and Ng Andrew Y. ....	455
<i>Discriminative state tracking for spoken dialog systems</i> Angeliki Metallinou, Dan Bohus and Jason Williams .....	466
<i>Leveraging Synthetic Discourse Data via Multi-task Learning for Implicit Discourse Relation Recognition</i> Man Lan, Yu Xu and Zhengyu Niu .....	476
<i>Combining Intra- and Multi-sentential Rhetorical Parsing for Document-level Discourse Analysis</i> Shafiq Joty, Giuseppe Carenini, Raymond Ng and Yashar Mehdad .....	486
<i>Improving pairwise coreference models through feature space hierarchy learning</i> Emmanuel Lassalle and Pascal Denis .....	497
<i>Feature-Based Selection of Dependency Paths in Ad Hoc Information Retrieval</i> K. Tamsin Maxwell, Jon Oberlander and W. Bruce Croft .....	507
<i>Coordination Structures in Dependency Treebanks</i> Martin Popel, David Mareček, Jan Štěpánek, Daniel Zeman and Zdeněk Žabokrtský .....	517
<i>GlossBoot: Bootstrapping Multilingual Domain Glossaries from the Web</i> Flavio De Benedictis, Stefano Faralli and Roberto Navigli .....	528
<i>Collective Annotation of Linguistic Resources: Basic Principles and a Formal Model</i> Ulle Endriss and Raquel Fernández .....	539

<i>ParGramBank: The ParGram Parallel Treebank</i>	
Sebastian Sulger, Miriam Butt, Tracy Holloway King, Paul Meurer, Tibor Laczkó, György Rákosi, Cheikh Bamba Dione, Helge Dyvik, Victoria Rosén, Koenraad De Smedt, Agnieszka Patejuk, Ozlem Cetinoglu, I Wayan Arka and Meladel Mistica . . . . .	550
<i>Identifying Bad Semantic Neighbors for Improving Distributional Thesauri</i>	
Olivier Ferret . . . . .	561
<i>Models of Semantic Representation with Visual Attributes</i>	
Carina Silberer, Vittorio Ferrari and Mirella Lapata . . . . .	572
<i>Real-World Semi-Supervised Learning of POS-Taggers for Low-Resource Languages</i>	
Dan Garrette, Jason Mielens and Jason Baldridge . . . . .	583
<i>Using subcategorization knowledge to improve case prediction for translation to German</i>	
Marion Weller, Alexander Fraser and Sabine Schulte im Walde . . . . .	593
<i>Name-aware Machine Translation</i>	
Haibo Li, Jing Zheng, Heng Ji, Qi Li and Wen Wang . . . . .	604
<i>Decipherment Complexity in 1:1 Substitution Ciphers</i>	
Malte Nuhn and Hermann Ney . . . . .	615
<i>Non-Monotonic Sentence Alignment via Semisupervised Learning</i>	
Xiaojun Quan, Chunyu Kit and Yan Song . . . . .	622
<i>Bootstrapping Entity Translation on Weakly Comparable Corpora</i>	
Taesung Lee and Seung-won Hwang . . . . .	631
<i>Transfer Learning Based Cross-lingual Knowledge Extraction for Wikipedia</i>	
Zhigang Wang, Zhixing Li, Juanzi Li, Jie Tang and Jeff Z. Pan . . . . .	641
<i>Bridging Languages through Etymology: The case of cross language text categorization</i>	
Vivi Nastase and Carlo Strapparava . . . . .	651
<i>Creating Similarity: Lateral Thinking for Vertical Similarity Judgments</i>	
Tony Veale and Guofu Li . . . . .	660
<i>Discovering User Interactions in Ideological Discussions</i>	
Arjun Mukherjee and Bing Liu . . . . .	671
<i>Multilingual Affect Polarity and Valence Prediction in Metaphor-Rich Texts</i>	
Zornitsa Kozareva . . . . .	682
<i>Large tagset labeling using Feed Forward Neural Networks. Case study on Romanian Language</i>	
Tiberiu Boros, Radu Ion and Dan Tufis . . . . .	692
<i>Learning to lemmatise Polish noun phrases</i>	
Adam Radziszewski . . . . .	701
<i>Using Conceptual Class Attributes to Characterize Social Media Users</i>	
Shane Bergsma and Benjamin Van Durme . . . . .	710
<i>The Impact of Topic Bias on Quality Flaw Prediction in Wikipedia</i>	
Oliver Ferschke, Iryna Gurevych and Marc Rittberger . . . . .	721

<i>Mining Informal Language from Chinese Microtext: Joint Word Recognition and Segmentation</i> Aobo Wang and Min-Yen Kan .....	731
<i>Generating Synthetic Comparable Questions for News Articles</i> Oleg Rokhlenko and Idan Szpektor .....	742
<i>Punctuation Prediction with Transition-based Parsing</i> Dongdong Zhang, Shuangzhi Wu, Nan Yang and Mu Li .....	752
<i>Discriminative Learning with Natural Annotations: Word Segmentation as a Case Study</i> Wenbin Jiang, Meng Sun, Yajuan Lü, Yating Yang and Qun Liu .....	761
<i>Graph-based Semi-Supervised Model for Joint Chinese Word Segmentation and Part-of-Speech Tagging</i> Xiaodong Zeng, Derek F. Wong, Lidia S. Chao and Isabel Trancoso .....	770
<i>An Infinite Hierarchical Bayesian Model of Phrasal Translation</i> Trevor Cohn and Gholamreza Haffari .....	780
<i>Additive Neural Networks for Statistical Machine Translation</i> Jiemao Liu, Taro Watanabe, Eiichiro Sumita and Tiejun Zhao .....	791
<i>Hierarchical Phrase Table Combination for Machine Translation</i> Conghui Zhu, Taro Watanabe, Eiichiro Sumita and Tiejun Zhao .....	802
<i>Shallow Local Multi-Bottom-up Tree Transducers in Statistical Machine Translation</i> Fabienne Braune, Nina Seemann, Daniel Quernheim and Andreas Maletti .....	811
<i>Enlisting the Ghost: Modeling Empty Categories for Machine Translation</i> Bing Xiang, Xiaoqiang Luo and Bowen Zhou .....	822
<i>A Multi-Domain Translation Model Framework for Statistical Machine Translation</i> Rico Sennrich, Holger Schwenk and Walid Aransa .....	832
<i>Part-of-Speech Induction in Dependency Trees for Statistical Machine Translation</i> Akihiro Tamura, Taro Watanabe, Eiichiro Sumita, Hiroya Takamura and Manabu Okumura ...	841
<i>Statistical Machine Translation Improves Question Retrieval in Community Question Answering via Matrix Factorization</i> Guangyou Zhou, Fang Liu, Yang Liu, Shizhu He and Jun Zhao .....	852
<i>Improved Lexical Acquisition through DPP-based Verb Clustering</i> Roi Reichart and Anna Korhonen .....	862
<i>Semantic Frames to Predict Stock Price Movement</i> Boyi Xie, Rebecca J. Passonneau, Leon Wu and Germán G. Creamer .....	873
<i>Density Maximization in Context-Sense Metric Space for All-words WSD</i> Koichi Tanigaki, Mitsuteru Shiba, Tatsuji Munaka and Yoshinori Sagisaka .....	884
<i>The Role of Syntax in Vector Space Models of Compositional Semantics</i> Karl Moritz Hermann and Phil Blunsom .....	894
<i>Margin-based Decomposed Amortized Inference</i> Gourab Kundu, Vivek Srikumar and Dan Roth .....	905

<i>Semi-Supervised Semantic Tagging of Conversational Understanding using Markov Topic Regression</i> Asli Celikyilmaz, Dilek Hakkani-Tur, Gokhan Tur and Ruhi Sarikaya .....	914
<i>Parsing Graphs with Hyperedge Replacement Grammars</i> David Chiang, Jacob Andreas, Daniel Bauer, Karl Moritz Hermann, Bevan Jones and Kevin Knight	924
<i>Grounded Unsupervised Semantic Parsing</i> Hoifung Poon .....	933
<i>Automatic detection of deception in child-produced speech using syntactic complexity features</i> Maria Yancheva and Frank Rudzicz .....	944
<i>Sentiment Relevance</i> Christian Scheible and Hinrich Schütze .....	954
<i>Predicting and Eliciting Addressee’s Emotion in Online Dialogue</i> Takayuki Hasegawa, Nobuhiro Kaji, Naoki Yoshinaga and Masashi Toyoda .....	964
<i>Utterance-Level Multimodal Sentiment Analysis</i> Veronica Perez-Rosas, Rada Mihalcea and Louis-Philippe Morency .....	973
<i>Probabilistic Sense Sentiment Similarity through Hidden Emotions</i> Mitra Mohtarami, Man Lan and Chew Lim Tan .....	983
<i>A user-centric model of voting intention from Social Media</i> Vasileios Lampos, Daniel Preoŧiuc-Pietro and Trevor Cohn .....	993
<i>Using Supervised Bigram-based ILP for Extractive Summarization</i> Chen Li, Xian Qian and Yang Liu .....	1004
<i>Summarization Through Submodularity and Dispersion</i> Anirban Dasgupta, Ravi Kumar and Sujith Ravi .....	1014
<i>Subtree Extractive Summarization via Submodular Maximization</i> Hajime Morita, Ryohei Sasano, Hiroya Takamura and Manabu Okumura .....	1023
<i>The effect of non-tightness on Bayesian estimation of PCFGs</i> Shay B. Cohen and Mark Johnson .....	1033
<i>Integrating Multiple Dependency Corpora for Inducing Wide-coverage Japanese CCG Resources</i> Sumire Uematsu, Takuya Matsuzaki, Hiroki Hanaoka, Yusuke Miyao and Hideki Mima .....	1042
<i>Transition-based Dependency Parsing with Selectional Branching</i> Jinho D. Choi and Andrew McCallum .....	1052
<i>Bilingually-Guided Monolingual Dependency Grammar Induction</i> Kai Liu, Yajuan Lü, Wenbin Jiang and Qun Liu .....	1063
<i>Joint Word Alignment and Bilingual Named Entity Recognition Using Dual Decomposition</i> Mengqiu Wang, Wanxiang Che and Christopher D. Manning .....	1073
<i>Resolving Entity Morphs in Censored Data</i> Hongzhao Huang, Zhen Wen, Dian Yu, Heng Ji, Yizhou Sun, Jiawei Han and He Li .....	1083

<i>Learning to Extract International Relations from Political Context</i> Brendan O'Connor, Brandon M. Stewart and Noah A. Smith .....	1094
<i>Graph Propagation for Paraphrasing Out-of-Vocabulary Words in Statistical Machine Translation</i> Majid Razmara, Maryam Siahbani, Reza Haffari and Anoop Sarkar .....	1105
<i>Online Relative Margin Maximization for Statistical Machine Translation</i> Vladimir Eidelman, Yuval Marton and Philip Resnik .....	1116
<i>Handling Ambiguities of Bilingual Predicate-Argument Structures for Statistical Machine Translation</i> Feifei Zhai, Jiajun Zhang, Yu Zhou and Chengqing Zong .....	1127
<i>Reconstructing an Indo-European Family Tree from Non-native English Texts</i> Ryo Nagata and Edward Whittaker .....	1137
<i>Word Association Profiles and their Use for Automated Scoring of Essays</i> Beata Beigman Klebanov and Michael Flor .....	1148
<i>Adaptive Parser-Centric Text Normalization</i> Congle Zhang, Tyler Baldwin, Howard Ho, Benny Kimelfeld and Yunyao Li .....	1159
<i>A Random Walk Approach to Selectional Preferences Based on Preference Ranking and Propagation</i> Zhenhua Tian, Hengheng Xiang, Ziqi Liu and Qinghua Zheng .....	1169
<i>ImpAr: A Deterministic Algorithm for Implicit Semantic Role Labelling</i> Egoitz Laparra and German Rigau .....	1180
<i>Cross-lingual Transfer of Semantic Role Labeling Models</i> Mikhail Kozhevnikov and Ivan Titov .....	1190
<i>DERivBase: Inducing and Evaluating a Derivational Morphology Resource for German</i> Britta Zeller, Jan Šnajder and Sebastian Padó .....	1201
<i>Crowdsourcing Interaction Logs to Understand Text Reuse from the Web</i> Martin Potthast, Matthias Hagen, Michael Völske and Benno Stein .....	1212
<i>SPred: Large-scale Harvesting of Semantic Predicates</i> Tiziano Flati and Roberto Navigli .....	1222
<i>Towards Robust Abstractive Multi-Document Summarization: A Caseframe Analysis of Centrality and Domain</i> Jackie Chi Kit Cheung and Gerald Penn .....	1233
<i>HEADY: News headline abstraction through event pattern clustering</i> Enrique Alfonseca, Daniele Pighin and Guillermo Garrido .....	1243
<i>Conditional Random Fields for Responsive Surface Realisation using Global Features</i> Nina Dethlefs, Helen Hastie, Heriberto Cuayáhuitl and Oliver Lemon .....	1254
<i>Two-Neighbor Orientation Model with Cross-Boundary Global Contexts</i> Hendra Setiawan, Bowen Zhou, Bing Xiang and Libin Shen .....	1264
<i>Cut the noise: Mutually reinforcing reordering and alignments for improved machine translation</i> Karthik Visweswariah, Mitesh M. Khapra and Ananthakrishnan Ramanathan .....	1275

<i>Vector Space Model for Adaptation in Statistical Machine Translation</i> Boxing Chen, Roland Kuhn and George Foster .....	1285
<i>From Natural Language Specifications to Program Input Parsers</i> Tao Lei, Fan Long, Regina Barzilay and Martin Rinard .....	1294
<i>Entity Linking for Tweets</i> Xiaohua Liu, Yitong Li, Haocheng Wu, Ming Zhou, Furu Wei and Yi Lu .....	1304
<i>Identification of Speakers in Novels</i> Hua He, Denilson Barbosa and Grzegorz Kondrak .....	1312
<i>Language Acquisition and Probabilistic Models: keeping it simple</i> Aline Villavicencio, Marco Idiart, Robert Berwick and Igor Malioutov .....	1321
<i>A Two Level Model for Context Sensitive Inference Rules</i> Oren Melamud, Jonathan Berant, Ido Dagan, Jacob Goldberger and Idan Szpektor .....	1331
<i>Align, Disambiguate and Walk: A Unified Approach for Measuring Semantic Similarity</i> Mohammad Taher Pilehvar, David Jurgens and Roberto Navigli .....	1341
<i>Linking and Extending an Open Multilingual Wordnet</i> Francis Bond and Ryan Foster .....	1352
<i>FrameNet on the Way to Babel: Creating a Bilingual FrameNet Using Wiktionary as Interlingual Connection</i> Silvana Hartmann and Iryna Gurevych .....	1363
<i>Dirt Cheap Web-Scale Parallel Text from the Common Crawl</i> Jason R. Smith, Herve Saint-Amand, Magdalena Plamada, Philipp Koehn, Chris Callison-Burch and Adam Lopez .....	1374
<i>A Sentence Compression Based Framework to Query-Focused Multi-Document Summarization</i> Lu Wang, Hema Raghavan, Vittorio Castelli, Radu Florian and Claire Cardie .....	1384
<i>Domain-Independent Abstract Generation for Focused Meeting Summarization</i> Lu Wang and Claire Cardie .....	1395
<i>A Statistical NLG Framework for Aggregated Planning and Realization</i> Ravi Kondadadi, Blake Howald and Frank Schilder .....	1406
<i>Models of Translation Competitions</i> Mark Hopkins and Jonathan May .....	1416
<i>Learning a Phrase-based Translation Model from Monolingual Data with Application to Domain Adaptation</i> Jiajun Zhang and Chengqing Zong .....	1425
<i>SenseSpotting: Never let your parallel data tie you to an old domain</i> Marine Carpuat, Hal Daume III, Katharine Henry, Ann Irvine, Jagadeesh Jagarlamudi and Rachel Rudinger .....	1435
<i>BRAINSUP: Brainstorming Support for Creative Sentence Generation</i> Gözde Özbal, Daniele Pighin and Carlo Strapparava .....	1446

<i>Grammatical Error Correction Using Integer Linear Programming</i> Yuanbin Wu and Hwee Tou Ng .....	1456
<i>Text-Driven Toponym Resolution using Indirect Supervision</i> Michael Speriosu and Jason Baldridge .....	1466
<i>Argument Inference from Relevant Event Mentions in Chinese Argument Extraction</i> Peifeng Li, Qiaoming Zhu and Guodong Zhou .....	1477
<i>Fine-grained Semantic Typing of Emerging Entities</i> Ndapandula Nakashole, Tomasz Tylenda and Gerhard Weikum .....	1488
<i>Embedding Semantic Similarity in Tree Kernels for Domain Adaptation of Relation Extraction</i> Barbara Plank and Alessandro Moschitti .....	1498
<i>A joint model of word segmentation and phonological variation for English word-final /t/-deletion</i> Benjamin Börschinger, Mark Johnson and Katherine Demuth .....	1508
<i>Compositional-ly Derived Representations of Morphologically Complex Words in Distributional Semantics</i> Angeliki Lazaridou, Marco Marelli, Roberto Zamparelli and Marco Baroni .....	1517
<i>Unsupervised Consonant-Vowel Prediction over Hundreds of Languages</i> Young-Bum Kim and Benjamin Snyder .....	1527
<i>Improving Text Simplification Language Modeling Using Unsimplified Text Data</i> David Kauchak .....	1537
<i>Combining Referring Expression Generation and Surface Realization: A Corpus-Based Investigation of Architectures</i> Sina Zarrieß and Jonas Kuhn .....	1547
<i>Named Entity Recognition using Cross-lingual Resources: Arabic as an Example</i> Kareem Darwish .....	1558
<i>Beam Search for Solving Substitution Ciphers</i> Malte Nuhn, Julian Schamper and Hermann Ney .....	1568
<i>Social Text Normalization using Contextual Graph Random Walks</i> Hany Hassan and Arul Menezes .....	1577
<i>Integrating Phrase-based Reordering Features into a Chart-based Decoder for Machine Translation</i> ThuyLinh Nguyen and Stephan Vogel .....	1587
<i>Machine Translation Detection from Monolingual Web-Text</i> Yuki Arase and Ming Zhou .....	1597
<i>Paraphrase-Driven Learning for Open Question Answering</i> Anthony Fader, Luke Zettlemoyer and Oren Etzioni .....	1608
<i>Aid is Out There: Looking for Help from Tweets during a Large Scale Disaster</i> István Varga, Motoki Sano, Kentaro Torisawa, Chikara Hashimoto, Kiyonori Ohtake, Takao Kawai, Jong-Hoon Oh and Stijn De Saeger .....	1619
<i>A Bayesian Model for Joint Unsupervised Induction of Sentiment, Aspect and Discourse Representations</i> Angeliki Lazaridou, Ivan Titov and Caroline Sporleder .....	1630

<i>Joint Inference for Fine-grained Opinion Extraction</i> Bishan Yang and Claire Cardie .....	1640
<i>Linguistic Models for Analyzing and Detecting Biased Language</i> Marta Recasens, Cristian Danescu-Niculescu-Mizil and Dan Jurafsky .....	1650
<i>Evaluating a City Exploration Dialogue System with Integrated Question-Answering and Pedestrian Navigation</i> Srinivasan Janarthanam, Oliver Lemon, Phil Bartie, Tiphaine Dalmas, Anna Dickinson, Xingkun Liu, William Mackaness and Bonnie Webber .....	1660
<i>Lightly Supervised Learning of Procedural Dialog Systems</i> Svitlana Volkova, Pallavi Choudhury, Chris Quirk, Bill Dolan and Luke Zettlemoyer .....	1669
<i>Public Dialogue: Analysis of Tolerance in Online Discussions</i> Arjun Mukherjee, Vivek Venkataraman, Bing Liu and Sharon Meraz .....	1680
<i>Offspring from Reproduction Problems: What Replication Failure Teaches Us</i> Antske Fokkens, Marieke van Erp, Marten Postma, Ted Pedersen, Piek Vossen and Nuno Freire	1691
<i>Evaluating Text Segmentation using Boundary Edit Distance</i> Chris Fournier .....	1702
<i>Crowd Prefers the Middle Path: A New IAA Metric for Crowdsourcing Reveals Turker Biases in Query Segmentation</i> Rohan Ramanath, Monojit Choudhury, Kalika Bali and Rishiraj Saha Roy .....	1713
<i>Deceptive Answer Prediction with User Preference Graph</i> Fangtao Li, Yang Gao, Shuchang Zhou, Xiance Si and Decheng Dai .....	1723
<i>Why-Question Answering using Intra- and Inter-Sentential Causal Relations</i> Jong-Hoon Oh, Kentaro Torisawa, Chikara Hashimoto, Motoki Sano, Stijn De Saeger and Kiyonori Ohtake .....	1733
<i>Question Answering Using Enhanced Lexical Semantic Models</i> Wen-tau Yih, Ming-Wei Chang, Christopher Meek and Andrzej Pastusiak .....	1744
<i>Syntactic Patterns versus Word Alignment: Extracting Opinion Targets from Online Reviews</i> Kang Liu, Liheng Xu and Jun Zhao .....	1754
<i>Mining Opinion Words and Opinion Targets in a Two-Stage Framework</i> Liheng Xu, Kang Liu, Siwei Lai, Yubo Chen and Jun Zhao .....	1764
<i>Connotation Lexicon: A Dash of Sentiment Beneath the Surface Meaning</i> Song Feng, Jun Seok Kang, Polina Kuznetsova and Yejin Choi .....	1774

# Conference Program

**Monday August 5, 2013**

**(7:30 - 17:00) Registration**

**(9:00 - 9:30) Opening session**

**(9:30) Invited Talk 1: Harald Baayen**

**(10:30) Coffee Break**

**Oral Presentations**

**(11:00 -12:15) LP 1a**

11:00 *A Shift-Reduce Parsing Algorithm for Phrase-based String-to-Dependency Translation*

Yang Liu

11:25 *Integrating Translation Memory into Phrase-Based Machine Translation during Decoding*

Kun Wang, Chengqing Zong and Keh-Yih Su

11:50 *Training Nondeficient Variants of IBM-3 and IBM-4 for Word Alignment*

Thomas Schoenemann

**(11:00 -12:15) LP 1b**

11:00 *Modelling Annotator Bias with Multi-task Gaussian Processes: An Application to Machine Translation Quality Estimation*

Trevor Cohn and Lucia Specia

11:25 *Smoothed marginal distribution constraints for language modeling*

Brian Roark, Cyril Allauzen and Michael Riley

11:50 *Grounded Language Learning from Video Described with Sentences*

Haonan Yu and Jeffrey Mark Siskind

**Monday August 5, 2013 (continued)**

**(11:00 -12:15) LP 1c**

- 11:00 *Plurality, Negation, and Quantification: Towards Comprehensive Quantifier Scope Disambiguation*  
Mehdi Manshadi, Daniel Gildea and James Allen
- 11:25 *Joint Event Extraction via Structured Prediction with Global Features*  
Qi Li, Heng Ji and Liang Huang
- 11:50 *Language-Independent Discriminative Parsing of Temporal Expressions*  
Gabor Angeli and Jakob Uszkoreit

**(11:00 -12:15) LP 1d**

- 11:00 *Graph-based Local Coherence Modeling*  
Camille Guinaudeau and Michael Strube
- 11:25 *Recognizing Rare Social Phenomena in Conversation: Empowerment Detection in Support Group Chatrooms*  
Elijah Mayfield, David Adamson and Carolyn Penstein Rosé
- 11:50 *Decentralized Entity-Level Modeling for Coreference Resolution*  
Greg Durrett, David Hall and Dan Klein

**(11:00 -12:15) LP 1e**

- 11:00 *Chinese Parsing Exploiting Characters*  
Meishan Zhang, Yue Zhang, Wanxiang Che and Ting Liu
- 11:25 *A Transition-Based Dependency Parser Using a Dynamic Parsing Strategy*  
Francesco Sartorio, Giorgio Satta and Joakim Nivre
- 11:50 *General binarization for parsing and translation*  
Matthias BÜchse, Alexander Koller and Heiko Vogler

**Monday August 5, 2013 (continued)**

**(12:15) Lunch break**

**(13:45 -15:00) LP 2a**

13:45 *Distortion Model Considering Rich Context for Statistical Machine Translation*  
Isao Goto, Masao Utiyama, Eiichiro Sumita, Akihiro Tamura and Sadao Kurohashi

14:10 *Word Alignment Modeling with Context Dependent Deep Neural Network*  
Nan Yang, Shujie Liu, Mu Li, Ming Zhou and Nenghai Yu

14:35 *Microblogs as Parallel Corpora*  
Wang Ling, Guang Xiang, Chris Dyer, Alan Black and Isabel Trancoso

**(13:45 -15:00) LP 2b**

13:45 *Improved Bayesian Logistic Supervised Topic Models with Data Augmentation*  
Jun Zhu, Xun Zheng and Bo Zhang

14:10 *Fast and Robust Compressive Summarization with Dual Decomposition and Multi-Task Learning*  
Miguel Almeida and Andre Martins

14:35 *Unsupervised Transcription of Historical Documents*  
Taylor Berg-Kirkpatrick, Greg Durrett and Dan Klein

**(13:45 -15:00) LP 2c**

13:45 *Adapting Discriminative Reranking to Grounded Language Learning*  
Joohyun Kim and Raymond Mooney

14:10 *Universal Conceptual Cognitive Annotation (UCCA)*  
Omri Abend and Ari Rappoport

14:35 *Linking Tweets to News: A Framework to Enrich Short Text Data in Social Media*  
Weiwei Guo, Hao Li, Heng Ji and Mona Diab

**Monday August 5, 2013 (continued)**

**(13:45 -15:00) LP 2d**

- 13:45 *A computational approach to politeness with application to social factors*  
Cristian Danescu-Niculescu-Mizil, Moritz Sudhof, Dan Jurafsky, Jure Leskovec and Christopher Potts
- 14:10 *Modeling Thesis Clarity in Student Essays*  
Isaac Persing and Vincent Ng
- 14:35 *Translating Italian connectives into Italian Sign Language*  
Camillo Lugaresi and Barbara Di Eugenio

**(13:45 -15:00) LP 2e**

- 13:45 *Stop-probability estimates computed on a large corpus improve Unsupervised Dependency Parsing*  
David Mareček and Milan Straka
- 14:10 *Transfer Learning for Constituency-Based Grammars*  
Yuan Zhang, Regina Barzilay and Amir Globerson
- 14:35 *A Context Free TAG Variant*  
Ben Swanson, Elif Yamangil, Eugene Charniak and Stuart Shieber

**(15:00 -16:15) LP 3a**

- 15:00 *Fast and Adaptive Online Training of Feature-Rich Translation Models*  
Spence Green, Sida Wang, Daniel Cer and Christopher D. Manning
- 15:25 *Advancements in Reordering Models for Statistical Machine Translation*  
Minwei Feng, Jan-Thorsten Peter and Hermann Ney
- 15:50 *A Markov Model of Machine Translation using Non-parametric Bayesian Inference*  
Yang Feng and Trevor Cohn

**Monday August 5, 2013 (continued)**

**(15:00 -16:15) LP 3b**

- 15:00 *Scaling Semi-supervised Naive Bayes with Feature Marginals*  
Michael Lucas and Doug Downey
- 15:25 *Learning Latent Personas of Film Characters*  
David Bamman, Brendan O'Connor and Noah A. Smith
- 15:50 *Scalable Decipherment for Machine Translation via Hash Sampling*  
Sujith Ravi

**(15:00 -16:15) LP 3c**

- 15:00 *Automatic Interpretation of the English Possessive*  
Stephen Tratz and Eduard Hovy
- 15:25 *Is a 204 cm Man Tall or Small ? Acquisition of Numerical Common Sense from the Web*  
Katsuma Narisawa, Yotaro Watanabe, Junta Mizuno, Naoaki Okazaki and Kentaro Inui
- 15:50 *Probabilistic Domain Modelling With Contextualized Distributional Semantic Vectors*  
Jackie Chi Kit Cheung and Gerald Penn

**(15:00 -16:15) LP 3d**

- 15:00 *Extracting bilingual terminologies from comparable corpora*  
Ahmet Aker, Monica Paramita and Rob Gaizauskas
- 15:25 *The Haves and the Have-Nots: Leveraging Unlabelled Corpora for Sentiment Analysis*  
Kashyap Popat, Balamurali A.R, Pushpak Bhattacharyya and Gholamreza Haffari
- 15:50 *Large-scale Semantic Parsing via Schema Matching and Lexicon Extension*  
Qingqing Cai and Alexander Yates

**Monday August 5, 2013 (continued)**

**(15:00 -16:15) LP 3e**

- 15:00 *Fast and Accurate Shift-Reduce Constituent Parsing*  
Muhua Zhu, Yue Zhang, Wenliang Chen, Min Zhang and Jingbo Zhu
- 15:25 *Nonconvex Global Optimization for Latent-Variable Models*  
Matthew R. Gormley and Jason Eisner

# A Shift-Reduce Parsing Algorithm for Phrase-based String-to-Dependency Translation

Yang Liu

State Key Laboratory of Intelligent Technology and Systems

Tsinghua University, Beijing 100084, China  
liuyang2011@tsinghua.edu.cn

## Abstract

We introduce a shift-reduce parsing algorithm for phrase-based string-to-dependency translation. As the algorithm generates dependency trees for partial translations left-to-right in decoding, it allows for efficient integration of both  $n$ -gram and dependency language models. To resolve conflicts in shift-reduce parsing, we propose a maximum entropy model trained on the derivation graph of training data. As our approach combines the merits of phrase-based and string-to-dependency models, it achieves significant improvements over the two baselines on the NIST Chinese-English datasets.

## 1 Introduction

Modern statistical machine translation approaches can be roughly divided into two broad categories: *phrase-based* and *syntax-based*. Phrase-based approaches treat phrase, which is usually a sequence of consecutive words, as the basic unit of translation (Koehn et al., 2003; Och and Ney, 2004). As phrases are capable of memorizing local context, phrase-based approaches excel at handling local word selection and reordering. In addition, it is straightforward to integrate  $n$ -gram language models into phrase-based decoders in which translation always grows left-to-right. As a result, phrase-based decoders only need to maintain the boundary words on one end to calculate language model probabilities. However, as phrase-based decoding usually casts translation as a string concatenation problem and permits arbitrary permutation, it proves to be NP-complete (Knight, 1999).

Syntax-based approaches, on the other hand, model the hierarchical structure of natural languages (Wu, 1997; Yamada and Knight, 2001; Chiang, 2005; Quirk et al., 2005; Galley et al.,

2006; Liu et al., 2006; Huang et al., 2006; Shen et al., 2008; Mi and Huang, 2008; Zhang et al., 2008). As syntactic information can be exploited to provide linguistically-motivated reordering rules, predicting non-local permutation is computationally tractable in syntax-based approaches. Unfortunately, as syntax-based decoders often generate target-language words in a bottom-up way using the CKY algorithm, integrating  $n$ -gram language models becomes more expensive because they have to maintain target boundary words at both ends of a partial translation (Chiang, 2007; Huang and Chiang, 2007). Moreover, syntax-based approaches often suffer from the rule coverage problem since syntactic constraints rule out a large portion of non-syntactic phrase pairs, which might help decoders generalize well to unseen data (Marcu et al., 2006). Furthermore, the introduction of non-terminals makes the grammar size significantly bigger than phrase tables and leads to higher memory requirement (Chiang, 2007).

As a result, incremental decoding with hierarchical structures has attracted increasing attention in recent years. While some authors try to integrate syntax into phrase-based decoding (Galley and Manning, 2008; Galley and Manning, 2009; Feng et al., 2010), others develop incremental algorithms for syntax-based models (Watanabe et al., 2006; Huang and Mi, 2010; Dyer and Resnik, 2010; Feng et al., 2012). Despite these successful efforts, challenges still remain for both directions. While parsing algorithms can be used to parse partial translations in phrase-based decoding, the search space is significantly enlarged since there are exponentially many parse trees for exponentially many translations. On the other hand, although target words can be generated left-to-right by altering the way of tree transversal in syntax-based models, it is still difficult to reach full rule coverage as compared with phrase table.

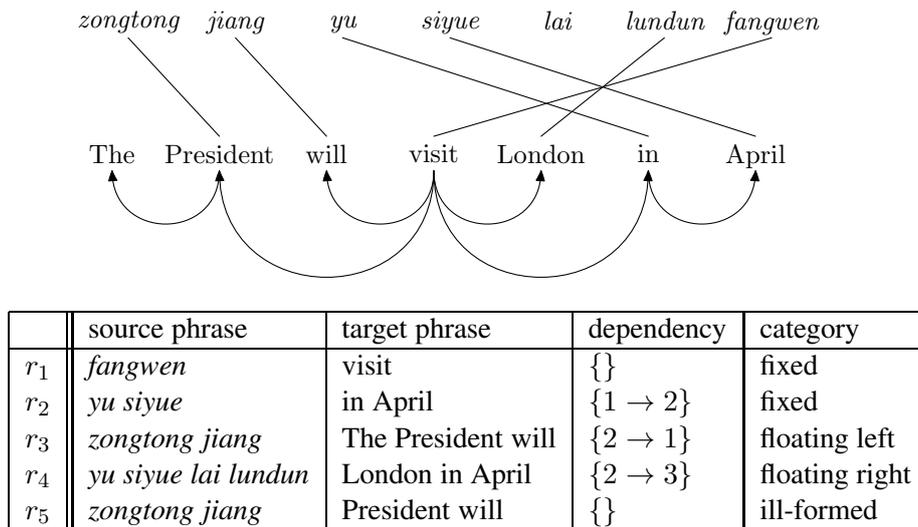

Figure 1: A training example consisting of a (romanized) Chinese sentence, an English dependency tree, and the word alignment between them. Each translation rule is composed of a source phrase, a target phrase with a set of dependency arcs. Following Shen et al. (2008), we distinguish between *fixed*, *floating*, and *ill-formed* structures.

In this paper, we propose a shift-reduce parsing algorithm for phrase-based string-to-dependency translation. The basic unit of translation in our model is *string-to-dependency phrase pair*, which consists of a phrase on the source side and a dependency structure on the target side. The algorithm generates well-formed dependency structures for partial translations left-to-right using string-to-dependency phrase pairs. Therefore, our approach is capable of combining the advantages of both phrase-based and syntax-based approaches:

1. **compact rule table:** our rule table is a subset of the original string-to-dependency grammar (Shen et al., 2008; Shen et al., 2010) by excluding rules with non-terminals.
2. **full rule coverage:** all phrase pairs, both syntactic and non-syntactic, can be used in our algorithm. This is the same with Moses (Koehn et al., 2007).
3. **efficient integration of  $n$ -gram language model:** as translation grows left-to-right in our algorithm, integrating  $n$ -gram language models is straightforward.
4. **exploiting syntactic information:** as the shift-reduce parsing algorithm generates target language dependency trees in decoding, dependency language models (Shen et al., 2008; Shen et al., 2010) can be used to encourage linguistically-motivated reordering.

5. **resolving local parsing ambiguity:** as dependency trees for phrases are memorized in rules, our approach avoids resolving local parsing ambiguity and explores in a smaller search space than parsing word-by-word on the fly in decoding (Galley and Manning, 2009).

We evaluate our method on the NIST Chinese-English translation datasets. Experiments show that our approach significantly outperforms both phrase-based (Koehn et al., 2007) and string-to-dependency approaches (Shen et al., 2008) in terms of BLEU and TER.

## 2 Shift-Reduce Parsing for Phrase-based String-to-Dependency Translation

Figure 1 shows a training example consisting of a (romanized) Chinese sentence, an English dependency tree, and the word alignment between them. Following Shen et al. (2008), string-to-dependency rules without non-terminals can be extracted from the training example. As shown in Figure 1, each rule is composed of a source phrase and a target dependency structure. Shen et al. (2008) divide dependency structures into two broad categories:

### 1. well-formed

- (a) **fixed:** the head is known or fixed;

step	action	rule	stack	coverage
0				○ ○ ○ ○ ○ ○ ○ ○
1	$S$	$r_3$	[The President will]	● ● ○ ○ ○ ○ ○ ○
2	$S$	$r_1$	[The President will] [visit]	● ● ○ ○ ○ ○ ●
3	$R_l$		[The President will visit]	● ● ○ ○ ○ ○ ●
4	$S$	$r_4$	[The President will visit] [London in April]	● ● ● ● ● ● ●
5	$R_r$		[The President will visit London in April]	● ● ● ● ● ● ●

Figure 2: Shift-reduce parsing with string-to-dependency phrase pairs. For each state, the algorithm maintains a stack to store items (i.e., well-formed dependency structures). At each step, it chooses one action to extend a state: shift ( $S$ ), reduce left ( $R_l$ ), or reduce right ( $R_r$ ). The decoding process terminates when all source words are covered and there is a complete dependency tree in the stack.

(b) **floating**: sibling nodes of a common head, but the head itself is unspecified or floating. Each of the siblings must be a complete constituent.

2. **ill-formed**: neither fixed nor floating.

We further distinguish between *left* and *right* floating structures according to the position of head. For example, as “The President will” is the left dependant of its head “visit”, it is a left floating structure.

To integrate the advantages of phrase-based and string-to-dependency models, we propose a shift-reduce algorithm for phrase-based string-to-dependency translation.

Figure 2 shows an example. We describe a *state* (i.e., parser configuration) as a tuple  $\langle \mathcal{S}, \mathcal{C} \rangle$  where  $\mathcal{S}$  is a *stack* that stores *items* and  $\mathcal{C}$  is a *coverage vector* that indicates which source words have been translated. Each item  $s \in \mathcal{S}$  is a well-formed dependency structure. The algorithm starts with an empty state. At each step, it chooses one of the three actions (Huang et al., 2009) to extend a state:

1. **shift** ( $S$ ): move a target dependency structure onto the stack;

2. **reduce left** ( $R_l$ ): combine the two items on the stack,  $s_t$  and  $s_{t-1}$  ( $t \geq 2$ ), with the root of  $s_t$  as the head and replace them with a combined item;

3. **reduce right** ( $R_r$ ): combine the two items on the stack,  $s_t$  and  $s_{t-1}$  ( $t \geq 2$ ), with the root of  $s_{t-1}$  as the head and replace them with a combined item.

The decoding process terminates when all source words are covered and there is a complete dependency tree in the stack.

Note that unlike monolingual shift-reduce parsers (Nivre, 2004; Zhang and Clark, 2008; Huang et al., 2009), our algorithm does not maintain a queue for remaining words of the input because the future dependency structure to be shifted is unknown in advance in the translation scenario. Instead, we use a coverage vector on the source side to determine when to terminate the algorithm.

For an input sentence of  $J$  words, the number of actions is  $2K - 1$ , where  $K$  is the number of rules used in decoding.<sup>1</sup> There are always  $K$  shifts and

<sup>1</sup>Empirically, we find that the average number of stacks for  $J$  words is about  $1.5 \times J$  on the Chinese-English data.

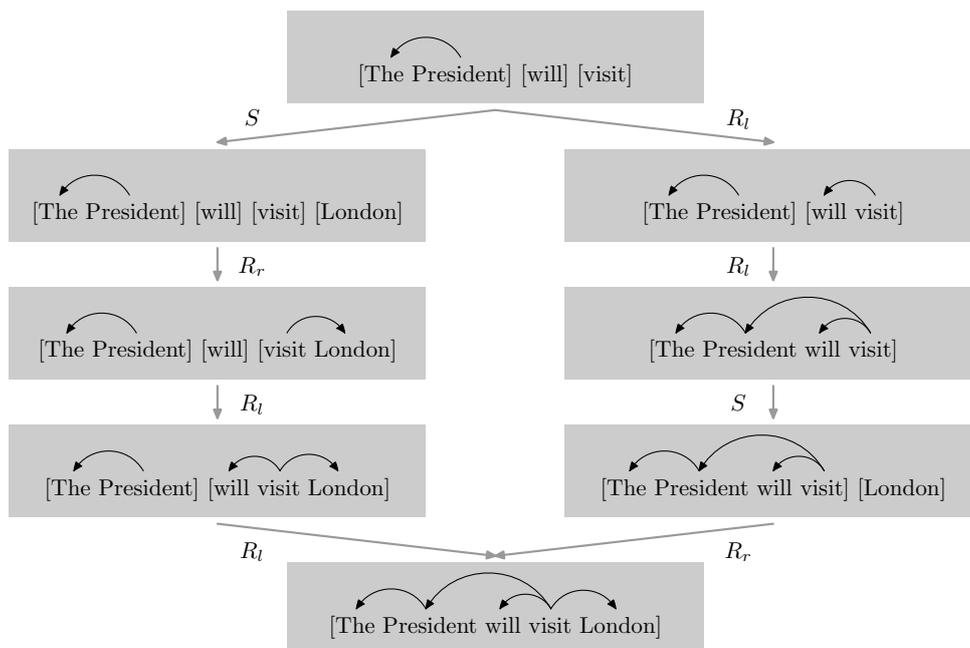

Figure 3: Ambiguity in shift-reduce parsing.

$s_{t-1}$	$s_t$	legal	action(s)
		yes	$S$
	h	yes	$S$
	l	yes	$S$
	r	no	
h	h	yes	$S, R_l, R_r$
h	l	yes	$S$
h	r	yes	$R_r$
l	h	yes	$R_l$
l	l	yes	$S$
l	r	no	
r	h	no	
r	l	no	
r	r	no	

Table 1: Conflicts in shift-reduce parsing.  $s_t$  and  $s_{t-1}$  are the top two items in the stack of a state. We use “h” to denote fixed structure, “l” to denote left floating structure, and “r” to denote right floating structure. It is clear that only “h+h” is ambiguous.

$K - 1$  reductions.

It is easy to verify that the reduce left and reduce right actions are equivalent to the left adjoining and right adjoining operations defined by Shen et al. (2008). They suffice to operate on well-formed structures and produce projective dependency parse trees.

Therefore, with dependency structures present in the stacks, it is possible to use dependency language models to encourage linguistically plausible phrase reordering.

### 3 A Maximum Entropy Based Shift-Reduce Parsing Model

Shift-reduce parsing is efficient but suffers from parsing errors caused by syntactic ambiguity. Figure 3 shows two (partial) derivations for a dependency tree. Consider the item on the top, the algorithm can either apply a shift action to move a new item or apply a reduce left action to obtain a bigger structure. This is often referred to as **conflict** in the shift-reduce dependency parsing literature (Huang et al., 2009). In this work, the shift-reduce parser faces four types of conflicts:

1. shift vs. shift;
2. shift vs. reduce left;
3. shift vs. reduce right;
4. reduce left vs. reduce right.

Fortunately, if we distinguish between left and right floating structures, it is possible to rule out most conflicts. Table 1 shows the relationship between conflicts, dependency structures and actions. We use  $s_t$  and  $s_{t-1}$  to denote the top two

	$T_h(s_{t-1})$	$T_{lc}(s_t)$	$T_{rc}(s_{t-1})$
Bigram	$W_h(s_t) \circ W_h(s_{t-1})$	$T_h(s_t) \circ T_h(s_{t-1})$	$W_h(s_t) \circ T_h(s_t)$
	$W_h(s_{t-1}) \circ T_h(s_{t-1})$	$W_h(s_t) \circ W_{rc}(s_{t-1})$	$W_h(s_{t-1}) \circ W_{lc}(s_t)$
Trigram	$c \circ W_h(s_t) \circ W_h(s_{t-1})$	$c \circ T_h(s_t) \circ T_h(s_{t-1})$	$W_h(s_t) \circ W_h(s_{t-1}) \circ T_{lc}(s_t)$
	$W_h(s_t) \circ W_h(s_{t-1}) \circ T_{rc}(s_{t-1})$	$T_h(s_t) \circ T_h(s_{t-1}) \circ T_{lc}(s_t)$	$T_h(s_t) \circ T_h(s_{t-1}) \circ T_{rc}(s_{t-1})$

Figure 4: Feature templates for maximum entropy based shift-reduce parsing model.  $c$  is a boolean value that indicate whether all source words are covered (shift is prohibited if true),  $W_h(\cdot)$  and  $T_h(\cdot)$  are functions that get the root word and tag of an item,  $W_{lc}(\cdot)$  and  $T_{lc}(\cdot)$  returns the word and tag of the left most child of the root,  $W_{rc}(\cdot)$  and  $T_{rc}(\cdot)$  returns the word and tag of the right most child of the root. Symbol  $\circ$  denotes feature conjunction. In this example,  $c = true$ ,  $W_h(s_t) = in$ ,  $T_h(s_t) = IN$ ,  $W_h(s_{t-1}) = visit$ ,  $W_{lc}(s_{t-1}) = London$ .

items in the stack. “h” stands for fixed structure, “l” for left floating structure, and “r” for right floating structure. If the stack is empty, the only applicable action is shift. If there is only one item in the stack and the item is either fixed or left floating, the only applicable action is shift. Note that it is illegal to shift a right floating structure onto an empty stack because it will never be reduced. If the stack contains at least two items, only “h+h” is ambiguous and the others are either unambiguous or illegal. Therefore, we only need to focus on how to resolve conflicts for the “h+h” case (i.e., the top two items in a stack are both fixed structures).

We propose a maximum entropy model to resolve the conflicts for “h+h”:<sup>2</sup>

$$P_\theta(a|c, s_t, s_{t-1}) = \frac{\exp(\theta \cdot h(a, c, s_t, s_{t-1}))}{\sum_a \exp(\theta \cdot h(a, c, s_t, s_{t-1}))}$$

where  $a \in \{S, R_l, R_r\}$  is an action,  $c$  is a boolean value that indicates whether all source words are covered (shift is prohibited if true),  $s_t$  and  $s_{t-1}$  are the top two items on the stack,  $h(a, c, s_t, s_{t-1})$  is a vector of binary features and  $\theta$  is a vector of feature weights.

Figure 4 shows the feature templates used in our experiments.  $W_h(\cdot)$  and  $T_h(\cdot)$  are functions that get the root word and tag of an item,  $W_{lc}(\cdot)$  and  $T_{lc}(\cdot)$  returns the word and tag of the left most child of the root,  $W_{rc}(\cdot)$  and  $T_{rc}(\cdot)$  returns the

<sup>2</sup>The shift-shift conflicts always exist because there are usually multiple rules that can be shifted. This can be resolved using standard features in phrase-based models.

word and tag of the right most child of the root. In this example,  $c = true$ ,  $W_h(s_t) = in$ ,  $T_h(s_t) = IN$ ,  $W_h(s_{t-1}) = visit$ ,  $W_{lc}(s_{t-1}) = London$ .

To train the model, we need an “oracle” or gold-standard action sequence for each training example. Unfortunately, such oracle turns out to be non-unique even for monolingual shift-reduce dependency parsing (Huang et al., 2009). The situation for phrase-based shift-reduce parsing aggravates because there are usually multiple ways of segmenting sentence into phrases.

To alleviate this problem, we introduce a structure called **derivation graph** to compactly represent all derivations of a training example. Figure 3 shows a (partial) derivation graph, in which a node corresponds to a state and an edge corresponds to an action. The graph begins with an empty state and ends with the given training example.

More formally, a derivation graph is a directed acyclic graph  $G = \langle V, E \rangle$  where  $V$  is a set of nodes and  $E$  is a set of edges. Each node  $v$  corresponds to a state in the shift-reduce parsing process. There are two distinguished nodes:  $v_0$ , the starting empty state, and  $v_{|V|}$ , the ending completed state. Each edge  $e = (a, i, j)$  transits node  $v_i$  to node  $v_j$  via an action  $a \in \{S, R_l, R_r\}$ .

To build the derivation graph, our algorithm starts with an empty state and iteratively extends an unprocessed state until reaches the completed state. During the process, states that violate the training example are discarded. Even so, there are still exponentially many states for a training example, especially for long sentences. Fortunately, we

only need to focus on “h+h” states. In addition, we follow Huang et al. (2009) to use the heuristic of “shortest stack” to always prefer  $R_l$  to  $S$ .

## 4 Decoding

Our decoder is based on a linear model (Och, 2003) with the following features:

1. relative frequencies in two directions;
2. lexical weights in two directions;
3. phrase penalty;
4. distance-based reordering model;
5. lexicaized reordering model;
6.  $n$ -gram language model model;
7. word penalty;
8. ill-formed structure penalty;
9. dependency language model;
10. maximum entropy parsing model.

In practice, we extend deterministic shift-reduce parsing with beam search (Zhang and Clark, 2008; Huang et al., 2009). As shown in Algorithm 1, the algorithm maintains a list of stacks  $\mathcal{V}$  and each stack groups states with the same number of accumulated actions (line 2). The stack list  $\mathcal{V}$  initializes with an empty state  $v_0$  (line 3). Then, the states in the stack are iteratively extended until there are no incomplete states (lines 4-12). The search space is constrained by discarding any state that has a score worse than:

1.  $\beta$  multiplied with the best score in the stack, or
2. the score of  $b$ -th best state in the stack.

As the stack of a state keeps changing during the decoding process, the context information needed to calculate dependency language model and maximum entropy model probabilities (e.g., root word, leftmost child, etc.) changes dynamically as well. As a result, the chance of risk-free *hypothesis recombination* (Koehn et al., 2003) significantly decreases because complicated contextual information is much less likely to be identical.

Therefore, we use *hypergraph reranking* (Huang and Chiang, 2007; Huang, 2008), which proves to be effective for integrating non-local features into dynamic programming, to alleviate this problem. The decoding process is divided into two passes. In the first pass, only **standard features** (i.e., features 1-7 in the list in the beginning of this section) are used to produce a hypergraph.<sup>3</sup> In the second pass, we use the hypergraph reranking algorithm (Huang, 2008) to find promising translations using additional **dependency features** (i.e., features 8-10 in the list). As hypergraph is capable of storing exponentially many derivations compactly, the negative effect of propagating mistakes made in the first pass to the second pass can be minimized.

To improve rule coverage, we follow Shen et al. (2008) to use ill-formed structures in decoding. If an ill-formed structure has a single root, it can be treated as a (pseudo) fixed structure; otherwise it is transformed to one (pseudo) left floating structure and one (pseudo) right floating structure. We use a feature to count how many ill-formed structures are used in decoding.

## 5 Experiments

We evaluated our phrase-based string-to-dependency translation system on Chinese-English translation. The training data consists of 2.9M pairs of sentences with 76.0M Chinese words and 82.2M English words. We used the Stanford parser (Klein and Manning, 2003) to get dependency trees for English sentences. We used the SRILM toolkit (Stolcke, 2002) to train a

---

<sup>3</sup>Note that the first pass does not work like a phrase-based decoder because it yields dependency trees on the target side. A uniform model (i.e., each action has a fixed probability of 1/3) is used to resolve “h+h” conflicts.

Table 2: Comparison with Moses (Koehn et al., 2007) and a re-implementation of the bottom-up string-to-dependency decoder (Shen et al., 2008) in terms of uncased BLEU and TER. We use randomization test (Riezler and Maxwell, 2005) to calculate statistical significance. \*: significantly better than Moses ( $p < 0.05$ ), \*\*: significantly better than Moses ( $p < 0.01$ ), +: significantly better than string-to-dependency ( $p < 0.05$ ), ++: significantly better than string-to-dependency ( $p < 0.01$ ).

features	BLEU	TER
standard	34.79	56.93
+ depLM	35.29*	56.17**
+ maxent	35.40**	56.09**
+ depLM & maxent	35.71**	55.87**

Table 3: Contribution of maximum entropy shift-reduce parsing model. “standard” denotes using standard features of phrase-based system. Adding dependency language model (“depLM”) and the maximum entropy shift-reduce parsing model (“maxent”) significantly improves BLEU and TER on the development set, both separately and jointly.

4-gram language model on the Xinhua portion of the GIGAWORD corpus, which contains 238M English words. A 3-gram dependency language model was trained on the English dependency trees. We used the 2002 NIST MT Chinese-English dataset as the development set and the 2003-2005 NIST datasets as the testsets. We evaluated translation quality using *uncased* BLEU (Papineni et al., 2002) and TER (Snover et al., 2006). The features were optimized with respect to BLEU using the minimum error rate training algorithm (Och, 2003).

We chose the following two systems that are closest to our work as baselines:

1. The Moses phrase-based decoder (Koehn et al., 2007).
2. A re-implementation of bottom-up string-to-dependency decoder (Shen et al., 2008).

All the three systems share with the same target-side parsed, word-aligned training data. The histogram pruning parameter  $b$  is set to 100 and

rules	coverage	BLEU	TER
well-formed	44.87	34.42	57.35
all	100.00	35.71**	55.87**

Table 4: Comparison of well-formed and ill-formed structures. Using all rules significantly outperforms using only well-formed structures. BLEU and TER scores are calculated on the development set.

phrase table limit is set to 20 for all the three systems. Moses shares the same feature set with our system except for the dependency features. For the bottom-up string-to-dependency system, we included both well-formed and ill-formed structures in chart parsing. To control the grammar size, we only extracted “tight” initial phrase pairs (i.e., the boundary words of a phrase must be aligned) as suggested by (Chiang, 2007). For our system, we used the Le Zhang’s maximum entropy modeling toolkit to train the shift-reduce parsing model after extracting 32.6M events from the training data.<sup>4</sup> We set the iteration limit to 100. The accuracy on the training data is 90.18%.

Table 2 gives the performance of Moses, the bottom-up string-to-dependency system, and our system in terms of uncased BLEU and TER scores. From the same training data, Moses extracted 103M bilingual phrases, the bottom-up string-to-dependency system extracted 587M string-to-dependency rules, and our system extracted 124M phrase-based dependency rules. We find that our approach outperforms both baselines systematically on all testsets. We use randomization test (Riezler and Maxwell, 2005) to calculate statistical significance. As our system can take full advantage of lexicalized reordering and depen-

<sup>4</sup><http://homepages.inf.ed.ac.uk/lzhang10/maxent.html>

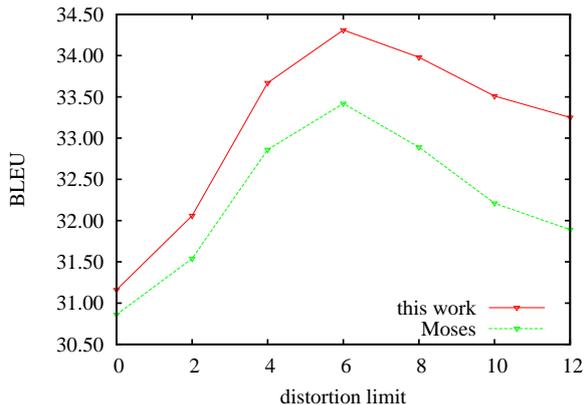

Figure 5: Performance of Moses and our system with various distortion limits.

dependency language models without loss in rule coverage, it achieves significantly better results than Moses on all test sets. The gains in TER are much larger than BLEU because dependency language models do not model  $n$ -grams directly. Compared with the bottom-up string-to-dependency system, our system outperforms consistently but not significantly in all cases. The average decoding time for Moses is 3.67 seconds per sentence, bottom-up string-to-dependency is 13.89 seconds, and our system is 4.56 seconds.

Table 3 shows the effect of hypergraph reranking. In the first pass, our decoder uses standard phrase-based features to build a hypergraph. The BLEU score is slightly lower than Moses with the same configuration. One possible reason is that our decoder organizes stacks with respect to actions, whereas Moses groups partial translations with the same number of covered source words in stacks. In the second pass, our decoder reranks the hypergraph with additional dependency features. We find that adding dependency language and maximum entropy shift-reduce models consistently brings significant improvements, both separately and jointly.

We analyzed translation rules extracted from the training data. Among them, well-formed structures account for 43.58% (fixed 33.21%, floating left 9.01%, and floating right 1.36%) and ill-formed structures 56.42%. As shown in Table 4, using all rules clearly outperforms using only well-formed structures.

Figure 5 shows the performance of Moses and our system with various distortion limits on the development set. Our system consistently outper-

forms Moses in all cases, suggesting that adding dependency helps improve phrase reordering.

## 6 Related Work

The work of Galley and Manning (2009) is closest in spirit to ours. They introduce maximum spanning tree (MST) parsing (McDonald et al., 2005) into phrase-based translation. The system is phrase-based except that an MST parser runs to parse partial translations at the same time. One challenge is that MST parsing itself is not incremental, making it expensive to identify loops during hypothesis expansion. On the contrary, shift-reduce parsing is naturally incremental and can be seamlessly integrated into left-to-right phrase-based decoding. More importantly, in our work dependency trees are memorized for phrases rather than being generated word by word on the fly in decoding. This treatment might not only reduce decoding complexity but also potentially revolve local parsing ambiguity.

Our decoding algorithm is similar to Gimpel and Smith (2011)’s lattice parsing algorithm as we divide decoding into two steps: hypergraph generation and hypergraph rescoring. The major difference is that our hypergraph is not a phrasal lattice because each phrase pair is associated with a dependency structure on the target side. In other words, our second pass is to find the Viterbi derivation with addition features rather than parsing the phrasal lattice. In addition, their algorithm produces phrasal dependency parse trees while the leaves of our dependency trees are words, making dependency language models can be directly used.

Shift-reduce parsing has been successfully used in phrase-based decoding but limited to adding structural constraints. Galley and Manning (2008) propose a shift-reduce algorithm to integrate a hierarchical reordering model into phrase-based systems. Feng et al. (2010) use shift-reduce parsing to impose ITG (Wu, 1997) constraints on phrase permutation. Our work differs from theirs by going further to incorporate linguistic syntax into phrase-based decoding.

Along another line, a number of authors have developed incremental algorithms for syntax-based models (Watanabe et al., 2006; Huang and Mi, 2010; Dyer and Resnik, 2010; Feng et al., 2012). Watanabe et al. (2006) introduce an Early-style top-down parser based on binary-branching Greibach Normal Form. Huang et al. (2010), Dyer

and Resnik (2010), and Feng et al. (2012) use dotted rules to change the tree transversal to generate target words left-to-right, either top-down or bottom-up.

## 7 Conclusion

We have presented a shift-reduce parsing algorithm for phrase-based string-to-dependency translation. The algorithm generates dependency structures incrementally using string-to-dependency phrase pairs. Therefore, our approach is capable of combining the advantages of both phrase-based and string-to-dependency models, it outperforms the two baselines on Chinese-to-English translation.

In the future, we plan to include more contextual information (e.g., the uncovered source phrases) in the maximum entropy model to resolve conflicts. Another direction is to adapt the dynamic programming algorithm proposed by Huang and Sagae (2010) to improve our string-to-dependency decoder. It is also interesting to compare with applying word-based shift-reduce parsing to phrase-based decoding similar to (Galley and Manning, 2009).

## Abstract

Since statistical machine translation (SMT) and translation memory (TM) complement each other in matched and unmatched regions, integrated models are proposed in this paper to incorporate TM information into phrase-based SMT. Unlike previous multi-stage pipeline approaches, which directly merge TM result into the final output, the proposed models refer to the corresponding TM information associated with each phrase at SMT decoding. On a Chinese–English TM database, our experiments show that the proposed integrated Model-III is significantly better than either the SMT or the TM systems when the fuzzy match score is above 0.4. Furthermore, integrated Model-III achieves overall 3.48 BLEU points improvement and 2.62 TER points reduction in comparison with the pure SMT system. Besides, the proposed models also outperform previous approaches significantly.

## 1 Introduction

Statistical machine translation (SMT), especially the phrase-based model (Koehn et al., 2003), has developed very fast in the last decade. For certain language pairs and special applications, SMT output has reached an acceptable level, especially in the domains where abundant parallel corpora are available (He et al., 2010). However, SMT is rarely applied to professional translation because its output quality is still far from satisfactory. Especially, there is no guarantee that a SMT system can produce translations in a consistent manner (Ma et al., 2011).

In contrast, translation memory (TM), which uses the most similar translation sentence (usually above a certain fuzzy match threshold) in the database as the reference for post-editing, has

been widely adopted in professional translation field for many years (Lagoudaki, 2006). TM is very useful for repetitive material such as updated product manuals, and can give high quality and consistent translations when the similarity of fuzzy match is high. Therefore, professional translators trust TM much more than SMT. However, high-similarity fuzzy matches are available unless the material is very repetitive.

In general, for those matched segments<sup>1</sup>, TM provides more reliable results than SMT does. One reason is that the results of TM have been revised by human according to the global context, but SMT only utilizes local context. However, for those unmatched segments, SMT is more reliable. Since TM and SMT complement each other in those matched and unmatched segments, the output quality is expected to be raised significantly if they can be combined to supplement each other.

In recent years, some previous works have incorporated TM matched segments into SMT in a pipelined manner (Koehn and Senellart, 2010; Zhechev and van Genabith, 2010; He et al., 2011; Ma et al., 2011). All these pipeline approaches translate the sentence in two stages. They first determine whether the extracted TM sentence pair should be adopted or not. Most of them use fuzzy match score as the threshold, but He et al. (2011) and Ma et al. (2011) use a classifier to make the judgment. Afterwards, they merge the relevant translations of matched segments into the source sentence, and then force the SMT system to only translate those unmatched segments at decoding.

There are three obvious drawbacks for the above pipeline approaches. Firstly, all of them determine whether those matched segments

---

<sup>1</sup> We mean “sub-sentential segments” in this work.

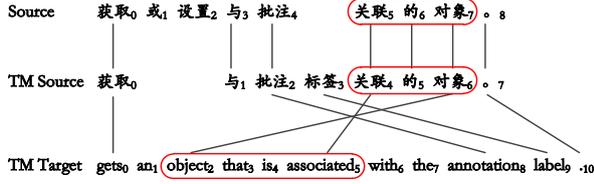

Figure 1: Phrase Mapping Example

should be adopted or not at sentence level. That is, they are either all adopted or all abandoned regardless of their individual quality. Secondly, as several TM target phrases might be available for one given TM source phrase due to insertions, the incorrect selection made in the merging stage cannot be remedied in the following translation stage. For example, there are six possible corresponding TM target phrases for the given TM source phrase “关联<sub>4</sub> 的<sub>5</sub> 对象<sub>6</sub>” (as shown in Figure 1) such as “object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>”, and “an<sub>1</sub> object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub> with<sub>6</sub>”, etc. And it is hard to tell which one should be adopted in the merging stage. Thirdly, the pipeline approach does not utilize the SMT probabilistic information in deciding whether a matched TM phrase should be adopted or not, and which target phrase should be selected when we have multiple candidates. Therefore, the possible improvements resulted from those pipeline approaches are quite limited.

On the other hand, instead of directly merging TM matched phrases into the source sentence, some approaches (Bi çici and Dymetman, 2008; Simard and Isabelle, 2009) simply add the longest matched pairs into SMT phrase table, and then associate them with a fixed large probability value to favor the corresponding TM target phrase at SMT decoding. However, since only one aligned target phrase will be added for each matched source phrase, they share most drawbacks with the pipeline approaches mentioned above and merely achieve similar performance.

To avoid the drawbacks of the pipeline approach (mainly due to making a hard decision *before* decoding), we propose several integrated models to completely make use of TM information *during* decoding. For each TM source phrase, we keep all its possible corresponding target phrases (instead of keeping only one of them). The integrated models then consider all corresponding TM target phrases and SMT preference during decoding. Therefore, the proposed integrated models combine SMT and TM at a deep level (versus the surface level at which TM result is directly plugged in under previous pipeline approaches).

On a Chinese–English computer technical documents TM database, our experiments have shown that the proposed Model-III improves the translation quality significantly over either the pure phrase-based SMT or the TM systems when the fuzzy match score is above 0.4. Compared with the pure SMT system, the proposed integrated Model-III achieves 3.48 BLEU points improvement and 2.62 TER points reduction overall. Furthermore, the proposed models significantly outperform previous pipeline approaches.

## 2 Problem Formulation

Compared with the standard phrase-based machine translation model, the translation problem is reformulated as follows (only based on the best TM, however, it is similar for multiple TM sentences):

$$\hat{t} = \arg \max_t P(t|s, [tm\_s, tm\_t, tm\_f, s\_a, tm\_a]) \quad (1)$$

Where  $s$  is the given source sentence to be translated,  $t$  is the corresponding target sentence and  $\hat{t}$  is the final translation;  $[tm\_s, tm\_t, tm\_f, s\_a, tm\_a]$  are the associated information of the best TM sentence-pair;  $tm\_s$  and  $tm\_t$  denote the corresponding TM sentence pair;  $tm\_f$  denotes its associated fuzzy match score (from 0.0 to 1.0);  $s\_a$  is the editing operations between  $tm\_s$  and  $s$ ; and  $tm\_a$  denotes the word alignment between  $tm\_s$  and  $tm\_t$ .

Let  $\bar{s}_{a(k)}$  and  $\bar{t}_k$  denote the  $k$ -th associated source phrase and target phrase, respectively. Also,  $\bar{s}_{a(1)}^{a(K)}$  and  $\bar{t}_1^K$  denote the associated source phrase sequence and the target phrase sequence, respectively (total  $K$  phrases without insertion). Then the above formula (1) can be decomposed as below:

$$\begin{aligned} \hat{t} &= \arg \max_t P(t|s, tm\_s, tm\_t, tm\_f, s\_a, tm\_a) \\ &= \arg \max_t \sum_{[\bar{s}_1^K = s, \bar{t}_1^K = t]} P(\bar{t}_1^K | \bar{s}_{a(1)}^{a(K)} | s, tm\_s, tm\_t, tm\_f, s\_a, tm\_a) \\ &\triangleq \arg \max_t \max_{[\bar{s}_1^K = s, \bar{t}_1^K = t]} \left\{ P(\bar{t}_1^K | \bar{s}_{a(1)}^{a(K)}, tm\_s, tm\_t, tm\_f, s\_a, tm\_a) \right\} \\ &\quad \times P(\bar{s}_1^K | s) \end{aligned} \quad (2)$$

Afterwards, for any given source phrase  $\bar{s}_{a(k)}$ , we can find its corresponding TM source phrase  $tm\_s_{\bar{s}_{a(k)}}$  and all possible TM target phrases (each of them is denoted by  $tm\_t_{\bar{t}_{a(k)}}$ ) with the help of corresponding editing operations  $s\_a$  and word alignment  $tm\_a$ . As mentioned above, we can have six different possible TM target phrases for the TM source phrase “关联<sub>4</sub> 的<sub>5</sub> 对象<sub>6</sub>”. This

is because there are insertions around the directly aligned TM target phrase.

In the above Equation (2), we first segment the given source sentence into various phrases, and then translate the sentence based on those source phrases. Also,  $\bar{s}_{a(1)}^{a(K)}$  is replaced by  $\bar{s}_1^K$ , as they are actually the same segmentation sequence. Assume that the segmentation probability  $P(\bar{s}_1^K|s)$  is a uniform distribution, with the corresponding TM source and target phrases obtained above, this problem can be further simplified as follows:

$$\begin{aligned}
& P(\bar{t}_1^K | \bar{s}_{a(1)}^{a(K)}, tm\_s, tm\_t, tm\_f, s\_a, tm\_a) \\
&= \sum_{tm\_t_{a(1)}^{a(K)}} P(\bar{t}_1^K, tm\_t_{a(1)}^{a(K)} | \bar{s}_{a(1)}^{a(K)}, tm\_s_{a(1)}^{a(K)}, tm\_t, z) \\
&\approx \max_{tm\_t_{a(1)}^{a(K)}} P(\bar{t}_1^K, tm\_t_{a(1)}^{a(K)} | \bar{s}_{a(1)}^{a(K)}, tm\_s_{a(1)}^{a(K)}, tm\_t, z) \\
&\approx \max_{tm\_t_{a(1)}^{a(K)}} P(\bar{t}_1^K, M_1^K | \bar{s}_{a(1)}^{a(K)}, L_1^K, z) \\
&\approx P(\bar{t}_1^K | \bar{s}_{a(1)}^{a(K)}) \times \prod_{k=1}^K \max_{tm\_t_{a(k)}} P(M_k | L_k, z)
\end{aligned} \tag{3}$$

Where  $M_k$  is the corresponding TM phrase matching status for  $\bar{t}_k$ , which is a vector consisting of various indicators (e.g., Target Phrase Content Matching Status, etc., to be defined later), and reflects the quality of the given candidate;  $L_k$  is the linking status vector of  $\bar{s}_{a(k)}$  (the aligned source phrase of  $\bar{t}_k$  within  $\bar{s}_1^K$ ), and indicates the matching and linking status in the source side (which is closely related to the status in the target side); also,  $z$  indicates the corresponding TM fuzzy match interval specified later.

In the second line of Equation (3), we convert the fuzzy match score  $tm\_f$  into its corresponding interval  $z$ , and incorporate all possible combinations of TM target phrases. Afterwards, we select the best one in the third line. Last, in the fourth line, we introduce the source matching status and the target linking status (detailed features would be defined later). Since we might have several possible TM target phrases  $tm\_t_{a(k)}$ , the one with the maximum score will be adopted during decoding.

The first factor  $P(\bar{t}_1^K | \bar{s}_{a(1)}^{a(K)})$  in the above formula (3) is just the typical phrase-based SMT model, and the second factor  $P(M_k | L_k, z)$  (to be specified in the Section 3) is the information derived from the TM sentence pair. Therefore, we can still keep the original phrase-based SMT model and only pay attention to how to extract

useful information from the best TM sentence pair to guide SMT decoding.

### 3 Proposed Models

Three integrated models are proposed to incorporate different features as follows:

#### 3.1 Model-I

In this simplest model, we only consider *Target Phrase Content Matching Status* (TCM) for  $M_k$ . For  $L_k$ , we consider four different features at the same time: *Source Phrase Content Matching Status* (SCM), *Number of Linking Neighbors* (NLN), *Source Phrase Length* (SPL), and *Sentence End Punctuation Indicator* (SEP). Those features will be defined below.  $P(M_k | L_k, z)$  is then specified as:

$$P(M_k | L_k, z) \triangleq P(TCM_k | SCM_k, NLN_k, SPL_k, SEP_k, z)$$

All features incorporated in this model are specified as follows:

**TM Fuzzy Match Interval (z):** The *fuzzy match score* (FMS) between source sentence  $s$  and TM source sentence  $tm\_s$  indicates the reliability of the given TM sentence, and is defined as (Sikes, 2007):

$$FMS(s, tm\_s) = 1 - \frac{\text{Levenshtein}(s, tm\_s)}{\max(|s|, |tm\_s|)}$$

Where  $\text{Levenshtein}(s, tm\_s)$  is the word-based Levenshtein Distance (Levenshtein, 1966) between  $s$  and  $tm\_s$ . We equally divide FMS into ten fuzzy match intervals such as: [0.9, 1.0), [0.8, 0.9) etc., and the index  $z$  specifies the corresponding interval. For example, since the fuzzy match score between  $s$  and  $tm\_s$  in Figure 1 is 0.667, then  $z = [0.6, 0.7)$ .

**Target Phrase Content Matching Status (TCM):** It indicates the content matching status between  $\bar{t}_k$  and  $tm\_t_{a(k)}$ , and reflects the quality of  $\bar{t}_k$ . Because  $tm\_t$  is nearly perfect when FMS is high, if the similarity between  $\bar{t}_k$  and  $tm\_t_{a(k)}$  is high, it implies that the given  $\bar{t}_k$  is possibly a good candidate. It is a member of  $\{Same, High, Low, NA (Not-Applicable)\}$ , and is specified as:

- (1) If  $tm\_t_{a(k)}$  is not null:
  - (a) if  $FMS(\bar{t}_k, tm\_t_{a(k)}) = 1.0$ ,  $TCM_k = Same$ ;
  - (b) else if  $FMS(\bar{t}_k, tm\_t_{a(k)}) > 0.5$ ,  $TCM_k = High$ ;
  - (c) else,  $TCM_k = Low$ ;
- (2) If  $tm\_t_{a(k)}$  is null,  $TCM_k = NA$ ;

Here  $tm\_t_{a(k)}$  is null means that either there is no corresponding TM source phrase  $tm\_s_{a(k)}$  or there is no corresponding TM target phrase

$tm_{\bar{t}_{a(k)}}$  aligned with  $tm_{\bar{s}_{a(k)}}$ . In the example of Figure 1, assume that the given  $\bar{s}_{a(k)}$  is “关联<sub>5</sub>的<sub>6</sub>对象<sub>7</sub>” and  $\bar{t}_k$  is “object that is associated”. If  $tm_{\bar{t}_{a(k)}}$  is “object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>”,  $TCM_k = Same$ ; if  $tm_{\bar{t}_{a(k)}}$  is “an<sub>1</sub> object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>”,  $TCM_k = High$ .

**Source Phrase Content Matching Status (SCM):** Which indicates the content matching status between  $\bar{s}_{a(k)}$  and  $tm_{\bar{s}_{a(k)}}$ , and it affects the matching status of  $\bar{t}_k$  and  $tm_{\bar{t}_{a(k)}}$  greatly. The more similar  $\bar{s}_{a(k)}$  is to  $tm_{\bar{s}_{a(k)}}$ , the more similar  $\bar{t}_k$  is to  $tm_{\bar{t}_{a(k)}}$ . It is a member of  $\{Same, High, Low, NA\}$  and is defined as:

- (1) If  $tm_{\bar{s}_{a(k)}}$  is not null:
  - (a) if  $FMS(\bar{s}_{a(k)}, tm_{\bar{s}_{a(k)}}) = 1.0$ ,  $SCM_k = Same$ ;
  - (b) else if  $FMS(\bar{s}_{a(k)}, tm_{\bar{s}_{a(k)}}) > 0.5$ ,  $SCM_k = High$ ;
  - (c) else,  $SCM_k = Low$ ;
- (2) If  $tm_{\bar{s}_{a(k)}}$  is null,  $SCM_k = NA$ ;

Here  $tm_{\bar{s}_{a(k)}}$  is null means that there is no corresponding TM source phrase  $tm_{\bar{s}_{a(k)}}$  for the given source phrase  $\bar{s}_{a(k)}$ . Take the source phrase  $\bar{s}_{a(k)}$  “关联<sub>5</sub>的<sub>6</sub>对象<sub>7</sub>” in Figure 1 for an example, since its corresponding  $tm_{\bar{s}_{a(k)}}$  is “关联<sub>4</sub>的<sub>5</sub>对象<sub>6</sub>”, then  $SCM_k = Same$ .

**Number of Linking Neighbors (NLN):** Usually, the context of a source phrase would affect its target translation. The more similar the context are, the more likely that the translations are the same. Therefore, this NLN feature reflects the number of matched neighbors (words) and it is a vector of  $\langle x, y \rangle$ . Where “x” denotes the number of matched source neighbors; and “y” denotes how many those neighbors are also linked to target words (not null), which also affects the TM target phrase selection. This feature is a member of  $\{\langle x, y \rangle: \langle 2, 2 \rangle, \langle 2, 1 \rangle, \langle 2, 0 \rangle, \langle 1, 1 \rangle, \langle 1, 0 \rangle, \langle 0, 0 \rangle\}$ . For the source phrase “关联<sub>5</sub>的<sub>6</sub>对象<sub>7</sub>” in Figure 1, the corresponding TM source phrase is “关联<sub>4</sub>的<sub>5</sub>对象<sub>6</sub>”. As only their right neighbors “。8” and “。7” are matched, and “。7” is aligned with “.10”, NLN will be  $\langle 1, 1 \rangle$ .

**Source Phrase Length (SPL):** Usually the longer the source phrase is, the more reliable the TM target phrase is. For example, the corresponding  $tm_{\bar{t}_{a(k)}}$  for the source phrase with 5 words would be more reliable than that with only one word. This feature denotes the number of words included in  $\bar{s}_{a(k)}$ , and is a member of  $\{1, 2, 3, 4, \geq 5\}$ . For the case “关联<sub>5</sub>的<sub>6</sub>对象<sub>7</sub>”, SPL will be 3.

**Sentence End Punctuation Indicator (SEP):** Which indicates whether the current phrase is a punctuation at the end of the sentence, and is a member of  $\{Yes, No\}$ . For example, the SEP for “关联<sub>5</sub>的<sub>6</sub>对象<sub>7</sub>” will be “No”. It is introduced because the SCM and TCM for a sentence-end-punctuation are always “Same” regardless of other features. Therefore, it is used to distinguish this special case from other cases.

### 3.2 Model-II

As Model-I ignores the relationship among various possible TM target phrases, we add two features *TM Candidate Set Status* (CSS) and *Longest TM Candidate Indicator* (LTC) to incorporate this relationship among them. Since CSS is redundant after LTC is known, we thus ignore it for evaluating TCM probability in the following derivation:

$$\begin{aligned}
P(M_k|L_k, z) &\triangleq P(TCM_k, LTC_k|SCM_k, NLN_k, CSS_k, SPL_k, SEP_k, z) \\
&\approx \left\{ \begin{array}{l} P(TCM_k|SCM_k, NLN_k, LTC_k, SPL_k, SEP_k, z) \\ \times P(LTC_k|CSS_k, SCM_k, NLN_k, SEP_k, z) \end{array} \right\}
\end{aligned}$$

The two new features CSS and LTC adopted in Model-II are defined as follows:

**TM Candidate Set Status (CSS):** Which restricts the possible status of  $tm_{\bar{t}_{a(k)}}$ , and is a member of  $\{Single, Left-Ext, Right-Ext, Both-Ext, NA\}$ . Where “Single” means that there is only one  $tm_{\bar{t}_{a(k)}}$  candidate for the given source phrase  $tm_{\bar{s}_{a(k)}}$ ; “Left-Ext” means that there are multiple  $tm_{\bar{t}_{a(k)}}$  candidates, and all the candidates are generated by extending only the left boundary; “Right-Ext” means that there are multiple  $tm_{\bar{t}_{a(k)}}$  candidates, and all the candidates are generated by only extending to the right; “Both-Ext” means that there are multiple  $tm_{\bar{t}_{a(k)}}$  candidates, and the candidates are generated by extending to both sides; “NA” means that  $tm_{\bar{t}_{a(k)}}$  is null.

For “关联<sub>4</sub>的<sub>5</sub>对象<sub>6</sub>” in Figure 1, the linked TM target phrase is “object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>”, and there are 5 other candidates by extending to both sides. Therefore,  $CSS_k = Both-Ext$ .

**Longest TM Candidate Indicator (LTC):** Which indicates whether the given  $tm_{\bar{t}_{a(k)}}$  is the longest candidate or not, and is a member of  $\{Original, Left-Longest, Right-Longest, Both-Longest, Medium, NA\}$ . Where “Original” means that the given  $tm_{\bar{t}_{a(k)}}$  is the one without extension; “Left-Longest” means that the given

$tm_{\bar{t}_{a(k)}}$  is only extended to the left and is the longest one; “*Right-Longest*” means that the given  $tm_{\bar{t}_{a(k)}}$  is only extended to the right and is the longest one; “*Both-Longest*” means that the given  $tm_{\bar{t}_{a(k)}}$  is extended to both sides and is the longest one; “*Medium*” means that the given  $tm_{\bar{t}_{a(k)}}$  has been extended but not the longest one; “*NA*” means that  $tm_{\bar{t}_{a(k)}}$  is null.

For  $tm_{\bar{t}_{a(k)}}$  “*object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>*” in Figure 1,  $LTC_k = Original$ ; for  $tm_{\bar{t}_{a(k)}}$  “*an<sub>1</sub> object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>*”,  $LTC_k = Left-Longest$ ; for the longest  $tm_{\bar{t}_{a(k)}}$  “*an<sub>1</sub> object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub> with<sub>6</sub> the<sub>7</sub>*”,  $LTC_k = Both-Longest$ .

### 3.3 Model-III

The abovementioned integrated models ignore the reordering information implied by TM. Therefore, we add a new feature *Target Phrase Adjacent Candidate Relative Position Matching Status* (CPM) into Model-II and Model-III is given as:

$$P(M_k|L_k, z) \triangleq P([TCM, LTC, CPM]_k | [SCM, NLN, CSS, SPL, SEP]_k, z) \approx \left\{ \begin{array}{l} P(TCM_k | SCM_k, NLN_k, LTC_k, SPL_k, SEP_k, z) \\ \times P(LTC_k | CSS_k, SCM_k, NLN_k, SEP_k, z) \\ \times P(CPM_k | TCM_k, SCM_k, NLN_k, z) \end{array} \right\}$$

We assume that CPM is independent with SPL and SEP, because the length of source phrase would not affect reordering too much and SEP is used to distinguish the sentence end punctuation with other phrases.

The new feature CPM adopted in Model-III is defined as:

**Target Phrase Adjacent Candidate Relative Position Matching Status (CPM):** Which indicates the matching status between the relative position of  $[\bar{t}_{k-1}, \bar{t}_k]$  and the relative position of  $[tm_{\bar{t}_{a(k-1)}}, tm_{\bar{t}_{a(k)}}]$ . It checks if  $[\bar{t}_{k-1}, \bar{t}_k]$  are positioned in the same order with  $[tm_{\bar{t}_{a(k-1)}}, tm_{\bar{t}_{a(k)}}]$ , and reflects the quality of ordering the given target candidate  $\bar{t}_k$ . It is a member of  $\{Adjacent-Same, Adjacent-Substitute, Linked-Interleaved, Linked-Cross, Linked-Reversed, Skip-Forward, Skip-Cross, Skip-Reversed, NA\}$ . Recall that  $\bar{t}_k$  is always right adjacent to  $\bar{t}_{k-1}$ , then various cases are defined as follows:

- (1) If both  $tm_{\bar{t}_{a(k-1)}}$  and  $tm_{\bar{t}_{a(k)}}$  are not null:
  - (a) If  $tm_{\bar{t}_{a(k)}}$  is on the right of  $tm_{\bar{t}_{a(k-1)}}$  and they are also adjacent to each other:
    - i. If the right boundary words of  $\bar{t}_{k-1}$  and  $tm_{\bar{t}_{a(k-1)}}$  are the same, and the left

boundary words of  $\bar{t}_k$  and  $tm_{\bar{t}_{a(k)}}$  are the same,  $CPM_k = Adjacent-Same$ ;

ii. Otherwise,  $CPM_k = Adjacent-Substitute$ ;

- (b) If  $tm_{\bar{t}_{a(k)}}$  is on the right of  $tm_{\bar{t}_{a(k-1)}}$  but they are not adjacent to each other,  $CPM_k = Linked-Interleaved$ ;

- (c) If  $tm_{\bar{t}_{a(k)}}$  is not on the right of  $tm_{\bar{t}_{a(k-1)}}$ :
  - i. If there are cross parts between  $tm_{\bar{t}_{a(k)}}$  and  $tm_{\bar{t}_{a(k-1)}}$ ,  $CPM_k = Linked-Cross$ ;

ii. Otherwise,  $CPM_k = Linked-Reversed$ ;

- (2) If  $tm_{\bar{t}_{a(k-1)}}$  is null but  $tm_{\bar{t}_{a(k)}}$  is not null, then find the first  $tm_{\bar{t}_{a(k-n)}} (k \geq n)$  which is not null ( $n$  starts from 2)<sup>2</sup>:
  - (a) If  $tm_{\bar{t}_{a(k)}}$  is on the right of  $tm_{\bar{t}_{a(k-n)}}$ ,  $CPM_k = Skip-Forward$ ;

- (b) If  $tm_{\bar{t}_{a(k)}}$  is not on the right of  $tm_{\bar{t}_{a(k-n)}}$ :
  - i. If there are cross parts between  $tm_{\bar{t}_{a(k)}}$  and  $tm_{\bar{t}_{a(k-n)}}$ ,  $CPM_k = Skip-Cross$ ;

ii. Otherwise,  $CPM_k = Skip-Reversed$ .

- (3) If  $tm_{\bar{t}_{a(k)}}$  is null,  $CPM_k = NA$ .

In Figure 1, assume that  $\bar{t}_{k-1}$ ,  $\bar{t}_k$  and  $tm_{\bar{t}_{a(k-1)}}$  are “*gets an*”, “*object that is associated with*” and “*gets<sub>0</sub> an<sub>1</sub>*”, respectively. For  $tm_{\bar{t}_{a(k)}}$  “*object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>*”, because  $tm_{\bar{t}_{a(k)}}$  is on the right of  $tm_{\bar{t}_{a(k-1)}}$  and they are adjacent pair, and both boundary words (“*an*” and “*an<sub>1</sub>*”; “*object*” and “*object<sub>2</sub>*”) are matched,  $CPM_k = Adjacent-Same$ ; for  $tm_{\bar{t}_{a(k)}}$  “*an<sub>1</sub> object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>*”, because there are cross parts “*an<sub>1</sub>*” between  $tm_{\bar{t}_{a(k)}}$  and  $tm_{\bar{t}_{a(k-1)}}$ ,  $CPM_k = Linked-Cross$ . On the other hand, assume that  $\bar{t}_{k-1}$ ,  $\bar{t}_k$  and  $tm_{\bar{t}_{a(k-1)}}$  are “*gets*”, “*object that is associated with*” and “*gets<sub>0</sub>*”, respectively. For  $tm_{\bar{t}_{a(k)}}$  “*an<sub>1</sub> object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>*”, because  $tm_{\bar{t}_{a(k)}}$  and  $tm_{\bar{t}_{a(k-1)}}$  are adjacent pair, but the left boundary words of  $\bar{t}_k$  and  $tm_{\bar{t}_{a(k)}}$  (“*object*” and “*an<sub>1</sub>*”) are not matched,  $CPM_k = Adjacent-Substitute$ ; for  $tm_{\bar{t}_{a(k)}}$  “*object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>*”, because  $tm_{\bar{t}_{a(k)}}$  is on the right of  $tm_{\bar{t}_{a(k-1)}}$  but they are not adjacent pair, therefore,  $CPM_k = Linked-Interleaved$ . One more example, assume that  $\bar{t}_{k-1}$ ,  $\bar{t}_k$  and  $tm_{\bar{t}_{a(k-1)}}$  are “*the annotation label*”, “*object that is associated with*” and “*the<sub>7</sub> annotation<sub>8</sub> label<sub>9</sub>*”, respectively. For  $tm_{\bar{t}_{a(k)}}$  “*an<sub>1</sub> object<sub>2</sub> that<sub>3</sub> is<sub>4</sub> associated<sub>5</sub>*”, because  $tm_{\bar{t}_{a(k)}}$  is on the left of  $tm_{\bar{t}_{a(k-1)}}$ , and there are no cross parts,  $CPM_k = Linked-Reversed$ .

<sup>2</sup> It can be identified by simply memorizing the index of nearest non-null  $tm_{\bar{t}_{a(k-n)}}$  during search.

## 4 Experiments

### 4.1 Experimental Setup

Our TM database consists of computer domain Chinese-English translation sentence-pairs, which contains about 267k sentence-pairs. The average length of Chinese sentences is 13.85 words and that of English sentences is 13.86 words. We randomly selected a development set and a test set, and then the remaining sentence pairs are for training set. The detailed corpus statistics are shown in Table 1. Furthermore, development set and test set are divided into various intervals according to their best fuzzy match scores. Corpus statistics for each interval in the test set are shown in Table 2.

For the phrase-based SMT system, we adopted the Moses toolkit (Koehn et al., 2007). The system configurations are as follows: GIZA++ (Och and Ney, 2003) is used to obtain the bidirectional word alignments. Afterwards, “intersection”<sup>3</sup> refinement (Koehn et al., 2003) is adopted to extract phrase-pairs. We use the SRI Language Model toolkit (Stolcke, 2002) to train a 5-gram model with modified Kneser-Ney smoothing (Kneser and Ney, 1995; Chen and Goodman, 1998) on the target-side (English) training corpus. All the feature weights and the weight for each probability factor (3 factors for Model-III) are tuned on the development set with minimum-error-rate training (MERT) (Och, 2003). The maximum phrase length is set to 7 in our experiments.

In this work, the translation performance is measured with case-insensitive BLEU-4 score (Papineni et al., 2002) and TER score (Snover et al., 2006). Statistical significance test is conducted with re-sampling (1,000 times) approach (Koehn, 2004) in 95% confidence level.

### 4.2 Cross-Fold Translation

To estimate the probabilities of proposed models, the corresponding phrase segmentations for bilingual sentences are required. As we want to check what actually happened during decoding in the real situation, cross-fold translation is used to obtain the corresponding phrase segmentations. We first extract 95% of the bilingual sentences as a new training corpus to train a SMT system. Afterwards, we generate the corresponding phrase segmentations for the remaining 5% bi-

<sup>3</sup> “grow-diag-final” and “grow-diag-final-and” are also tested. However, “intersection” is the best option in our experiments, especially for those high fuzzy match intervals.

	Train	Develop	Test
#Sentences	261,906	2,569	2,576
#Chn. Words	3,623,516	38,585	38,648

lingual sentences with *Forced Decoding* (Li et al., 2000; Zollmann et al., 2008; Auli et al., 2009; Wisniewski et al., 2010), which searches the best phrase segmentation for the specified output. Having repeated the above steps 20 times<sup>4</sup>, we obtain the corresponding phrase segmentations for the SMT training data (which will then be used to train the integrated models).

Due to OOV words and insertion words, not all given source sentences can generate the desired results through forced decoding. Fortunately, in our work, 71.7% of the training bilingual sentences can generate the corresponding target results. The remaining 28.3% of the sentence pairs are thus not adopted for generating training samples. Furthermore, more than 90% obtained source phrases are observed to be less than 5 words, which explains why five different quantization levels are adopted for Source Phrase Length (SPL) in section 3.1.

### 4.3 Translation Results

After obtaining all the training samples via cross-fold translation, we use Factored Language Model toolkit (Kirchhoff et al., 2007) to estimate the probabilities of integrated models with Witten-Bell smoothing (Bell et al., 1990; Witten et al., 1991) and Back-off method. Afterwards, we incorporate the TM information  $P(M_k|L_k, z)$  for each phrase at decoding. All experiments are

<sup>4</sup> This training process only took about 10 hours on our Ubuntu server (Intel 4-core Xeon 3.47GHz, 132 GB of RAM).

Table 4: Translation Results (TER%). Scores marked by “\*” are significantly better ( $p < 0.05$ ) than both TM and SMT systems, and those marked by “#” are significantly better ( $p < 0.05$ ) than Koehn-10.

conducted using the Moses phrase-based decoder (Koehn et al., 2007).

Table 3 and 4 give the translation results of TM, SMT, and three integrated models in the test set. In the tables, the best translation results (either in BLEU or TER) at each interval have been marked in bold. Scores marked by “\*” are significantly better ( $p < 0.05$ ) than both the TM and the SMT systems.

It can be seen that TM significantly exceeds SMT at the interval [0.9, 1.0) in TER score, which illustrates why professional translators prefer TM rather than SMT as their assistant tool. Compared with TM and SMT, Model-I is significantly better than the SMT system in either BLEU or TER when the fuzzy match score is above 0.7; Model-II significantly outperforms both the TM and the SMT systems in either BLEU or TER when the fuzzy match score is above 0.5; Model-III significantly exceeds both the TM and the SMT systems in either BLEU or TER when the fuzzy match score is above 0.4. All these improvements show that our integrated models have combined the strength of both TM and SMT.

However, the improvements from integrated models get less when the fuzzy match score decreases. For example, Model-III outperforms

SMT 8.03 BLEU points at interval [0.9, 1.0), while the advantage is only 2.97 BLEU points at interval [0.6, 0.7). This is because lower fuzzy match score means that there are more unmatched parts between  $s$  and  $tm_s$ ; the output of TM is thus less reliable.

Across all intervals (the last row in the table), Model-III not only achieves the best BLEU score (56.51), but also gets the best TER score (33.26). If intervals are evaluated separately, when the fuzzy match score is above 0.4, Model-III outperforms both Model-II and Model-I in either BLEU or TER. Model-II also exceeds Model-I in either BLEU or TER. The only exception is at interval [0.5, 0.6), in which Model-I achieves the best TER score. This might be due to that the optimization criterion for MERT is BLEU rather than TER in our work.

#### 4.4 Comparison with Previous Work

In order to compare our proposed models with previous work, we re-implement two XML-Markup approaches: (Koehn and Senellart, 2010) and (Ma et al, 2011), which are denoted as **Koehn-10** and **Ma-11**, respectively. They are selected because they report superior performances in the literature. A brief description of them is as follows:

<b>Source</b>	如果 <sub>0</sub> 禁用 <sub>1</sub> 此 <sub>2</sub> 策略 <sub>3</sub> 设置 <sub>4</sub> ， <sub>5</sub> internet <sub>6</sub> explorer <sub>7</sub> 不 <sub>8</sub> 搜索 <sub>9</sub> internet <sub>10</sub> 查找 <sub>11</sub> 浏览器 <sub>12</sub> 的 <sub>13</sub> 新 <sub>14</sub> 版本 <sub>15</sub> ， <sub>16</sub> 因此 <sub>17</sub> 不 <sub>18</sub> 会 <sub>19</sub> 提示 <sub>20</sub> 用户 <sub>21</sub> 安装 <sub>22</sub> 。 <sub>23</sub>
<b>Reference</b>	if <sub>0</sub> you <sub>1</sub> disable <sub>2</sub> this <sub>3</sub> policy <sub>4</sub> setting <sub>5</sub> , <sub>6</sub> internet <sub>7</sub> explorer <sub>8</sub> does <sub>9</sub> not <sub>10</sub> check <sub>11</sub> the <sub>12</sub> internet <sub>13</sub> for <sub>14</sub> new <sub>15</sub> versions <sub>16</sub> of <sub>17</sub> the <sub>18</sub> browser <sub>19</sub> , <sub>20</sub> so <sub>21</sub> does <sub>22</sub> not <sub>23</sub> prompt <sub>24</sub> users <sub>25</sub> to <sub>26</sub> install <sub>27</sub> them <sub>28</sub> . <sub>29</sub>
<b>TM Source</b>	如果 <sub>0</sub> 不 <sub>1</sub> 配置 <sub>2</sub> 此 <sub>3</sub> 策略 <sub>4</sub> 设置 <sub>5</sub> ， <sub>6</sub> internet <sub>7</sub> explorer <sub>8</sub> 不 <sub>9</sub> 搜索 <sub>10</sub> internet <sub>11</sub> 查找 <sub>12</sub> 浏览器 <sub>13</sub> 的 <sub>14</sub> 新 <sub>15</sub> 版本 <sub>16</sub> ， <sub>17</sub> 因此 <sub>18</sub> 不 <sub>19</sub> 会 <sub>20</sub> 提示 <sub>21</sub> 用户 <sub>22</sub> 安装 <sub>23</sub> 。 <sub>24</sub>
<b>TM Target</b>	if <sub>0</sub> you <sub>1</sub> do <sub>2</sub> not <sub>3</sub> configure <sub>4</sub> this <sub>5</sub> policy <sub>6</sub> setting <sub>7</sub> , <sub>8</sub> internet <sub>9</sub> explorer <sub>10</sub> does <sub>11</sub> not <sub>12</sub> check <sub>13</sub> the <sub>14</sub> internet <sub>15</sub> for <sub>16</sub> new <sub>17</sub> versions <sub>18</sub> of <sub>19</sub> the <sub>20</sub> browser <sub>21</sub> , <sub>22</sub> so <sub>23</sub> does <sub>24</sub> not <sub>25</sub> prompt <sub>26</sub> users <sub>27</sub> to <sub>28</sub> install <sub>29</sub> them <sub>30</sub> . <sub>31</sub>
<b>TM Alignment</b>	0-0 1-3 2-4 3-5 4-6 5-7 6-8 7-9 8-10 9-11 11-15 13-21 14-19 15-17 16-18 17-22 18-23 19-24 21-26 22-27 23-29 24-31
<b>SMT</b>	if you disable this policy setting , internet explorer does not <i>prompt users to install</i> internet for new versions of the browser . [Miss 7 target words: 9~12, 20~21, 28; Has one wrong permutation]
<b>Koehn-10</b>	if you do you disable this policy setting , internet explorer does not check the internet for new versions of the browser , so does not prompt users to install them . [Insert two spurious target words]
<b>Ma-11</b>	if you disable this policy setting , internet explorer does not <i>prompt users to install</i> internet for new versions of the browser . [Miss 7 target words: 9~12, 20~21, 28; Has one wrong permutation]
<b>Model-I</b>	if you disable this policy setting , internet explorer does not <i>prompt users to install</i> new versions of the browser , so does not <i>check the internet</i> . [Miss 2 target words: 14, 28; Has one wrong permutation]
<b>Model-II</b>	if you disable this policy setting , internet explorer does not <i>prompt users to install</i> new versions of the browser , so does not <i>check the internet</i> . [Miss 2 target words: 14, 28; Has one wrong permutation]
<b>Model-III</b>	if you disable this policy setting , internet explorer does not check the internet for new versions of the browser , so does not prompt users to install them . [Exactly the same as the reference]

Figure 2: A Translation Example at Interval [0.9, 1.0] (with FMS=0.920)

Koehn et al. (2010) first find out the unmatched parts between the given source sentence and TM source sentence. Afterwards, for each *unmatched* phrase in the TM source sentence, they replace its corresponding translation in the *TM target sentence* by the corresponding *source phrase* in the input sentence, and then mark the substitution part. After replacing the corresponding translations of all unmatched source phrases in the TM target sentence, an XML input sentence (with mixed TM target phrases and marked input source phrases) is thus obtained. The SMT decoder then only translates the unmatched/marked source phrases and gets the desired results. Therefore, the *inserted* parts in the TM target sentence are automatically *included*. They use fuzzy match score to determine whether the current sentence should be marked or not; and their experiments show that this method is only effective when the fuzzy match score is above 0.8.

Ma et al. (2011) think fuzzy match score is not reliable and use a discriminative learning method to decide whether the current sentence should be

marked or not. Another difference between Ma-11 and Koehn-10 is how the XML input is constructed. In constructing the XML input sentence, Ma-11 replaces each *matched* source phrase in the *given source sentence* with the corresponding TM target phrase. Therefore, the *inserted* parts in the TM target sentence are *not included*. In Ma’s another paper (He et al., 2011), more linguistic features for discriminative learning are also added. In our work, we only re-implement the XML-Markup method used in (He et al., 2011; Ma et al., 2011), but do not implement the discriminative learning method. This is because the features adopted in their discriminative learning are complicated and difficult to re-implement. However, the proposed Model-III even outperforms the upper bound of their methods, which will be discussed later.

Table 3 and 4 give the translation results of Koehn-10 and Ma-11 (without the discriminator). Scores marked by “#” are significantly better ( $p < 0.05$ ) than Koehn-10. Besides, the upper bound of (Ma et al, 2011) is also given in the tables, which is denoted as **Ma-11-U**. We calculate this

upper bound according to the method described in (Ma et al., 2011). Since He et al., (2011) only add more linguistic features to the discriminative learning method, the upper bound of (He et al., 2011) is still the same with (Ma et al., 2011); therefore, Ma-11-U applies for both cases.

It is observed that Model-III significantly exceeds Koehn-10 at all intervals. More importantly, the proposed models achieve much better TER score than the TM system does at interval [0.9, 1.0), but Koehn-10 does not even exceed the TM system at this interval. Furthermore, Model-III is much better than Ma-11-U at most intervals. Therefore, it can be concluded that the proposed models outperform the pipeline approaches significantly.

Figure 2 gives an example at interval [0.9, 1.0), which shows the difference among different system outputs. It can be seen that “you do” is redundant for Koehn-10, because they are insertions and thus are kept in the XML input. However, SMT system still inserts another “you”, regardless of “you do” has already existed. This problem does not occur at Ma-11, but it misses some words and adopts one wrong permutation. Besides, Model-I selects more right words than SMT does but still puts them in wrong positions due to ignoring TM reordering information. In this example, Model-II obtains the same results with Model-I because it also lacks reordering information. Last, since Model-III considers both TM content and TM position information, it gives a perfect translation.

## 5 Conclusion and Future Work

Unlike the previous pipeline approaches, which directly merge TM phrases into the final translation result, we integrate TM information of each source phrase into the phrase-based SMT at decoding. In addition, all possible TM target phrases are kept and the proposed models select the best one during decoding via referring SMT information. Besides, the integrated model considers the probability information of both SMT and TM factors.

The experiments show that the proposed Model-III outperforms both the TM and the SMT systems significantly ( $p < 0.05$ ) in either BLEU or TER when fuzzy match score is above 0.4. Compared with the pure SMT system, Model-III achieves overall 3.48 BLEU points improvement and 2.62 TER points reduction on a Chinese-English TM database. Furthermore, Model-III significantly exceeds all previous pipeline ap-

proaches. Similar improvements are also observed on the Hansards parts of LDC2004T08 (not shown in this paper due to space limitation). Since no language-dependent feature is adopted, the proposed approaches can be easily adapted for other language pairs.

Moreover, following the approaches of Koehn-10 and Ma-11 (to give a fair comparison), training data for SMT and TM are the same in the current experiments. However, the TM is expected to play an even more important role when the SMT training-set differs from the TM database, as additional phrase-pairs that are unseen in the SMT phrase table can be extracted from TM (which can then be dynamically added into the SMT phrase table at decoding time). Our another study has shown that the integrated model would be even more effective when the TM database and the SMT training data-set are from different corpora in the same domain (not shown in this paper). In addition, more source phrases can be matched if a set of high-FMS sentences, instead of only the sentence with the highest FMS, can be extracted and referred at the same time. And it could further raise the performance.

Last, some related approaches (Smith and Clark, 2009; Phillips, 2011) combine SMT and example-based machine translation (EBMT) (Nagao, 1984). It would be also interesting to compare our integrated approach with that of theirs.

## Acknowledgments

The research work has been funded by the Hi-Tech Research and Development Program (“863” Program) of China under Grant No. 2011AA01A207, 2012AA011101, and 2012AA011102 and also supported by the Key Project of Knowledge Innovation Program of Chinese Academy of Sciences under Grant No.KGZD-EW-501.

The authors would like to thank the anonymous reviewers for their insightful comments and suggestions. Our sincere thanks are also extended to Dr. Yanjun Ma and Dr. Yifan He for their valuable discussions during this study.

# Training Nondeficient Variants of IBM-3 and IBM-4 for Word Alignment

Thomas Schoenemann

Heinrich-Heine-Universität Düsseldorf, Germany

Universitätsstr. 1

40225 Düsseldorf, Germany

## Abstract

We derive variants of the fertility based models IBM-3 and IBM-4 that, while maintaining their zero and first order parameters, are nondeficient. Subsequently, we proceed to derive a method to compute a likely alignment and its neighbors as well as give a solution of EM training. The arising M-step energies are non-trivial and handled via projected gradient ascent.

Our evaluation on gold alignments shows substantial improvements (in weighted F-measure) for the IBM-3. For the IBM-4 there are no consistent improvements. Training the nondeficient IBM-5 in the regular way gives surprisingly good results.

Using the resulting alignments for phrase-based translation systems offers no clear insights w.r.t. BLEU scores.

## 1 Introduction

While most people think of the translation and word alignment models IBM-3 and IBM-4 as inherently deficient models (i.e. models that assign non-zero probability mass to impossible events), in this paper we derive nondeficient variants maintaining their zero order (IBM-3) and first order (IBM-4) parameters. This is possible as IBM-3 and IBM-4 are very special cases of general log-linear models: they are properly derived by the chain rule of probabilities. Deficiency is only introduced by ignoring a part of the history to be conditioned on in the individual factors of the chain rule factorization. While at first glance this seems necessary to obtain zero and first order de-

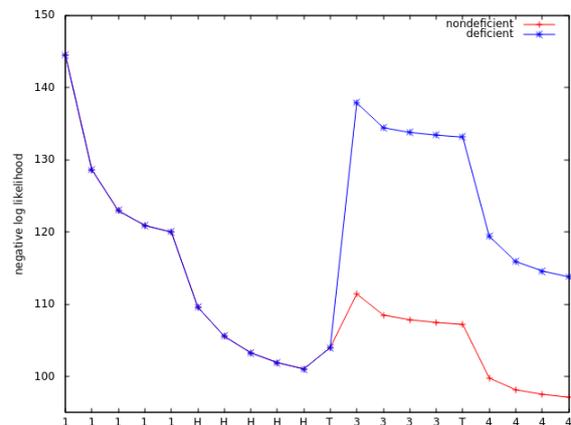

Figure 1: Plot of the negative log. likelihoods (the quantity to be minimized) arising in training deficient and nondeficient models (for Europarl German | English, training scheme  $1^5H^53^54^5$ ).  $1/3/4=IBM-1/3/4$ , H=HMM, T=Transfer iteration. The curves are identical up to iteration 11.

Iteration 11 shows that merely 5.14% of the (HMM) probability mass are covered by the Viterbi alignment and its neighbors. With deficient models (and deficient empty words) the final negative log likelihood is higher than the initial HMM one, with nondeficient models it is lower than for the HMM, as it should be for a better model.

dependencies, we show that with proper renormalization all factors can be made nondeficient.

Having introduced the model variants, we proceed to derive a hillclimbing method to compute a likely alignment (ideally the Viterbi alignment) and its neighbors. As for the deficient models, this plays an important role in the E-step of the subsequently derived expectation maximization (EM) training scheme. As usual, expectations in EM are approximated, but we now also get non-trivial M-step energies. We deal with these via projected gradient ascent.

The downside of our method is its resource consumption, but still we present results on corpora with 100.000 sentence pairs. The source code of this project is available in our word alignment software RegAligner<sup>1</sup>, version 1.2 and later.

Figure 1 gives a first demonstration of how much the proposed variants differ from the standard models by visualizing the resulting negative log likelihoods<sup>2</sup>, the quantity to be minimized in EM-training. The nondeficient IBM-4 derives a lower negative log likelihood than the HMM, the regular deficient variant only a lower one than the IBM-1. As an aside, the transfer iteration from HMM to IBM3 (iteration 11) reveals that only 5.14% of the probability mass<sup>3</sup> are preserved when using the Viterbi alignment and its neighbors instead of all alignments.

Indeed, it is widely recognized that – with proper initialization – fertility based models outperform sequence based ones. In particular, sequence based models can simply ignore a part of the sentence to be conditioned on, while fertility based models explicitly factor in a probability of words in this sentence to have no aligned words (or any other number of aligned words, called the *fertility*). Hence, it is encouraging to see that the nondeficient IBM-4 indeed derives a higher likelihood than the sequence based HMM.

**Related Work** Today’s most widely used models for word alignment are still the models IBM 1-5 of Brown et al. (1993) and the HMM of Vogel et al. (1996), thoroughly evaluated in (Och and Ney, 2003). While it is known that fertility-based models outperform sequence-based ones, the large bulk of word alignment literature following these publications has mostly ignored fertility-based models. This is different in the present paper which deals exclusively with such models.

One reason for the lack of interest is surely that computing expectations and Viterbi alignments for these models is a hard problem (Udupa and Maji, 2006). Nevertheless, computing Viterbi align-

ments for the IBM-3 has been shown to often be practicable (Ravi and Knight, 2010; Schoenemann, 2010).

Much work has been spent on HMM-based formulations, focusing on the computationally tractable side (Toutanova et al., 2002; Sumita et al., 2004; Deng and Byrne, 2005). In addition, some rather complex models have been proposed that usually aim to replace the fertility based models (Wang and Waibel, 1998; Fraser and Marcu, 2007a).

Another line of models (Melamed, 2000; Marcu and Wong, 2002; Cromières and Kurohashi, 2009) focuses on joint probabilities to get around the garbage collection effect (i.e. that for conditional models, rare words in the given language align to too many words in the predicted language). The downside is that these models are computationally harder to handle.

A more recent line of work introduces various forms of regularity terms, often in the form of symmetrization (Liang et al., 2006; Graça et al., 2010; Bansal et al., 2011) and recently by using  $L_0$  norms (Vaswani et al., 2012).

## 2 The models IBM-3, IBM-4 and IBM-5

We begin with a short review of fertility-based models in general and IBM-3, IBM-4 and IBM-5 specifically. All are due to (Brown et al., 1993) who proposed to use the deficient models IBM-3 and IBM-4 to initialize the nondeficient IBM-5.

For a foreign sentence  $\mathbf{f} = f_1^J = (f_1, \dots, f_J)$  with  $J$  words and an English one  $\mathbf{e} = e_1^I = (e_1, \dots, e_I)$  with  $I$  words, the (conditional) probability  $p(f_1^J | e_1^I)$  of getting the foreign sentence as a translation of the English one is modeled by introducing the word alignment  $\mathbf{a}$  as a hidden variable:

$$p(f_1^J | e_1^I) = \sum_{\mathbf{a}} p(f_1^J, \mathbf{a} | e_1^I)$$

All IBM models restrict the space of alignments to those where a foreign word can align to at most one target word. The resulting alignment is then written as a vector  $a_1^J$ , where each  $a_j$  takes integral values between 0 and  $I$ , with 0 indicating that  $f_j$  has no English correspondence.

The fertility-based models IBM-3, IBM-4 and IBM-5 factor the (conditional) probability  $p(f_1^J, a_1^J | e_1^I)$  of obtaining an alignment and a translation given an English sentence according to the following generative story:

<sup>1</sup><https://github.com/Thomas1205/RegAligner>, for the reported results we used a slightly earlier version.

<sup>2</sup>Note that the figure slightly favors IBM-1 and HMM as for them the length  $J$  of the foreign sequence is assumed to be known whereas IBM-3 and IBM-4 explicitly predict it.

<sup>3</sup>This number regards the corpus probability as in (9) to the power of  $1/S$ , i.e. the objective function in maximum likelihood training. The number is not entirely fair as alignments where more than half the words align to the empty word are assigned a probability of 0. Still, this is an issue only for short sentences.

1. For  $i = 1, 2, \dots, I$ , decide on the number  $\Phi_i$  of foreign words aligned to  $e_i$ . This number is called the *fertility* of  $e_i$ . Choose with probability  $p(\Phi_i|e_i^I, \Phi_1^{i-1}) = p(\Phi_i|e_i)$ .
2. Choose the number  $\Phi_0$  of unaligned words in the (still unknown) foreign sequence. Choose with probability  $p(\Phi_0|e_1^I, \Phi_1^I) = p(\Phi_0|\sum_{i=1}^I \Phi_i)$ . Since each foreign word belongs to exactly one English position (including 0), the foreign sequence is now known to be of length  $J = \sum_{i=0}^I \Phi_i$ .
3. For each  $i = 1, 2, \dots, I$ , and  $k = 1, \dots, \Phi_i$  decide on
  - (a) the identity  $f_{i,k}$  of the next foreign word aligned to  $e_i$ . Choose with probability  $p(f_{i,k}|e_i^I, \Phi_0^I, \mathbf{d}_1^{i-1}, d_{i,1}, \dots, d_{i,k-1}, \mathbf{f}_{i,k}) = p(f_{i,k}|e_i)$ , where  $\mathbf{d}_i$  comprises all  $d_{i,k}$  for word  $i$  (see point b) below) and  $\mathbf{f}_{i,k}$  comprises all foreign words known at that point.
  - (b) the position  $d_{i,k}$  of the just generated foreign word  $f_{i,k}$ , with probability  $p(d_{i,k}|e_i^I, \Phi_0^I, \mathbf{d}_1^{i-1}, d_{i,1}, \dots, d_{i,k-1}, \mathbf{f}_{i,k}, f_{i,k}) = p(d_{i,k}|e_i, \mathbf{d}_1^{i-1}, d_{i,1}, \dots, d_{i,k-1}, f_{i,k}, J)$ .
4. The remaining  $\Phi_0$  open positions in the foreign sequence align to position 0. Decide on the corresponding foreign words with  $p(f_{d_{0,k}}|e_0)$ , where  $e_0$  is an artificial ‘‘empty word’’.

To model the probability for the number of unaligned words in step 2, each of the  $\sum_{i=1}^I \Phi_i$  properly aligned foreign words generates an unaligned foreign word with probability  $p_0$ , resulting in

$$p(\Phi_0|\sum_{i=1}^I \Phi_i) = \binom{\sum_{i=1}^I \Phi_i}{\Phi_0} p_0^{\Phi_0} (1-p_0)^{(\sum_{i=1}^I \Phi_i) - \Phi_0},$$

with a base probability  $p_0$  and the combinatorial coefficients  $\binom{n}{k} = \frac{n!}{k!(n-k)!}$ , where  $n! = \prod_{k=1}^n k$  denotes the factorial of  $n$ . The main difference between IBM-3, IBM-4 and IBM-5 is the choice of probability model in step 3 b), called a *distortion model*. The choices are now detailed.

## 2.1 IBM-3

The IBM-3 implements a zero order distortion model, resulting in

$$p(d_{i,k}|i, J) .$$

Since most of the context to be conditioned on is ignored, this allows invalid configurations to occur with non-zero probability: some foreign positions can be chosen several times, while others remain empty. One says that the model is *deficient*. On the other hand, the model for  $p(\Phi_0|\sum_{i=1}^I \Phi_i)$  is nondeficient, and in training this often results in very high probabilities  $p_0$ . To prevent this it is common to make this model deficient as well (Och and Ney, 2003), which improves performance immensely and gives much better results than simply fixing  $p_0$  in the original model.

As for each  $i$  the  $d_{i,k}$  can appear in any order (i.e. need not be in ascending order), there are  $\prod_{i=1}^I \Phi_i!$  ways to generate the same alignment  $a_1^J$  (where the  $\Phi_i$  are the fertilities induced by  $a_1^J$ ). In total, the IBM-3 has the following probability model:

$$p(f_1^J, a_1^J|e_1^I) = \prod_{j=1}^J \left[ p(f_j|e_{a_j}) \cdot p(j|a_j, J) \right] \cdot p(\Phi_0|\sum_{i=1}^I \Phi_i) \cdot \prod_{i=1}^I \Phi_i! p(\Phi_i|e_i) . \quad (1)$$

**Reducing the Number of Parameters** While using non-parametric models  $p(j|i, J)$  is convenient for closed-form M-steps in EM training, these parameters are not very intuitive. Instead, in this paper we use the *parametric* model

$$p(j|i, J) = \frac{p(j|i)}{\sum_{j=1}^J p(j|i)} \quad (2)$$

with the more intuitive parameters  $p(j|i)$ . The arising M-step energy is addressed by projected gradient ascent (see below).

These parameters are also used for the nondeficient variants. Using the original non-parametric ones can be handled in a very similar manner to the methods set forth below.

## 2.2 IBM-4

The distortion model of the IBM-4 is a first order one that generates the  $d_{i,k}$  of each English position  $i$  in ascending order (i.e. for  $1 < k \leq \Phi_i$  we have  $d_{i,k} > d_{i,k-1}$ ). There is then a one-to-one correspondence between alignments  $a_1^J$  and (valid) distortion parameters  $(d_{i,k})_{i=1, \dots, I, k=1, \dots, \Phi_i}$  and therefore no longer a factor of  $\prod_{i=1}^I \Phi_i!$ .

The IBM-4 has two sub-distortion models, one for the first aligned word ( $k = 1$ ) of an English position and one for all following words ( $k > 1$ , only

if  $\Phi_i > 1$ ). For position  $i$ , let  $[i] = \arg \max\{i' | 1 \leq i' < i, \Phi_{i'} > 0\}$  denote<sup>4</sup> the closest preceding English word that has aligned foreign words. The aligned foreign positions of  $[i]$  are combined into a *center position*  $\odot_{[i]}$ , the rounded average of the positions. Now, the distortion probability for the first word ( $k = 1$ ) is

$$p_{=1}(d_{i,1} | \odot_{[i]}, \mathcal{A}(f_{i,1}), \mathcal{B}(e_{[i]}), J),$$

where  $\mathcal{A}$  gives the word class of a foreign word and  $\mathcal{B}$  the word class of an English word (there are typically 50 classes per language, derived by machine learning techniques). The probability is further reduced to a dependency on the difference of the positions, i.e.  $p_{=1}(d_{i,1} - \odot_{[i]} | \mathcal{A}(f_{i,1}), \mathcal{B}(e_{[i]}))$ . For  $k > 1$  the model is

$$p_{>1}(d_{i,k} | d_{i,k-1}, \mathcal{A}(f_{i,k}), J),$$

which is likewise reduced to  $p_{>1}(d_{i,k} - d_{i,k-1} | \mathcal{A}(f_{i,k}))$ . Note that in both difference-based formulations the dependence on  $J$  has to be dropped to get closed-form solutions of the M-step in EM training, and Brown et al. note themselves that the IBM-4 can place words before the start and after the end of the sentence.

**Reducing Deficiency** In this paper, we also investigate the effect of reducing the amount of wasted probability mass by enforcing the dependence on  $J$  by proper renormalization, i.e. using

$$p_{=1}(j | j', \mathcal{A}(f_{i,1}), \mathcal{B}(e_{[i]}), J) = \frac{p_{=1}(j - j' | \mathcal{A}(f_{i,1}), \mathcal{B}(e_{[i]}))}{\sum_{j''=1}^J p_{=1}(j'' - j' | \mathcal{A}(f_{i,1}), \mathcal{B}(e_{[i]}))}, \quad (3)$$

for the first aligned word and

$$p_{>1}(j | j', \mathcal{A}(f_{i,k}), J) = \frac{p_{>1}(j - j' | \mathcal{A}(f_{i,k}))}{\sum_{j''=1}^J p_{>1}(j'' - j' | \mathcal{A}(f_{i,k}))} \quad (4)$$

for all following words, again handling the M-step in EM training via projected gradient ascent. With this strategy words can no longer be placed outside the sentence, but a lot of probability mass is still wasted on configurations where at least one foreign (or predicted) position  $j$  aligns to two or more positions  $i, i'$  in the English (or given) language (and consequently there are more unaligned

<sup>4</sup>If the set is empty, instead a sentence start probability is used. Note that we differ slightly in notation compared to (Brown et al., 1993).

source words than the generated  $\Phi_0$ ). Therefore, here, too, the probability for  $\Phi_0$  has to be made deficient to get good performance.

In summary, the base model for the IBM-4 is:

$$p(f_1^J, a_1^J | e_1^I) = p\left(\Phi_0 \mid \sum_{i=1}^I \Phi_i\right) \cdot \prod_{j=1}^J p(f_j | e_{a_j}) \cdot \prod_{i=1}^I p(\Phi_i | e_i) \cdot \prod_{i:\Phi_i>0} \left[ p_{=1}(d_{i,1} - \odot_{[i]} | \mathcal{A}(f_{i,1}), \mathcal{B}(e_{[i]})) \cdot \prod_{k=2}^{\Phi_i} p_{>1}(d_{i,k} - d_{i,k-1} | \mathcal{A}(f_{i,k})) \right], \quad (5)$$

where empty products are understood to be 1.

### 2.3 IBM-5

We note in passing that the distortion model of the IBM-5 is nondeficient and has parameters for filling the  $n$ th open gap in the foreign sequence given that there are  $N$  positions to choose from – see the next section for exactly what positions one can choose from. There is also a dependence on word classes for the foreign language.

This is neither a zero order nor a first order dependence, and in (Och and Ney, 2003) the first order model of the IBM-4, though deficient, outperformed the IBM-5. The IBM-5 is therefore rarely used in practice. This motivated us to instead reformulate IBM-3 and IBM-4 as nondeficient models. In our results, however, the IBM-5 gave surprisingly good results and was often superior to all variants of the IBM-4.

## 3 Nondeficient Variants of IBM-3 and IBM-4

From now on we always enforce that for each position  $i$  the indices  $d_{i,k}$  are generated in ascending order ( $d_{i,k} > d_{i,k-1}$  for  $k > 1$ ). A central concept for the generation of  $d_{i,k}$  in step 3(b) is the set of positions in the foreign sequence that are still without alignment. We denote the set of these positions by

$$\mathcal{J}_{i,k,J} = \{1, \dots, J\} - \{d_{i,k'} | 1 \leq k' < k\} - \{d_{i',k'} | 1 \leq i' < i, 1 \leq k' \leq \Phi_{i'}\}$$

where the dependence on the various  $d_{i',k'}$  is not made explicit in the following.

It is tempting to think that in a nondeficient model all members of  $\mathcal{J}_{i,k,J}$  can be chosen for

$d_{i,k}$ , but this holds only  $\Phi_i = 1$ . Otherwise, the requirement of generating the  $d_{i,k}$  in ascending order prevents us from choosing the  $(\Phi_i - k)$  largest entries in  $\mathcal{J}_{i,k,J}$ . For  $k > 1$  we also have to remove all positions smaller than  $d_{i,k-1}$ .

Let  $\mathcal{J}_{i,k,J}^{\Phi_i}$  denote the set where these positions have been removed. With that, we can state the nondeficient variants of IBM-3 and IBM-4.

### 3.1 Nondeficient IBM-3

For the IBM-3, we define the auxiliary quantity

$$q(d_{i,k} = j | i, \mathcal{J}_{i,k,J}^{\Phi_i}) = \begin{cases} p(j|i) & \text{if } j \in \mathcal{J}_{i,k,J}^{\Phi_i} \\ 0 & \text{else,} \end{cases}$$

where we use the zero order parameters  $p(j|i)$  we also use for the standard (deficient) IBM-3, compare (2). To get a nondeficient variant, it remains to renormalize, resulting in

$$p(d_{i,k} = j | i, \mathcal{J}_{i,k,J}^{\Phi_i}) = \frac{q(j|i, \mathcal{J}_{i,k,J}^{\Phi_i})}{\sum_{j=1}^J q(j|i, \mathcal{J}_{i,k,J}^{\Phi_i})}. \quad (6)$$

Further, note that the factors  $\Phi_i!$  now have to be removed from (1) as the  $d_{i,k}$  are generated in ascending order. Lastly, here we use the original nondeficient empty word model  $p(\Phi_0 | \sum_{i=1}^I \Phi_i)$ , resulting in a totally nondeficient model.

### 3.2 Nondeficient IBM-4

With the notation set up, it is rather straightforward to derive a nondeficient variant of the IBM-4. Here, there are the two cases  $k = 1$  and  $k > 1$ . We begin with the case  $k = 1$ . Abbreviating  $\alpha = \mathcal{A}(f_{i,1})$  and  $\beta = \mathcal{B}(e_{[i]})$ , we define the auxiliary quantity

$$q_{=1}(d_{i,1} = j | \odot_{[i]}, \alpha, \beta, \mathcal{J}_{i,k,J}^{\Phi_i}) = \begin{cases} p_{=1}(j - \odot_{[i]} | \alpha, \beta) & \text{if } j \in \mathcal{J}_{i,k,J}^{\Phi_i} \\ 0 & \text{else,} \end{cases} \quad (7)$$

again using the - now first order - parameters of the base model. The nondeficient distribution  $p_{=1}(d_{i,1} = j | \odot_{[i]}, \alpha, \beta, \mathcal{J}_{i,k,J}^{\Phi_i})$  is again obtained by renormalization.

For the case  $k > 1$ , we abbreviate  $\alpha = \mathcal{A}(f_{i,k})$  and introduce the auxiliary quantity

$$q_{>1}(d_{i,k} = j | d_{i,k-1}, \alpha, \mathcal{J}_{i,k,J}^{\Phi_i}) = \begin{cases} p_{>1}(j - d_{i,k-1} | \alpha) & \text{if } j \in \mathcal{J}_{i,k,J}^{\Phi_i} \\ 0 & \text{else,} \end{cases} \quad (8)$$

from which the nondeficient distribution  $p_{>1}(d_{i,k} = j | d_{i,k-1}, \alpha, \mathcal{J}_{i,k,J}^{\Phi_i})$  is again obtained by renormalization.

## 4 Training the New Variants

For the task of word alignment, we infer the parameters of the models using the maximum likelihood criterion

$$\max_{\theta} \prod_{s=1}^S p_{\theta}(\mathbf{f}_s | \mathbf{e}_s) \quad (9)$$

on a set of training data (i.e. sentence pairs  $s = 1, \dots, S$ ). Here,  $\theta$  comprises all base parameters of the respective model (e.g. for the IBM-3 all  $p(f|e)$ , all  $p(\Phi, e)$  and all  $p(j|i)$ ) and  $p_{\theta}$  signifies the dependence of the model on the parameters. Note that (9) is truly a *constrained* optimization problem as the parameters  $\theta$  have to satisfy a number of probability normalization constraints.

When  $p_{\theta}(\cdot)$  denotes a fertility based model the resulting problem is a non-concave maximization problem with many local minima and no (known) closed-form solutions. Hence, it is handled by computational methods, which typically apply the logarithm to the above function.

Our method of choice to attack the maximum likelihood problem is expectation maximization (EM), the standard in the field, which we explain below. Due to non-concaveness the starting point for EM is of extreme importance. As is common, we first train an IBM-1 and then an HMM before proceeding to the IBM-3 and finally the IBM-4.

As in the training of the deficient IBM-3 and IBM-4 models, we approximate the expectations in the E-step by a set of likely alignments, ideally centered around the Viterbi alignment, but already for the regular deficient variants computing it is NP-hard (Udapa and Maji, 2006). A first task is therefore to compute such a set. This task is also needed for the actual task of word alignment (annotating a given sentence pair with an alignment).

### 4.1 Alignment Computation

For computing alignments, we use the common procedure of hillclimbing where we start with an alignment, then iteratively compute the probabilities of all alignments differing by a move or a swap (Brown et al., 1993) and move to the best of these if it beats the current alignment.

Since we cannot ignore parts of the history and still get a nondeficient model, computing the probabilities of the neighbors cannot be handled incrementally (or rather only partially, for the dictionary and fertility models). While this does increase running times, in practice the M-steps take longer than the E-steps.

For self-containment, we recall here that for an alignment  $a_1^J$  applying the **move**  $a_1^J[j \rightarrow i]$  results in the alignment  $\hat{a}_1^J$  defined by  $\hat{a}_j = i$  and  $\hat{a}_{j'} = a_{j'}$  for  $j' \neq j$ . Applying the **swap**  $a_1^J[j_1 \leftrightarrow j_2]$  results in the alignment  $\hat{a}_1^J$  defined by  $\hat{a}_{j_1} = a_{j_2}$ ,  $\hat{a}_{j_2} = a_{j_1}$  and  $\hat{a}_{j'} = a_{j'}$  elsewhere. If  $a_1^J$  is the alignment produced by hillclimbing, the **move matrix**  $m \in \mathbb{R}^{J \times I+1}$  is defined by  $m_{j,i}$  being the probability of  $a_1^J[j \rightarrow i]$  as long as  $a_j \neq i$ , otherwise 0. Likewise the **swap matrix**  $s \in \mathbb{R}^{J \times J}$  is defined as  $s_{j_1, j_2}$  being the probability of  $a_1^J[j_1 \leftrightarrow j_2]$  for  $a_{j_1} \neq a_{j_2}$ , 0 otherwise. The move and swap matrices are used to approximate expectations in EM training (see below).

## 4.2 Parameter Update

**Naive Scheme** It is tempting to account for the changes in the model in hillclimbing, but to otherwise use the regular M-step procedures (closed form solution when not conditioning on  $J$  for the IBM-4 and for the non-parametric IBM-3, otherwise projected gradient ascent) for the deficient models. However, we verified that this is not a good idea: not only can the likelihood go down in the process (even if we could compute expectations exactly), but these schemes also heavily increase  $p_0$  in each iteration, i.e. the same problem Och and Ney (2003) found for the deficient models. There is therefore the need to execute the M-step properly, and when done the problem is indeed resolved.

**Proper EM** The expectation maximization (EM) framework (Dempster et al., 1977; Neal and Hinton, 1998) is a class of template procedures (rather than a proper algorithm) that iteratively requires solving the task

$$\max_{\theta_k} \sum_{s=1}^S \sum_{\mathbf{a}_s} p_{\theta_{k-1}}(\mathbf{a}_s | \mathbf{f}_s, \mathbf{e}_s) \log(p_{\theta_k}(\mathbf{f}_s, \mathbf{a}_s | \mathbf{e}_s)) \quad (10)$$

by appropriate means. Here,  $\theta_{k-1}$  are the parameters from the previous iteration, while  $\theta_k$  are those derived in the current iteration. Of course, here and in the following the normalization constraints on  $\theta$  apply, as already in (9). On explicit request of a reviewer we give a detailed account for our setting here. Readers not interested in the details can safely move on to the next section.

**Details on EM** For the corpora occurring in practice, the function (10) has many more terms than there are atoms in the universe. The trick is

that  $p_{\theta_k}(\mathbf{f}_s, \mathbf{a}_s | \mathbf{e}_s)$  is a product of factors, where each factor depends on very few components of  $\theta_k$  only. Taking the logarithm gives a sum of logarithms, and in the end we are left with the problem of computing the weights of each factor, which turn out to be expectations. To apply this to the (deficient) **IBM-3** model with parametric distortion we simplify  $p_{\theta_{k-1}}(\mathbf{a}_s | \mathbf{f}_s, \mathbf{e}_s) = p(\mathbf{a}_s)$  and define the counts  $n_{f,e}(\mathbf{a}_s) = \sum_{j=1}^J \delta(f_j^s, f) \cdot \delta(e_{a_j^s}^s, e)$ ,  $n_{\Phi,e}(\mathbf{a}_s) = \sum_{i=1}^I \delta(e_i^s, e) \cdot \delta(\Phi_i(\mathbf{a}_s), \Phi)$  and  $n_{j,i}(\mathbf{a}_s) = \delta(a_{j_1}^s, i)$ . We also use short hand notations for sets, e.g.  $\{p(f|e)\}$  is meant as the set of all translation probabilities induced by the given corpus. With this notation, after reordering the terms problem (10) can be written as

$$\begin{aligned} & \max_{\{p(f|e)\}, \{p(\Phi|e)\}, \{p(j|i)\}} \quad (11) \\ & \sum_{e,f} \left[ \sum_{s=1}^S \sum_{\mathbf{a}_s} p(\mathbf{a}_s) n_{f,e}(\mathbf{a}_s) \right] \log(p(f|e)) \\ & + \sum_{e,\Phi} \left[ \sum_{s=1}^S \sum_{\mathbf{a}_s} p(\mathbf{a}_s) n_{\Phi,e}(\mathbf{a}_s) \right] \log(p(\Phi|e)) \\ & + \sum_{i,j} \left[ \sum_{s=1}^S \sum_{\mathbf{a}_s} p(\mathbf{a}_s) n_{j,i}(\mathbf{a}_s) \right] \log(p(j|i, J)). \end{aligned}$$

Indeed, the weights in each line turn out to be nothing else than expectations of the respective factor under the distribution  $p_{\theta_{k-1}}(\mathbf{a}_s | \mathbf{f}_s, \mathbf{e}_s)$  and will henceforth be written as  $w_{f,e}$ ,  $w_{\Phi,e}$  and  $w_{j,i,J}$ . Therefore, executing an iteration of EM requires first calculating all expectations (E-step) and then solving the maximization problems (M-step). For models such as IBM-1 and HMM the expectations can be calculated efficiently, so the enormous sum of terms in (10) is equivalently written as a manageable one. In this case it can be shown<sup>5</sup> that the new  $\theta_k$  must have a higher likelihood (9) than  $\theta_{k-1}$  (unless a stationary point is reached). In fact, any  $\theta$  that has a higher value in the auxiliary function (11) than  $\theta_{k-1}$  must also have a higher likelihood. This is an important background for parametric models such as (2) where the M-step cannot be solved exactly.

For IBM-3/4/5 computing exact expectations is intractable (Udapa and Maji, 2006) and approximations have to be used (in fact, even computing the likelihood for a given  $\theta$  is intractable). We

<sup>5</sup>See e.g. the author's course notes (in German), currently <http://user.phil-fak.uni-duesseldorf.de/~tosch/downloads/statmt/wordalign.pdf>.

use the common procedure based on hillclimbing and the move/swap matrices. The likelihood is not guaranteed to increase but it (or rather its approximation) always did in each of the five run iterations. Nevertheless, the main advantage of EM is preserved: problem (11) decomposes into several smaller problems, one for each probability distribution since the parameters are tied by the normalization constraints. The result is one problem for each  $e$  involving all  $p(f|e)$ , one for each  $e$  involving all  $p(\Phi|e)$  and one for each  $i$  involving all  $p(j|i)$ .

The problems for the translation probabilities and the fertility probabilities yield the known standard update rules. The most interesting case is the problem for the (parametric) distortion models. In the deficient setting, the problem for each  $i$  is

$$\max_{\{p(j|i)\}} \sum_J w_{i,j,J} \log \left( \frac{p(j|i)}{\sum_{j'=1}^J p(j'|i)} \right)$$

In the nondeficient setting, we now drop the subscripts  $i, k, J$  and the superscript  $\Phi$  from the sets defined in the previous sections, i.e. we write  $\mathcal{J}$  instead of  $\mathcal{J}_{i,k,J}^\Phi$ . The M-step problem is then

$$\max_{\{p(j|i)\}} E_i = \sum_j \sum_{\mathcal{J}:j \in \mathcal{J}} w_{j,i,\mathcal{J}} \log(p(j|i, \mathcal{J})),$$

where  $w_{j,i,\mathcal{J}}$  (with  $j \in \mathcal{J}$ ) is the expectation for aligning  $j$  to  $i$  when one can choose among the positions in  $\mathcal{J}$ , and with  $p(j|i, \mathcal{J})$  as in (6). In principle there is an exponential number of expectations  $w_{j,i,\mathcal{J}}$ . However, since we approximate expectations from the move and swap matrices, and hence by  $\mathcal{O}((I+J) \cdot J)$  alignments per sentence pair, in the end we get a polynomial number of terms. Currently we only consider alignments with (approximated)  $p_{\theta_{k-1}}(\mathbf{a}_s | \mathbf{f}_s, \mathbf{e}_s) > 10^{-6}$ .

Importantly, the fact that we get separate M-step problems for different  $i$  allows us to reduce memory consumption by using refined data structures when storing the expectations.

For both the deficient and the nondeficient variants, the M-step problems for the distortion parameters  $p(j|i)$  are non-trivial, non-concave and have no (known) closed form solutions. We approach them via the method of projected gradient ascent (PGA), where the gradient for the nondeficient problem is

$$\frac{\partial E_i}{\partial p(j|i)} = \sum_{\mathcal{J}:j \in \mathcal{J}} \left[ \frac{w_{j,\mathcal{J}}}{p(j|i)} - \frac{\sum_{j' \in \mathcal{J}} w_{j',\mathcal{J}}}{\sum_{j' \in \mathcal{J}} p(j'|i)} \right].$$

When running PGA we guarantee that the resulting  $\{p(j|i)\}$  has a higher function value  $E_i$  than the input ones (unless a stationary point is input). We stop when a cutoff criterion indicates a local maximum or 250 iterations are used up.

**Projected Gradient Ascent** This method is used in a couple of recent papers, notably (Schoenemann, 2011; Vaswani et al., 2012) and is briefly sketched here for self-containment (see those papers for more details). To solve a maximization problem

$$\max_{p(j|i) \geq 0, \sum_j p(j|i)=1} E_i(\{p(j|i)\})$$

for some (differentiable) function  $E_i(\cdot)$ , one iteratively starts at the current point  $\{p_k(j|i)\}$ , computes the gradient  $\nabla E_i(\{p_k(j|i)\})$  and goes to the point

$$q(j|i) = p_k(j|i) + \alpha \nabla E_i(p_k(j|i)), j = 1, \dots, J$$

for some step-length  $\alpha$ . This point is generally not a probability distribution, so one computes the *nearest* probability distribution

$$\min_{q'(j|i) \geq 0, \sum_j q'(j|i)=1} \sum_{j=1}^J (q'(j|i) - q(j|i))^2,$$

a step known as *projection* which we solve with the method of (Michelot, 1986). The new distribution  $\{q'(j|i)\}$  is not guaranteed to have a higher  $E_i(\cdot)$ , but (since the constraint set is a convex one) a suitable interpolation of  $\{p_k(j|i)\}$  and  $\{q'(j|i)\}$  is guaranteed to have a higher value (unless  $\{p_k(j|i)\}$  is a local maximum or minimum of  $E_i(\cdot)$ ). Such a point is computed by backtracking line search and defines the next iterate  $\{p_{k+1}(j|i)\}$ .

**IBM-4** When moving from the IBM-3 to the IBM-4, only the last line in (11) changes. In the end one gets two new kinds of problems, for  $p_{=1}(\cdot)$  and  $p_{>1}(\cdot)$ . For  $p_{=1}(\cdot)$  we have one problem for each foreign class  $\alpha$  and each English class  $\beta$ , of the form

$$\max_{\{p_{=1}(j|j',\alpha,\beta)\}} \sum_{j,j',J} w_{j,j',J,\alpha,\beta} \log(p_{=1}(j|j',\alpha,\beta, J))$$

for reduced deficiency (with  $p_{=1}(j|j',\alpha,\beta, J)$  as in (3)) and of the form

$$\max_{\{p_{>1}(j|j',\alpha,\beta)\}} \sum_{j,j',J} w_{j,j',J,\alpha,\beta} \log(p_{>1}(j|j',\alpha,\beta, J))$$

Model	Degree of Deficiency	De En	En De	Es En	En Es
HMM	nondeficient (our)	73.8	77.6	77.4	76.1
IBM-3	full (GIZA++)	74.2	76.5	74.3	74.5
IBM-3	full (our)	75.6	79.2	75.2	73.7
IBM-3	nondeficient (our)	76.1	79.8	76.8	75.5
IBM-4, 1 x 1 word class	full (GIZA++)	77.9	79.4	78.6	78.4
IBM-4, 1 x 1 word class	full (our)	76.1	81.5	77.8	78.0
IBM-4, 1 x 1 word class	reduced (our)	77.2	80.6	77.9	78.3
IBM-4, 1 x 1 word class	nondeficient (our)	77.6	81.5	80.0	78.4
IBM-4, 50 x 50 word classes	full (GIZA++)	78.6	80.4	79.3	79.3
IBM-4, 50 x 50 word classes	full (our)	78.0	82.4	79.2	79.4
IBM-4, 50 x 50 word classes	reduced (our)	78.5	82.1	79.2	79.0
IBM-4, 50 x 50 word classes	nondeficient (our)	77.9	82.5	79.7	78.2
IBM-5, 50 word classes	nondeficient (GIZA++)	79.4	81.1	80.0	79.5
IBM-5, 50 word classes	nondeficient (our)	79.2	82.7	79.7	79.5

Table 1: **Alignment accuracy** (weighted F-measure times 100,  $\alpha = 0.1$ ) on Europarl with 100.000 sentence pairs. Reduced deficiency means renormalization as in (3) and (4), so that words cannot be placed before or after the sentence. **For the IBM-3**, the nondeficient variant is clearly best. **For the IBM-4** it is better in roughly half the cases, both with and without word classes.

for the nondeficient variant, with  $p_{=1}(j|j', \alpha, \beta, \mathcal{J})$  based on (7).

For  $p_{>1}(\cdot)$  we have one problem per foreign class  $\alpha$ , of the form

$$\max_{\{p_{>1}(j|j', \alpha)\}} \sum_{j, j', J} w_{j, j', J, \alpha} \log(p_{>1}(j|j', \alpha, J))$$

for reduced deficiency, with  $p_{>1}(j|j', \alpha, J)$  based on (4), and for the nondeficient variant it has the form

$$\max_{\{p_{>1}(j|j', \alpha)\}} \sum_{j, j', \mathcal{J}} w_{j, j', \mathcal{J}, \alpha} \log(p_{>1}(j|j', \alpha, \mathcal{J})),$$

with  $p_{>1}(j|j', \alpha, \mathcal{J})$  based on (8). Calculating the gradients is analogous to the IBM-3.

## 5 Experiments

We test the proposed methods on subsets of the Europarl corpus for German and English as well as Spanish and English, using lower-cased corpora. We evaluate alignment accuracies on gold alignments<sup>6</sup> in the form of weighted F-measures with  $\alpha = 0.1$ , which performed well in (Fraser and Marcu, 2007b). In addition we evaluate the effect on phrase-based translation on one of the tasks.

We implement the proposed methods in our own framework RegAligner rather than GIZA++,

<sup>6</sup>from (Lambert et al., 2005) and from <http://user.phil-fak.uni-duesseldorf.de/~tosch/downloads.html>.

which is only rudimentally maintained. Therefore, we compare to the deficient models in our own software as well as to those in GIZA++.

We run 5 iterations of IBM-1, followed by 5 iterations of HMM, 5 of IBM-3 and finally 5 of IBM-4. The first iteration of the IBM-3 collects counts from the HMM, and likewise the first iteration of the IBM-4 collects counts from the IBM-3 (in both cases the move and swap matrices are filled with probabilities of the former model, then these matrices are used as in a regular model iteration). A nondeficient IBM-4 is always initialized by a nondeficient IBM-3. We did not set a fertility limit (except for GIZA++).

Experiments were run on a Core i5 with 2.5 GHz and 8 GB of memory. The latter was the main reason why we did not use still larger corpora<sup>7</sup>. The running times for the entire training were half a day without word classes and a day with word classes. With 50 instead of 250 PGA iterations in all M-steps we get only half these running times, but the resulting F-measures deteriorate, especially for the IBM-4 with classes.

The running times of our implementation of the IBM-5 are much more favorable: the entire training then runs in little more than an hour.

<sup>7</sup>The main memory bottleneck is the IBM-4 (6 GB without classes, 8 GB with). Using refined data structures should reduce this bottleneck.

## 5.1 Alignment Accuracy

The alignment accuracies – weighted F-measures with  $\alpha = 0.1$  – for the tested corpora and model variants are given in Table 1. Clearly, nondeficiency greatly improves the accuracy of the IBM-3, both compared to our deficient implementation and that of GIZA++.

For the IBM-4 we get improvements for the nondeficient variant in roughly half the cases, both with and without word classes. We think this is an issue of local minima, inexactly solved M-steps and sensitiveness to initialization.

Interestingly, also the reduced deficient IBM-4 is not always better than the fully deficient variant. Again, we think this is due to problems with the non-concave nature of the models.

There is also quite some surprise regarding the IBM-5: contrary to the findings of (Och and Ney, 2003) the IBM-5 in GIZA++ performs best in three out of four cases - when competing with both deficient and nondeficient variants of IBM-3 and IBM-4. Our own implementation gives slightly different results (as we do not use smoothing), but it, too, performs very well.

## 5.2 Effect on Translation Performance

We also check the effect of the various alignments (all produced by RegAligner) on translation performance for phrase-based translation, randomly choosing translation from German to English. We use MOSES with a 5-gram language model (trained on 500.000 sentence pairs) and the standard setup in the MOSES Experiment Management System: training is run in both directions, the alignments are combined using `diag-grow-final-and` (Och and Ney, 2003) and the parameters of MOSES are optimized on 750 development sentences.

The resulting BLEU-scores are shown in Table 2. However, the table shows no clear trends and even the IBM-3 is not clearly inferior to the IBM-4. We think that one would need to handle larger corpora (or run multiple instances of Minimum Error Rate Training with different random seeds) to get more meaningful insights. Hence, at present our paper is primarily of theoretical value.

## 6 Conclusion

We have shown that the word alignment models IBM-3 and IBM-4 can be turned into nondeficient

Model	#Classes	Deficiency	BLEU
HMM	-	nondeficient	29.72
IBM-3	-	deficient	29.63
IBM-3	-	nondeficient	29.73
IBM-4	1 x 1	fully deficient	29.91
IBM-4	1 x 1	reduced deficient	29.88
IBM-4	1 x 1	nondeficient	30.18
IBM-4	50 x 50	fully deficient	29.86
IBM-4	50 x 50	reduced deficient	30.14
IBM-4	50 x 50	nondeficient	29.90
IBM-5	50	nondeficient	29.84

Table 2: Evaluation of **phrase-based translation** from German to English with the obtained alignments (for 100.000 sentence pairs). Training is run in both directions and the resulting alignments are combined via `diag-grow-final-and`. The table shows no clear superiority of any method. In fact, the IBM-4 is not superior to the IBM-3 and the HMM is about equal to the IBM-3. We think that one needs to handle larger corpora to get clearer insights.

variants, an important aim of probabilistic modeling for word alignment.

Here we have exploited that the models are proper applications of the chain rule of probabilities, where deficiency is only introduced by ignoring parts of the history for the distortion factors in the factorization. By proper renormalization the desired nondeficient variants are obtained.

The arising models are trained via expectation maximization. In the E-step we use hillclimbing to get a likely alignment (ideally the Viterbi alignment). While this cannot be handled fully incrementally, it is still fast enough in practice. The M-step energies are non-concave and have no (known) closed-form solutions. They are handled via projected gradient ascent.

For the IBM-3 nondeficiency clearly improves alignment accuracy. For the IBM-4 we get improved accuracies in roughly half the cases, both with and without word classes. The IBM-5 performs surprisingly well, it is often best and hence much better than its reputation. An evaluation of phrase based translation showed no clear insights.

Nevertheless, we think that nondeficiency in fertility based models is an important issue, and that at the very least our paper is of theoretical value. The implementations are publicly available in RegAligner 1.2.

# Modelling Annotator Bias with Multi-task Gaussian Processes: An Application to Machine Translation Quality Estimation

Trevor Cohn and Lucia Specia

Department of Computer Science

University of Sheffield

Sheffield, United Kingdom

{t.cohn, l.specia}@sheffield.ac.uk

## Abstract

Annotating linguistic data is often a complex, time consuming and expensive endeavour. Even with strict annotation guidelines, human subjects often deviate in their analyses, each bringing different biases, interpretations of the task and levels of consistency. We present novel techniques for learning from the outputs of multiple annotators while accounting for annotator specific behaviour. These techniques use multi-task Gaussian Processes to learn jointly a series of annotator and metadata specific models, while explicitly representing correlations between models which can be learned directly from data. Our experiments on two machine translation quality estimation datasets show uniform significant accuracy gains from multi-task learning, and consistently outperform strong baselines.

## 1 Introduction

Most empirical work in Natural Language Processing (NLP) is based on supervised machine learning techniques which rely on human annotated data of some form or another. The annotation process is often time consuming, expensive, and prone to errors; moreover there is often considerable disagreement amongst annotators.

In general, the predominant perspective to deal with these data annotation issues in previous work has been that there is a single underlying *ground truth*, and that the annotations collected are noisy and/or biased samples of this. The challenge is then one of quality control, in order to process the data by filtering, averaging or similar to distil the truth. We posit that this perspective is too limiting, especially with respect to linguistic data, where each individual's idiolect and linguistic background can give rise to many different

– and yet equally valid – truths. Particularly in highly subjective annotation tasks, the differences between annotators cannot be captured by simple models such as scaling all instances of a certain annotator by a factor. They can originate from a number of nuanced aspects. This is the case, for example, of annotations on the quality of sentences generated using machine translation (MT) systems, which are often used to build **quality estimation** models (Blatz et al., 2004; Specia et al., 2009) – our application of interest.

In addition to annotators' own perceptions and expectations with respect to translation quality, a number of factors can affect their judgements on specific sentences. For example, certain annotators may prefer translations produced by rule-based systems as these tend to be more grammatical, while others would prefer sentences produced by statistical systems with more adequate lexical choices. Likewise, some annotators can be biased by the complexity of the source sentence: lengthy sentences are often (subconsciously) assumed to be of low quality by some annotators. An extreme case is the judgement of quality through post-editing *time*: annotators have different typing speeds, as well as levels of expertise in the task of post-editing, proficiency levels in the language pair, and knowledge of the terminology used in particular sentences. These variations result in time measurements that are not comparable across annotators. Thus far, the use of post-editing time has been done on an per-annotator basis (Specia, 2011), or simply averaged across multiple translators (Plitt and Masselot, 2010), both strategies far from ideal.

Overall, these myriad of factors affecting quality judgements make the modelling of multiple annotators a very challenging problem. This problem is exacerbated when annotations are provided by non-professional annotators, e.g., through crowdsourcing – a common strategy used

to make annotation cheaper and faster, however at the cost of less reliable outcomes.

Most related work on quality assurance for data annotation has been developed in the context of crowdsourcing. Common practices include filtering out annotators who substantially deviate from a gold-standard set or present unexpected behaviours (Raykar et al., 2010; Raykar and Yu, 2012), or who disagree with others using, e.g., majority or consensus labelling (Snow et al., 2008; Sheng et al., 2008). Another relevant strand of work aims to model legitimate, systematic biases in annotators (including both non-experts and experts), such as the fact that some annotators tend to be more negative than others, and that some annotators use a wider or narrower range of values (Flach et al., 2010; Ipeirotis et al., 2010). However, with a few exceptions in Computer Vision (e.g., Whitehill et al. (2009), Welinder et al. (2010)), existing work disregard metadata and its impact on labelling.

In this paper we model the task of predicting the quality of sentence translations using datasets that have been annotated by several judges with different levels of expertise and reliability, containing translations from a variety of MT systems and on a range of different types of sentences. We address this problem using **multi-task learning** in which we learn individual models for each context (the *task*, incorporating the annotator and other metadata: translation system and the source sentence) while also modelling correlations between tasks such that related tasks can mutually inform one another. Our use of multi-task learning allows the modelling of a diversity of *truths*, while also recognising that they are rarely independent of one another (annotators often agree) by explicitly accounting for inter-annotator correlations.

Our approach is based on Gaussian Processes (GPs) (Rasmussen and Williams, 2006), a kernelised Bayesian non-parametric learning framework. We develop multi-task learning models by representing intra-task transfer simply and explicitly as part of a parameterised kernel function. GPs are an extremely flexible probabilistic framework and have been successfully adapted for multi-task learning in a number of ways, e.g., by learning multi-task correlations (Bonilla et al., 2008), modelling per-task variance (Groot et al., 2011) or per-annotator biases (Rogers et al., 2010). Our method builds on the work of Bonilla et al. (2008) by

explicitly modelling intra-task transfer, which is learned automatically from the data, in order to robustly handle outlier tasks and task variances. We show in our experiments on two translation quality datasets that these multi-task learning strategies are far superior to training individual per-task models or a single pooled model, and moreover that our multi-task learning approach can achieve similar performance to these baselines using only a fraction of the training data.

In addition to showing empirical performance gains on quality estimation applications, an important contribution of this paper is in introducing Gaussian Processes to the NLP community,<sup>1</sup> a technique that has great potential to further performance in a wider range of NLP applications. Moreover, the algorithms proposed herein can be adapted to improve future annotation efforts, and subsequent use of noisy crowd-sourced data.

## 2 Quality Estimation

Quality estimation (QE) for MT aims at providing an estimate on the quality of each translated segment – typically a sentence – without access to reference translations. Work in this area has become increasingly popular in recent years as a consequence of the widespread use of MT among real-world users such as professional translators. Examples of applications of QE include improving post-editing efficiency by filtering out low quality segments which would require more effort and time to correct than translating from scratch (Specia et al., 2009), selecting high quality segments to be published as they are, without post-editing (Soricut and Echiabi, 2010), selecting a translation from either an MT system or a translation memory for post-editing (He et al., 2010), selecting the best translation from multiple MT systems (Specia et al., 2010), and highlighting sub-segments that need revision (Bach et al., 2011).

QE is generally addressed as a machine learning task using a variety of linear and kernel-based regression or classification algorithms to induce models from examples of translations described through a number of features and annotated for quality. For an overview of various algorithms and features we refer the reader to the WMT12 shared task on QE (Callison-Burch et al., 2012).

While initial work used annotations derived

---

<sup>1</sup>We are not strictly the first, Polajnar et al. (2011) used GPs for text classification.

from automatic MT evaluation metrics (Blatz et al., 2004) such as BLEU (Papineni et al., 2002) at training time, it soon became clear that human labels result in significantly better models (Quirk, 2004). Current work at sentence level is thus based on some form of human supervision.

As typical of subjective annotation tasks, QE datasets should contain multiple annotators to lead to models that are representative. Therefore, work in QE faces all common issues regarding variability in annotators’ judgements. The following are a few other features that make our datasets particularly interesting:

- In order to minimise annotation costs, translation instances are often spread among annotators, such that each instance is only labelled by one or a few judges. In fact, for a sizeable dataset (thousands of instances), the annotation of a complete dataset by a single judge may become infeasible.
- It is often desirable to include alternative translations of source sentences produced by multiple MT systems, which requires multiple annotators for unbiased judgements, particularly for labels such as post-editing time (a translation seen a second time will require less editing effort).
- For crowd-sourced annotations it is often impossible to ensure that the same annotators will label the same subset of cases.

These features – which are also typical of many other linguistic annotation tasks – make the learning process extremely challenging. Learning models from datasets annotated by multiple annotators remains an open challenge in QE, as we show in Section 4. In what follows, we present our QE datasets in more detail.

## 2.1 Datasets

We use two freely available QE datasets to experiment with the techniques proposed in this paper:<sup>2</sup>

**WMT12:** This dataset was distributed as part of the WMT12 shared task on QE (Callison-Burch et al., 2012). It contains 1,832 instances for training, and 422 for test. The English source sentences are a subset of WMT09-12 test sets. The Spanish MT outputs were created using a standard PBSMT Moses engine. Each instance was annotated with post-editing effort scores from highest

effort (score 1) to lowest effort (score 5), where each score identifies an estimated percentage of the MT output that needs to be corrected. The post-editing effort scores were produced independently by three professional translators based on a previously post-edited translation by a fourth translator. In an attempt to accommodate for systematic biases among annotators, the final effort score was computed as the weighted average between the three PE-effort scores, with more weight given to the judges with higher standard deviation from their own mean score. This resulted in scores spread more evenly in the [1, 5] range.

**WPTP12:** This dataset was distributed by Koponen et al. (2012). It contains 299 English sentences translated into Spanish using two or more of eight MT systems randomly selected from all system submissions for WMT11 (Callison-Burch et al., 2011). These MT systems range from online and customised SMT systems to commercial rule-based systems. Translations were post-edited by humans while time was recorded. The labels are the number of seconds spent by a translator editing a sentence normalised by source sentence length. The post-editing was done by eight native speakers of Spanish, including five professional translators and three translation students. Only 20 translations were edited by all eight annotators, with the remaining translations randomly distributed amongst them. The resulting dataset contains 1,624 instances, which were randomly split into 1,300 for training and 300 for test. According to the analysis in (Koponen et al., 2012), while on average certain translators were found to be faster than others, their speed in post-editing individual sentences varies considerably, i.e., certain translators are faster at certain sentences. To our knowledge, no previous work has managed to successfully model the prediction of post-editing time from datasets with multiple annotators.

## 3 Gaussian Process Regression

Machine learning models for quality estimation typically treat the problem as regression, seeking to model the relationship between features of the text input and the human quality judgement as a continuous response variable. Popular choices include Support Vector Machines (SVMs), which have been shown to perform well for quality estimation (Callison-Burch et al., 2012) using non-linear kernel functions such as radial basis func-

<sup>2</sup>Both datasets can be downloaded from <http://www.dcs.shef.ac.uk/~lucia/resources.html>.

tions. In this paper we consider Gaussian Processes (GP) (Rasmussen and Williams, 2006), a probabilistic machine learning framework incorporating kernels and Bayesian non-parametrics, widely considered state-of-the-art for regression. Despite this GPs have not been used widely to date in statistical NLP. GPs are particularly suitable for modelling QE for a number of reasons: 1) they explicitly model uncertainty, which is rife in QE datasets; 2) they allow fitting of expressive kernels to data, in order to modulate the effect of features of varying usefulness; and 3) they can naturally be extended to model correlated tasks using multi-task kernels. We now give a brief overview of GPs, following Rasmussen and Williams (2006).

In our regression task<sup>3</sup> the data consists of  $n$  pairs  $\mathcal{D} = \{(\mathbf{x}_i, y_i)\}$ , where  $\mathbf{x}_i \in \mathbb{R}^F$  is a  $F$ -dimensional feature vector and  $y_i \in \mathbb{R}$  is the response variable. Each instance is a translation and the feature vector encodes its linguistic features; the response variable is a numerical quality judgement: post editing time or likert score. As usual, the modelling challenge is to automatically predict the value of  $y$  based on the  $\mathbf{x}$  for unseen test input.

GP regression assumes the presence of a latent function,  $f : \mathbb{R}^F \rightarrow \mathbb{R}$ , which maps from the input space of feature vectors  $\mathbf{x}$  to a scalar. Each response value is then generated from the function evaluated at the corresponding data point,  $y_i = f(\mathbf{x}_i) + \eta$ , where  $\eta \sim \mathcal{N}(0, \sigma_n^2)$  is added white-noise. Formally  $f$  is drawn from a GP prior,

$$f(\mathbf{x}) \sim \mathcal{GP}(\mathbf{0}, k(\mathbf{x}, \mathbf{x}')) \quad ,$$

which is parameterised by a mean (here, 0) and a covariance kernel function  $k(\mathbf{x}, \mathbf{x}')$ . The kernel function represents the covariance (i.e., similarities in the response) between pairs of data points. Intuitively, points that are in close proximity should have high covariance compared to those that are further apart, which constrains  $f$  to be a smoothly varying function of its inputs. This intuition is embodied in the squared exponential kernel (*a.k.a.* radial basis function or Gaussian),

$$k(\mathbf{x}, \mathbf{x}') = \sigma_f^2 \exp\left(-\frac{1}{2}(\mathbf{x} - \mathbf{x}')^T A^{-1}(\mathbf{x} - \mathbf{x}')\right) \quad (1)$$

where  $\sigma_f^2$  is a scaling factor describing the overall levels of variance, and  $A = \text{diag}(\mathbf{a})$  is a diagonal

<sup>3</sup>Our approach generalises to classification, ranking (ordinal regression) or various other training objectives, including mixtures of objectives. In this paper we use regression for simplicity of exposition and implementation.

matrix of length scales, encoding the smoothness of functions  $f$  with respect to each feature. Non-uniform length scales allow for different degrees of smoothness of  $f$  in each dimension, such that e.g., for unimportant features  $f$  is relatively flat whereas for very important features  $f$  is jagged, such that a small change in the feature value has a large effect. When the values of  $\mathbf{a}$  are learned automatically from data, as we do herein, this is referred to as the *automatic relevance determination* (ARD) kernel.

Given the generative process defined above, we formulate prediction as Bayesian inference under the posterior, namely

$$p(y_* | \mathbf{x}_*, \mathcal{D}) = \int_f p(y_* | \mathbf{x}_*, f) p(f | \mathcal{D})$$

where  $\mathbf{x}_*$  is a test input and  $y_*$  is its response value. The posterior  $p(f | \mathcal{D})$  reflects our updated belief over possible functions after observing the training set  $\mathcal{D}$ , i.e.,  $f$  should pass close to the response values for each training instance (but need not fit exactly due to additive noise). This is balanced against the smoothness constraints that arise from the GP prior. The predictive posterior can be solved analytically, resulting in

$$y_* \sim \mathcal{N}(\mathbf{k}_*^T (K + \sigma_n^2 I)^{-1} \mathbf{y}, \quad (2)$$

$$k(\mathbf{x}_*, \mathbf{x}_*) - \mathbf{k}_*^T (K + \sigma_n^2 I)^{-1} \mathbf{k}_*)$$

where  $\mathbf{k}_* = [k(\mathbf{x}_*, \mathbf{x}_1) \ k(\mathbf{x}_*, \mathbf{x}_2) \ \dots \ k(\mathbf{x}_*, \mathbf{x}_n)]^T$  are the kernel evaluations between the test point and the training set, and  $\{K_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)\}$  is the kernel (gram) matrix over the training points. Note that the posterior in Eq. 2 includes not only the expected response (the mean) but also the variance, encoding the model’s uncertainty, which is important for integration into subsequent processing, e.g., as part of a larger probabilistic model.

GP regression also permits an analytic formulation of the marginal likelihood,  $p(\mathbf{y} | X) = \int_f p(\mathbf{y} | X, f) p(f)$ , which can be used for model training ( $X$  are the training inputs). Specifically, we can derive the gradient of the (log) marginal likelihood with respect to the model hyperparameters (i.e.,  $\mathbf{a}, \sigma_n, \sigma_s$  etc.) and thereby find the type II maximum likelihood estimate using gradient ascent. Note that in general the marginal likelihood is non-convex in the hyperparameter values, and consequently the solutions may only be locally optimal. Here we bootstrap the learning of complex models with many hyperparameters by initialising

with the (good) solutions found for simpler models, thereby avoiding poor local optima. We refer the reader to Rasmussen and Williams (2006) for further details.

At first glance GPs resemble SVMs, which also admit kernels such as the popular squared exponential kernel in Eq. 1. The key differences are that GPs are probabilistic models and support exact Bayesian inference in the case of regression (approximate inference is required for classification (Rasmussen and Williams, 2006)). Moreover GPs provide greater flexibility in fitting the kernel hyperparameters even for complex composite kernels. In typical usage, the kernel hyperparameters for an SVM are fit using held-out estimation, which is inefficient and often involves tying together parameters to limit the search complexity (e.g., using a single scale parameter in the squared exponential). Multiple-kernel learning (Gönen and Alpaydm, 2011) goes some way to addressing this problem within the SVM framework, however this technique is limited to reweighting linear combinations of kernels and has high computational complexity.

### 3.1 Multi-task Gaussian Process Models

Until now we have considered a standard regression scenario, where each training point is labelled with a single output variable. In order to model multiple different annotators jointly, i.e., multi-task learning, we need to extend the model to handle many tasks. Conceptually, we can consider the multi-task model drawing a latent function for each task,  $f_m(\mathbf{x})$ , where  $m \in 1, \dots, M$  is the task identifier. This function is then used to explain the response values for all the instances for that task (subject to noise). Importantly, for multi-task learning to be of benefit, the prior over  $\{f_m\}$  must correlate the functions over different tasks, e.g., by imposing similarity constraints between the values for  $f_m(\mathbf{x})$  and  $f_{m'}(\mathbf{x})$ .

We can consider two alternative perspectives for framing the multi-task learning problem: either *isotopic* where we associate each input point  $\mathbf{x}$  with a vector of outputs,  $\mathbf{y} \in \mathbb{R}^M$ , one for each of the  $M$  tasks; or *heterotopic* where some of the outputs are missing, i.e., tasks are not constrained to share the same data points (Alvarez et al., 2011). Given the nature of our datasets, we opted for the heterotopic approach, which can handle both singly annotated and multiply annotated

data. This can be implemented by augmenting each input point with an additional task identity feature, which is paired with a single  $y$  response, and integrated into a GP model with the standard training and inference algorithms.<sup>4</sup>

In moving to a task-augmented data representation, we need to revise our kernel function. We use a separable multi-task kernel (Bonilla et al., 2008; Alvarez et al., 2011) of the form

$$k((\mathbf{x}, d), (\mathbf{x}', d')) = k^{\text{data}}(\mathbf{x}, \mathbf{x}')B_{d,d'}, \quad (3)$$

where  $k^{\text{data}}(\mathbf{x}, \mathbf{x}')$  is a standard kernel over the input points, typically a squared exponential (see Eq. 1), and  $B \in \mathbb{R}^{D \times D}$  is a positive semi-definite matrix encoding task covariances. We develop a series of increasingly complex choices for  $B$ , which we compare empirically in Section 4.2:

**Independent** The simplest case is where  $B = I$ , i.e., all pairs of different tasks have zero covariance. This corresponds to independent modelling of each task, although all models share the same data kernel, so this setting is not strictly equivalent to independent training with independent per-task data kernels (with different hyperparameters). Similarly, we might choose to use a single noise variance,  $\sigma_n^2$ , or an independent noise variance hyperparameter per task.

**Pooled** Another extreme is  $B = \mathbf{1}$ , which ignores the task identity, corresponding to pooling the multi-task data into one large set. Groot et al. (2011) present a method for applying GPs for modelling multi-annotator data using this **pooling** kernel with independent per-task noise terms. They show on synthetic data experiments that this approach works well at extracting the signal from noise-corrupted inputs.

**Combined** A simple approach for  $B$  is a weighted combination of **Independent** and **Pool**, i.e.,  $B = \mathbf{1} + aI$ , where the hyperparameter  $a \geq 0$  controls the amount of inter-task transfer between each task and the global ‘pooled’ task.<sup>5</sup> For dissimilar tasks, a high value of  $a$  allows each task to be modelled independently, while for more similar tasks low  $a$  allows the use of a large pool of

<sup>4</sup>Note that the separable kernel (Eq. 3) gives rise to block structured kernel matrices which permit various optimisations (Bonilla et al., 2008) to reduce the computational complexity of inference, e.g., the matrix inversion in Eq. 2.

<sup>5</sup>Note that larger values of  $a$  need not affect the overall magnitude of  $k$ , which can be down-scaled by the  $\sigma_f^2$  factor in the data kernel (Eq. 1).

similar data. A scaled version of this kernel has been shown to correspond to mean regularisation in SVMs when combined with a linear data kernel (Evgeniou et al., 2006). A similar multi-task kernel was proposed by Daumé III (2007), using a linear data kernel and  $a = 1$ , which has shown to result in excellent performance across a range of NLP problems. In contrast to these earlier approaches, we learn the hyperparameter  $a$  directly, fitting the relative amounts of inter- versus intra-task transfer to the dataset.

**Combined+** We consider an extension to the **Combined** kernel,  $B = \mathbf{1} + \text{diag}(\mathbf{a})$ ,  $a_d \geq 0$  in which each task has a different hyperparameter modulating its independence from the global pool. This additional flexibility can be used, e.g., to allow individual outlier annotators to be modelled independently of the others, by assigning a high value to  $a_d$ . In contrast, **Combined** ties together the parameters for all tasks, i.e., all annotators are assumed to have similar quality in that they deviate from the mean to the same degree.

### 3.2 Integrating metadata

The approaches above assume that the data is split into an unstructured set of  $M$  tasks, e.g., by annotator. However, it is often the case that we have additional information about each data instance in the form of metadata. In our quality estimation experiments we consider as metadata the MT system which produced the translation, and the identity of the source sentence being translated. Many other types of metadata, such as the level of experience of the annotator, could also be used. One way of integrating such metadata would be to define a separate task for every observed combination of metadata values, in which case we treat the metadata as a *task descriptor*. Doing so naively would however incur a significant penalty, as each task will have very few training instances resulting in inaccurate models, even with the inter-task kernel approaches defined above.

We instead extend the task-level kernels to use the task descriptors directly to represent task correlations. Let  $B^{(i)}$  be a square covariance matrix for the  $i^{\text{th}}$  task descriptor of  $M$ , with a column and row for each value (e.g., annotator identity, translation system, etc.). We redefine the task level kernel using paired inputs  $(\mathbf{x}, \mathbf{m})$ , where  $\mathbf{m}$  are the

task descriptors,

$$k((\mathbf{x}, \mathbf{m}), (\mathbf{x}', \mathbf{m}')) = k^{\text{data}}(\mathbf{x}, \mathbf{x}') \prod_{i=1}^M B_{m_i, m'_i}^{(i)}.$$

This is equivalent to using a structured task-kernel  $B = B^{(1)} \otimes B^{(2)} \otimes \dots \otimes B^{(M)}$  where  $\otimes$  is the Kronecker product. Using this formulation we can consider any of the above choices for  $B$  applied to each task descriptor. In our experiments we consider the **Combined** and **Combined+** kernels, which allow the model to learn the relative importance of each descriptor in terms of independent modelling versus pooling the data.

## 4 Multi-task Quality Estimation

### 4.1 Experimental Setup

**Feature sets:** In all experiments we use 17 shallow QE features that have been shown to perform well in previous work. These were used by a highly competitive baseline entry in the WMT12 shared task, and were extracted here using the system provided by that shared task.<sup>6</sup> They include simple counts, e.g., the tokens in sentences, as well as source and target language model probabilities. Each feature was scaled to have zero mean and unit standard deviation on the training set.

**Baselines:** The baselines use the SVM regression algorithm with radial basis function kernel and parameters  $\gamma$ ,  $\epsilon$  and  $C$  optimised through grid-search and 5-fold cross validation on the training set. This is generally a very strong baseline: in the WMT12 QE shared task, only five out of 19 submissions were able to significantly outperform it, and only by including many complex additional features, tree kernels, etc. We also present  $\mu$ , a trivial baseline based on predicting for each test instance the training mean (overall, and for specific tasks).

**GP:** All GP models were implemented using the GPML Matlab toolbox.<sup>7</sup> Hyperparameter optimisation was performed using conjugate gradient ascent of the log marginal likelihood function, with up to 100 iterations. The simpler models were initialised with all hyperparameters set to one, while more complex models were initialised using the

<sup>6</sup>The software used to extract these (and other) features can be downloaded from <http://www.quest.dcs.shef.ac.uk/>

<sup>7</sup><http://www.gaussianprocess.org/gpml/code>

Model	MAE	RMSE
$\mu$	0.8279	0.9899
SVM	0.6889	0.8201

Table 1: Single-task learning results on the WMT12 dataset, trained and evaluated against the weighted averaged response variable.  $\mu$  is a baseline which predicts the training mean, SVM uses the same system as the WMT12 QE task, and the remainder are GP regression models with different kernels (all include additive noise).

solution for a simpler model. For instance, models using ARD kernels were initialised from an equivalent isotropic kernel (which ties all the hyperparameters together), and independent per-task noise models were initialised from a single noise model. This approach was more reliable than random restarts in terms of accuracy and runtime efficiency.

**Evaluation:** We evaluate predictive accuracy using two measures: mean absolute error,  $MAE = \frac{1}{N} \sum_{i=1}^N |y_i - \hat{y}_i|$  and root mean square error,  $RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2}$ , where  $y_i$  are the gold standard response values and  $\hat{y}_i$  are the model predictions.

## 4.2 Results

Our experiments aim to demonstrate the efficacy of GP regression, both the single task and multi-task settings, compared to competitive baselines.

**WMT12: Single task** We start by comparing GP regression with alternative approaches using the WMT12 dataset on the standard task of predicting a weighted mean quality rating (as it was done in the WMT12 QE shared task). Table 1 shows the results for baseline approaches and the GP models, using a variety of different kernels (see Rasmussen and Williams (2006) for details of the kernel functions). From this we can see that all models do much better than the mean baseline and that most of the GP models have lower error than the state-of-the-art SVM. In terms of kernels, the linear kernel performs comparatively worse than non-linear kernels. Overall the squared exponen-

Model	MAE	RMSE
$\mu$	0.8541	1.0119
Independent SVMs	0.7967	0.9673
EasyAdapt SVM	0.7655	0.9105
Independent	0.7061	0.8534
Pooled	0.7252	0.8754
Pooled & {N}	0.7050	0.8497
Combined	<b>0.6966</b>	<b>0.8448</b>
Combined & {N}	0.6975	0.8476
Combined+	0.6975	0.8463
Combined+ & {N}	0.7046	0.8595

Table 2: Results on the WMT12 dataset, trained and evaluated over all three annotator’s judgements. Shown above are the training mean baseline  $\mu$ , single-task learning approaches, and multi-task learning models, with the columns showing macro average error rates over all three response values. All systems use a squared exponential ARD kernel in a product with the named task-kernel, and with added noise (per-task noise is denoted {N}, otherwise has shared noise).

tial ARD kernel has the best performance under both measures of error, and for this reason we use this kernel in our subsequent experiments.

**WMT12: Multi-task** We now turn to the multi-task setting, where we seek to model each of the three annotators’ predictions. Table 2 presents the results. Note that here error rates are measured over all of the three annotators’ judgements, and consequently are higher than those measured against their average response in Table 1. For comparison, taking the predictions of the best model, **Combined**, in Table 2 and evaluating its averaged prediction has a MAE of 0.6588 vs. the averaged gold standard, significantly outperforming the best model in Table 1.

There are a number of important findings in Table 2. First, the independently trained models do well, outperforming the pooled model with fixed noise, indicating that naively pooling the data is counter-productive and that there are annotator-specific biases. Including per-annotator noise to the pooled model provides a boost in performance, however the best results are obtained using the **Combined** kernel which brings the strengths of both the independent and pooled settings. There are only minor differences between the different multi-task kernels, and in this case per-annotator noise made little difference. An explanation for the contradictory findings about the importance

of independent noise is that differences between annotators can already be explained by the MTL model using the multi-task kernel, and need not be explained as noise.

The GP models significantly improve over the baselines, including an SVM trained independently and using the EasyAdapt method for multi-task learning (Daumé III, 2007). While EasyAdapt showed an improvement over the independent SVM, it was a long way short of the GP models. A possible explanation is that in EasyAdapt the multi-task sharing parameter is set at  $a = 1$ , which may not be appropriate for the task. In contrast the **Combined** GP model learned a value of  $a = 0.01$ , weighting the value of pooling much more highly than independent training.

A remaining question is how these approaches cope with smaller datasets, where issues of data sparsity become more prevalent. To test this, we trained single-task, pooled and multi-task models on randomly sub-sampled training sets of different sizes, and plot their error rates in Figure 1. As expected, for very small datasets pooling outperforms single task learning, however for modest sized datasets of  $\geq 90$  training instances pooling was inferior. For all dataset sizes multi-task learning is superior to the other approaches, making much better use of small and large training sets. The MTL model trained on 500 samples had an MAE of  $0.7082 \pm 0.0042$ , close to the best results from the full dataset in Table 2, despite using  $\frac{1}{9}$  as much data: here we use  $\frac{1}{3}$  as many training instances where each is singly (cf. triply) annotated. The same experiments run with multiply-annotated instances showed much weaker performance, presumably due to the more limited sample of input points and poorer fit of the ARD kernel hyperparameters. This finding suggests that our multi-task learning approach could be used to streamline annotation efforts by reducing the need for extensive multiple annotations.

**WPTP12** This dataset involves predicting the post-editing time for eight annotators, where we seek to test our model’s capability to use additional metadata. We model the logarithm of the per-word post-editing time, in order to make the response variable more comparable between annotators and across sentences, and generally more Gaussian in shape. In Table 3 immediately we can see that the baseline of predicting the training mean is very difficult to beat, and the trained

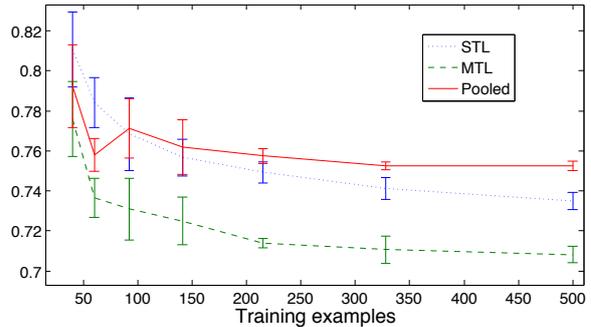

Figure 1: Learning curve comparing MAE for different training methods on the **WMT12** dataset, all using a squared exponential ARD data kernel and tied noise parameter. The MTL model uses the **Combined** task kernel. Each point is the average of 5 runs, and the error bars show  $\pm 1$  s.d.

systems often do worse. Partitioning the data by annotator ( $\mu_A$ ) gives the best baseline result, while there is less information from the MT system or sentence identity. Single-task learning performs only a little better than these baselines, although some approaches such as the naive pooling perform terribly. This suggests that the tasks are highly different to one another. Interestingly, adding the per-task noise models to the pooling approach greatly improves its performance.

The multi-task learning methods performed best when using the annotator identity as the task descriptor, and less well for the MT system and sentence pair, where they only slightly improved over the baseline. However, making use of all these layers of metadata together gives substantial further improvements, reaching the best result with **Combined**<sub>A,S,T</sub>. The effect of adding per-task noise to these models was less marked than for the pooled models, as in the WMT12 experiments. Inspecting the learned hyperparameters, the combined models learned a large bias towards independent learning over pooling, in contrast to the WMT12 experiments. This may explain the poor performance of EasyAdapt on this dataset.

## 5 Conclusion

This paper presented a novel approach for learning from human linguistic annotations by explicitly training models of individual annotators (and possibly additional metadata) using multi-task learning. Our method using Gaussian Processes is flexible, allowing easy learning of inter-dependences between different annotators and other task meta-

Table 3: Results on the **WPTP12** dataset, using the log of the post-editing time per word as the response variable. Shown above are the training mean and SVM baselines, single-task learning and multi-task learning results (micro average). The subscripts denote the task split: annotator (A), MT system (S) and sentence identity (T).

data. Our experiments showed how our approach outperformed competitive baselines on two machine translation quality regression problems, including the highly challenging problem of predicting post-editing time.

In future work we plan to apply these techniques to new datasets, particularly noisy crowd-sourced data with much large numbers of annotators, as well as a wider range of task types and mixtures thereof (regression, ordinal regression, ranking, classification). We also have preliminary positive results for more advanced multi-task kernels, e.g., general dense matrices, which can induce clusters of related tasks.

Our multi-task learning approach has much wider application. Models of individual annotators could be used to train machine translation systems to optimise an annotator-specific quality measure, or in active learning for corpus annotation, where the model can suggest the most appropriate instances for each annotator or the best annotator for a given instance. Further, our approach contributes to work based on cheap and fast crowdsourcing of linguistic annotation by minimising the need for careful data curation and quality control.

## Abstract

We present an algorithm for re-estimating parameters of backoff n-gram language models so as to preserve given marginal distributions, along the lines of well-known Kneser-Ney (1995) smoothing. Unlike Kneser-Ney, our approach is designed to be applied to any given smoothed backoff model, including models that have already been heavily pruned. As a result, the algorithm avoids issues observed when pruning Kneser-Ney models (Siivola et al., 2007; Chelba et al., 2010), while retaining the benefits of such marginal distribution constraints. We present experimental results for heavily pruned backoff n-gram models, and demonstrate perplexity and word error rate reductions when used with various baseline smoothing methods. An open-source version of the algorithm has been released as part of the OpenGrm ngram library.<sup>1</sup>

## 1 Introduction

Smoothed n-gram language models are the de-facto standard statistical models of language for a wide range of natural language applications, including speech recognition and machine translation. Such models are trained on large text corpora, by counting the frequency of n-gram collocations, then normalizing and smoothing (regularizing) the resulting multinomial distributions. Standard techniques store the observed n-grams and derive probabilities of unobserved n-grams via their longest observed suffix and “backoff” costs associated with the prefix histories of the unobserved suffixes. Hence the size of the model grows with the number of observed n-grams, which is very large for typical training corpora.

Natural language applications, however, are commonly used in scenarios requiring relatively small footprint models. For example, applications running on mobile devices or in low latency streaming scenarios may be required to limit the complexity of models and algorithms to achieve the desired operating profile. As a result, statistical language models – an important component of many such applications – are often trained on very large corpora, then modified to fit within some pre-specified size bound. One method to achieve significant space reduction is through randomized data structures, such as Bloom (Talbot and Osborne, 2007) or Bloomier (Talbot and Brants, 2008) filters. These data structures permit efficient querying for specific n-grams in a model that has been stored in a fraction of the space required to store the full, exact model, though with some probability of false positives. Another common approach – which we pursue in this paper – is model pruning, whereby some number of the n-grams are removed from explicit storage in the model, so that their probability must be assigned via backoff smoothing. One simple pruning method is count thresholding, i.e., discarding n-grams that occur less than  $k$  times in the corpus. Beyond count thresholding, the most widely used pruning methods (Seymore and Rosenfeld, 1996; Stolcke, 1998) employ greedy algorithms to reduce the number of stored n-grams by comparing the stored probabilities to those that would be assigned via the backoff smoothing mechanism, and removing those with the least impact according to some criterion.

While these greedy pruning methods are highly effective for models estimated with most common smoothing approaches, they have been shown to be far less effective with Kneser-Ney trained language models (Siivola et al., 2007; Chelba et al., 2010), leading to severe degradation in model quality relative to other standard smoothing meth-

4-gram models Smoothing method	Backoff			Interpolated		
	Perplexity full	pruned	n-grams ( $\times 1000$ )	Perplexity full	pruned	n-grams ( $\times 1000$ )
Absolute Discounting (Ney et al., 1994)	120.5	197.3	383.4	119.8	198.1	386.2
Witten-Bell (Witten and Bell, 1991)	118.8	196.3	380.4	121.6	202.3	396.4
Ristad (1995)	126.4	203.6	395.6	----- N/A -----		
Katz (1987)	119.8	198.1	386.2	----- N/A -----		
Kneser-Ney (Kneser and Ney, 1995)	114.5	285.1	388.2	115.8	274.3	398.7
Mod. Kneser-Ney (Chen and Goodman, 1998)	116.3	280.6	396.2	112.8	270.7	399.1

Table 1: Reformatted version of Table 3 in Chelba et al. (2010), demonstrating perplexity degradation of Kneser-Ney smoothed models in contrast to other common smoothing methods. Data: English Broadcast News, 128M words training; 692K words test; 143K word vocabulary. 4-gram language models, pruned using Stolcke (1998) relative entropy pruning to approximately 1.3% of the original size of 31,095,260 n-grams.

ods. Thus, while Kneser-Ney may be the preferred smoothing method for large, unpruned models – where it can achieve real improvements over other smoothing methods – when relatively sparse, pruned models are required, it has severely diminished utility.

Table 1 presents a slightly reformatted version of Table 3 from Chelba et al. (2010). In their experiments (see Table 1 caption for specifics on training/test setup), they trained 4-gram Broadcast News language models using a variety of both backoff and interpolated smoothing methods and measured perplexity before and after Stolcke (1998) relative entropy based pruning. With this size training data, the perplexity of all of the smoothing methods other than Kneser-Ney degrades from around 120 with the full model to around 200 with the heavily pruned model. Kneser-Ney smoothed models have lower perplexity with the full model than the other methods by about 5 points, but degrade with pruning to far higher perplexity, between 270-285.

The cause of this degradation is Kneser-Ney’s unique method for estimating smoothed language models, which will be presented in more detail in Section 3. Briefly, the smoothing method reestimates lower-order n-gram parameters in order to avoid over-estimating the likelihood of n-grams that already have ample probability mass allocated as part of higher-order n-grams. This is done via a marginal distribution constraint which requires the expected frequency of the lower-order n-grams to match their observed frequency in the training data, much as is commonly done for maximum entropy model training. Goodman (2001) proved that, under certain assumptions, such constraints can only improve language models. Lower-order n-gram parameters resulting from Kneser-Ney are not relative frequency estimates, as with other smoothing methods; rather they are parameters

estimated specifically for use within the larger smoothed model.

There are (at least) a couple of reasons why such parameters do not play well with model pruning. First, the pruning methods commonly use lower order n-gram probabilities to derive an estimate of state marginals, and, since these parameters are no longer smoothed relative frequency estimates, they do not serve that purpose well. For this reason, the widely-used SRILM toolkit recently provided switches to modify their pruning algorithm to use another model for state marginal estimates (Stolcke et al., 2011). Second, and perhaps more importantly, the marginal constraints that were applied prior to smoothing will not in general be consistent with the much smaller pruned model. For example, if a bigram parameter is modified due to the presence of some set of trigrams, and then some or all of those trigrams are pruned from the model, the bigram associated with the modified parameter will be unlikely to have an overall expected frequency equal to its observed frequency anymore. As a result, the resulting model degrades dramatically with pruning.

In this paper, we present an algorithm that imposes marginal distribution constraints of the sort used in Kneser-Ney modeling on arbitrary smoothed backoff n-gram language models. Our approach makes use of the same sort of derivation as the original Kneser-Ney modeling, but, among other differences, relies on smoothed estimates of the empirical relative frequency rather than the unsmoothed observed frequency. The algorithm can be applied after the smoothed model has been pruned, hence avoiding the pitfalls associated with Kneser-Ney modeling. Furthermore, while Kneser-Ney is conventionally defined as a variant of absolute discounting, our method can be applied to models smoothed with any backoff smoothing, including mixtures of models, widely

used for domain adaptation.

We next establish formal preliminaries and our smoothed marginal distribution constraints method.

## 2 Preliminaries

N-gram language models are typically presented mathematically in terms of words  $w$ , the strings (histories)  $h$  that precede them, and the suffixes of the histories (backoffs)  $h'$  that are used in the smoothing recursion. Let  $V$  be a vocabulary (alphabet), and  $V^*$  a string of zero or more symbols drawn from  $V$ . Let  $V^k$  denote the set of strings  $\mathbf{w} \in V^*$  of length  $k$ , i.e.,  $|\mathbf{w}| = k$ . We will use variables  $u, v, w, x, y, z \in V$  to denote single symbols from the vocabulary;  $h, g \in V^*$  to denote history sequences preceding the specific word; and  $h', g' \in V^*$  the respective backoff histories of  $h$  and  $g$  as typically defined (see below). For a string  $\mathbf{w} = w_1 \dots w_{|\mathbf{w}|}$  we can calculate the smoothed conditional probability of each word  $w_i$  in the sequence given the  $k$  words that preceded it, depending on the order of the Markov model. Let  $h_i^k = w_{i-k} \dots w_{i-1}$  be the previous  $k$  words in the sequence. Then the smoothed model is defined recursively as follows:

$$P(w_i | h_i^k) = \begin{cases} \bar{P}(w_i | h_i^k) & \text{if } c(h_i^k w_i) > 0 \\ \alpha(h_i^k) P(w_i | h_i^{k-1}) & \text{otherwise} \end{cases}$$

where  $c(h_i^k w_i)$  is the count of the n-gram sequence  $w_{i-k} \dots w_i$  in the training corpus;  $\bar{P}$  is a regularized probability estimate that provides some probability mass for unobserved n-grams; and  $\alpha(h_i^k)$  is a factor that ensures normalization. Note that for  $h = h_i^k$ , the typically defined backoff history  $h' = h_i^{k-1}$ , i.e., the longest suffix of  $h$  that is not  $h$  itself. When we use  $h'$  and  $g'$  (for notational convenience) in future equations, it is this definition that we are using.

There are many ways to estimate  $\bar{P}$ , including absolute discounting (Ney et al., 1994), Katz (1987) and Witten and Bell (1991). Interpolated models are special cases of this form, where the  $\bar{P}$  is determined using model mixing, and the  $\alpha$  parameter is exactly the mixing factor value for the lower order model.

N-gram language models allow for a sparse representation, so that only a subset of the possible n-grams must be explicitly stored. Probabilities for the rest of the n-grams are calculated through the “otherwise” semantics in the equation above. For

an n-gram language model  $G$ , we will say that an n-gram  $hw \in G$  if it is explicitly represented in the model; otherwise  $hw \notin G$ . In the standard n-gram formulation above, the assumption is that if  $c(h_i^k w_i) > 0$  then the n-gram has a parameter; yet with pruning, we remove many observed n-grams from the model, hence this is no longer the appropriate criterion. We reformulate the standard equation as follows:

$$P(w_i | h_i^k) = \begin{cases} \beta(h_i^k w_i) & \text{if } h_i^k w_i \in G \\ \alpha(h_i^k, h_i^{k-1}) P(w_i | h_i^{k-1}) & \text{otherwise} \end{cases} \quad (1)$$

where  $\beta(h_i^k w_i)$  is the parameter associated with the n-gram  $h_i^k w_i$  and  $\alpha(h_i^k, h_i^{k-1})$  is the backoff cost associated with going from state  $h_i^k$  to state  $h_i^{k-1}$ . We assume that, if  $hw \in G$  then all prefixes and suffixes of  $hw$  are also in  $G$ .

Figure 1 presents a schema of an automaton representation of an n-gram model, of the sort used in the OpenGrm library (Roark et al., 2012). States represent histories  $h$ , and the words  $w$ , whose probabilities are conditioned on  $h$ , label the arcs, leading to the history state for the subsequent word. State labels are provided in Figure 1 as a convenience, to show the (implicit) history encoded by the state, e.g., ‘xyz’ indicates that the state represents a history with the previous three symbols being x, y and z. Failure arcs, labeled with a  $\phi$  in Figure 1, encode an “otherwise” semantics and have as destination the origin state’s backoff history. Many higher order states will back off to the same lower order state, specifically those that share the same suffix.

Note that, in general, the recursive definition of backoff may require the traversal of several back-

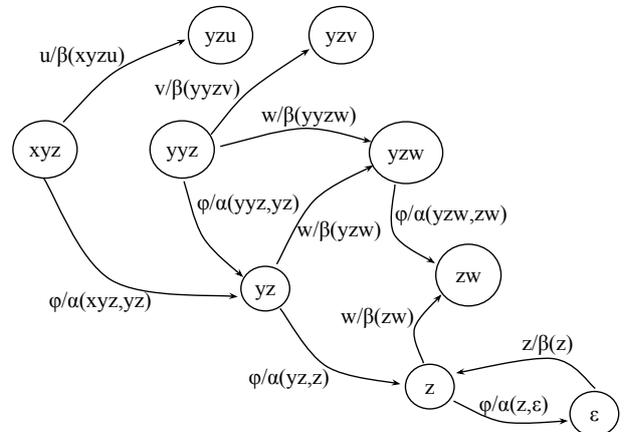

Figure 1: N-gram weighted automaton schema. State labels are presented for convenience, to specify the history implicitly encoded by the state.

off arcs before emitting a word, e.g., the highest order states in Figure 1 needing to traverse a couple of  $\phi$  arcs to reach state ‘z’. We can define the backoff cost between a state  $h_i^k$  and any of its suffix states as follows. Let  $\alpha(h, h) = 1$  and for  $m > 1$ ,

$$\alpha(h_i^k, h_i^{k-m}) = \prod_{j=1}^m \alpha(h_i^{k-j+1}, h_i^{k-j}).$$

If  $h_i^k w \notin G$  then the probability of that n-gram will be defined in terms of backoff to its longest suffix  $h_i^{k-m} w \in G$ . Let  $h^{wG}$  denote the longest suffix of  $h$  such that  $h^{wG} w \in G$ . Note that this is not necessarily a proper suffix, since  $h^{wG}$  could be  $h$  itself or it could be  $\epsilon$ . Then

$$P(w | h) = \alpha(h, h^{wG}) \beta(h^{wG} w) \quad (2)$$

which is equivalent to equation 1.

### 3 Marginal distribution constraints

Marginal distribution constraints attempt to match the expected frequency of an n-gram with its observed frequency. In other words, if we use the model to randomly generate a very large corpus, the n-grams should occur with the same relative frequency in both the generated and original (training) corpus. Standard smoothing methods overgenerate lower-order n-grams. Using standard n-gram notation (where  $g'$  is the backoff history for  $g$ ), this constraint is stated in Kneser and Ney (1995) as

$$\hat{P}(w | h') = \sum_{g:g'=h'} P(g, w | h') \quad (3)$$

where  $\hat{P}$  is the empirical relative frequency estimate. Taking this approach, certain base smoothing methods end up with very nice, easy to calculate solutions based on counts. Absolute discounting (Ney et al., 1994) in particular, using the above approach, leads to the well-known Kneser-Ney smoothing approach (Kneser and Ney, 1995; Chen and Goodman, 1998). We will follow this same approach, with a couple of changes. First, we will make use of regularized estimates of relative frequency  $\bar{P}$  rather than raw relative frequency  $\hat{P}$ . Second, rather than just looking at observed histories  $h$  that back off to  $h'$ , we will look at all histories (observed or not) of the length of the longest history in the model. For notational simplicity, suppose we have an  $n+1$ -gram model,

hence the longest history in the model is of length  $n$ . Assume the length of the particular backoff history  $|h'| = k$ . Let  $V^{n-k}h'$  be the set of strings  $h \in V^n$  with  $h'$  as a suffix. Then we can restate the marginal distribution constraint in equation 3 as

$$\bar{P}(w | h') = \sum_{h \in V^{n-k}h'} P(h, w | h') \quad (4)$$

Next we solve for  $\beta(h'w)$  parameters used in equation 1. Note that  $h'$  is a suffix of any  $h \in V^{n-k}h'$ , so conditioning probabilities on  $h$  and  $h'$  is the same as conditioning on just  $h$ . Each of the following derivation steps simply relies on the chain rule or definition of conditional probability, as well as pulling terms out of the summation.

$$\begin{aligned} \bar{P}(w | h') &= \sum_{h \in V^{n-k}h'} P(h, w | h') \\ &= \sum_{h \in V^{n-k}h'} P(w | h, h') P(h | h') \\ &= \sum_{h \in V^{n-k}h'} P(w | h) \frac{P(h)}{\sum_{g \in V^{n-k}h'} P(g)} \\ &= \frac{1}{\sum_{g \in V^{n-k}h'} P(g)} \sum_{h \in V^{n-k}h'} P(w | h) P(h) \quad (5) \end{aligned}$$

Then, multiplying both sides by the normalizing denominator on the right-hand side and using equation 2 to substitute  $\alpha(h, h^{wG}) \beta(h^{wG} w)$  for  $P(w | h)$ :

$$\begin{aligned} \bar{P}(w | h') \sum_{g \in V^{n-k}h'} P(g) &= \sum_{h \in V^{n-k}h'} P(w | h) P(h) \\ &= \sum_{h \in V^{n-k}h'} \alpha(h, h^{wG}) \beta(h^{wG} w) P(h) \quad (6) \end{aligned}$$

Note that we are only interested in  $h'w \in G$ , hence there are two disjoint subsets of histories  $h \in V^{n-k}h'$  that are being summed over: those such that  $h^{wG} = h'$  and those such that  $|h^{wG}| > |h'|$ . We next separate these sums in the next step of the derivation:

$$\begin{aligned} \bar{P}(w | h') \sum_{g \in V^{n-k}h'} P(g) &= \\ &= \sum_{h \in V^{n-k}h': |h^{wG}| > |h'|} \alpha(h, h^{wG}) \beta(h^{wG} w) P(h) + \\ &= \sum_{h \in V^{n-k}h': h^{wG} = h'} \alpha(h, h') \beta(h'w) P(h) \quad (7) \end{aligned}$$

Finally, we solve for  $\beta(h'w)$  in the second sum on the right-hand side of equation 7, yielding the formula in equation 8. Note that this equation is the correlate of equation (6) in Kneser and Ney

$$\beta(h'w) = \frac{\bar{P}(w | h') \sum_{g \in V^{n-k}h'} P(g) - \sum_{h \in V^{n-k}h': |h^{wG}| > |h'|} \alpha(h, h^{wG}) \beta(h^{wG}w) P(h)}{\sum_{h \in V^{n-k}h': h^{wG}=h'} \alpha(h, h') P(h)} \quad (8)$$

(1995), modulo the two differences noted earlier: use of smoothed probability  $\bar{P}$  rather than raw relative frequency; and summing over all history substrings in  $V^{n-k}h'$  rather than just those with count greater than zero, which is also a change due to smoothing. Keep in mind,  $\bar{P}$  is the target expected frequency from a given smoothed model. Kneser-Ney models are not useful input models, since their  $\bar{P}$  n-gram parameters are not relative frequency estimates. This means that we cannot simply ‘repair’ pruned Kneser-Ney models, but must use other smoothing methods where the smoothed values are based on relative frequency estimation.

There are, in addition, two other important differences in our approach from that in Kneser and Ney (1995), which would remain as differences even if our target expected frequency were the unsmoothed relative frequency  $\hat{P}$  instead of the smoothed estimate  $\bar{P}$ . First, the sum in the numerator is over histories of length  $n$ , the highest order in the n-gram model, whereas in the Kneser-Ney approach the sum is over histories that immediately back off to  $h'$ , i.e., from the next highest order in the n-gram model. Thus the unigram distribution is with respect to the bigram model, the bigram model is with respect to the trigram model, and so forth. In our optimization, we sum instead over all possible history sequences of length  $n$ . Second, an early assumption made in Kneser and Ney (1995) is that the denominator term in their equation (6) (our Eq. 8) is constant across all words for a given history, which is clearly false. We do not make this assumption. Of course, the probabilities must be normalized, hence the final values of  $\beta(h'w)$  will be proportional to the values in Eq. 8.

We briefly note that, like Kneser-Ney, if the baseline smoothing method is consistent, then the amount of smoothing in the limit will go to zero and our resulting model will also be consistent.

The smoothed relative frequency estimate  $\bar{P}$  and higher order  $\beta$  values on the right-hand side of Eq. 8 are given values (from the input smoothed model and previous stages in the algorithm, respectively), implying an algorithm that estimates highest orders of the model first. In addition, steady state

history probabilities  $P(h)$  must be calculated. We turn to the estimation algorithm next.

## 4 Model constraint algorithm

Our algorithm takes a smoothed backoff n-gram language model in an automaton format (see Figure 1) and returns a smoothed backoff n-gram language model with the same topology. For all n-grams in the model that are suffixes of other n-grams in the model – i.e., that are backed-off to – we calculate the weight provided by equation 8 and assign it (after normalization) to the appropriate n-gram arc in the automaton. There are several important considerations for this algorithm, which we address in this section. First, we must provide a probability for every state in the model. Second, we must memoize summed values that are used repeatedly. Finally, we must iterate the calculation of certain values that depend on the n-gram weights being re-estimated.

### 4.1 Steady state probability calculation

The steady state probability  $P(h)$  is taken to be the probability of observing  $h$  after a long word sequence, i.e., the state’s relative frequency in a long sequence of randomly-generated sentences from the model:

$$P(h) = \lim_{m \rightarrow \infty} \sum_{w_1 \dots w_m} \hat{P}(w_1 \dots w_m h) \quad (9)$$

where  $\hat{P}$  is the *corpus* probability derived as follows: The smoothed  $n$ -gram probability model  $P(w | h)$  is naturally extended to a sentence  $s = w_0 \dots w_l$ , where  $w_0 = \langle s \rangle$  and  $w_l = \langle /s \rangle$  are the sentence initial and final words, by  $P(s) = \prod_{i=1}^l P(w_i | h_i^n)$ . The corpus probability  $s_1 \dots s_r$  is taken as:

$$\hat{P}(s_1 \dots s_r) = (1 - \lambda) \lambda^{r-1} \prod_{i=1}^r P(s_i) \quad (10)$$

where  $\lambda$  parameterizes the corpus length distribution.<sup>2</sup> Assuming the n-gram language model automaton  $G$  has a single final state  $\langle /s \rangle$  into

<sup>2</sup> $\hat{P}$  models words in a corpus rather than a single sentence since Equation 9 tends to zero as  $m \rightarrow \infty$  otherwise. In Markov chain terms, the corpus distribution is made irreducible to allow a non-trivial stationary distribution.

which all  $\langle /s \rangle$  arcs enter, adding a  $\lambda$  weighted  $\epsilon$  arc from the  $\langle /s \rangle$  state to the initial state and having a final weight  $1 - \lambda$  in order to leave the automaton at the  $\langle /s \rangle$  state will model this corpus distribution. According to Eq. 9,  $P(h)$  is then the stationary distribution of the finite irreducible Markov Chain defined by this altered automaton. There are many methods for computing such a stationary distribution; we use the well-known power method (Stewart, 1999).

One difficulty remains to be resolved. The backoff arcs have a special interpretation in the automaton: they are traversed only if a word fails to match at the higher order. These failure arcs must be properly handled before applying standard stationary distribution calculations. A simple approach would be for each word  $w'$  and state  $h$  such that  $hw' \notin G$ , but  $h'w' \in G$ , add a  $w'$  arc from state  $h$  to  $h'w'$  with weight  $\alpha(h, h')\beta(h'w')$  and then remove all failure arcs (see Figure 2a). This however results in an automaton with  $|V|$  arcs leaving every state, which is unwieldy with larger vocabularies and n-gram orders. Instead, for each word  $w$  and state  $h$  such that  $hw \in G$ , add a  $w$  arc from state  $h$  to  $h'w$  with weight  $-\alpha(h, h')\beta(h'w)$  and then replace all failure labels with  $\epsilon$  labels (see Figure 2b). In this case, the added negatively-weighted arcs compensate for the excess probability mass allowed by the epsilon arcs<sup>3</sup>. The number of added arcs is no more than found in the original model.

## 4.2 Accumulation of higher order values

We are summing over all possible histories of length  $n$  in equation 8, and the steady state probability calculation outlined in the previous section includes the probability mass for histories  $h \notin G$ . The probability mass of states not in  $G$  ends up being allocated to the state representing their longest suffix that is explicitly in  $G$ . That is the state that would be active when these histories are encountered. Hence, once we have calculated the steady state probabilities for each state in the smoothed model, we only need to sum over states explicitly in the model.

As stated earlier, the use of  $\beta(h^wGw)$  in the numerator of equation 8 for  $h^wG$  that are larger than  $h'$  implies that the longer n-grams must be

<sup>3</sup>Since each negatively-weighted arc leaving a state exactly cancels an epsilon arc followed by a matching positively-weighted arc in each iteration of the power method, convergence is assured.

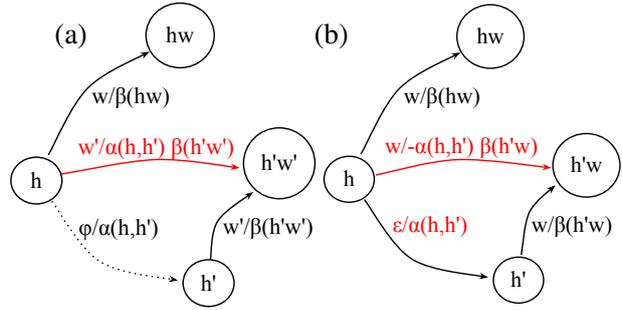

Figure 2: Schemata showing failure arc handling: (a)  $\phi$  removal: add  $w'$  arc (red), delete  $\phi$  arc; (b)  $\phi$  replacement: add  $w$  arc (red), replace  $\phi$  by  $\epsilon$  (red)

re-estimated first. Thus we process each history length in descending order, finishing with the unigram state. Since we assume that, for every n-gram  $hw \in G$ , every prefix and suffix is also in  $G$ , we know that if  $h'w \notin G$  then there is no history  $h$  such that  $h'$  is a suffix of  $h$  and  $hw \in G$ . This allows us to recursively accumulate the  $\alpha(h, h')P(h)$  in the denominator of Eq. 8.

For every n-gram, we can accumulate values required to calculate the three terms in equation 8, and pass them along to calculate lower order n-gram values. Note, however, that a naive implementation of an algorithm to assign these values is  $O(|V|^n)$ . This is due to the fact that the denominator factor must be accumulated for all higher order states that do *not* have the given n-gram. Hence, for every state  $h$  directly backing off to  $h'$  (order  $|V|$ ), and for every n-gram arc leaving state  $h'$  (order  $|V|$ ), some value must be accumulated. This can be particularly clearly seen at the unigram state, which has an arc for every unigram (the size of the vocabulary): for every bigram state (also order of the vocabulary), in the naive algorithm we must look for every possible arc. Since there are  $O(|V|^{n-2})$  lower order histories in the model in the worst case, we have overall complexity  $O(|V|^n)$ . However, we know that the number of stored n-grams is very sparse relative to the possible number of n-grams, so the typical case complexity is far lower. Importantly, the denominator is calculated by first assuming that *all* higher order states back off to the current n-gram, then subtract out the mass associated with those that are already observed at the higher order. In such a way, we need only perform work for higher order n-grams  $hw$  that are explicitly in the model. This optimization achieves orders-of-magnitude speedups, so that models take seconds to process.

Because smoothing is not necessarily con-

strained across n-gram orders, it is possible that higher-order n-grams could be smoothed less than lower order n-grams, so that the numerator of equation 8 can be less than zero, which is not valid. A value less than zero means that the higher order n-grams will already produce the n-gram more frequently than its smoothed expected frequency. We set a minimum value  $\epsilon$  for the numerator, and any n-gram numerator value less than  $\epsilon$  is replaced with  $\epsilon$  (for the current study,  $\epsilon = 0.001$ ). We find this to be relatively infrequent, about 1% of n-grams for most models.

### 4.3 Iteration

Recall that  $\bar{P}$  and  $\beta$  terms on the right-hand side of equation 8 are given and do not change. But there are two other terms in the equation that change as we update the n-gram parameters. The  $\alpha(h, h')$  backoff weights in the denominator ensure normalization at the higher order states, and change as the n-gram parameters at the current state are modified. Further, the steady state probabilities will change as the model changes. Hence, at each state, we must iterate the calculation of the denominator term: first adjust n-gram weights and normalize; then recalculate backoff weights at higher order states and iterate. Since this only involves the denominator term, each n-gram weight can be updated by multiplying by the ratio of the old term and the new term.

After the entire model has been re-estimated, the steady state probability calculation presented in Section 4.1 is run again and model estimation happens again. As we shall see in the experimental results, this typically converges after just a few iterations. At this time, we have no convergence proofs for either of these iterative components to the algorithm, but expect that something can be said about this, which will be a priority in future work.

## 5 Experimental results

All results presented here are for English Broadcast News. We received scripts for replicating the Chelba et al. (2010) results from the authors, and we report statistics on our replication of their paper’s results in Table 2. The scripts are distributed in such a way that the user supplies the data from LDC98T31 (1996 CSR HUB4 Language Model corpus) and the script breaks the collection into training and testing sets, normalizes the text, and

Smoothing method	Perplexity		n-grams ( $\times 1000$ )	
	full	pruned	model	diff
Abs.Disc.	120.4	197.1	382.3	-1.1
Witten-Bell	118.7	196.1	379.3	-1.1
Ristad	126.2	203.4	394.6	-1.1
Katz	119.7	197.9	385.1	-1.1
Kneser-Ney <sup>†</sup>	114.4	234.1	375.4	-12.7

Table 2: Replication of Chelba et al. (2010) using provided script. Using the script, the size of the unpruned model is 31,091,219 ngrams, 4,041 fewer than Chelba et al. (2010). <sup>†</sup> Kneser-Ney model pruned using `-prune-history-lm` switch in SRILM.

trains and prunes the language models using the SRILM toolkit (Stolcke et al., 2011). Presumably due to minor differences in text normalization, resulting in very slightly fewer n-grams in all conditions, we achieve negligibly lower perplexities (one or two tenths of a point) in all conditions, as can be seen when comparing with Table 1. All of the same trends result, thus that paper’s result is successfully replicated here. Note that we ran our Kneser-Ney pruning (noted with a <sup>†</sup> in the table), using the new `-prune-history-lm` switch in SRILM – created in response to the Chelba et al. (2010) paper – which allows the use of another model to calculate the state marginals for pruning. This fixes part of the problem – perplexity does not degrade as much as the Kneser-Ney pruned model in Table 1 – but, as argued earlier in this paper, this is not the sole reason for the degradation and the perplexity remains extremely inflated.

We follow Chelba et al. (2010) in training and test set definition, vocabulary size, and parameters for reporting perplexity. Note that unigrams in the models are never pruned, hence all models assign probabilities over an identical vocabulary and perplexity is comparable across models. For all results reported here, we use the SRILM toolkit for baseline model training and pruning, then convert from the resulting ARPA format model to an OpenFst format (Allauzen et al., 2007), as used in the OpenGrm n-gram library (Roark et al., 2012). We then apply the marginal distribution constraints, and convert the result back to ARPA format for perplexity evaluation with the SRILM toolkit. All models are subjected to full normalization sanity checks, as with typical model functions in the OpenGrm library.

Recall that our algorithm assumes that, for every n-gram in the model, all prefix and suffix n-grams are also in the model. For pruned models, the SRILM toolkit does not impose such a requirement, hence explicit arcs are added to the

Table 3: Perplexity reductions achieved with marginal distribution constraints (MDC) on the heavily pruned models from Chelba et al. (2010), and a mixture model. WFST n-gram counts are slightly higher than ARPA format in Table 2 due to adding prefix and suffix n-grams.

model during conversion, with probability equal to what they would receive in the the original model. The resulting model is equivalent, but with a small number of additional arcs in the explicit representation (around 1% for the most heavily pruned models).

Table 3 presents perplexity results for models that result from applying our marginal distribution constraints to the four heavily pruned models from Table 2. In all four cases, we get perplexity reductions of around 10 points. We present the number of n-grams represented explicitly in the WFST, which is a slight increase from those presented in Table 2 due to the reintroduction of prefix and suffix n-grams.

In addition to the four models reported in Chelba et al. (2010), we produced a mixture model by interpolating (with equal weight) smoothed n-gram probabilities from the full (unpruned) absolute discounting, Witten-Bell and Katz models, which share the same set of n-grams. After renormalizing and pruning to approximately the same size as the other models, we get commensurate gains using this model as with the other models.

Figure 3 demonstrates the importance of iterating the steady state history calculation. All of the methods achieve perplexity reductions with subsequent iterations. Katz and absolute discounting achieve very little reduction in the first iteration, but catch back up in the second iteration.

The other iterative part of the algorithm, discussed in Section 4.3, is the denominator of equation 8, which changes due to adjustments in the backoff weights required by the revised n-gram probabilities. If we do not iteratively update the backoff weights when reestimating the weights, the ‘Pruned+MDC’ perplexities in Table 3 increase by between 0.2–0.4 points. Hence, iterating the steady state probability calculation is quite important, as illustrated by Figure 3; iterating the

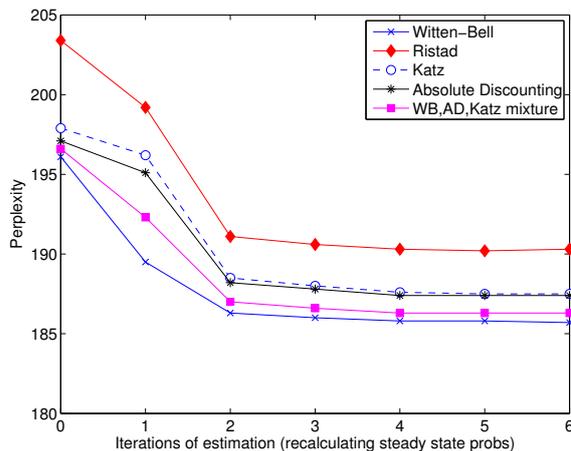

Figure 3: Models resulting from different numbers of parameter re-estimation iterations. Iteration 0 is the baseline pruned model.

denominator calculation much less so, at least for these models. We noted in Section 3 that a key difference between our approach and Kneser and Ney (1995) is that their approach treated the denominator as a constant. If we do this, the ‘Pruned+MDC’ perplexities increase by between 4.5–5.6 points, i.e., about half of the perplexity reduction is lost for each method. Thus, while iteration of denominator calculation may not be critical, it should not be treated as a constant.

We now look at the impacts on system performance we can achieve with these new models<sup>4</sup>, and whether the perplexity differences that we observe translate to real error rate reductions.

For automatic speech recognition experiments, we used as test set the 1997 Hub4 evaluation set consisting of 32,689 words. The acoustic model is a tied-state triphone GMM-based HMM whose input features are 9-frame stacked 13-dimensional PLP-cepstral coefficients projected down to 39 dimensions using LDA. The model was trained on the 1996 and 1997 Hub4 acoustic model training sets (about 150 hours of data) using semi-tied covariance modeling and CMLLR-based speaker adaptive training and 4 iterations of boosted MMI.

We used a multi-pass decoding strategy: two quick passes for adaptation supervision, CMLLR and MLLR estimation; then a slower full decoding pass running about 3 times slower than real time.

Table 4 presents recognition results for the heavily pruned models that we have been considering, both for first pass decoding and rescoreing of the resulting lattices using failure transitions rather than epsilon backoff approximations.

<sup>4</sup>For space purposes, we exclude the Ristad method from this point forward since it is not competitive with the others.

Smoothing Method	Word error rate (WER)			
	First pass		Rescoring	
	Pruned Model	Pruned +MDC	Pruned Model	Pruned +MDC
Abs.Disc.	20.5	19.7	20.2	19.6
Witten-Bell	20.5	19.9	20.1	19.6
Katz	20.5	19.7	20.2	19.7
Mixture	20.5	19.6	20.2	19.6
Kneser-Ney <sup>a</sup>	22.1		22.2	
Kneser-Ney <sup>b</sup>	20.5		20.6	

Table 4: WER reductions achieved with marginal distribution constraints (MDC) on the heavily pruned models from Chelba et al. (2010), and a mixture model. Kneser-Ney results are shown for: a) original pruning; and b) with `-prune-history-lm` switch.

The perplexity reductions that were achieved for these models do translate to real word error rate reductions at both stages of between 0.5 and 0.9 percent absolute. All of these gains are statistically significant at  $p < 0.0001$  using the stratified shuffling test (Yeh, 2000). For pruned Kneser-Ney models, fixing the state marginals with the `-prune-history-lm` switch reduces the WER versus the original pruned model, but no reductions were achieved vs. baseline methods.

Table 5 presents perplexity and WER results for less heavily pruned models, where the pruning thresholds were set to yield approximately 1.5 million n-grams (4 times more than the previous models); and another set at around 5 million n-grams, as well as the full, unpruned models. While the robust gains we’ve observed up to now persist with the 1.5M n-gram models (WER reductions significant, Witten-Bell at  $p < 0.02$ , others at  $p < 0.0001$ ), the larger models yield diminishing gains, with no real WER improvements. Performance of Witten-Bell models with the marginal distribution constraints degrade badly for the larger models, indicating that this method of regularization, unmodified by aggressive pruning, does not provide a well suited distribution for

this sort of optimization. We speculate that this is due to underregularization, having noted some floating point precision issues when allowing the backoff recalculation to run indefinitely.

## 6 Summary and Future Directions

The presented method reestimates lower order n-gram model parameters for a given smoothed backoff model, achieving perplexity and WER reductions for many smoothed models. There remain a number of open questions to investigate in the future. Recall that the numerator in Eq. 8 can be less than zero, meaning that no parameterization would lead to a model with the target frequency of the lower order n-gram, presumably due to over- or under-regularization. We anticipate a pre-constraint on the baseline smoothing method, that would recognize this problem and adjust the smoothing to ensure that a solution does exist. Additionally, it is clear that different regularization methods yield different behaviors, notably that large, relatively lightly pruned Witten-Bell models yield poor results. We will look to identify the issues with such models and provide general guidelines for prepping models prior to processing. Finally, we would like to perform extensive controlled experimentation to examine the relative contribution of the various aspects of our approach.

## Abstract

We present a method that learns representations for word meanings from short video clips paired with sentences. Unlike prior work on learning language from symbolic input, our input consists of video of people interacting with multiple complex objects in outdoor environments. Unlike prior computer-vision approaches that learn from videos with verb labels or images with noun labels, our labels are sentences containing nouns, verbs, prepositions, adjectives, and adverbs. The correspondence between words and concepts in the video is learned in an unsupervised fashion, even when the video depicts simultaneous events described by multiple sentences or when different aspects of a single event are described with multiple sentences. The learned word meanings can be subsequently used to automatically generate description of new video.

## 1 Introduction

People learn language through exposure to a rich perceptual context. Language is grounded by mapping words, phrases, and sentences to meaning representations referring to the world. Siskind (1996) has shown that even with referential uncertainty and noise, a system based on *cross-situational* learning can robustly acquire a lexicon, mapping words to word-level meanings from sentences paired with sentence-level meanings. However, it did so only for symbolic representations of word- and sentence-level meanings that were not perceptually grounded. An ideal system would not require detailed word-level labelings to acquire word meanings from video but rather could learn language in a largely unsupervised fashion, just as a child does, from video paired with sentences.

There has been recent research on grounded language learning. Roy (2002) pairs training sentences with vectors of real-valued features extracted from synthesized images which depict 2D blocks-world scenes, to learn a specific set of features for adjectives, nouns, and adjuncts. Yu and Ballard (2004) paired training images containing multiple objects with spoken name candidates for the objects to find the correspondence between lexical items and visual features. Dominey and Boucher (2005) paired narrated sentences with symbolic representations of their meanings, automatically extracted from video, to learn object names, spatial-relation terms, and event names as a mapping from the grammatical structure of a sentence to the semantic structure of the associated meaning representation. Chen and Mooney (2008) learned the language of sportscasting by determining the mapping between game commentaries and the meaning representations output by a rule-based simulation of the game. Kwiatkowski et al. (2012) present an approach that learns Montague-grammar representations of word meanings together with a combinatory categorial grammar (CCG) from child-directed sentences paired with first-order formulas that represent their meaning.

Although most of these methods succeed in learning word meanings from sentential descriptions they do so only for symbolic or simple visual input (often synthesized); they fail to bridge the gap between language and computer vision, *i.e.*, they do not attempt to extract meaning representations from complex visual scenes. On the other hand, there has been research on training object and event models from large corpora of complex images and video in the computer-vision community (Kuznetsova et al., 2012; Sadanand and Corso, 2012; Kulkarni et al., 2011; Ordonez et al., 2011; Yao et al., 2010). However, most such work requires training data that labels individual concepts with individual words (*i.e.*, ob-

jects delineated via bounding boxes in images as nouns and events that occur in short video clips as verbs). There is no attempt to model phrasal or sentential meaning, let alone acquire the object or event models from training data labeled with phrasal or sentential annotations. Moreover, such work uses distinct representations for different parts of speech; *i.e.*, object and event recognizers use different representations.

In this paper, we present a method that learns representations for word meanings from short video clips paired with sentences. Our work differs from prior work in three ways. First, our input consists of realistic video filmed in an outdoor environment. Second, we learn the entire lexicon, including nouns, verbs, prepositions, adjectives, and adverbs, simultaneously from video described with whole sentences. Third we adopt a uniform representation for the meanings of words in all parts of speech, namely Hidden Markov Models (HMMs) whose states and distributions allow for multiple possible interpretations of a word or a sentence in an ambiguous perceptual context.

We employ the following representation to ground the meanings of words, phrases, and sentences in video clips. We first run an object detector on each video frame to yield a set of *detections*, each a subregion of the frame. In principle, the object detector need just detect the objects rather than classify them. In practice, we employ a collection of class-, shape-, pose-, and viewpoint-specific detectors and pool the detections to account for objects whose shape, pose, and viewpoint may vary over time. Our methods can learn to associate a single noun with detections produced by multiple detectors. We then string together detections from individual frames to yield *tracks* for objects that temporally span the video clip. We associate a feature vector with each frame (detection) of each such track. This feature vector can encode image features (including the identity of the particular detector that produced that detection) that correlate with object class; region color, shape, and size features that correlate with object properties; and motion features, such as linear and angular object position, velocity, and acceleration, that correlate with event properties. We also compute features between pairs of tracks to encode the relative position and motion of the pairs of objects that participate in events that involve two participants. In principle, we can also compute features

between tuples of any number of tracks.

Following Yamoto et al. (1992), Siskind and Morris (1996), and Starner et al. (1998), we represent the meaning of an intransitive verb, like *jump*, as a two-state HMM over the velocity-direction feature, modeling the requirement that the participant move upward then downward. We represent the meaning of a transitive verb, like *pick up*, as a two-state HMM over both single-object and object-pair features: the agent moving toward the patient while the patient is at rest, followed by the agent moving together with the patient. We extend this general approach to other parts of speech. Nouns, like *person*, can be represented as one-state HMMs over image features that correlate with the object classes denoted by those nouns. Adjectives, like *red*, *round*, and *big*, can be represented as one-state HMMs over region color, shape, and size features that correlate with object properties denoted by such adjectives. Adverbs, like *quickly*, can be represented as one-state HMMs over object-velocity features. Intransitive prepositions, like *leftward*, can be represented as one-state HMMs over velocity-direction features. Static transitive prepositions, like *to the left of*, can be represented as one-state HMMs over the relative position of a pair of objects. Dynamic transitive prepositions, like *towards*, can be represented as HMMs over the changing distance between a pair of objects. Note that with this formulation, the representation of a verb, like *approach*, might be the same as a dynamic transitive preposition, like *towards*. While it might seem like overkill to represent the meanings of words as one-state-HMMs, in practice, we often instead encode such concepts with multiple states to allow for temporal variation in the associated features due to changing pose and viewpoint as well as deal with noise and occlusion. Moreover, the general framework of modeling word meanings as temporally variant time series via multi-state HMMs allows one to model denominalized verbs, *i.e.*, nouns that denote events, as in *The jump was fast*.

Our HMMs are parameterized with varying arity. Some, like  $jump(\alpha)$ ,  $person(\alpha)$ ,  $red(\alpha)$ ,  $round(\alpha)$ ,  $big(\alpha)$ ,  $quickly(\alpha)$ , and  $leftward(\alpha)$  have one argument, while others, like  $pick-up(\alpha, \beta)$ ,  $to-the-left-of(\alpha, \beta)$ , and  $towards(\alpha, \beta)$ , have two arguments (In principle, any arity can be supported.). HMMs are instantiated by mapping their arguments to tracks. This

involves computing the associated feature vector for that HMM over the detections in the tracks chosen to fill its arguments. This is done with a two-step process to support compositional semantics. The meaning of a multi-word phrase or sentence is represented as a joint likelihood of the HMMs for the words in that phrase or sentence. Compositionality is handled by *linking* or *coindexing* the arguments of the conjoined HMMs. Thus a sentence like *The person to the left of the backpack approached the trash-can* would be represented as a conjunction of  $person(p_0)$ ,  $to\text{-}the\text{-}left\text{-}of(p_0, p_1)$ ,  $backpack(p_1)$ ,  $approached(p_0, p_2)$ , and  $trash\text{-}can(p_2)$  over the three participants  $p_0$ ,  $p_1$ , and  $p_2$ . This whole sentence is then grounded in a particular video by mapping these participants to particular tracks and instantiating the associated HMMs over those tracks, by computing the feature vectors for each HMM from the tracks chosen to fill its arguments.

Our algorithm makes six assumptions. First, we assume that we know the part of speech  $C_m$  associated with each lexical entry  $m$ , along with the part-of-speech dependent number of states  $I_c$  in the HMMs used to represent word meanings in that part of speech, the part-of-speech dependent number of features  $N_c$  in the feature vectors used by HMMs to represent word meanings in that part of speech, and the part-of-speech dependent feature-vector computation  $\Phi_c$  used to compute the features used by HMMs to represent word meanings in that part of speech. Second, we pair individual sentences each with a short video clip that depicts that sentence. The algorithm is not able to determine the alignment between multiple sentences and longer video segments. Note that there is no requirement that the video depict *only* that sentence. Other objects may be present and other events may occur. In fact, nothing precludes a training corpus with multiple copies of the same video, each paired with a different sentence describing a different aspect of that video. Moreover, our algorithm potentially can handle a small amount of noise, where a video clip is paired with an incorrect sentence that the video does not depict. Third, we assume that we already have (pre-trained) low-level object detectors capable of detecting instances of our target event participants in individual frames of the video. We allow such detections to be unreliable; our method can handle a moderate amount of false positives

and false negatives. We do not need to know the mapping from these object-detection classes to words; our algorithm determines that. Fourth, we assume that we know the arity of each word in the corpus, *i.e.*, the number of arguments that that word takes. For example, we assume that we know that the word  $person(\alpha)$  takes one argument and the word  $approached(\alpha, \beta)$  takes two arguments. Fifth, we assume that we know the total number of distinct participants that collectively fill all of the arguments for all of the words in each training sentence. For example, for the sentence *The person to the left of the backpack approached the trash-can*, we assume that we know that there are three distinct objects that participate in the event denoted. Sixth, we assume that we know the *argument-to-participant mapping* for each training sentence. Thus, for example, for the above sentence we would know  $person(p_0)$ ,  $to\text{-}the\text{-}left\text{-}of(p_0, p_1)$ ,  $backpack(p_1)$ ,  $approached(p_0, p_2)$ , and  $trash\text{-}can(p_2)$ . The latter two items can be determined by parsing the sentence, which is what we do. One can imagine learning the ability to automatically perform the latter two items, and even the fourth item above, by learning the grammar and the part of speech of each word, such as done by Kwiatkowski et al. (2012). We leave such for future work.

Figure 1 illustrates a single frame from a potential training sample provided as input to our learner. It consists of a video clip paired with a sentence, where the arguments of the words in the sentence are mapped to participants. From a sequence of such training samples, our learner determines the objects tracks and the mapping from participants to those tracks, together with the meanings of the words.

The remainder of the paper is organized as follows. Section 2 generally describes our problem of lexical acquisition from video. Section 3 introduces our work on the sentence tracker, a method for jointly tracking the motion of multiple objects in a video that participate in a sentimentally-specified event. Section 4 elaborates on the details of our problem formulation in the context of this sentence tracker. Section 5 describes how to generalize and extend the sentence tracker so that it can be used to support lexical acquisition. We demonstrate this lexical acquisition algorithm on a small example in Section 6. Finally, we conclude with a discussion in Section 7.

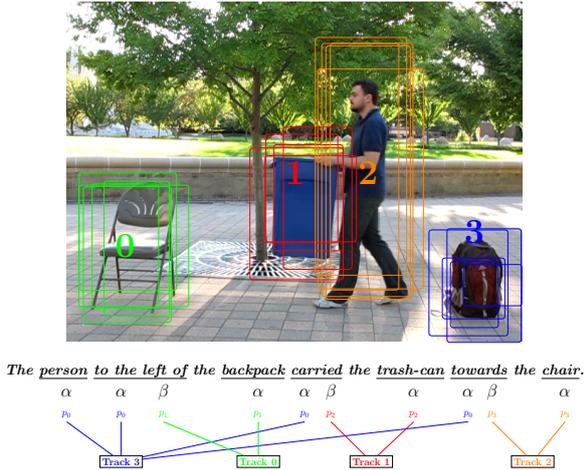

Figure 1: An illustration of our problem. Each word in the sentence has one or more arguments ( $\alpha$  and possibly  $\beta$ ), each argument of each word is assigned to a participant ( $p_0, \dots, p_3$ ) in the event described by the sentence, and each participant can be assigned to any object track in the video. This figure shows a possible (but erroneous) interpretation of the sentence where the mapping is:  $p_0 \mapsto$  **Track 3**,  $p_1 \mapsto$  **Track 0**,  $p_2 \mapsto$  **Track 1**, and  $p_3 \mapsto$  **Track 2**, which might (incorrectly) lead the learner to conclude that the word *person* maps to the backpack, the word *backpack* maps to the chair, the word *trash-can* maps to the trash-can, and the word *chair* maps to the person.

## 2 General Problem Formulation

Throughout this paper, lowercase letters are used for variables or hidden quantities while uppercase ones are used for constants or observed quantities.

We are given a lexicon  $\{1, \dots, M\}$ , letting  $m$  denote a lexical entry. We are given a sequence  $D = (D_1, \dots, D_R)$  of video clips  $D_r$ , each paired with a sentence  $S_r$  from a sequence  $S = (S_1, \dots, S_R)$  of sentences. We refer to  $D_r$  paired with  $S_r$  as a *training sample*. Each sentence  $S_r$  is a sequence  $(S_{r,1}, \dots, S_{r,L_r})$  of words  $S_{r,l}$ , each an entry from the lexicon. A given entry may potentially appear in multiple sentences and even multiple times in a given sentence. For example, the third word in the first sentence might be the same entry as the second word in the fourth sentence, in which case  $S_{1,3} = S_{4,2}$ . This is what allows cross-situational learning in our algorithm.

Let us assume, for a moment, that we can process each video clip  $D_r$  to yield a sequence  $(\tau_{r,1}, \dots, \tau_{r,U_r})$  of object tracks  $\tau_{r,u}$ . Let us also assume that  $D_r$  is paired with a sen-

tence  $S_r =$  *The person approached the chair*, specified to have two participants,  $p_{r,0}$  and  $p_{r,1}$ , with the mapping *person*( $p_{r,0}$ ), *chair*( $p_{r,1}$ ), and *approached*( $p_{r,0}, p_{r,1}$ ). Let us further assume, for a moment, that we are given a mapping from participants to object tracks, say  $p_{r,0} \mapsto \tau_{r,39}$  and  $p_{r,1} \mapsto \tau_{r,51}$ . This would allow us to instantiate the HMMs with object tracks for a given video clip: *person*( $\tau_{r,39}$ ), *chair*( $\tau_{r,51}$ ), and *approached*( $\tau_{r,39}, \tau_{r,51}$ ). Let us further assume that we can score each such instantiated HMM and aggregate the scores for all of the words in a sentence to yield a sentence score and further aggregate the scores for all of the sentences in the corpus to yield a corpus score. However, we don't know the parameters of the HMMs. These constitute the unknown meanings of the words in our corpus which we wish to learn. The problem is to simultaneously determine (a) those parameters along with (b) the object tracks and (c) the mapping from participants to object tracks. We do this by finding (a)–(c) that maximizes the corpus score.

## 3 The Sentence Tracker

Barbu et al. (2012a) presented a method that first determines object tracks from a single video clip and then uses these fixed tracks with HMMs to recognize actions corresponding to verbs and construct sentential descriptions with templates. Later Barbu et al. (2012b) addressed the problem of solving (b) and (c), for a single object track constrained by a single intransitive verb, without solving (a), in the context of a single video clip. Our group has generalized this work to yield an algorithm called the *sentence tracker* which operates by way of a factorial HMM framework. We introduce that here as the foundation of our extension.

Each video clip  $D_r$  contains  $T_r$  frames. We run an object detector on each frame to yield a set  $D_r^t$  of detections. Since our object detector is unreliable, we bias it to have high recall but low precision, yielding multiple detections in each frame. We form an object track by selecting a single detection for that track for each frame. For a moment, let us consider a single video clip with length  $T$ , with detections  $D^t$  in frame  $t$ . Further, let us assume that we seek a single object track in that video clip. Let  $j^t$  denote the index of the detection from  $D^t$  in frame  $t$  that is selected to form the track. The object detector scores each detection. Let  $F(D^t, j^t)$  denote that score. More-

over, we wish the track to be temporally coherent; we want the objects in a track to move smoothly over time and not jump around the field of view. Let  $G(D^{t-1}, j^{t-1}, D^t, j^t)$  denote some measure of coherence between two detections in adjacent frames. (One possible such measure is consistency of the displacement of  $D^t$  relative to  $D^{t-1}$  with the velocity of  $D^{t-1}$  computed from the image by optical flow.) One can select the detections to yield a track that maximizes both the aggregate detection score and the aggregate temporal coherence score.

$$\max_{j^1, \dots, j^T} \left( \begin{array}{l} \sum_{t=1}^T F(D^t, j^t) \\ + \sum_{t=2}^T G(D^{t-1}, j^{t-1}, D^t, j^t) \end{array} \right) \quad (1)$$

This can be determined with the Viterbi (1967) algorithm and is known as *detection-based tracking* (Viterbi, 1971).

Recall that we model the meaning of an intransitive verb as an HMM over a time series of features extracted for its participant in each frame. Let  $\lambda$  denote the parameters of this HMM,  $(q^1, \dots, q^T)$  denote the sequence of states  $q^t$  that leads to an observed track,  $B(D^t, j^t, q^t, \lambda)$  denote the conditional log probability of observing the feature vector associated with the detection selected by  $j^t$  among the detections  $D^t$  in frame  $t$ , given that the HMM is in state  $q^t$ , and  $A(q^{t-1}, q^t, \lambda)$  denote the log transition probability of the HMM. For a given track  $(j^1, \dots, j^T)$ , the state sequence that yields the maximal likelihood is given by:

$$\max_{q^1, \dots, q^T} \left( \begin{array}{l} \sum_{t=1}^T B(D^t, j^t, q^t, \lambda) \\ + \sum_{t=2}^T A(q^{t-1}, q^t, \lambda) \end{array} \right) \quad (2)$$

which can also be found by the Viterbi algorithm.

A given video clip may depict multiple objects, each moving along its own trajectory. There may be both a person jumping and a ball rolling. How are we to select one track over the other? The key insight of the sentence tracker is to bias the selection of a track so that it matches an HMM. This is done by combining the cost function of Eq. 1 with the cost function of Eq. 2 to yield Eq. 3, which can also be determined using the Viterbi algorithm. This is done by forming the cross product of the

two lattices. This jointly selects the optimal detections to form the track, together with the optimal state sequence, and scores that combination.

$$\max_{\substack{j^1, \dots, j^T \\ q^1, \dots, q^T}} \left( \begin{array}{l} \sum_{t=1}^T F(D^t, j^t) \\ + B(D^t, j^t, q^t, \lambda) \\ + \sum_{t=2}^T G(D^{t-1}, j^{t-1}, D^t, j^t) \\ + A(q^{t-1}, q^t, \lambda) \end{array} \right) \quad (3)$$

While we formulated the above around a single track and a word that contains a single participant, it is straightforward to extend this so that it supports multiple tracks and words of higher arity by forming a larger cross product. When doing so, we generalize  $j^t$  to denote a sequence of detections from  $D^t$ , one for each of the tracks. We further need to generalize  $F$  so that it computes the joint score of a sequence of detections, one for each track,  $G$  so that it computes the joint measure of coherence between a sequence of pairs of detections in two adjacent frames, and  $B$  so that it computes the joint conditional log probability of observing the feature vectors associated with the sequence of detections selected by  $j^t$ . When doing this, note that Eqs. 1 and 3 maximize over  $j^1, \dots, j^T$  which denotes  $T$  sequences of detection indices, rather than  $T$  individual indices.

It is further straightforward to extend the above to support a sequence  $(S_1, \dots, S_L)$  of words  $S_l$  denoting a sentence, each of which applies to different subsets of the multiple tracks, again by forming a larger cross product. When doing so, we generalize  $q^t$  to denote a sequence  $(q_1^t, \dots, q_L^t)$  of states  $q_l^t$ , one for each word  $l$  in the sentence, and use  $q_l$  to denote the sequence  $(q_l^1, \dots, q_l^T)$  and  $q$  to denote the sequence  $(q_1, \dots, q_L)$ . We further need to generalize  $B$  so that it computes the joint conditional log probability of observing the feature vectors for the detections in the tracks that are assigned to the arguments of the HMM for each word in the sentence and  $A$  so that it computes the joint log transition probability for the HMMs for all words in the sentence. This allows selection of an optimal sequence of tracks that yields the highest score for the sentential meaning of a sequence of words. Modeling the meaning of a sentence through a sequence of words whose meanings are modeled by HMMs, defines a *factorial* HMM for that sentence, since the overall Markov process for that sentence can be factored into inde-

pendent component processes (Brand et al., 1997; Zhong and Ghosh, 2001) for the individual words. In this view,  $q$  denotes the state sequence for the combined factorial HMM and  $q_l$  denotes the factor of that state sequence for word  $l$ . The remainder of this paper wraps this sentence tracker in Baum Welch (Baum et al., 1970; Baum, 1972).

#### 4 Detailed Problem Formulation

We adapt the sentence tracker to training a corpus of  $R$  video clips, each paired with a sentence. Thus we augment our notation, generalizing  $j^t$  to  $j_r^t$  and  $q_l^t$  to  $q_{r,l}^t$ . Below, we use  $j_r$  to denote  $(j_r^1, \dots, j_r^{T_r})$ ,  $j$  to denote  $(j_1, \dots, j_R)$ ,  $q_{r,l}$  to denote  $(q_{r,l}^1, \dots, q_{r,l}^{T_r})$ ,  $q_r$  to denote  $(q_{r,1}, \dots, q_{r,L_r})$ , and  $q$  to denote  $(q_1, \dots, q_R)$ .

We use discrete features, namely natural numbers, in our feature vectors, quantized by a binning process. We assume the part of speech of entry  $m$  is known as  $C_m$ . The length of the feature vector may vary across parts of speech. Let  $N_c$  denote the length of the feature vector for part of speech  $c$ ,  $x_{r,l}$  denote the time-series  $(x_{r,l}^1, \dots, x_{r,l}^{T_r})$  of feature vectors  $x_{r,l}^t$ , associated with  $S_{r,l}$  (which recall is some entry  $m$ ), and  $x_r$  denote the sequence  $(x_{r,1}, \dots, x_{r,L_r})$ . We assume that we are given a function  $\Phi_c(D_r^t, j_r^t)$  that computes the feature vector  $x_{r,l}^t$  for the word  $S_{r,l}$  whose part of speech is  $C_{S_{r,l}} = c$ . Note that we allow  $\Phi$  to be dependent on  $c$  allowing different features to be computed for different parts of speech, since we can determine  $m$  and thus  $C_m$  from  $S_{r,l}$ . We choose to have  $N_c$  and  $\Phi_c$  depend on the part of speech  $c$  and not on the entry  $m$  since doing so would be tantamount to encoding the to-be-learned word meaning in the provided feature-vector computation.

The goal of training is to find a sequence  $\lambda = (\lambda_1, \dots, \lambda_M)$  of parameters  $\lambda_m$  that best explains the  $R$  training samples. The parameters  $\lambda_m$  constitute the meaning of the entry  $m$  in the lexicon. Collectively, these are the initial state probabilities  $a_{0,k}^m$ , for  $1 \leq k \leq I_{C_m}$ , the transition probabilities  $a_{i,k}^m$ , for  $1 \leq i, k \leq I_{C_m}$ , and the output probabilities  $b_{i,n}^m(x)$ , for  $1 \leq i \leq I_{C_m}$  and  $1 \leq n \leq N_{C_m}$ , where  $I_{C_m}$  denotes the number of states in the HMM for entry  $m$ . Like before, we could have a distinct  $I_m$  for each entry  $m$  but instead have  $I_{C_m}$  depend only on the part of speech of entry  $m$ , and assume that we know the fixed  $I$  for each part of speech. In our case,  $b_{i,n}^m$  is a discrete distribution because the features are binned.

## 5 The Learning Algorithm

Instantiating the above approach requires a definition for what it means to *best explain the  $R$  training samples*. Towards this end, we define the score of a video clip  $D_r$  paired with sentence  $S_r$  given the parameter set  $\lambda$  to characterize how well this training sample is explained. While the cost function in Eq. 3 may qualify as a score, it is easier to fit a likelihood calculation into the Baum-Welch framework than a MAP estimate. Thus we replace the max in Eq. 3 with a  $\sum$  and redefine our scoring function as follows:

$$L(D_r; S_r, \lambda) = \sum_{j_r} P(j_r | D_r) P(x_r | S_r, \lambda) \quad (4)$$

The score in Eq. 4 can be interpreted as an expectation of the HMM likelihood over all possible mappings from participants to all possible tracks. By definition,  $P(j_r | D_r) = \frac{V(D_r, j_r)}{\sum_{j_r'} V(D_r, j_r')}$ , where the numerator is the score of a particular track sequence  $j_r$  while the denominator sums the scores over all possible track sequences. The log of the numerator  $V(D_r, j_r)$  is simply Eq. 1 without the max. The log of the denominator can be computed efficiently by the forward algorithm (Baum and Petrie, 1966). The likelihood for a factorial HMM can be computed as:

$$P(x_r | S_r, \lambda) = \sum_{q_r} \prod_l P(x_{r,l}, q_{r,l} | S_{r,l}, \lambda) \quad (5)$$

*i.e.*, summing the likelihoods for all possible state sequences. Each summand is simply the joint likelihood for all the words in the sentence conditioned on a state sequence  $q_r$ . For HMMs we have

$$P(x_{r,l}, q_{r,l} | S_{r,l}, \lambda) = \prod_t a_{q_{r,l}^{t-1}, q_{r,l}^t}^{S_{r,l}} \prod_n b_{q_{r,l}^t, n}^{S_{r,l}}(x_{r,l,n}^t) \quad (6)$$

Finally, for a training corpus of  $R$  samples, we seek to maximize the joint score:

$$L(D; S, \lambda) = \prod_r L(D_r; S_r, \lambda) \quad (7)$$

A local maximum can be found by employing the Baum-Welch algorithm (Baum et al., 1970; Baum, 1972). By constructing an auxiliary function (Bilmes, 1997), one can derive the reestimation formulas in Eq. 8, where  $x_{r,l,n}^t = h$  denotes the selection of all possible  $j_r^t$  such that the  $n$ th

$$\begin{aligned}
a_{i,k}^m &= \theta_i^m \sum_{r=1}^R \sum_{l=1}^{L_r} \sum_{t=1}^{T_r} \underbrace{\frac{L(q_{r,l}^{t-1} = i, q_{r,l}^t = k, D_r; S_r, \lambda')}{L(D_r; S_r, \lambda')}}_{\xi(r,l,i,k,t)} \\
b_{i,n}^m(h) &= \psi_{i,n}^m \sum_{r=1}^R \sum_{l=1}^{L_r} \sum_{t=1}^{T_r} \underbrace{\frac{L(q_{r,l}^t = i, x_{r,l,n}^t = h, D_r; S_r, \lambda')}{L(D_r; S_r, \lambda')}}_{\gamma(r,l,n,i,h,t)}
\end{aligned} \tag{8}$$

feature computed by  $\Phi_{C_m}(D_r^t, j_r^t)$  is  $h$ . The coefficients  $\theta_i^m$  and  $\psi_{i,n}^m$  are for normalization.

The reestimation formulas involve *occurrence counting*. However, since we use a factorial HMM that involves a cross-product lattice and use a scoring function derived from Eq. 3 that incorporates both tracking (Eq. 1) and word models (Eq. 2), we need to count the frequency of transitions in the whole cross-product lattice. As an example of such cross-product occurrence counting, when counting the transitions from state  $i$  to  $k$  for the  $l$ th word from frame  $t - 1$  to  $t$ , i.e.,  $\xi(r, l, i, k, t)$ , we need to count all the possible paths through the adjacent factorial states  $(j_r^{t-1}, q_{r,1}^{t-1}, \dots, q_{r,L_r}^{t-1})$  and  $(j_r^t, q_{r,1}^t, \dots, q_{r,L_r}^t)$  such that  $q_{r,l}^{t-1} = i$  and  $q_{r,l}^t = k$ . Similarly, when counting the frequency of being at state  $i$  while observing  $h$  as the  $n$ th feature in frame  $t$  for the  $l$ th word of entry  $m$ , i.e.,  $\gamma(r, l, n, i, h, t)$ , we need to count all the possible paths through the factorial state  $(j_r^t, q_{r,1}^t, \dots, q_{r,L_r}^t)$  such that  $q_{r,l}^t = i$  and the  $n$ th feature computed by  $\Phi_{C_m}(D_r^t, j_r^t)$  is  $h$ .

The reestimation of a single component HMM can depend on the previous estimate for other component HMMs. This dependence happens because of the argument-to-participant mapping which coindexes arguments of different component HMMs to the same track. **It is precisely this dependence that leads to cross-situational learning of two kinds: both inter-sentential and intra-sentential.** Acquisition of a word meaning is driven across sentences by entries that appear in more than one training sample and within sentences by the requirement that the meanings of all of the individual words in a sentence be consistent with the collective sentential meaning.

## 6 Experiment

We filmed 61 video clips (each 3–5 seconds at 640×480 resolution and 40 fps) that depict a variety of different compound events. Each clip depicts multiple simultaneous events between some

Table 1: The grammar used for our annotation and generation. Our lexicon contains 1 determiner, 4 nouns, 2 spatial relation prepositions, 4 verbs, 2 adverbs, and 2 motion prepositions for a total of 15 lexical entries over 6 parts of speech.

subset of four objects: a person, a backpack, a chair, and a trash-can. These clips were filmed in three different outdoor environments which we use for cross validation. We manually annotated each video with several sentences that describe what occurs in that video. The sentences were constrained to conform to the grammar in Table 1. Our corpus of 159 training samples pairs some videos with more than one sentence and some sentences with more than one video, with an average of 2.6 sentences per video <sup>1</sup>.

We model and learn the semantics of all words except determiners. Table 2 specifies the arity, the state number  $I_c$ , and the features computed by  $\Phi_c$  for the semantic models for words of each part of speech  $c$ . While we specify a different subset of features for each part of speech, we presume that, in principle, with enough training data, we could include all features in all parts of speech and automatically learn which ones are noninformative and lead to uniform distributions.

We use an off-the-shelf object detector (Felzenszwalb et al., 2010a; Felzenszwalb et al., 2010b) which outputs detections in the form of scored axis-aligned rectangles. We trained four object detectors, one for each of the four object classes in

<sup>1</sup>Our code, videos, and sentential annotations are available at <http://haonanyu.com/research/acl2013/>.

our corpus: person, backpack, chair, and trash-can. For each frame, we pick the two highest-scoring detections produced by each object detector and pool the results yielding eight detections per frame. Having a larger pool of detections per frame can better compensate for false negatives in the object detection and potentially yield smoother tracks but it increases the size of the lattice and the concomitant running time and does not lead to appreciably better performance on our corpus.

We compute continuous features, such as velocity, distance, size ratio, and x-position solely from the detection rectangles and quantize the features into bins as follows:

**velocity** To reduce noise, we compute the velocity of a participant by averaging the optical flow in the detection rectangle. The velocity magnitude is quantized into 5 levels: *absolutely stationary*, *stationary*, *moving*, *fast moving*, and *quickly*. The velocity orientation is quantized into 4 directions: *left*, *up*, *right*, and *down*.

**distance** We compute the Euclidean distance between the detection centers of two participants, which is quantized into 3 levels: *near*, *normal*, and *far away*.

**size ratio** We compute the ratio of detection area of the first participant to the detection area of the second participant, quantized into 2 possibilities: *larger/smaller than*.

**x-position** We compute the difference between the x-coordinates of the participants, quantized into 2 possibilities: *to the left/right of*.

The binning process was determined by a preprocessing step that clustered a subset of the training data. We also incorporate the index of the detector that produced the detection as a feature. The par-

ticular features computed for each part of speech are given in Table 2.

Note that while we use English phrases, like *to the left of*, to refer to particular bins of particular features, and we have object detectors which we train on samples of a particular object class such as *backpack*, such phrases are only mnemonic of the clustering and object-detector training process. We do not have a fixed correspondence between the lexical entries and any particular feature value. Moreover, that correspondence need not be one-to-one: a given lexical entry may correspond to a (time variant) constellation of feature values and any given feature value may participate in the meaning of multiple lexical entries.

We perform a three-fold cross validation, taking the test data for each fold to be the videos filmed in a given outdoor environment and the training data for that fold to be all training samples that contain other videos. For testing, we hand selected 24 sentences generated by the grammar in Table 1, where each sentence is true for at least one test video. Half of these sentences (designated NV) contain only nouns and verbs while the other half (designated ALL) contain other parts of speech. The latter are longer and more complicated than the former. We score each testing video paired with every sentence in both NV and ALL. To evaluate our results, we manually annotated the correctness of each such pair.

Video-sentence pairs could be scored with Eq. 4. However, the score depends on the sentence length, the collective numbers of states and features in the HMMs for words in that sentence, and the length of the video clip. To render the scores comparable across such variation we incorporate a sentence prior to the per-frame score:

$$\hat{L}(D_r, S_r; \lambda) = [L(D_r; S_r, \lambda)]^{\frac{1}{|T_r|}} \pi(S_r) \quad (9)$$

where

$$\pi(S_r) = \exp \sum_{l=1}^{L_r} \left( \begin{array}{c} E(I_{C_{S_r,l}}) \\ N_{C_{S_r,l}} \\ + \sum_{n=1} E(Z_{C_{S_r,l},n}) \end{array} \right) \quad (10)$$

In the above,  $Z_{C_{S_r,l},n}$  is the number of bins for the  $n$ th feature of  $S_{r,l}$  of part of speech  $C_{S_r,l}$  and  $E(Y) = -\sum_{y=1}^Y \frac{1}{Y} \log \frac{1}{Y} = \log Y$  is the entropy of a uniform distribution over  $Y$  bins. This prior prefers longer sentences which describe more information in the video.

	CHANCE	BLIND	OUR	HAND
NV	0.155	0.265	0.545	0.748
ALL	0.099	0.198	0.639	0.786

Table 3: F1 scores of different methods.

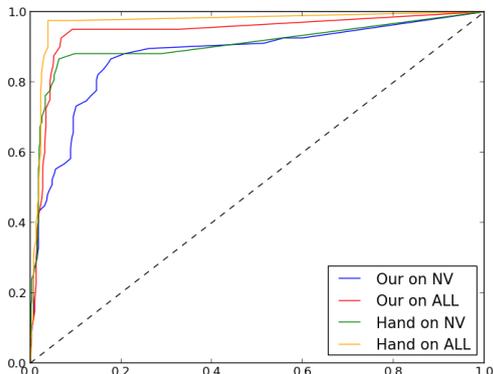

Figure 2: ROC curves of trained models and hand-written models.

The scores are thresholded to decide hits, which together with the manual annotations, can generate TP, TN, FP, and FN counts. We select the threshold that leads to the maximal F1 score on the training set, use this threshold to compute F1 scores on the test set in each fold, and average F1 scores across the folds.

The F1 scores are listed in the column labeled **Our** in Table 3. For comparison, we also report F1 scores for three baselines: **Chance**, **Blind**, and **Hand**. The **Chance** baseline randomly classifies a video-sentence pair as a hit with probability 0.5. The **Blind** baseline determines hits by potentially looking at the sentence but never looking at the video. We can find an upper bound on the F1 score that any blind method could have on each of our test sets by solving a 0-1 fractional programming problem (Dinkelbach, 1967) (see Appendix A for details). The **Hand** baseline determines hits with hand-coded HMMs, carefully designed to yield what we believe is near-optimal performance. As can be seen from Table 3, our trained models perform substantially better than the **Chance** and **Blind** baselines and approach the performance of the ideal **Hand** baseline. One can further see from the ROC curves in Figure 2, comparing the trained and hand-written models on both NV and ALL, that the trained models are close to optimal. Note that performance on ALL exceeds that on NV with the trained models. This is because longer sentences with varied parts of speech incorporate more information into the scoring process.

## 7 Conclusion

We presented a method that learns word meanings from video paired with sentences. Unlike prior work, our method deals with realistic video scenes labeled with whole sentences, not individual words labeling hand delineated objects or events. The experiment shows that it can correctly learn the meaning representations in terms of HMM parameters for our lexical entries, from highly ambiguous training data. Our maximum-likelihood method makes use of only positive sentential labels. As such, it might require more training data for convergence than a method that also makes use of negative training sentences that are not true of a given video. Such can be handled with discriminative training, a topic we plan to address in the future. We believe that this will allow learning larger lexicons from more complex video without excessive amounts of training data.

## A An Upper Bound on the F1 Score of any Blind Method

A **Blind** algorithm makes identical decisions on the same sentence paired with different video clips. An optimal algorithm will try to find a decision  $s_i$  for each test sentence  $i$  that maximizes the F1 score. Suppose, the ground-truth yields  $FP_i$  false positives and  $TP_i$  true positives on the test set when  $s_i = 1$ . Also suppose that setting  $s_i = 0$  yields  $FN_i$  false negatives. Then the F1 score is

$$F1 = \frac{1}{1 + \underbrace{\frac{\sum_i s_i FP_i + (1 - s_i) FN_i}{\sum_i 2s_i TP_i}}_{\Delta}}$$

Thus we want to minimize the term  $\Delta$ . This is an instance of a 0-1 fractional programming problem which can be solved by binary search or Dinkelbach’s algorithm (Dinkelbach, 1967).

## Abstract

Recent work on statistical quantifier scope disambiguation (QSD) has improved upon earlier work by scoping an arbitrary number and type of noun phrases. No corpus-based method, however, has yet addressed QSD when incorporating the implicit universal of plurals and/or operators such as negation. In this paper we report early, though promising, results for automatic QSD when handling both phenomena. We also present a general model for learning to build partial orders from a set of pairwise preferences. We give an  $n \log n$  algorithm for finding a guaranteed approximation of the optimal solution, which works very well in practice. Finally, we significantly improve the performance of the previous model using a rich set of automatically generated features.

## 1 Introduction

The sentence *there is one faculty member in every graduate committee* is ambiguous with respect to quantifier scoping, since there are at least two possible readings: If *one* has **wide scope**, there is a unique faculty member on every committee. If *every* has wide scope, there can be different faculty members on each committee. Over the past decade there has been some work on statistical quantifier scope disambiguation (QSD) (Higgins and Sadock, 2003; Galen and MacCartney, 2004; Manshadi and Allen, 2011a). However, the extent of the work has been quite limited for several reasons. First, in the past two decades, the main focus of the NLP community has been on shallow text processing. As a deep processing task, QSD is not essential for many NLP applications that do not require deep understanding. Second, there has been a lack of comprehensive scope-disambiguated corpora, resulting in the lack of work on extensive

statistical QSD. Third, QSD has often been considered only in the context of explicit quantification such as *each* and *every* versus *some* and *a/an*. These co-occurrences do not happen very often in real-life data. For example, Higgins and Sadock (2003) find fewer than 1000 sentences with two or more explicit quantifiers in the Wall Street journal section of Penn Treebank. Furthermore, for more than 60% of those sentences, the order of the quantifiers does not matter, either as a result of the logical equivalence (as in two existentials), or because they do not have any scope interaction.

Having said that, with deep language processing receiving more attention in recent years, QSD is becoming a real-life issue.<sup>1</sup> At the same time, new scope-disambiguated corpora have become available (Manshadi et al., 2011b). In this paper, we aim at tackling the third issue mentioned above. We push statistical QSD beyond explicit quantification, and address an interesting, yet practically important, problem in QSD: plurality and quantification. In spite of an extensive literature in theoretical semantics (Hamm and Hinrichs, 2010; Landmann, 2000), this topic has not been well investigated in computational linguistics. To illustrate the phenomenon, consider (1):

1. *Three words start with a capital letter.*

A deep understanding of this sentence, requires deciding whether each *word* in the set, referred to by *Three words*, starts with a potentially distinct *capital letter* (as in *Apple, Orange, Banana*) or there is a unique *capital letter* which each *word* starts with (as in *Apple, Adam, Athens*). By treating the NP *Three words* as a single atomic entity, earlier work on automatic QSD has overlooked this problem. In general, every plural NP potentially introduces an **implicit universal**, ranging

<sup>1</sup>For example, Liang et al. (2011) in their state-of-the-art statistical semantic parser within the domain of natural language queries to databases, explicitly devise quantifier scoping in the semantic model.

over the collection of entities introduced by the plural.<sup>2</sup> Scoping this implicit universal is just as important. While explicit universals may not occur very often in natural language, the usage of plurals is very common. Plurals form 18% of the NPs in our corpus and 20% of the nouns in Penn Treebank. Explicit universals, on the other hand, form less than 1% of the determiners in Penn Treebank. Quantifiers are also affected by negation. Previous work (e.g., Morante and Blanco, 2012) has investigated automatically detecting the scope and focus of negation. However, the scope of negation with respect to quantifiers is a different phenomenon. Consider the following sentence.

2. *The word does not start with a capital letter.*

Transforming this sentence into a meaning representation language, for almost any practical purposes, requires deciding whether the NP *a capital letter* lies in the scope of the negation or outside of it. The former describes the preferred reading where *The word* starts with a lowercase letter as in *apple, orange, banana*, but the latter gives the unlikely reading, according to which there exists a particular *capital letter*, say *A*, that *The word* starts with, as in *apple, Orange, Banana*. By not involving negation in quantifier scoping, a semantic parser may produce an unintended interpretation.

Previous work on statistical QSD has been quite restricted. Higgins and Sadock (2003), which we refer to as **HS03**, developed the first statistical QSD system for English. Their system disambiguates the scope of exactly two explicitly quantified NPs in a sentence, ignoring indefinite *a/an*, definites and bare NPs. Manshadi and Allen (2011a), hence **MA11**, go beyond those limitations and scope an arbitrary number of NPs in a sentence with no restriction on the type of quantification. However, although their corpus annotates the scope of negations and the implicit universal of plurals, their QSD system does not handle those.

As a step towards comprehensive automatic QSD, in this paper we present our work on automatic scoping of the implicit universal of plurals and negations. For data, we use a new revision of MA11’s corpus, first introduced in Manshadi et al. (2011b). The new revision, called **QuanText**, carries a more detailed, fine-grained scope annotation (Manshadi et al., 2012). The performance of

<sup>2</sup>Although plurals carry different types of quantification (Herbelot and Copestake, 2010), almost always there exists an implicit universal. The importance of scoping this universal, however, may vary based on the type of quantification.

our model defines a baseline for future efforts on (comprehensive) QSD over QuanText. In addition to addressing plurality and negation, this work improves upon MA11’s in two directions.

- We theoretically justify MA11’s ternary-classification approach, formulating it as a general framework for learning to build partial orders. An  $n \log n$  algorithm is then given to find a guaranteed approximation within a fixed ratio of the optimal solution from a set of pairwise preferences (Sect. 3.1).
- We replace MA11’s hand-annotated features with a set of automatically generated linguistic features. Our rich set of features significantly improves the performance of the QSD model, even though we give up the gold-standard dependency features (Sect. 3.3).

## 2 Task definition

In QuanText, scope-bearing elements (or, as we call them, scopal terms) of each sentence have been identified using labeled **chunks**, as in (3).

3. *Replace [1/ every line] in [2/ the file] ending in [3/ punctuation] with [4/ a blank line].*

NP chunks follow the definition of **baseNP** (Ramshaw and Marcus, 1995) and hence are flat. Outscoping relations are used to specify the relative scope of scopal terms. The relation  $i > j$  means that chunk  $i$  **outscopes** (or has **wide scope** over) chunk  $j$ . Equivalently, chunk  $j$  is said to have **narrow scope** with respect to  $i$ . Each sentence is annotated with its most preferred scoping (according to the annotators’ judgement), represented as a **partial order**:

4.  $SI : (2 > 1 > 4; 1 > 3)$

If neither  $i > j$  nor  $j > i$  is entailed from the scoping,  $i$  and  $j$  are **incomparable**. This happens if both orders are equivalent (as in two existentials) or when the two chunks have no scope interaction.

Since a partial order can be represented by a **Directed Acyclic Graph** (DAG), we use DAGs to represent scopings. For example,  $G_1$  in Figure 1 represents the scoping in (4).

### 2.1 Evaluation metrics

Given the gold standard DAG  $G_g = (V, E_g)$  and the predicted DAG  $G_p = (V, E_p)$ , a similarity measure may be defined based on the ratio of the number of pairs (of nodes) labeled correctly to the

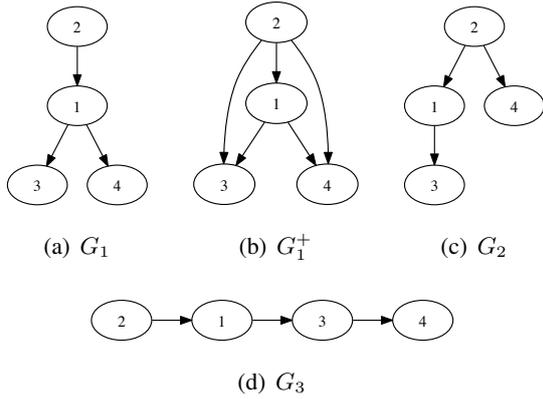

Figure 1: Scoping as DAG

total number of pairs. In order to take the transitivity of outscoping relations into account, we use the **transitive closure** (TC) of DAGs. Let  $G^+ = (V, E^+)$  represent the TC of a DAG  $G = (V, E)$ .<sup>3</sup>  $G_1$  and  $G_1^+$  in Figure 1 illustrate this concept. We now define the similarity metric  $S^+$  as follows:

$$\sigma^+ = \frac{|E_p^+ \cap E_g^+| \cup |E_p^{\bar{+}} \cap E_g^{\bar{+}}|}{|V|(|V| - 1)/2} \quad (1)$$

in which  $\bar{G} = (V, \bar{E})$  is the complement of the underlying undirected version of  $G$ .

HS03 and others have used such a similarity measure for evaluation purposes. A disadvantage of this metric is that it gives the same weight to outscoping and incomparability relations. In practice, if two scopal terms with equivalent ordering (and hence, no outscoping relation) are incorrectly labeled with an outscoping, the logical form still remains valid. But if an outscoping relation is mislabeled, it will change the interpretation of the sentence. Therefore, in MA11, we suggest defining a precision/recall based on the number of outscoping relations recovered correctly:<sup>4</sup>

$$P^+ = \frac{|E_p^+ \cap E_g^+|}{|E_p^+|}, R^+ = \frac{|E_p^+ \cap E_g^+|}{|E_g^+|} \quad (2)$$

<sup>3</sup>  $(u, v) \in G^+ \iff ((u, v) \in G \vee \exists w_1 \dots w_n \in V, (u, w_1) \dots (w_n, v) \in E)$

<sup>4</sup>MA11 argues that TC-based metrics tend to produce higher numbers. For example if  $G_3$  in Figure 1 is a gold-standard DAG and  $G_1$  is a candidate DAG, TC-based metrics count  $2 > 3$  as another match, even though it is entailed from  $2 > 1$  and  $1 > 3$ . They give an alternative metric based on **transitive reduction** (TR), obtained by removing all the redundant edges of a DAG. TR-based metrics, however, have their own disadvantage. For example, if  $G_2$  is another candidate for  $G_3$ , TR-based metrics produce the same numbers for both  $G_1$  and  $G_2$ , even though  $G_1$  is clearly closer to  $G_3$  than  $G_2$ . Therefore, in this paper we stick to TC-based metrics.

### 3 Our framework

#### 3.1 Learning to do QSD

Since we defined QSD as a partial ordering, automatic QSD would become the problem of learning to build partial orders. The machine learning community has studied the problem of learning **total orders (ranking)** in depth (Cohen et al., 1999; Furnkranz and Hullermeier, 2003; Hullermeier et al., 2008). Many ranking systems create partial orders as output when the confidence level for the relative order of two objects is below some threshold. However, the target being a partial order is a fundamentally different problem. While the lack of order between two elements is interpreted as the lack of confidence in the former, it should be interpreted as **incomparability** in the latter. Learning to build partial orders has not attracted much attention in the learning community, although as seen shortly, the techniques developed for ranking can be adopted for learning to build partial orders.

As mentioned before, a partial order  $P$  can be represented by a DAG  $G$ , with  $a$  preceding  $b$  in  $P$  if and only if  $a$  reaches  $b$  in  $G$  by a directed path. Although there could be many DAGs representing a partial order  $P$ , only one of those is a **transitive DAG**.<sup>5</sup> Therefore, in order to have a one-to-one relationship between QSDs and DAGs, we only consider the class of transitive DAGs, or **TDAG**. Every non-transitive DAG will be converted into its transitive counterpart by taking its transitive closure (as shown in Figure 1).

Consider  $V$ , a set of nodes and a TDAG  $G = (V, E)$ . It would help to think of disconnected nodes  $u, v$  of  $G$ , as connected with a null edge  $\epsilon$ . We define the labeling function  $\delta_G : V \times V \rightarrow \{+, -, \epsilon\}$  assigning one of the three labels to each pair of nodes in  $G$ :

$$\delta_G(u, v) = \begin{cases} + & (u, v) \in G \\ - & (v, u) \in G \\ \epsilon & \text{otherwise} \end{cases} \quad (3)$$

Given the true TDAG  $\hat{G} = (V, \hat{E})$ , and a candidate TDAG  $G$ , we define the **Loss** function to be the total number of incorrect edges:

$$L(G, \hat{G}) = \sum_{u \prec v \in V} I(\delta_G(u, v) \neq \delta_{\hat{G}}(u, v)) \quad (4)$$

in which  $\prec$  is an arbitrary total order over the nodes in  $V$ ,<sup>6</sup> and  $I(\cdot)$  is the indicator function. We

<sup>5</sup> $G$  is transitive iff  $(u, v), (v, w) \in G \implies (u, w) \in G$ .

<sup>6</sup>E.g., the left-to-right order of the corresponding chunks in the sentence.

adopt a **minimum Bayes risk** (MBR) approach, with the goal of finding the graph with the lowest expected loss against the (unknown) target graph:

$$G^* = \operatorname{argmin}_{G \in \text{TDAG}} E_{\hat{G}} [L(G, \hat{G})] \quad (5)$$

Substituting in the definition of the loss function and exchanging the order of the expectation and summation, we get:

$$\begin{aligned} G^* &= \operatorname{argmin}_{G \in \text{TDAG}} \sum_{u \prec v \in V} E_{\hat{G}} [I(\delta_G(u, v) \neq \delta_{\hat{G}}(u, v))] \\ &= \operatorname{argmin}_{G \in \text{TDAG}} \sum_{u \prec v \in V} P(\delta_G(u, v) \neq \delta_{\hat{G}}(u, v)) \quad (6) \end{aligned}$$

This means that in order to solve Eq. (5), we need only the probabilities of each of the three labels for each of the  $C(n, 2) = n(n-1)/2$  pairs of nodes<sup>7</sup> in the graph, rather than a probability for each of the superexponentially many possible graphs. We train a classifier to estimate these probabilities directly for a given pair. Therefore, we have reduced the problem of predicting a partial order to **pairwise comparison**, analogous to ranking by pairwise comparison or **RPC** (Hullermeier et al., 2008; Furnkranz and Hullermeier, 2003), a popular technique in learning total orders. The difference though is that in RPC, the comparison is a (soft) binary classification, while for partial orders we have the case of incomparability (the label  $\epsilon$ ), hence a (soft) ternary classification.

A soft ternary classifier generates three probabilities,  $p_{u,v}(+)$ ,  $p_{u,v}(-)$ , and  $p_{u,v}(\epsilon)$  for each pair  $(u, v)$ ,<sup>8</sup> corresponding to the three labels. Hence, equation Eq. (6) can be rearranged as follows:

$$G^* = \operatorname{argmax}_{G \in \text{TDAG}} \sum_{u \prec v \in V} p_{u,v}(\delta_G(u, v)) \quad (7)$$

Let  $\Gamma_p$  be a graph like the one in Figure 2, containing exactly three edges between every two nodes, weighted by the probabilities from the  $n(n-1)/2$  classifiers. We call  $\Gamma_p$  the **preference graph**. Intuitively speaking, the solution to Eq. (7) is the transitive directed acyclic subgraph of  $\Gamma_p$  that has the maximum sum of weights. Unfortunately finding this subgraph is an NP-hard problem.<sup>9</sup>

<sup>7</sup>Throughout this subsection, unless otherwise specified, by a pair of nodes we mean a pair  $(u, v)$  with  $u \prec v$ .

<sup>8</sup> $p_{v,u}$  for  $u \prec v$  is defined in the obvious way:  $p_{v,u}(+) = p_{u,v}(-)$ ,  $p_{v,u}(-) = p_{u,v}(+)$ , and  $p_{v,u}(\epsilon) = p_{u,v}(\epsilon)$ .

<sup>9</sup>The proof is beyond the scope of this paper, but the idea is similar to that of Cohen et al. (1999), on finding total orders. Although they don't use an RPC technique, Cohen et

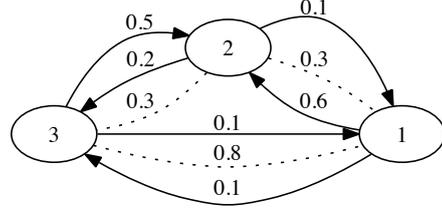

Figure 2: A preference graph over three nodes.

1. Let  $\Gamma_p$  be the preference graph and set  $G$  to  $\emptyset$ .
2.  $\forall u \in V$ , let  $\pi(u) = \sum_v p_{u,v}(+) - \sum_v p_{u,v}(-)$ .
3. Let  $u^* = \operatorname{argmax}_u \pi(u)$ ,  $S^- = \sum_{v \in G} p_{v,u^*}(-)$  &  $S^\epsilon = \sum_{v \in G} p_{v,u^*}(\epsilon)$ .
4. Remove  $u^*$  and all its incident edges from  $\Gamma_p$ .
5. Add  $u^*$  to  $G$ ; also if  $S^- > S^\epsilon$ , for every  $v \in G - u^*$ , add  $(v, u^*)$  to  $G$ .
6. If  $\Gamma_p$  is empty, output  $G$ , otherwise repeat steps 2-5.

Figure 3: An approximation algorithm for Eq. (7)

Since it is very unlikely to find an efficient algorithm to solve Eq. (7), instead, we propose the algorithm in Figure 3 which finds an approximate solution. The idea of the algorithm is simple. By finding  $u^*$  with the highest  $\pi(u)$  in step 3, we form a **topological order** for the nodes in  $G$  in a greedy way (see Footnote 9). We then add  $u^*$  to  $G$ . A directed edge is added either from every node in  $G - u^*$  to  $u^*$  or from no node, depending on which case makes the sum of the weights in  $G$  higher.

**Theorem 1** *The algorithm in Figure 3 is a 1/3-OPT approximation algorithm for Eq. (7).*

*Proof idea.* First of all, note that  $G$  is a TDAG, because edges are only added to the most recently created node in step 5. Let  $OPT$  be the optimum value of the right hand side of Eq. (7). The sum of all the weights in  $\Gamma_p$  is an upper bound for  $OPT$ :

$$\sum_{u \prec v \in V} \sum_{\lambda \in \{+, -, \epsilon\}} p_{u,v}(\lambda) \geq OPT$$

Step 5 of the algorithm guarantees that the labels  $\delta_G(u, v)$  satisfy:

$$\sum_{u \prec v \in V} p_{u,v}(\delta_G(u, v)) \geq \sum_{u \prec v \in V} p_{u,v}(\lambda) \quad (8)$$

al. (1999) encounter a similar optimization problem. They propose an approximation algorithm which finds the solution (a total order) in a greedy way. Here we use the same greedy technique to find a total order, but take it only as the topological order of the solution (Figure 3).

for any  $\lambda \in \{+, -, \epsilon\}$ . Hence:

$$\begin{aligned} \sum_{u \prec v \in V} p_{u,v}(\delta_G(u, v)) &= \frac{1}{3} \left( 3 \sum_{u \prec v \in V} p_{u,v}(\delta_G(u, v)) \right) \\ &\geq \frac{1}{3} \sum_{u \prec v \in V} \sum_{\lambda \in \{+, -, \epsilon\}} p_{u,v}(\lambda) \\ &\geq \frac{1}{3} OPT \end{aligned}$$

In practice, we improve the algorithm in Figure 3, while maintaining the approximation guarantee, as follows. When adding a node  $u^*$  to graph  $G$ , we do not make a binary decision as to whether connect every node in  $G$  to  $u^*$  or none, but we use some heuristics to choose a subset of nodes (possibly empty) in  $G$  that if connected to  $u^*$  results in a TDAG whose sum of weights is at least as big as the binary none-vs-all case. As described in Sec. 4, the algorithm works very well in our QSD system, finding the optimum solution in virtually all cases we examined.

### 3.2 Dealing with plurality and negation

Consider the following sentence with the plural NP chunk *the lines*.

5. Merge [**1p**/ the lines], ending in [**2**/ a punctuation], with [**3**/ the next non-blank line].

6. *SI* : ( $1c > 1d > 2$ ;  $1d > 3$ )<sup>10</sup>

In QuanText, plural chunks are indexed with a number followed by the lowercase letter “p”. As seen in (6), the scoping looks different from before in that the terms *1d* and *1c* are not the label of any chunk. These two terms refer to the two quantified terms introduced by the plural chunk *1p*: *1c* (for **collection**) represents the set (or in better words collection) of entities, defined by the plural, and *1d* (for **distribution**) refers to the implicit universal, introduced by the plural. In other words, for a plural chunk *ip*, *id* represents the universally quantified entity over the collection *ic*. The outscoping relation  $1d > 2$  in (6) states that every *line* in the collection, denoted by *1c*, starts with its own *punctuation* character. Similarly,  $1d > 3$  indicates that every *line* has its own *next non-blank line*. Figure 4(a) shows a DAG for the scoping in (6).

In (7) we have a sentence containing a negation. In QuanText, negation chunks are labeled with an uppercase “N” followed by a number.

<sup>10</sup>This scoping corresponds to the logical formula:  
 $\mathcal{D}x_{1c}, \text{Collection}(x_{1c}) \wedge \forall x_{1d}, \text{In}(x_{1d}, x_{1c}) \Rightarrow$   
 $(\text{Line}(x_{1d}) \wedge (\exists x_2, \text{Punctuation}(x_2) \wedge \text{EndIn}(x_{1d}, x_2)) \wedge$   
 $(\mathcal{D}x_3, \neg \text{blank}(x_3) \wedge \text{next}(x_{1d}, x_3) \wedge \text{merge}(x_{1d}, x_3)))$   
It is straightforward to write a formula for, say,  $1c > 2 > 1d$ .

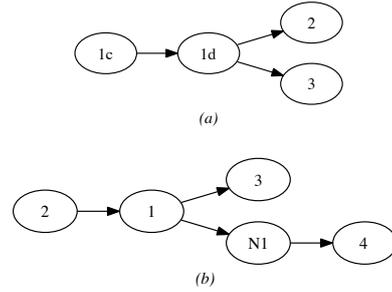

Figure 4: DAGs for scopings in (6) and (8)

7. Extract [**1**/ every word] in [**2**/ file “1.txt”], which starts with [**3**/ a capital letter], but does [**N1**/ not] end with [**4**/ a capital letter].
8. *SI* : ( $2 > 1 > 3$ ;  $1 > N1 > 4$ )

As seen here, a negation simply introduces a chunk, which participates in outscoping relations like an NP chunk. Figure 4(b) represents the scoping in (8) as a DAG.

From these examples, as long as we create two nodes in the DAG corresponding to each plural chunk, and one node corresponding to each negation, there is no need to modify the underlying model (defined in the previous section). However, when  $u$  (or  $v$ ) is a negation (*Ni*) or an implicit universal (*id*) node, the probabilities  $p_{u,v}^\lambda$  ( $\lambda \in \{+, -, \epsilon\}$ ) may come from a different source, e.g. a different classification model or the same model with a different set of features, as described in the following section.

### 3.3 Feature selection

Previous work has shown that the lexical item of quantifiers and syntactic clues (often extracted from phrase structure trees) are good at predicting quantifier scoping. Srinivasan and Yates (2009) use the semantics of the head noun in a quantified NP to predict the scoping. MA11 also find the lexical item of the head noun to be a good predictor. In this paper, we introduce a new set of syntactic features which we found very informative: the “type” dependency features of de Marneffe et al. (2006). Adopting this new set of features, we outperform MA11’s system by a large margin. Another point to mention here is that the features that are predictive of the relative scope of quantifiers are not necessarily as helpful when determining the scope of negation and vice versa. Therefore we do not use exactly the same set of features when

one of the scopal terms in the pair<sup>11</sup> is a negation, although most of the features are quite similar.

### 3.3.1 NP chunks

We first describe the set of features we have adopted when both scopal terms in a pair are NP-chunks. We have organized the features into different categories listed below.

#### Individual NP-chunk features

Following features are extracted for both NP chunks in a pair.

- The part-of-speech (POS) tag of the head of chunk
- The lexical item of the head noun
- The lexical item of the determiner/quantifier
- The lexical item of the pre-determiner
- Does the chunk contain a constant (e.g. “do”, ‘x’)?
- Is the NP-chunk a plural?

#### Implicit universal of a plural

Remember that every plural chunk  $i$  introduces two nodes in the DAG,  $ic$  and  $id$ . Both nodes are introduced by the same chunk  $i$ , therefore they use the same set of features. The only exception is a single additional binary feature for plural NP chunks, which determines whether the given node refers to the implicit universal of the plural (i.e.  $id$ ) or to the collection itself (i.e.  $ic$ ).

- Does this node refer to an implicit universal?

#### Syntactic features – phrase structure tree

As mentioned above, we have used two sets of syntactic features. The first is motivated by HS03’s work and is based on the constituency (i.e. phrase structure) tree  $T$  of the sentence. Since our model is based on pairwise comparison, the following features are defined for each pair of chunks. In the following, by chunk we mean the deepest phrase-level node in  $T$  dominating all the words in the chunk. If the constituency tree is correct, this node is usually an NP node. Also,  $P$  refers to the undirected path in  $T$  connecting the two chunks.

- Syntactic category of the deepest common ancestor
- Does 1st/2nd chunk  $C$ -command 2nd/1st one?
- Length of the path  $P$
- Syntactic categories of nodes on  $P$
- Is there a conjoined node on  $P$ ?
- List of punctuation marks dominated by nodes on  $P$

#### Syntactic features – dependency tree

Although regular “untyped” dependency relations do not seem to help our QSD system in the presence of phrase-structure trees, we found the *col-*

<sup>11</sup>Since our model is based on pairwise comparison, every sample is in fact a pair of nodes  $(u, v)$  of the DAG.

*lapsed typed dependencies* (de Marneffe and Manning, 2008) very helpful, even when used on top of the phrase-structure features. Below is the list of features we extract from the collapsed typed dependency tree  $T_d$  of each sentence. In the following, by noun we mean the node in  $T_d$  which corresponds to the head of the chunk. The choice of the word *noun*, however, may be sloppy, as the head of an NP chunk may not be a noun.

- Does 1st/2nd noun dominate 2nd/1st noun?
- Does 1st/2nd noun immediately dominate 2nd/1st?
- Type of incoming dependency relation of each noun
- Syntactic category of the deepest common ancestor
- Lexical item of the deepest common ancestor
- Length of the undirected path between the two

### 3.3.2 Negations

There are no sentences in our corpus with more than one negation. Therefore, for every pair of nodes with one negation, the other node must refer to an NP chunk. We use the following word-level, phrase-structure, and dependency features for these pairs.

- Lexical item of the determiner for the NP chunk
- Does the NP chunk contain a constant?
- Is the NP chunk a plural?
- If so, does this node refer to its implicit universal?
- Does the negation  $C$ -command the NP chunk in  $T$ ?
- Does the NP chunk  $C$ -command the negation in  $T$ ?
- What is the POS of the parent  $p$  of negation in  $T_d$ ?
- Does  $p$  dominate the noun in  $T_d$ ?
- Does the noun dominate  $p$  in  $T_d$ ?
- Does  $p$  immediately dominate the noun in  $T_d$ ?
- If so, what is the type of the dependency?
- Does the noun immediately dominate  $p$  in  $T_d$ ?
- If so, what is the type of the dependency?
- Length of the undirected path between the two in  $T_d$

## 4 Experiments

QuantText contains 500 sentences with a total of 1750 chunks, that is 3.5 chunks/sentence on average. Of those, 1700 chunks are NP chunks. The rest are scopal operators, mainly negation. Of all the NP chunks, 320 (more than 18%) are plural, each introducing an implicit universal, that is, an additional node in the DAG. Since we feed each pair of elements to the classifiers independently, each (unordered) pair introduces one sample. Therefore, a sentence with  $n$  scopal elements creates  $C(n, 2) = n(n - 1)/2$  samples for classification. When all the elements are taken into account,<sup>12</sup> the total number of samples in the corpus will be:

<sup>12</sup>Here by all elements we mean explicit chunks and the implicit universals. QuantText labels some other (implicit) elements, which we have not been handled in this work. In particular, some nouns introduce two entities: a **type** and a

$$\sum_i C(n_i, 2) \approx 4500 \quad (9)$$

Where  $n_i$  is the number of scopal terms introduced by sentence  $i$ . Out of the 4500 samples, around 1800 involve at least one implicit universal (i.e., *id*), but only 120 samples contain a negation. We evaluate the performance of the system for implicit universals and negation both separately and in the context of full scope disambiguation. We split the corpus at random into three sets of 50, 100, and 350 sentences, as development, test, and train sets respectively.<sup>13</sup>

To extract part-of-speech tags, phrase structure trees, and typed dependencies, we use the Stanford parser (Klein and Manning, 2003; de Marneffe et al., 2006) on both train and test sets. Since we are using SVM, we have passed the confidence levels through a softmax function to convert them into probabilities  $P_{u,v}^\lambda$  before applying the algorithm of Section 3. We take MA11’s system as the baseline. However, in order to have a fair comparison, we have used the output of the Stanford parser to automatically generate the same features that MA11 have hand-annotated.<sup>14</sup> In order to run the baseline system on implicit universals, we take the feature vector of a plural NP and add a feature to indicate that this feature vector represents the implicit universal of the corresponding chunk. Similarly, for negation we add a feature to show that the chunk represents a negation. As shown in Section 3.3.2, we have used a more compact set of features for negations. Once again, in order to have a fair comparison, we apply a similar modification to the baseline system. We also use the exact same classifier as used in MA11.<sup>15</sup> Figure 5(a) compares the performance of our model, which we refer to as RPC-SVM-13, with the baseline system, but only on explicit NP chunks.<sup>16</sup> The goal for running this experiment has been to compare the performance of our model to the baseline system, as described by Manshadi et al. (2012). In this work, we have only considered the token entity introduced by those nouns and have ignored the type entity.

<sup>13</sup>Since the percentage of sentences with negation is small, we made sure that those sentences are distributed uniformly between three sets.

<sup>14</sup>MA11’s features are similar to part-of-speech tags and typed dependency relations.

<sup>15</sup>*SVM<sup>Multiclass</sup>* from *SVM-light* (Joachims, 1999).

<sup>16</sup>In all experiments, we ignore NP conjunctions. Previous work treats a conjunction of NPs as separate NPs. However, similar to plurals, NP conjunctions (disjunctions) introduce an extra scopal element: a universal (existential). We are working on an annotation scheme for NP conjunctions, so we have left this for after the annotations become available.

NP-Chunks only (no <i>id</i> or negation)	$\sigma^+$	$P^+$	$R^+$	$F^+$	AR	A
Baseline (MA11)	0.762	0.638	0.484	0.550	0.59	0.47
Our model (RPC-SVM-13)	0.827	0.743	0.677	0.709	0.68	0.55

(a) Scoping explicit NP chunks

Overall system (including negation and implicit universals)	$\sigma^+$	$P^+$	$R^+$	$F^+$	AR	A
Baseline (MA11)	0.787	0.688	0.469	0.557	0.59	0.47
Our model (RPC-SVM-13)	0.863	0.784	0.720	0.751	0.69	0.55

(b) Scoping all elements (including *id* and  $N_i$ )

Figure 5: Performance on QuanText data

tem on the task that it was actually defined to perform (that is scoping only explicit NP chunks).

As seen in this table, by incorporating a richer set of features and a better learning algorithm, our model outperforms the baseline by almost 15%. The measure  $A$  in these figures shows sentence-based accuracy. A sentence counts as correct iff every pair of scopal elements has been labeled correctly. Therefore  $A$  is a tough measure. Furthermore, it is sensitive to the length of the sentence. Following MA11, we have computed another sentence-based accuracy measure,  $AR$ . In computing  $AR$ , a sentence counts as correct iff all the outscoping relations have been recovered correctly – in other words, iff  $R = 100\%$ , regardless of the value of  $P$ .  $AR$  may be more practically meaningful, because if in the correct scoping of the sentence there is no outscoping between two elements, inserting one does not affect the interpretation of the sentence. In other words, precision is less important for QSD in practice.

Figure 5(b) gives the performance of the overall model when all the elements including the implicit universals and the negations are taken into account. That the F-score of our model for the second experiment is 0.042 higher than F-score for the first indicates that scoping implicit universals and/or negations must be easier than scoping explicit NP chunks. In order to find how much one or both of the two elements contribute to this gain, we have run two more experiments, scoping only the pairs with at least one implicit universal and pairs with one negation, respectively. Figure 6 reports the results. As seen, the contribution in boosting the overall performance comes from the implicit universals while negations, in fact, lower the performance. The performance for pairs with implicit universal is higher because universals, in general,

<b>Implicit universals only</b> (pairs with at least one <i>id</i> )	<b>P<sup>+</sup></b>	<b>R<sup>+</sup></b>	<b>F<sup>+</sup></b>
Baseline (MA11)	0.776	0.458	0.576
Our model (RPC-SVM-13)	0.836	0.734	0.782

(a) Pairs with at least one implicit universal

<b>Negation only</b> (pairs with one negation)	<b>P<sup>+</sup></b>	<b>R<sup>+</sup></b>	<b>F<sup>+</sup></b>
Baseline (MA11)	0.502	0.571	0.534
Our model (RPC-SVM-13)	0.733	0.55	0.629

(b) Pairs with at least one negation

Figure 6: Implicit universals and negations

are easier to scope, even for the human annotators.<sup>17</sup> There are several reasons for poor performance with negations as well. First, the number of negations in the corpus is small, therefore the data is very sparse. Second, the RPC model does not work well for negations. Scoping a negation relative to an NP chunk, with which it has a long distance dependency, often depends on the scope of the elements in between. Third, scoping negation usually requires a deep semantic analysis.

In order to see how well our approximation algorithm is working, similar to the approach of Chambers and Jurafsky (2008), we tried an ILP solver<sup>18</sup> for DAGs with at most 8 nodes to find the optimum solution, but we found the difference insignificant. In fact, the approximation algorithm finds the optimum solution in all but one case.<sup>19</sup>

## 5 Related work

Since automatic QSD is in general challenging, traditionally quantifier scoping is left underspecified in deep linguistic processing systems (Alshawi and Crouch, 1992; Bos, 1996; Copestake et al., 2001). Some efforts have been made to move underspecification frameworks towards weighted constraint-based graphs in order to produce the most preferred reading (Koller et al., 2008), but the source of these types of constraint are often discourse, pragmatics, world knowledge, etc., and hence, they are hard to obtain automatically. In or-

<sup>17</sup>Trivially, we have taken the relation outscoping  $ic > id$  for granted and not counted it towards higher performance.

<sup>18</sup>lpsolve: <http://sourceforge.net/projects/lpsolve>

<sup>19</sup>To find the gain that can be obtained with gold-standard parses, we used MA11’s system with their hand-annotated and the equivalent automatically generated features. The former boost the performance by 0.04. Incidentally, HS03 lose almost 0.04 when switching to automatically generated parses.

der to evade scope disambiguation, yet be able to perform entailment, Koller and Thater (2010) propose an algorithm to calculate the weakest readings<sup>20</sup> from a scope-underspecified representation.

Early efforts on automatic QSD (Moran, 1988; Hurum, 1988) were based on heuristics, manually formed into rules with manually assigned weights for resolving conflicts. To the best of our knowledge, there have been four major efforts on statistical QSD for English: Higgins and Sadock (2003), Galen and MacCartney (2004), Srinivasan and Yates (2009), and Manshadi and Allen (2011a). The first three only scope two scopal terms in a sentence, where the scopal term is an NP with an explicit quantification. MA11 is the first to scope any number of NPs in a sentence with no restriction on the type of quantification. Besides ignoring negation and implicit universals, their system has some other limitations too. First, the learning model is not theoretically justified. Second, hand-annotated features (e.g. dependency relations) are used on both the train and the test data.

## 6 Summary and future work

We develop the first statistical QSD model addressing the interaction of quantifiers with negation and the implicit universal of plurals, defining a baseline for this task on QuanText data (Manshadi et al., 2012). In addition, our work improves upon Manshadi and Allen (2011a)’s work by (approximately) optimizing a well justified criterion, by using automatically generated features instead of hand-annotated dependencies, and by boosting the performance by a large margin with the help of a rich feature vector.

This work can be improved in many directions, among which are scoping more elements such as other scopal operators and implicit entities, deploying more complex learning models, and developing models which require less supervision.

## Abstract

Traditional approaches to the task of ACE event extraction usually rely on sequential pipelines with multiple stages, which suffer from error propagation since event triggers and arguments are predicted in isolation by independent local classifiers. By contrast, we propose a joint framework based on structured prediction which extracts triggers and arguments together so that the local predictions can be mutually improved. In addition, we propose to incorporate global features which explicitly capture the dependencies of multiple triggers and arguments. Experimental results show that our joint approach with local features outperforms the pipelined baseline, and adding global features further improves the performance significantly. Our approach advances state-of-the-art sentence-level event extraction, and even outperforms previous argument labeling methods which use external knowledge from other sentences and documents.

## 1 Introduction

Event extraction is an important and challenging task in Information Extraction (IE), which aims to discover event triggers with specific types and their arguments. Most state-of-the-art approaches (Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011) use sequential pipelines as building blocks, which break down the whole task into separate subtasks, such as trigger identification/classification and argument identification/classification. As a common drawback of the staged architecture, errors in upstream component are often compounded and propagated to the downstream classifiers. The downstream components, however, cannot impact earlier deci-

sions. For example, consider the following sentences with an ambiguous word “fired”:

- (1) In Baghdad, a cameraman **died** when an *American tank* **fired** on the Palestine Hotel.
- (2) He has **fired** his *air defense chief*.

In sentence (1), “fired” is a trigger of type *Attack*. Because of the ambiguity, a local classifier may miss it or mislabel it as a trigger of *End-Position*. However, knowing that “tank” is very likely to be an *Instrument* argument of *Attack* events, the correct event subtype assignment of “fired” is obviously *Attack*. Likewise, in sentence (2), “air defense chief” is a job title, hence the argument classifier is likely to label it as an *Entity* argument for *End-Position* trigger.

In addition, the local classifiers are incapable of capturing inter-dependencies among multiple event triggers and arguments. Consider sentence (1) again. Figure 1 depicts the corresponding event triggers and arguments. The dependency between “fired” and “died” cannot be captured by the local classifiers, which may fail to attach “cameraman” to “fired” as a *Target* argument. By using global features, we can propagate the *Victim* argument of the *Die* event to the *Target* argument of the *Attack* event. As another example, knowing that an *Attack* event usually only has one *Attacker* argument, we could penalize assignments in which one trigger has more than one *Attacker*. Such global features cannot be easily exploited by a local classifier.

Therefore, we take a fresh look at this problem and formulate it, for the first time, as a *structured learning* problem. We propose a novel joint event extraction algorithm to predict the triggers and arguments simultaneously, and use the structured perceptron (Collins, 2002) to train the joint model. This way we can capture the dependencies between triggers and argument as well as explore

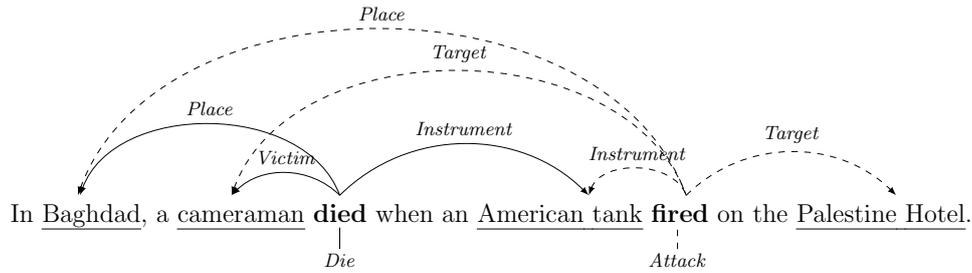

Figure 1: Event mentions of example (1). There are two event mentions that share three arguments, namely the *Die* event mention triggered by “died”, and the *Attack* event mention triggered by “fired”.

arbitrary global features over multiple local predictions. However, different from easier tasks such as part-of-speech tagging or noun phrase chunking where efficient dynamic programming decoding is feasible, here exact joint inference is intractable. Therefore we employ beam search in decoding, and train the model using the early-update perceptron variant tailored for beam search (Collins and Roark, 2004; Huang et al., 2012).

We make the following contributions:

1. Different from traditional pipeline approach, we present a novel framework for sentence-level event extraction, which predicts triggers and their arguments jointly (Section 3).
2. We develop a rich set of features for event extraction which yield promising performance even with the traditional pipeline (Section 3.4.1). In this paper we refer to them as local features.
3. We introduce various global features to exploit dependencies among multiple triggers and arguments (Section 3.4.2). Experiments show that our approach outperforms the pipelined approach with the same set of local features, and significantly advances the state-of-the-art with the addition of global features which brings a notable further improvement (Section 4).

## 2 Event Extraction Task

In this paper we focus on the event extraction task defined in Automatic Content Extraction (ACE) evaluation.<sup>1</sup> The task defines 8 event types and 33 subtypes such as *Attack*, *End-Position* etc. We introduce the terminology of the ACE event extraction that we used in this paper:

<sup>1</sup><http://projects.ldc.upenn.edu/ace/>

- Event mention: an occurrence of an event with a particular type and subtype.
- Event trigger: the word most clearly expresses the event mention.
- Event argument: an entity mention, temporal expression or value (e.g. *Job-Title*) that serves as a participant or attribute with a specific role in an event mention.
- Event mention: an instance that includes one event trigger and some arguments that appear within the same sentence.

Given an English text document, an event extraction system should predict event triggers with specific subtypes and their arguments from each sentence. Figure 1 depicts the event triggers and their arguments of sentence (1) in Section 1. The outcome of the entire sentence can be considered a graph in which each argument role is represented as a typed edge from a trigger to its argument.

In this work, we assume that argument candidates such as entities are part of the input to the event extraction, and can be from either gold standard or IE system output.

## 3 Joint Framework for Event Extraction

Based on the hypothesis that facts are interdependent, we propose to use structured perceptron with inexact search to jointly extract triggers and arguments that co-occur in the same sentence. In this section, we will describe the training and decoding algorithms for this model.

### 3.1 Structured perceptron with beam search

Structured perceptron is an extension to the standard linear perceptron for structured prediction, which was proposed in (Collins, 2002). Given a sentence instance  $x \in \mathcal{X}$ , which in our case is a sentence with argument candidates, the structured perceptron involves the following *decoding prob-*

lem which finds the best configuration  $z \in \mathcal{Y}$  according to the current model  $\mathbf{w}$ :

$$z = \underset{y' \in \mathcal{Y}(x)}{\operatorname{argmax}} \quad \mathbf{w} \cdot \mathbf{f}(x, y') \quad (1)$$

where  $\mathbf{f}(x, y')$  represents the feature vector for instance  $x$  along with configuration  $y'$ .

The perceptron learns the model  $\mathbf{w}$  in an on-line fashion. Let  $\mathcal{D} = \{(x^{(j)}, y^{(j)})\}_{j=1}^n$  be the set of training instances (with  $j$  indexing the current training instance). In each iteration, the algorithm finds the best configuration  $z$  for  $x$  under the current model (Eq. 1). If  $z$  is incorrect, the weights are updated as follows:

$$\mathbf{w} = \mathbf{w} + \mathbf{f}(x, y) - \mathbf{f}(x, z) \quad (2)$$

The key step of the training and test is the decoding procedure, which aims to search for the best configuration under the current parameters. In simpler tasks such as part-of-speech tagging and noun phrase chunking, efficient dynamic programming algorithms can be employed to perform exact inference. Unfortunately, it is intractable to perform the exact search in our framework because: (1) by jointly modeling the trigger labeling and argument labeling, the search space becomes much more complex. (2) we propose to make use of arbitrary global features, which makes it infeasible to perform exact inference efficiently.

To address this problem, we apply beam-search along with early-update strategy to perform inexact decoding. Collins and Roark (2004) proposed the early-update idea, and Huang et al. (2012) later proved its convergence and formalized a general framework which includes it as a special case. Figure 2 describes the skeleton of perceptron training algorithm with beam search. In each step of the beam search, if the prefix of oracle assignment  $y$  falls out from the beam, then the top result in the beam is returned for early update. One could also use the standard-update for inference, however, with highly inexact search the standard-update generally does not work very well because of “invalid updates”, i.e., updates that do not fix a violation (Huang et al., 2012). In Section 4.5 we will show that the standard perceptron introduces many invalid updates especially with smaller beam sizes, also observed by Huang et al. (2012).

To reduce overfitting, we used averaged parameters after training to decode test instances in our experiments. The resulting model is called averaged perceptron (Collins, 2002).

**Input:** Training set  $\mathcal{D} = \{(x^{(j)}, y^{(j)})\}_{i=1}^n$ ,  
maximum iteration number  $T$

**Output:** Model parameters  $\mathbf{w}$

```

1 Initialization: Set  $\mathbf{w} = 0$ ;
2 for  $t \leftarrow 1 \dots T$  do
3   foreach  $(x, y) \in \mathcal{D}$  do
4      $z \leftarrow \text{beamSearch}(x, y, \mathbf{w})$ 
5     if  $z \neq y$  then
6        $\mathbf{w} \leftarrow \mathbf{w} + \mathbf{f}(x, y_{[1:|z|]}) - \mathbf{f}(x, z)$ 

```

Figure 2: Perceptron training with beam-search (Huang et al., 2012). Here  $y_{[1:i]}$  denotes the prefix of  $y$  that has length  $i$ , e.g.,  $y_{[1:3]} = (y_1, y_2, y_3)$ .

### 3.2 Label sets

Here we introduce the label sets for trigger and argument in the model. We use  $\mathcal{L} \cup \{\perp\}$  to denote the trigger label alphabet, where  $\mathcal{L}$  represents the 33 event subtypes, and  $\perp$  indicates that the token is not a trigger. Similarly,  $\mathcal{R} \cup \{\perp\}$  denotes the argument label sets, where  $\mathcal{R}$  is the set of possible argument roles, and  $\perp$  means that the argument candidate is not an argument for the current trigger. It is worth to note that the set  $\mathcal{R}$  of each particular event subtype is subject to the entity type constraints defined in the official ACE annotation guideline<sup>2</sup>. For example, the *Attacker* argument for an *Attack* event can only be one of *PER*, *ORG* and *GPE* (Geo-political Entity).

### 3.3 Decoding

Let  $x = \langle (x_1, x_2, \dots, x_s), \mathcal{E} \rangle$  denote the sentence instance, where  $x_i$  represents the  $i$ -th token in the sentence and  $\mathcal{E} = \{e_k\}_{k=1}^m$  is the set of argument candidates. We use

$$y = (t_1, a_{1,1}, \dots, a_{1,m}, \dots, t_s, a_{s,1}, \dots, a_{s,m})$$

to denote the corresponding gold standard structure, where  $t_i$  represents the trigger assignment for the token  $x_i$ , and  $a_{i,k}$  represents the argument role label for the edge between  $x_i$  and argument candidate  $e_k$ .

<sup>2</sup>[http://projects.ldc.upenn.edu/ace/docs/English-Events-Guidelines\\_v5.4.3.pdf](http://projects.ldc.upenn.edu/ace/docs/English-Events-Guidelines_v5.4.3.pdf)

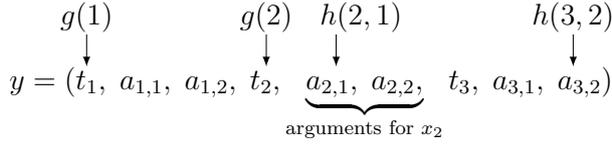

Figure 3: Example notation with  $s = 3, m = 2$ .

For simplicity, throughout this paper we use  $y_{g(i)}$  and  $y_{h(i,k)}$  to represent  $t_i$  and  $a_{i,k}$ , respectively. Figure 3 demonstrates the notation with  $s = 3$  and  $m = 2$ . The variables for the toy sentence “Jobs founded Apple” are as follows:

$$x = \langle (\underbrace{Jobs, founded, Apple}_{x_2}, \underbrace{Jobs_{PER}, Apple_{ORG}}_{\mathcal{E}}) \rangle$$

$$y = (\perp, \perp, \perp, \underbrace{Start\_Org}_{t_2}, \underbrace{Agent, Org}_{args\ for\ founded}, \perp, \perp, \perp)$$

Figure 4 describes the beam-search procedure with early-update for event extraction. During each step with token  $i$ , there are two sub-steps:

- **Trigger labeling** We enumerate all possible trigger labels for the current token. The linear model defined in Eq. (1) is used to score each partial configuration. Then the  $K$ -best partial configurations are selected to the beam, assuming the beam size is  $K$ .
- **Argument labeling** After the trigger labeling step, we traverse all configurations in the beam. Once a trigger label for  $x_i$  is found in the beam, the decoder searches through the argument candidates  $\mathcal{E}$  to label the edges between each argument candidate and the trigger. After labeling each argument candidate, we again score each partial assignment and select the  $K$ -best results to the beam.

After the second step, the rank of different trigger assignments can be changed because of the argument edges. Likewise, the decision on later argument candidates may be affected by earlier argument assignments.

The overall time complexity for decoding is  $O(K \cdot s \cdot m)$ .

### 3.4 Features

In this framework, we define two types of features, namely local features and global features. We first introduce the definition of local and global features in this paper, and then describe the implementation details later. Recall that in the linear model defined in Eq. (1),  $\mathbf{f}(x, y)$  denotes the features extracted from the input instance  $x$  along

**Input:** Instance  $x = \langle (x_1, x_2, \dots, x_s), \mathcal{E} \rangle$  and the oracle output  $y$  if for training.

$K$ : Beam size.

$\mathcal{L} \cup \{\perp\}$ : trigger label alphabet.

$\mathcal{R} \cup \{\perp\}$ : argument label alphabet.

**Output:** 1-best prediction  $z$  for  $x$

```

1 Set beam  $\mathcal{B} \leftarrow [\epsilon]$  /*empty configuration*/
2 for  $i \leftarrow 1 \dots s$  do
3    $buf \leftarrow \{z' \circ l \mid z' \in \mathcal{B}, l \in \mathcal{L} \cup \{\perp\}\}$ 
4    $\mathcal{B} \leftarrow K\text{-best}(buf)$ 
5   if  $y_{[1:g(i)]} \notin \mathcal{B}$  then
6     return  $\mathcal{B}[0]$  /*for early-update*/
7   for  $e_k \in \mathcal{E}$  do /*search for arguments*/
8      $buf \leftarrow \emptyset$ 
9     for  $z' \in \mathcal{B}$  do
10       $buf \leftarrow buf \cup \{z' \circ \perp\}$ 
11      if  $z'_{g(i)} \neq \perp$  then /* $x_i$  is a trigger*/
12         $buf \leftarrow buf \cup \{z' \circ r \mid r \in \mathcal{R}\}$ 
13       $\mathcal{B} \leftarrow K\text{-best}(buf)$ 
14      if  $y_{[1:h(i,k)]} \notin \mathcal{B}$  then
15        return  $\mathcal{B}[0]$  /*for early-update*/
16 return  $\mathcal{B}[0]$ 

```

Figure 4: Decoding algorithm for event extraction.  $z \circ l$  means appending label  $l$  to the end of  $z$ . During test, lines 4-5 & 13-14 are omitted.

with configuration  $y$ . In general, each feature instance  $f$  in  $\mathbf{f}$  is a function  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ , which maps  $x$  and  $y$  to a feature value. Local features are only related to predictions on individual trigger or argument. In the case of unigram tagging for trigger labeling, each local feature takes the form of  $f(x, i, y_{g(i)})$ , where  $i$  denotes the index of the current token, and  $y_{g(i)}$  is its trigger label. In practice, it is convenient to define the local feature function as an indicator function, for example:

$$f_1(x, i, y_{g(i)}) = \begin{cases} 1 & \text{if } y_{g(i)} = \text{Attack and } x_i = \text{“fire”} \\ 0 & \text{otherwise} \end{cases}$$

The global features, by contrast, involve longer range of the output structure. Formally, each global feature function takes the form of  $f(x, i, k, y)$ , where  $i$  and  $k$  denote the indices of the current token and argument candidate in decoding, respectively. The following indicator function is a simple example of global features:

$$f_{101}(x, i, k, y) = \begin{cases} 1 & \text{if } y_{g(i)} = \text{Attack and} \\ & \text{y has only one “Attacker”} \\ 0 & \text{otherwise} \end{cases}$$

Category	Type	Feature Description
Trigger	Lexical	<ol style="list-style-type: none"> <li>1. unigrams/bigrams of the current and context words within the window of size 2</li> <li>2. unigrams/bigrams of part-of-speech tags of the current and context words within the window of size 2</li> <li>3. lemma and synonyms of the current token</li> <li>4. base form of the current token extracted from Nomlex (Macleod et al., 1998)</li> <li>5. Brown clusters that are learned from ACE English corpus (Brown et al., 1992; Miller et al., 2004; Sun et al., 2011). Table 1: Local features.

### 3.4.1 Local features

In general there are two kinds of local features:

**Trigger features** The local feature function for trigger labeling can be factorized as  $f(x, i, y_{g(i)}) = p(x, i) \circ q(y_{g(i)})$ , where  $p(x, i)$  is a predicate about the input, which we call text feature, and  $q(y_{g(i)})$  is a predicate on the trigger label. In practice, we define two versions of  $q(y_{g(i)})$ :

$$q_0(y_{g(i)}) = y_{g(i)} \text{ (event subtype)}$$

$$q_1(y_{g(i)}) = \text{event type of } y_{g(i)}$$

$q_1(y_{g(i)})$  is a backoff version of the standard unigram feature. Some text features for the same event type may share a certain distributional similarity regardless of the subtypes. For example, if the nearest entity mention is “*Company*”, the current token is likely to be *Personnel* no matter whether it is *End-Position* or *Start-Position*.

**Argument features** Similarly, the local feature function for argument labeling can be represented as  $f(x, i, k, y_{g(i)}, y_{h(i,k)}) = p(x, i, k) \circ q(y_{g(i)}, y_{h(i,k)})$ , where  $y_{h(i,k)}$  denotes the argument assignment for the edge between trigger word  $i$  and argument candidate  $e_k$ . We define two

versions of  $q(y_{g(i)}, y_{h(i,k)})$ :

$$q_0(y_{g(i)}, y_{h(i,k)}) = \begin{cases} y_{h(i,k)} & \text{if } y_{h(i,k)} \text{ is } Place, \\ & Time \text{ or } None \\ y_{g(i)} \circ y_{h(i,k)} & \text{otherwise} \end{cases}$$

$$q_1(y_{g(i)}, y_{h(i,k)}) = \begin{cases} 1 & \text{if } y_{h(i,k)} \neq None \\ 0 & \text{otherwise} \end{cases}$$

It is notable that *Place* and *Time* arguments are applicable and behave similarly to all event subtypes. Therefore features for these arguments are not conjuncted with trigger labels.  $q_1(y_{h(i,k)})$  can be considered as a backoff version of  $q_0(y_{h(i,k)})$ , which does not discriminate different argument roles but only focuses on argument identification. Table 1 summarizes the text features about the input for trigger and argument labeling. In our experiments, we used the Stanford parser (De Marneffe et al., 2006) to create dependency parses.

### 3.4.2 Global features

Table 2 summarizes the 8 types of global features we developed in this work. They can be roughly divided into the following two categories:

Category	Feature Description
Trigger	<ol style="list-style-type: none"> <li>1. bigram of trigger types occur in the same sentence or the same clause</li> <li>2. binary feature indicating whether synonyms in the same sentence have the same trigger label</li> <li>3. context and dependency paths between two triggers conjuncted with their types</li> </ol>
Argument	<ol style="list-style-type: none"> <li>4. context and dependency features about two argument candidates which share the same role within the same event mention</li> <li>5. features about one argument candidate which plays as arguments in two event mentions in the same sentence</li> <li>6. features about two arguments of an event mention which are overlapping</li> <li>7. the number of arguments with each role type of an event mention conjuncted with the event subtype</li> <li>8. the pairs of time arguments within an event mention conjuncted with the event subtype</li> </ol>

Table 2: Global features.

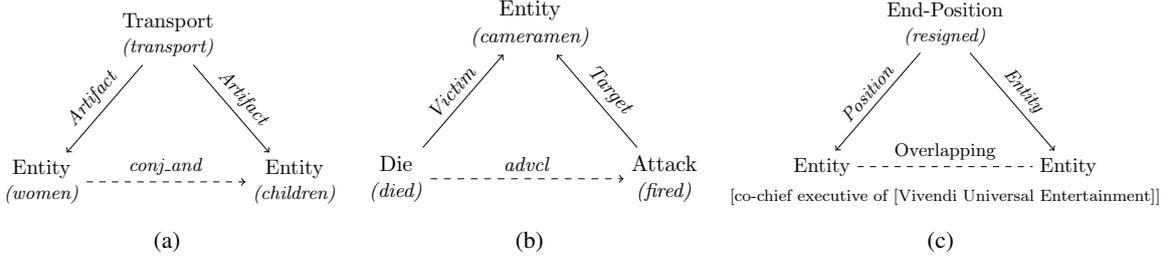

Figure 5: Illustration of global features (4-6) in Table 2.

Event	Probability
Attack	0.34
Die	0.14
Transport	0.08
Injure	0.04
Meet	0.02

Table 3: Top 5 event subtypes that co-occur with *Attack* event in the same sentence.

**Trigger global feature** This type of feature captures the dependencies between two triggers within the same sentence. For instance: feature (1) captures the co-occurrence of trigger types. This kind of feature is motivated by the fact that two event mentions in the same sentence tend to be semantically coherent. As an example, from Table 3 we can see that *Attack* event often co-occur with *Die* event in the same sentence, but rarely co-occur with *Start-Position* event. Feature (2) encourages synonyms or identical tokens to have the same label. Feature (3) exploits the lexical and syntactic relation between two triggers. A simple example is whether an *Attack* trigger and a *Die* trigger are linked by the dependency relation *conj\_and*.

**Argument global feature** This type of feature is defined over multiple arguments for the same or different triggers. Consider the following sentence:

(3) Trains running to southern Sudan were used

to *transport* abducted women and children.

The *Transport* event mention “*transport*” has two *Artifact* arguments, “*women*” and “*children*”. The dependency edge *conj\_and* between “*women*” and “*children*” indicates that they should play the same role in the event mention. The triangle structure in Figure 5(a) is an example of feature (4) for the above example. This feature encourages entities that are linked by dependency relation *conj\_and* to play the same role *Artifact* in any *Transport* event.

Similarly, Figure 5(b) depicts an example of feature (5) for sentence (1) in Section 1. In this example, an entity mention is *Victim* argument to *Die* event and *Target* argument to *Attack* event, and the two event triggers are connected by the typed dependency *advcl*. Here *advcl* means that the word “*fired*” is an adverbial clause modifier of “*died*”.

Figure 5(c) shows an example of feature (6) for the following sentence:

(4) Barry Diller *resigned* as co-chief executive of Vivendi Universal Entertainment.

The job title “*co-chief executive of Vivendi Universal Entertainment*” overlaps with the *Organization* mention “*Vivendi Universal Entertainment*”. The feature in the triangle shape can be considered as a soft constraint such that if a *Job-Title* mention is a *Position* argument to an *End-Position* trigger, then the *Organization* mention

which appears at the end of it should be labeled as *Entity* argument for the same trigger.

Feature (7-8) are based on the statistics about different arguments for the same trigger. For instance, in many cases, a trigger can only have one *Place* argument. If a partial configuration mistakenly classifies more than one entity mention as *Place* arguments for the same trigger, then it will be penalized.

## 4 Experiments

### 4.1 Data set and evaluation metric

We utilized the ACE 2005 corpus as our testbed. For comparison, we used the same test set with 40 newswire articles (672 sentences) as in (Ji and Grishman, 2008; Liao and Grishman, 2010) for the experiments, and randomly selected 30 other documents (863 sentences) from different genres as the development set. The rest 529 documents (14,840 sentences) are used for training.

Following previous work (Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011), we use the following criteria to determine the correctness of an predicted event mention:

- A trigger is correct if its event subtype and offsets match those of a reference trigger.
- An argument is correctly *identified* if its event subtype and offsets match those of any of the reference argument mentions.
- An argument is correctly *identified* and *classified* if its event subtype, offsets and argument role match those of any of the reference argument mentions.

Finally we use *Precision (P)*, *Recall (R)* and *F-measure (F<sub>1</sub>)* to evaluate the overall performance.

### 4.2 Baseline system

Chen and Ng (2012) have proven that performing identification and classification in one step is better than two steps. To compare our proposed method with the previous pipelined approaches, we implemented two Maximum Entropy (Max-Ent) classifiers for trigger labeling and argument labeling respectively. To make a fair comparison, the feature sets in the baseline are identical to the local text features we developed in our framework (see Figure 1).

### 4.3 Training curves

We use the *harmonic mean* of the trigger’s  $F_1$  measure and argument’s  $F_1$  measure to measure the performance on the development set.

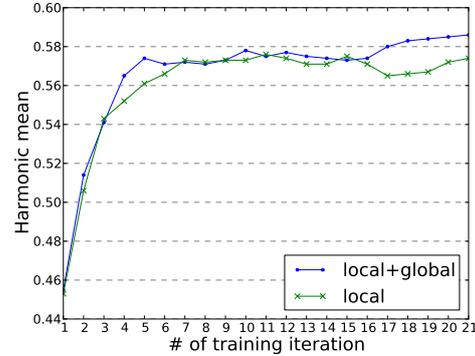

Figure 6: Training curves on dev set.

Figure 6 shows the training curves of the averaged perceptron with respect to the performance on the development set when the beam size is 4. As we can see both curves converge around iteration 20 and the global features improve the overall performance, compared to its counterpart with only local features. Therefore we set the number of iterations as 20 in the remaining experiments.

### 4.4 Impact of beam size

The beam size is an important hyper parameter in both training and test. Larger beam size will increase the computational cost while smaller beam size may reduce the performance. Table 4 shows the performance on the development set with several different beam sizes. When beam size = 4, the algorithm achieved the highest performance on the development set with trigger  $F_1 = 67.9$ , argument  $F_1 = 51.5$ , and harmonic mean = 58.6. When the size is increased to 32, the accuracy was not improved. Based on this observation, we chose beam size as 4 for the remaining experiments.

### 4.5 Early-update vs. standard-update

Huang et al. (2012) define “invalid update” to be an update that does not fix a violation (and instead reinforces the error), and show that it strongly (anti-)correlates with search quality and learning quality. Figure 7 depicts the percentage of invalid updates in standard-update with and without global features, respectively. With global features, there are numerous invalid updates when the

Beam size	1	2	4	8	16	32
Training time (sec)	993	2,034	3,982	8,036	15,878	33,026
Harmonic mean	57.6	57.7	<b>58.6</b>	58.0	57.8	57.8

Table 4: Comparison of training time and accuracy on the dev set.

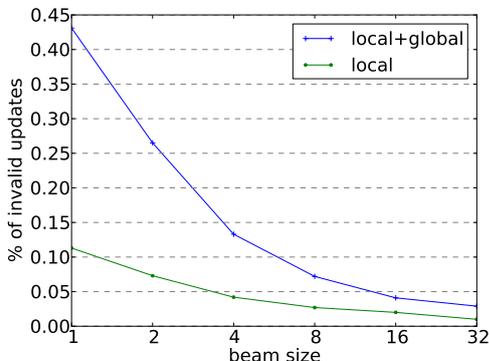

Figure 7: Percentage of the so-called “invalid updates” (Huang et al., 2012) in standard perceptron.

Strategy	F <sub>1</sub> on Dev		F <sub>1</sub> on Test	
	Trigger	Arg	Trigger	Arg
Standard ( $b = 1$ )	68.3	47.4	64.4	49.8
Early ( $b = 1$ )	<b>68.9</b>	<b>49.5</b>	<b>65.2</b>	<b>52.1</b>
Standard ( $b = 4$ )	<b>68.4</b>	50.5	67.1	51.4
Early ( $b = 4$ )	67.9	<b>51.5</b>	<b>67.5</b>	<b>52.7</b>

Table 5: Comparison between the performance (%) of standard-update and early-update with global features. Here  $b$  stands for beam size.

beam size is small. The ratio decreases monotonically as beam size increases. The model with only local features made much smaller numbers of invalid updates, which suggests that the use of global features makes the search problem much harder. This observation justifies the application of early-update in this work. To further investigate the difference between early-update and standard-update, we tested the performance of both strategies, which is summarized in Table 5. As we can see the performance of standard-update is generally worse than early-update. When the beam size is increased ( $b = 4$ ), the gap becomes smaller as the ratio of invalid updates is reduced.

#### 4.6 Overall performance

Table 6 shows the overall performance on the blind test set. In addition to our baseline, we compare against the sentence-level system reported in Hong et al. (2011), which, to the best of our knowledge,

is the best-reported system in the literature based on gold standard argument candidates. The proposed joint framework with local features achieves comparable performance for triggers and outperforms the staged baseline especially on arguments. By adding global features, the overall performance is further improved significantly. Compared to the staged baseline, it gains 1.6% improvement on trigger’s F-measure and 8.8% improvement on argument’s F-measure. Remarkably, compared to the cross-entity approach reported in (Hong et al., 2011), which attained 68.3% F<sub>1</sub> for triggers and 48.3% for arguments, our approach with global features achieves even better performance on argument labeling although we only used sentence-level information.

We also tested the performance with argument candidates automatically extracted by a high-performing name tagger (Li et al., 2012b) and an IE system (Grishman et al., 2005). The results are summarized in Table 7. The joint approach with global features significantly outperforms the baseline and the model with only local features. We also show that it outperforms the sentence-level baseline reported in (Ji and Grishman, 2008; Liao and Grishman, 2010), both of which attained 59.7% F<sub>1</sub> for triggers and 36.6% for arguments. Our approach aims to tackle the problem of sentence-level event extraction, thereby only using intra-sentential evidence. Nevertheless, the performance of our approach is still comparable with the best-reported methods based on cross-document and cross-event inference (Ji and Grishman, 2008; Liao and Grishman, 2010).

## 5 Related Work

Most recent studies about ACE event extraction rely on staged pipeline which consists of separate local classifiers for trigger labeling and argument labeling (Grishman et al., 2005; Ahn, 2006; Ji and Grishman, 2008; Chen and Ji, 2009; Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2012a; Chen and Ng, 2012). To the best of our knowledge, our work is the first attempt to jointly model these two ACE event subtasks.

Joint w/ local	63.7 (↓2.0)	35.8 (↓10.7)
Joint w/ local + global	<b>65.6 (↓1.9)</b>	<b>41.8 (↓10.9)</b>

Table 7: Overall performance (%) with predicted entities, timex, and values. ↓ indicates the performance drop from experiments with gold-standard argument candidates (see Table 6).

For the Message Understanding Conference (MUC) and FAS Program for Monitoring Emerging Diseases (ProMED) event extraction tasks, Patwardhan and Riloff (2009) proposed a probabilistic framework to extract event role fillers conditioned on the sentential event occurrence. Besides having different task definitions, the key difference from our approach is that their role filler recognizer and sentential event recognizer are trained independently but combined in the test stage. Our experiments, however, have demonstrated that it is more advantageous to do *both* training and testing with joint inference.

There has been some previous work on joint modeling for biomedical events (Riedel and McCallum, 2011a; Riedel et al., 2009; McClosky et al., 2011; Riedel and McCallum, 2011b). (McClosky et al., 2011) is most closely related to our approach. They casted the problem of biomedical event extraction as a dependency parsing problem. The key assumption that event structure can be considered as trees is incompatible with ACE event extraction. In addition, they used a separate classifier to predict the event triggers before applying the parser, while we extract the triggers and argument jointly. Finally, the features in the parser are edge-factorized. To exploit global features,

they applied a MaxEnt-based global re-ranker. In comparison, our approach is a unified framework based on beam search, which allows us to exploit arbitrary global features efficiently.

## 6 Conclusions and Future Work

We presented a joint framework for ACE event extraction based on structured perceptron with inexact search. As opposed to traditional pipelined approaches, we re-defined the task as a structured prediction problem. The experiments proved that the perceptron with local features outperforms the staged baseline and the global features further improve the performance significantly, surpassing the current state-of-the-art by a large margin.

As shown in Table 7, the overall performance drops substantially when using predicted argument candidates. To improve the accuracy of end-to-end IE system, we plan to develop a complete joint framework to recognize entities together with event mentions for future work. Also we are interested in applying this framework to other IE tasks such as relation extraction.

## Abstract

Temporal resolution systems are traditionally tuned to a particular language, requiring significant human effort to translate them to new languages. We present a language independent semantic parser for learning the interpretation of temporal phrases given only a corpus of utterances and the times they reference. We make use of a latent parse that encodes a language-flexible representation of time, and extract rich features over both the parse and associated temporal semantics. The parameters of the model are learned using a weakly supervised bootstrapping approach, without the need for manually tuned parameters or any other language expertise. We achieve state-of-the-art accuracy on all languages in the TempEval-2 temporal normalization task, reporting a 4% improvement in both English and Spanish accuracy, and to our knowledge the first results for four other languages.

## 1 Introduction

Temporal resolution is the task of mapping from a textual phrase describing a potentially complex time, date, or duration to a normalized (*grounded*) temporal representation. For example, possibly complex phrases such as *the week before last*<sup>1</sup> are often more useful in their grounded form – e.g., August 4 – August 11.

Many approaches to this problem make use of rule-based methods, combining regular-expression matching and hand-written interpretation functions. In contrast, we would like to learn the interpretation of a temporal expression probabilistically. This allows propagation of uncertainty to higher-level components, and the potential to

dynamically back off to a rule-based system in the case of low confidence parses. In addition, we would like to use a representation of time which is broadly applicable to multiple languages, without the need for language-specific rules or manually tuned parameters.

Our system requires annotated data consisting only of an input phrase and an associated *grounded* time, relative to some reference time; the language-flexible parse is entirely latent. Training data of this weakly-supervised form is generally easier to collect than the alternative of manually creating and tuning potentially complex interpretation rules.

A large number of languages conceptualize time as lying on a one dimensional line. Although the surface forms of temporal expressions differ, the basic operations many languages use can be mapped to operations on this time line (see Section 3). Furthermore, many common languages share temporal units (hours, weekdays, etc.). By structuring a latent parse to reflect these semantics, we can define a single model which performs well on multiple languages.

A discriminative parsing model allows us to define sparse features over not only lexical cues but also the temporal value of our prediction. For example, it allows us to learn that we are much more likely to express *March 14<sup>th</sup>* than *2pm in March* – despite the fact that both interpretations are composed of similar types of components. Furthermore, it allows us to define both sparse n-gram and denser but less informative bag-of-words features over multi-word phrases, and allows us to handle numbers in a flexible way.

We briefly describe our temporal representation and grammar, followed by a description of the learning algorithm; we conclude with experimental results on the six languages of the TempEval-2 A task.

<sup>1</sup>Spoken on, for instance, August 20.

## 2 Related Work

Our approach follows the work of Angeli et al. (2012), both in the bootstrapping training methodology and the temporal grammar. Our foremost contributions over this prior work are: (i) the utilization of a discriminative parser trained with rich features; (ii) simplifications to the temporal grammar which nonetheless maintain high accuracy; and (iii) experimental results on 6 different languages, with state-of-the-art performance on both datasets on which we know of prior work.

As in this previous work, our approach draws inspiration from work on semantic parsing. The latent parse parallels the formal semantics in previous work. Supervised approaches to semantic parsing prominently include Zelle and Mooney (1996), Zettlemoyer and Collins (2005), Kate et al. (2005), Zettlemoyer and Collins (2007), *inter alia*. For example, Zettlemoyer and Collins (2007) learn a mapping from textual queries to a logical form. Importantly, the logical form of these parses contain all of the predicates and entities used in the parse – unlike the label provided in our case, where a grounded time can correspond to any of a number of latent parses. Along this line, recent work by Clarke et al. (2010) and Liang et al. (2011) relax supervision to require only annotated answers rather than full logical forms.

Related work on interpreting temporal expressions has focused on constructing hand-crafted interpretation rules (Mani and Wilson, 2000; Saquete et al., 2003; Puscasu, 2004; Grover et al., 2010). Of these, HeidelTime (Strötgen and Gertz, 2010) and SUTime (Chang and Manning, 2012) provide a strong comparison in English.

Recent probabilistic approaches to temporal resolution include UzZaman and Allen (2010), who employ a parser to produce deep logical forms, in conjunction with a CRF classifier. In a similar vein, Kolomiyets and Moens (2010) employ a maximum entropy classifier to detect the location and temporal type of expressions; the grounding is then done via deterministic rules.

In addition, there has been work on parsing Spanish expressions; UC3M (Vicente-Díez et al., 2010) produce the strongest results on the TempEval-2 corpus. Of the systems entered in the original task, TIPSem (Llorens et al., 2010) was the only system to perform bilingual interpretation for English and Spanish. Both of the above systems rely primarily on hand-built rules.

## 3 Temporal Representation

We define a compositional representation of time, similar to Angeli et al. (2012), but with a greater focus on efficiency and simplicity. The representation makes use of a notion of temporal *types* and their associated semantic *values*; a grammar is constructed over these types, and is grounded by appealing to the associated values.

A summary of the temporal type system is provided in Section 3.1; the grammar is described in Section 3.2; key modifications from previous work are highlighted in Section 3.3.

### 3.1 Temporal Types

Temporal expressions are represented either as a Range, Sequence, or Duration. The root of a parse tree should be one of these types. In addition, phrases can be tagged as a Function; or, as a special Nil type corresponding to segments without a direct temporal interpretation. Lastly, a type is allocated for numbers. We describe each of these briefly below.

**Range [and Instant]** A period between two dates (or times), as per an interval-based theory of time (Allen, 1981). This includes entities such as *Today*, *1987*, or *Now*.

**Sequence** A sequence of Ranges, occurring at regular but not necessarily constant intervals. This includes entities such as *Friday*, *November 27<sup>th</sup>*, or *last Friday*. A Sequence is defined in terms of a partial completion of calendar fields. For example, *November 27<sup>th</sup>* would define a Sequence whose year is unspecified, month is November, and day is the 27<sup>th</sup>; spanning the entire range of the lower order fields (in this case, a day). This example is illustrated in Figure 1. Note that a Sequence implicitly selects a possibly infinite number of possible Ranges.

To select a particular grounded time for a Sequence, we appeal to a notion of a *reference time* (Reichenbach, 1947). For the TempEval-2 corpus, we approximate this as the publication time of the article. While this is conflating Reichenbach’s reference time with speech time, and comes at the expense of certain mistakes (see Section 5.3), it is nonetheless useful in practice.

To a first approximation, grounding a sequence given a reference time corresponds to filling in the unspecified fields of the sequence with the fully-specified fields of the reference time. This pro-

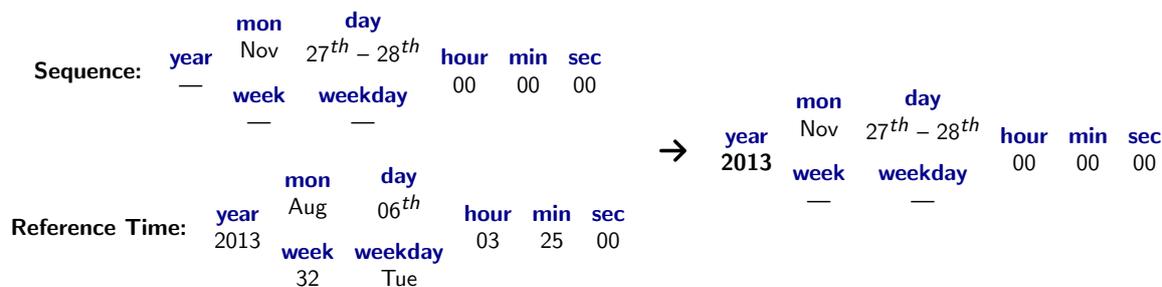

Figure 1: An illustration of grounding a Sequence. When grounding the Sequence November 27<sup>th</sup> with a reference time 2013-08-06 03:25:00, we complete the missing fields in the Sequence (the year) with the corresponding field in the reference time (2013).

cess has a number of special cases not enumerated here,<sup>2</sup> but the complexity remains constant time.

**Duration** A period of time. This includes entities like *Week*, *Month*, and *7 days*. A special case of the Duration type is defined to represent *approximate* durations, such as *a few years* or *some days*.

**Function** A function of arity less than or equal to two representing some general modification to one of the above types. This captures semantic entities such as those implied in *last x*, *the third x [of y]*, or *x days ago*. The particular functions are enumerated in Table 2.

**Nil** A special Nil type denotes terms which are not directly contributing to the semantic meaning of the expression. This is intended for words such as *a* or *the*, which serve as cues without bearing temporal content themselves.

**Number** Lastly, a special Number type is defined for tagging numeric expressions.

### 3.2 Temporal Grammar

Our approach assumes that natural language descriptions of time are compositional in nature; that is, each word attached to a temporal phrase is compositionally modifying the meaning of the phrase. We define a grammar jointly over temporal *types* and *values*. The types serve to constrain the parse and allow for coarse features; the values encode specific semantics, and allow for finer features. At the root of a parse tree, we recursively apply

<sup>2</sup>Some of these special cases are caused by variable days of the month, daylight savings time, etc. Another class arises from pragmatically peculiar utterances; e.g., *the next Monday in August* uttered in the last week of August should ground to August of next year (rather than the reference time’s year).

the functions in the tree to obtain a final temporal value.

This approach can be presented as a rule-to-rule translation (Bach, 1976; Allen, 1995, p. 263), or a constrained Synchronous PCFG (Yamada and Knight, 2001).

Formally, we define our grammar as  $G = (\Sigma, S, \mathcal{V}, T, \mathcal{R})$ . The alphabet  $\Sigma$  and start symbol  $S$  retain their usual interpretations. We define a set  $\mathcal{V}$  to be the set of types, as described in Section 3.1. For each  $v \in \mathcal{V}$  we define an (infinite) set  $T_v$  corresponding to the possible instances of type  $v$ . Each node in the tree defines a pair  $(v, \tau)$  such that  $\tau \in T_v$ . A rule  $R \in \mathcal{R}$  is defined as a pair  $R = (v_i \rightarrow v_j v_k, f : (T_{v_j}, T_{v_k}) \rightarrow T_{v_i})$ . This definition is trivially adapted for the case of unary rules.

The form of our rules reveals the synchronous aspect of our grammar. The structure of the tree is bound by the first part over types  $v$  – these types are used to populate the chart, and allow for efficient inference. The second part is used to evaluate the semantics of the parse,  $\tau \in T_{v_i}$ , and allows partial derivations to be discriminated based on richer information than the coarse types.

We adopt the preterminals of Angeli et al. (2012). Each preterminal consists of a *type* and a *value*; neither which are lexically informed. That is, the word *week* and preterminal (*Week*, *Duration*) are not tied in any way. A total of 62 preterminals are defined corresponding to instances of Ranges, Sequences, and Durations; these are summarized in Table 1.

In addition, 10 functions are defined for manipulating temporal expressions (see Table 2). The majority of these mirror generic operations on intervals on a timeline, or manipulations of a sequence. Notably, like intervals, times can be

Type	Example Instances
Range	Past, Future, Yesterday, Tomorrow, Today, Reference, Year ( $n$ ), Century ( $n$ )
Sequence	Friday, January, ... DayOfMonth, DayOfWeek, ... EveryDay, EveryWeek, ...
Duration	Second, Minute, Hour, Day, Week, Month, Quarter, Year, Decade, Century

Table 1: The content-bearing preterminals of the grammar, arranged by their types. Note that the Sequence type contains more elements than enumerated here; however, only a few of each characteristic type are shown here for brevity.

Function	Description
shiftLeft	Shift a Range left by a Duration
shiftRight	Shift a Range right by a Duration
shrinkBegin	Take the first Duration of a Range
shrinkEnd	Take the last Duration of a Range
catLeft	Take the Duration after a Range
catRight	Take the Duration before a Range
moveLeft1	Shift a Sequence left by 1
moveRight1	Shift a Sequence right by 1
$n^{\text{th}}$ $x$ of $y$	Take the $n^{\text{th}}$ element in $y$
approximate	Make a Duration approximate

Table 2: The functional preterminals of the grammar. The name and a brief description of the function are given; the functions are most easily interpreted as operations on either an interval or sequence. All operations on Ranges can equivalently be applied to Sequences.

moved (*3 weeks ago*) or their size changed (*the first two days of the month*), or a new interval can be started from one of the endpoints (*the last 2 days*). Additionally, a sequence can be modified by shifting its origin (*last Friday*), or taking the  $n^{\text{th}}$  element of the sequence within some bound (*fourth Sunday in November*).

Combination rules in the grammar mirror type-checked curried function application. For instance, the function `moveLeft1` applied to `week` (as in *last week*) yields a grammar rule:

$$\begin{array}{c}
 (\text{EveryWeek } -1, \text{Seq.}) \\
 \swarrow \quad \searrow \\
 (\text{moveLeft1}, \text{Seq.} \rightarrow \text{Seq.}) \quad (\text{EveryWeek}, \text{Seq.})
 \end{array}$$

In more generality, we create grammar rules for applying a function on either the left or the right, for all possible type signatures of  $f: f(x, y) \odot x$  or  $x \odot f(x, y)$ .

Additionally, a grammar rule is created for intersecting two Ranges or Sequences, for multiplying a duration by a number, and for absorbing a Nil span. Each of these can be thought of as an implicit function application (in the last case, the identity function).

### 3.3 Differences From Previous Work

While the grammar formalism is strongly inspired by Angeli et al. (2012), a number of key differences are implemented to both simplify the framework, and make inference more efficient.

**Sequence Grounding** The most time-consuming and conceptually nuanced aspect of temporal inference in Angeli et al. (2012) is intersecting Sequences. In particular, there are two modes of expressing dates which resist intersection: a day-of-month-based mode and a week-based mode. Properly grounding a sequence which defines both a day of the month and a day of the week (or week of the year) requires backing off to an expensive search problem.

To illustrate, consider the example: *Friday the 13<sup>th</sup>*. Although both a Friday and a 13<sup>th</sup> of the month are easily found, the intersection of the two requires iterating through elements of one until it overlaps with an element of the other. At training time, a number of candidate parses are generated for each phrase. When considering that these parses can become both complex and pragmatically unreasonable, this can result in a noticeable efficiency hit; e.g., during training a sentence could have a [likely incorrect] candidate interpretation of: *nineteen ninety-six Friday the 13<sup>th</sup>s from now*.

In our Sequence representation, such intersections are disallowed, in the same fashion as February 30<sup>th</sup> would be.

**Sequence Pragmatics** For the sake of simplicity the pragmatic distribution over possible groundings of a sequence is replaced with the single most likely offset, as learned empirically from the English TempEval-2 corpus by Angeli et al. (2012).

**No Tag Splitting** The Number and Nil types are no longer split according to their ordinality/magnitude and subsumed phrase, respectively.

More precisely, there is a single nonterminal (Nil), rather than a nonterminal symbol characterizing the phrase it is subsuming (Nil-*the*, Nil-*a*, etc.). This information is encoded more elegantly as features.

## 4 Learning

The system is trained using a discriminative  $k$ -best parser, which is able to incorporate arbitrary features over partial derivations. We describe the parser below, followed by the features implemented.

### 4.1 Parser

**Inference** A discriminative  $k$ -best parser was used to allow for arbitrary features in the parse tree. In the first stage, spans of the input sentence are tagged as either text or numbers. A rule-based number recognizer was used for each language to recognize and ground numeric expressions, including information on whether the number was an ordinal (e.g., *two* versus *second*). Note that unlike conventional parsing, a tag can span multiple words. Numeric expressions are treated as if the numeric value replaced the expression.

Each rule of the parse derivation was assigned a score according to a log-linear factor. Specifically, each rule  $R = (v_i \rightarrow v_j v_k, f)$  with features over the rule and derivation so far  $\phi(R)$ , subject to parameters  $\theta$ , is given a probability:

$$P(v_i | v_j, v_k, f; \theta) \propto e^{\theta^T \phi(R)} \quad (1)$$

Naïvely, this parsing algorithm gives us a complexity of  $O(n^3 k^2)$ , where  $n$  is the length of the sentence, and  $k$  is the size of the beam. However, we can approximate the algorithm in  $O(n^3 k \log k)$  time with cube pruning (Chiang, 2007). With features which are not context-free, we are not guaranteed an optimal beam with this approach; however, empirically the approximation yields a significant efficiency improvement without noticeable loss in performance.

**Training** We adopt an EM-style bootstrapping approach similar to Angeli et al. (2012), in order to handle the task of parsing the temporal expression without annotations for the latent parses. Each training instance is a tuple consisting of the words in the temporal phrase, the annotated grounded time  $\tau^*$ , and the reference time.

Given an input sentence, our parser will output  $k$  possible parses; when grounded to the

reference time these correspond to  $k$  candidate times:  $\tau_1 \dots \tau_k$ , each with a normalized probability  $P(\tau_i)$ . This corresponds to an approximate E step in the EM algorithm, where the distribution over latent parses is approximated by a beam of size  $k$ . Although for long sentences the number of parses is far greater than the beam size, as the parameters improve, increasingly longer sentences will have correct derivations in the beam. In this way, a progressively larger percentage of the data is available to be learned from at each iteration.

To approximate the M step, we define a multi-class hinge loss  $l(\theta)$  over the beam, and optimize using Stochastic Gradient Descent with AdaGrad (Duchi et al., 2010):

$$l(\theta) = \max_{0 \leq i < k} \mathbb{1}[\tau_i \neq \tau^*] + P_\theta(\tau_i) - P_\theta(\tau^*) \quad (2)$$

We proceed to describe our features.

### 4.2 Features

Our framework allows us to define arbitrary features over partial derivations. Importantly, this allows us to condition not only on the PCFG probabilities over *types* but also the partial semantics of the derivation. We describe the features used below; a summary of these features for a short phrase is illustrated in Figure 2.

**Bracketing Features** A feature is defined over every nonterminal combination, consisting of the pair of children being combined in that rule. In particular, let us consider a rule  $R = (v_i \rightarrow v_j v_k, f)$  corresponding to a CFG rule  $v_i \rightarrow v_j v_k$  over *types*, and a function  $f$  over the semantic values corresponding to  $v_j$  and  $v_k$ :  $\tau_j$  and  $\tau_k$ . Two classes of bracketing features are extracted: features are extracted over the types of nonterminals being combined ( $v_j$  and  $v_k$ ), and over the top-level semantic derivation of the nonterminals ( $f$ ,  $\tau_j$ , and  $\tau_k$ ).

Unlike syntactic parsing, child types of a parse tree uniquely define the parent type of the rule; this is a direct consequence of our combination rules being functions with domains defined in terms of the temporal types, and therefore necessarily projecting their inputs into a single output type. Therefore, the first class of bracketing features – over types – reduce to have the exact same expressive power as the nonterminal CFG rules of Angeli et al. (2012). Examples of features in this class are features 13 and 15 in Figure 2 (b).

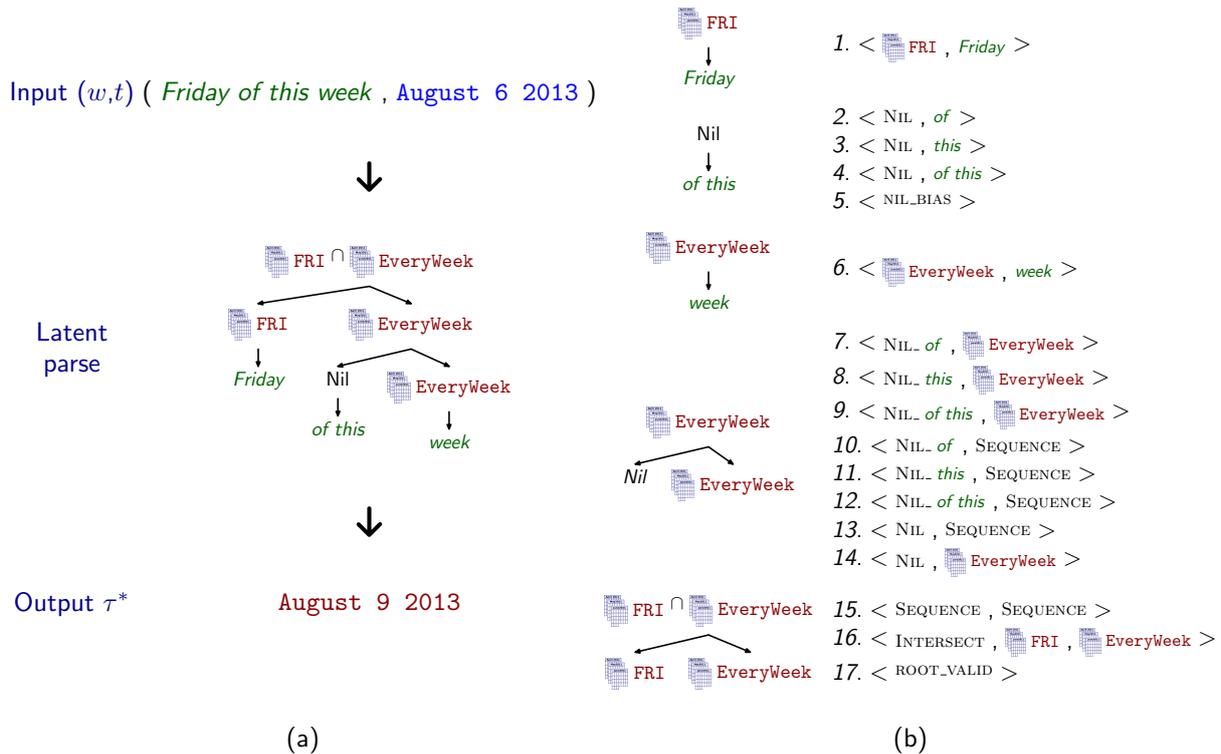

Figure 2: An example parse of *Friday of this week*, along with the features extracted from the parse. A summary of the input, latent parse, and output for a particular example is given in (a). The features extracted for each fragment of the parse are given in (b), and described in detail in Section 4.2.

We now also have the flexibility to extract a second class of features from the semantics of the derivation. We define a feature bracketing the most recent semantic function applied to each of the two child derivations; along with the function being applied in the rule application. If the child is a preterminal, the semantics of the preterminal are used; otherwise, the outermost (most recent) function to be applied to the derivation is used. To illustrate, a tree fragment combining *August* and *2013* into *August 2013* would yield the feature  $\langle \text{INTERSECT} , \text{AUGUST} , \text{2013} \rangle$ . This can be read as a feature for the rule applying the intersect function to *August* and *2013*. Furthermore, intersecting *August 2013* with the *12<sup>th</sup>* of the month would yield a feature  $\langle \text{INTERSECT} , \text{INTERSECT} , \text{12<sup>th</sup>} \rangle$ . This can be read as applying the intersect function to a subtree which is the intersection of two terms, and to the *12<sup>th</sup>* of the month. Features 14 and 16 in Figure 2 (b) are examples of such features.

**Lexical Features** The second large class of features extracted are lexicalized features. These are primarily used for tagging phrases with pretermi-

nals; however, they are also relevant in incorporating cues from the yield of Nil spans. To illustrate, *a week* and *the week* have very different meanings, despite differing by only their Nil tagged tokens.

In the first case, a feature is extracted over the *value* of the preterminal being extracted, and the phrase it is subsuming (e.g., features 1–4 and 6 in Figure 2 (b)). As the type of the preterminal is deterministic from the value, encoding a feature on the type of the preterminal would be a coarser encoding of the same information, and is empirically not useful in this case. Since a multi-word expression can parse to a single nonterminal, a feature is extracted for the entire  $n$ -gram in addition to features for each of the individual words. For example, the phrase *of this* – of type Nil – would have features extracted:  $\langle \text{NIL} , \text{of} \rangle$ ,  $\langle \text{NIL} , \text{this} \rangle$ , and  $\langle \text{NIL} , \text{of this} \rangle$ .

In the second case – absorbing Nil-tagged spans – we extract features over the words under the Nil span joined with the type and value of the other derivation (e.g., features 7–12 in Figure 2 (b)). As above, features are extracted for both  $n$ -grams and for each word in the phrase. For example, combining *of this* and *week* would yield features

System	Train		Test

System	Train		Test	
	Type	Value	Type	Value
UC3M	—	—	0.79	0.72
OurSystem	0.90	0.84	<b>0.92</b>	<b>0.76</b>

Table 4: Spanish results for TempEval-2 attribute scores for our system and the best known previous system. The scores are calculated using gold extents, forcing an interpretation for each parse.

<of, EVERYWEEK>, <this, EVERYWEEK>, and <of this, EVERYWEEK>.

In both cases, numbers are featurized according to their order of magnitude, and whether they are ordinal. Thus, the number tagged from *thirty-first* would be featurized as an ordinal number of magnitude 2.

**Semantic Validity** Although some constraints can be imposed to help ensure that a top-level parse will be valid, absolute guarantees are difficult. For instance, February 30 is never a valid date; but, it would be difficult to disallow any local rule in its derivation. To mediate this, an indicator feature is extracted denoting whether the grounded semantics of the derivation is valid. This is illustrated in Figure 2 (b) by feature 17.

**Nil Bias** Lastly, an indicator feature is extracted for each Nil span tagged (feature 5 in Figure 2 (b)). In part, this discourages over-generation of the type; in another part, it encourages Nil spans to absorb as many adjacent words as possible.

We proceed to describe our experimental setup and results.

## 5 Evaluation

We evaluate our model on all six languages in the TempEval-2 Task A dataset (Verhagen et al.,

2010), comparing against state-of-the-art systems for English and Spanish. New results are reported on smaller datasets from the four other languages. To our knowledge, there has not been any prior work on these corpora.

We describe the TempEval-2 datasets in Section 5.1, present experimental results in Section 5.2, and discuss system errors in Section 5.3.

### 5.1 TempEval-2 Datasets

TempEval-2, from SemEval 2010, focused on retrieving and reasoning about temporal information from newswire. Our system evaluates against Task A – detecting and resolving temporal expressions. Since we perform only the second of these, we evaluate our system assuming gold detection.

The dataset annotates six languages: English, Spanish, Italian, French, Chinese, and Korean; of these, English and Spanish are the most mature. We describe each of these languages, along with relevant quirks, below:

**English** The English dataset consists of 1052 training examples, and 156 test examples. Evaluation was done using the official evaluation script, which checks for exact match between `TIMEX3` tags. Note that this is stricter than our training objective; for instance, *24 hours* and *a day* have the same interpretation, but have different `TIMEX3` strings. System output was heuristically converted to the `TIMEX3` format; where ambiguities arose, the convention which maximized training accuracy was chosen.

**Spanish** The Spanish dataset consists of 1092 training examples, and 198 test examples. Evaluation was identical to the English, with the heuristic `TIMEX3` conversion adapted somewhat.

**Italian** The Italian dataset consists of 523 training examples, and 126 test examples. Evaluation was identical to English and Spanish.

**Chinese** The Chinese dataset consists of 744 training examples, and 190 test examples. Of these, only 659 training and 143 test examples had a temporal value marked; the remaining examples had a type but no value, and are therefore impossible to predict. Results are also reported on a clean corpus with these impossible examples omitted.

The Chinese, Korean, and French corpora had noticeable inconsistencies in the `TIMEX3` annotation. Thus, evaluations are reported according

Language	Train			Test		
	# examples	Type	Value	# examples	Type	Value
English	1052	0.94	0.81	156	0.91	0.76
Spanish	1092	0.90	0.84	198	0.92	0.76
Italian	523	0.89	0.85	126	0.84	0.38
Chinese <sup>†</sup>	744	0.95	0.65	190	0.87	0.48
Chinese (clean) <sup>†</sup>	659	0.97	0.73	143	0.97	0.60
Korean <sup>†</sup>	247	0.83	0.67	91	0.82	0.42
French <sup>†</sup>	206	0.78	0.76	83	0.78	0.35

Table 5: Our system’s accuracy on all 6 languages of the TempEval-2 corpus. Chinese is divided into two results: one for the entire corpus, and one which considers only examples for which a temporal value is annotated. Languages with a dagger (<sup>†</sup>) were evaluated based on semantic rather than string-match correctness.

to the training objective: if two `TIMEX3` values ground to the same grounded time, they are considered equal. For example, in the example above, *24 hours* and *a day* would be marked identical despite having different `TIMEX3` strings.

Most `TIMEX3` values convert naturally to a grounded representation; values with wildcards representing Sequences (e.g., `1998-QX` or `1998-XX-12`) ground to the same value as the Sequence encoding that value would. For instance, `1998-QX` is parsed as *every quarter in 1998*.

**Korean** The Korean dataset consists of 287 training examples, and 91 test examples. 40 of the training examples encoded dates as a long integer. For example: `003000000200001131951006` grounds to January 13, 2000 at the time 19:51. These were removed from the training set, yielding 247 examples; however, all three such examples were left in the test set. Evaluation was done identically to the Chinese data.

**French** Lastly, a dataset for French temporal expressions was compiled from the TempEval-2 data. Unlike the other 5 languages, the French data included only the raw `TIMEX3` annotated newswire documents, encoded as XML. These documents were scraped to recover 206 training examples and 83 test examples. Evaluation was done identically to the Chinese and Korean data.

We proceed to describe our experimental results on these datasets.

## 5.2 Results

We compare our system with state-of-the-art systems for both English and Spanish. To the best of our knowledge, no prior work exists for the other

four languages.

We evaluate in the same framework as Angeli et al. (2012). We compare to previous system scores when constrained to make a prediction on every example; if no guess is made, the output is considered incorrect. This in general yields lower results for those systems, as the system is not allowed to abstain on expressions it does not recognize.

The systems compared against are:

- GUTime (Mani and Wilson, 2000), a widely used, older rule-based system.
- HeidelTime (Strötgen and Gertz, 2010), the top system at the TempEval-2 task for English.
- SUTime (Chang and Manning, 2012), a more recent rule-based system for English.
- ParsingTime (Angeli et al., 2012), a semantic parser for temporal expressions, similar to this system (see Section 2).
- UC3M (Vicente-Díez et al., 2010), a rule-based system for Spanish.

Results for the English corpus are shown in Table 3. Results for Spanish are shown in Table 4. Lastly, a summary of results in all six languages is shown in Table 5.

A salient trend emerges from the results – while training accuracy is consistently high, test accuracy drops sharply for the data-impooverished languages. This is consistent with what would be expected from a discriminatively trained model in data-impooverished settings; however, the consistent training accuracy suggests that the model nonetheless captures the phenomena it sees in

Error Class	English	Spanish
Pragmatics	29%	23%
Type error	16%	5%
Incorrect number	10%	5%
Relative Range	7%	2%
Incorrect parse	19%	36%
Missing context	16%	23%
Bad reference time	3%	6%

Table 6: A summary of errors of our system, by percentage of incorrect examples for the English and Spanish datasets. The top section describes errors which could be handled in our framework, while the bottom section describes examples which are either ambiguous (missing context), or are annotated inconsistently relative the reference time.

training. This suggests the possibility for improving accuracy further by making use of more data during training.

### 5.3 Discussion

We characterize the examples our system parses incorrectly on the English and Spanish datasets in Table 6, expanding on each class of error below.

**Pragmatics** This class of errors is a result of pragmatic ambiguity over possible groundings of a sequence – for instance, it is often ambiguous whether *next weekend* refers to the coming or subsequent weekend. These errors manifest in either dropping a function (*next*, *last*), or imagining one that is not supported by the text (e.g., *this week* parsed as next week).

**Type error** Another large class of errors – particularly in the English dataset – arise from not matching the annotation’s type, but otherwise producing a reasonable response. For instance, the system may mistake a day on the calendar (a Range), with a day, the period of time.

**Incorrect number** A class of mistakes arises from either omitting numbers from the parse, or incorrectly parsing numbers – the second case is particularly prevalent for written years, such as *seventeen seventy-six*.

**Relative Range** These errors arise from attempting to parse a grounded Range by applying functions to the reference time. For example, from a reference time of August 8<sup>th</sup>, it is possible to

“correctly” parse the phrase *August 1* as a week ago; but, naturally, this parse does not generalize well. This class of errors, although relatively small, merits special designation as it suggests a class of correct responses which are correct for the wrong reasons. Future work could explore mitigating these errors for domains where the text is further removed from the events it is describing than most news stories are.

**Incorrect parse** Errors in this class are a result of failing to find the correct parse, for a number of reasons not individually identified. A small subset of these errors (notably, 6% on the Spanish dataset) are a result of the grammar being insufficiently expressive with the preterminals we defined. For instance, we cannot capture fractional units, such as in *half an hour*.

**Missing context** A fairly large percentage of our errors arise from failing to classify inputs which express ambiguous or poorly defined times. For example, *from time to time* (annotated as the future), or *that time* (annotated as 5 years). Many of these require either some sort of inference or a broader understanding of the context in which the temporal phrase is uttered, which our system does not attempt to capture.

**Bad reference time** The last class of errors cover cases where the temporal phrase is clear, but annotation differs from our judgment of what would be reasonable. These are a result of assuming that the reference time of an utterance is the publication time of the article.

## 6 Conclusion

We have presented a discriminative, multilingual approach to resolving temporal expressions, using a language-flexible latent parse and rich features on both the *types* and *values* of partial derivations in the parse. We showed state-of-the-art results on both languages in TempEval-2 with prior work, and presented results on four additional languages.

**Acknowledgments** Work was done in the summer of 2012 while the first author was an intern at Google. We would like to thank Chris Manning, and our co-workers at Google for their insight and help.

## Abstract

We propose a computationally efficient graph-based approach for local coherence modeling. We evaluate our system on three tasks: sentence ordering, summary coherence rating and readability assessment. The performance is comparable to entity grid based approaches though these rely on a computationally expensive training phase and face data sparsity problems.

## 1 Introduction

Many NLP applications which process or generate texts rely on information about local coherence, i.e. information about which entities occur in which sentence and how the entities are distributed in the text. This led to the development of many theories and models accounting for local coherence. One popular model, the centering model (Grosz et al., 1995), uses a ranking of discourse entities realized in particular sentences and computes transitions between adjacent sentences to provide insight in the felicity of texts. Centering models local coherence rather generally and has been applied to the generation of referring expressions (Kibble and Power, 2004), to resolve pronouns (Brennan et al., 1987, inter alia), to score essays (Miltakaki and Kukich, 2004), to arrange sentences in the correct order (Karamanis et al., 2009), and to many other tasks. Poesio et al. (2004) observe that it is not clear how to set parameters in the centering model so that optimal performance in different tasks and languages can be achieved. Barzilay and Lapata (2008) criticize research on centering to be too dependent on manually annotated input. This led them to propose a local coherence model relying on a more parsimonious representation, the entity grid model.

The entity grid is a two dimensional array where the rows represent sentences and the columns discourse entities. From this grid Barzilay and Lapata (2008) derive probabilities of transitions between adjacent sentences which are used as features for machine learning algorithms. They evaluate this approach successfully on sentence ordering, summary coherence rating, and readability assessment. However, their approach has some disadvantages which they point out themselves: data sparsity, domain dependence and computational complexity, especially in terms of feature space issues while building their model (Barzilay and Lapata (2008, p.8, p.10, p.30), Elsner and Charniak (2011, p.126, p.127)).

In order to overcome these problems we propose to represent entities in a graph and then model local coherence by applying centrality measures to the nodes in the graph (Section 3). We claim that a graph is a more powerful representation for local coherence than the entity grid (Barzilay and Lapata, 2008) which is restricted to transitions between adjacent sentences. The graph can easily span the entire text without leading to computational complexity and data sparsity problems. Similar to the application of graph-based methods in other areas of NLP (e.g. work on word sense disambiguation by Navigli and Lapata (2010); for an overview over graph-based methods in NLP see Mihalcea and Radev (2011)) we model local coherence by relying only on centrality measures applied to the nodes in the graph. We apply our graph-based model to the three tasks handled by Barzilay and Lapata (2008) to show that it provides the same flexibility over disparate tasks as the entity grid model: sentence ordering (Section 4.1), summary coherence ranking (Section 4.2), and readability assessment (Section 4.3). In the

The Turkish government fell after mob-tie allegations.

Turkey’s constitution mandates a secular republic despite its Muslim majority.

Military and secular leaders pressured President Demirel to keep the Islamic-oriented Virtue Party on the fringe.

Business leaders feared Virtue would alienate the EU.

Table 1: Excerpt of a manual summary M from DUC2003

experiments sections, we discuss the impact of genre and stylistic properties of documents on the local coherence computation. We also show that, though we do not need a computationally expensive learning phase, our model achieves state-of-the-art performance. From this we conclude that a graph is an alternative to the entity grid model: it is computationally more tractable for modeling local coherence and does not suffer from data sparsity problems (Section 5).

## 2 The Entity Grid Model

Barzilay and Lapata (2005; 2008) introduced the entity grid, a method for local coherence modeling that captures the distribution of discourse entities across sentences in a text.

An entity grid is a two dimensional array, where rows correspond to sentences and columns to discourse entities. For each discourse entity  $e_j$  and each sentence  $s_i$  in the text, the corresponding grid cell  $c_{ij}$  contains information about the presence or absence of the entity in the sentence. If the entity does not appear in the sentence, the corresponding grid cell contains an absence marker “-”. If the entity is present in the sentence, the cell contains a representation of the entity’s syntactic role: “S” if the entity is a subject, “O” if it is an object and “X” for all other syntactic roles (cf. Table 2). When a noun is attested more than once with a different grammatical role in the same sentence, the role with the highest grammatical ranking is chosen to represent the entity (a subject is ranked higher than an object, which is ranked higher than other syntactic roles).

Barzilay and Lapata (2008) capture local coherence by means of local entity transitions, i.e. sequences of grid cells  $(c_{1j} \dots c_{ij} \dots c_{nj})$  representing the syntactic function or absence of an entity in adjacent sentences<sup>1</sup>. The coherence of a sentence in relation to its local context is determined by the

<sup>1</sup>For complexity reasons, Barzilay and Lapata consider only transitions between at most three sentences.

	GOVERNMENT	ALLEGATION	TURKEY	CONSTITUTION	SECULAR	REPUBLIC	MAJORITY	MILITARY	LEADER	PRESIDENT	DEMIREL	VIRTUE	PARTY	FRINGE	BUSINESS	EU
$s_1$	S	X	-	-	-	-	-	-	-	-	-	-	-	-	-	-
$s_2$	-	-	X	S	X	O	X	-	-	-	-	-	-	-	-	-
$s_3$	-	-	-	-	X	-	-	X	S	X	S	X	O	X	-	-
$s_4$	-	-	-	-	-	-	-	-	S	-	-	S	-	-	X	O

Table 2: Entity Grid representation of summary M

local entity transitions of the entities present or absent in the sentence. To make this representation accessible to machine learning algorithms, Barzilay and Lapata (2008) compute for each document the probability of each transition and generate feature vectors representing the sentences. Coherence assessment is then formulated as a ranking learning problem where the ranking function is learned with SVM<sup>light</sup> (Joachims, 2002).

The entity grid approach has already been applied to many applications relying on local coherence estimation: summary rating (Barzilay and Lapata, 2005), essay scoring (Burstein et al., 2010) or story generation (McIntyre and Lapata, 2010). It was also used successfully in combination with other systems or features. Soricut and Marcu (2006) show that the entity grid model is a critical component in their sentence ordering model for discourse generation. Barzilay and Lapata (2008) combine the entity grid with readability-related features to discriminate documents between easy- and difficult-to-read categories. Lin et al. (2011) use discourse relations to transform the entity grid representation into a discourse role matrix that is used to generate feature vectors for machine learning algorithms similarly to Barzilay and Lapata (2008).

Several studies propose to extend the entity grid model using different strategies for entity selection. Filippova and Strube (2007) aim to improve the entity grid model performance by grouping entities by means of semantic relatedness. In their studies, Elsner and Charniak extend the number and type of entities selected and consider that each entity has to be dealt with accordingly with its information status (Elsner et al., 2007) or its named-entity category (Elsner and Charniak, 2011). Finally, they include a heuristic coreference resolution component by linking mentions which share a

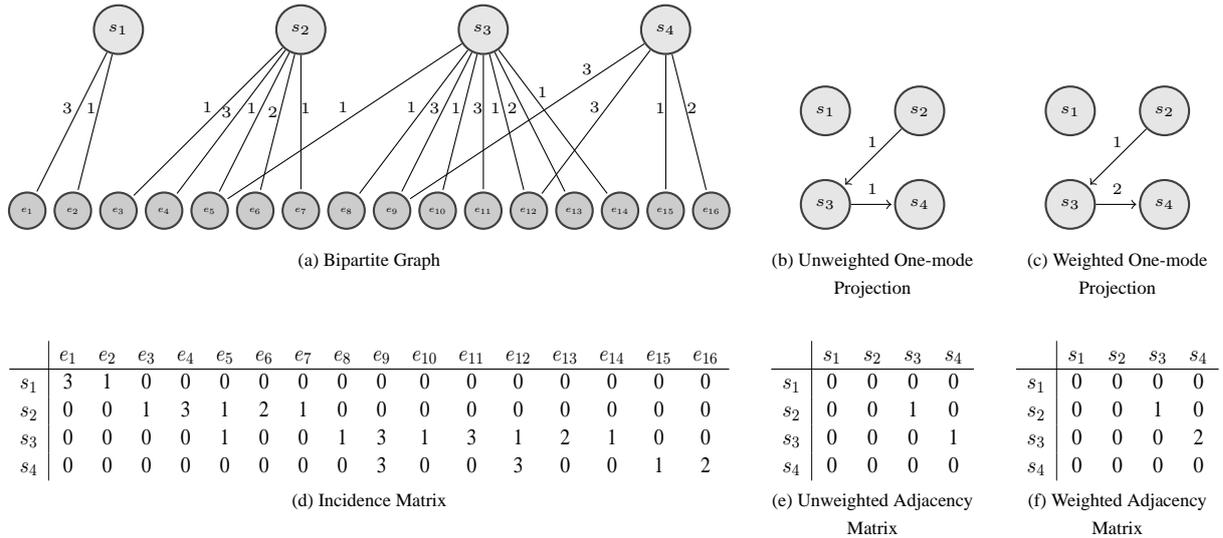

Figure 1: Bipartite graph for summary M from Table 1, one-mode projections and associated incidence and adjacency matrices. Weights in Figure 1(a) are assigned as follows: “S” = 3, “O” = 2, “X” = 1, “-” = 0 (no edge).

head noun. These extensions led to the best results reported so far for the sentence ordering task.

### 3 Method

Our model is based on the insight that the entity grid (Barzilay and Lapata, 2008) corresponds to the incidence matrix of a bipartite graph representing the text (see Newman (2010) for more details on graph representation). A fundamental assumption underlying our model is that this bipartite graph contains the entity transition information needed for local coherence computation, rendering feature vectors and learning phase unnecessary. The bipartite graph  $G = (V_s, V_e, L, w)$  is defined by two independent sets of nodes – that correspond to the set of sentences  $V_s$  and the set of entities  $V_e$  of the text – and a set of edges  $L$  associated with weights  $w$ . An edge between a sentence node  $s_i$  and an entity node  $e_j$  is created in the bipartite graph if the corresponding cell  $c_{ij}$  in the entity grid is not equal to “-”. Each edge is associated with a weight  $w(e_j, s_i)$  that depends on the grammatical role of the entity  $e_j$  in the sentence  $s_i$ <sup>2</sup>. In contrast to Barzilay and Lapata’s entity grid that contains information about absent entities, our graph-based representation only contains “positive” information. Figure 1(a) shows an example of the bipartite graph that corresponds to the grid in Table 2. The incidence matrix of this graph (Figure 1(d)) is very similar to the entity grid.

<sup>2</sup>The assignment of weights is described in Section 4.

By modeling entity transitions, Barzilay and Lapata rely on links that exist between sentences to model local coherence. In the same spirit, we apply different kinds of one-mode projections to the sentence node set  $V_s$  of the bipartite graph to represent the connections that exist between – potentially non adjacent – sentences in the graph. These projections result in graphs where nodes correspond to sentences. An edge is created between two nodes if the corresponding sentences have a least one entity in common. Contrary to the bipartite graph, one-mode projections are directed as they follow the text order. Therefore, in projection graphs an edge can exist between the first and the second sentence while the inverse is not possible. In our model, we define three kinds of projection graphs,  $P_U$ ,  $P_W$  and  $P_{Acc}$ , depending on the weighting scheme associated with their edges. In  $P_U$ , weights are binary and equal 1 when two sentences have a least one entity in common (Figure 1(b)). In  $P_W$ , edges are weighted according to the number of entities “shared” by two sentences (Figure 1(c)). In  $P_{Acc}$  syntactic information is accounted for by integrating the edge weights in the bipartite graph. In this case, weights are equal to

$$W_{ik} = \sum_{e \in E_{ik}} w(e, s_i) \cdot w(e, s_k),$$

where  $E_{ik}$  is the set of entities shared by  $s_i$  and  $s_k$ . Distance between sentences  $s_i$  and  $s_k$  can also be integrated in the weight of one-mode projections to decrease the importance of links that ex-

ists between non adjacent sentences. In this case, the weights of the projection graphs are divided by  $k - i$ .

From this graph-based representation, the local coherence of a text  $T$  can be measured by computing the average outdegree of a projection graph  $P$ . This centrality measure was chosen for two main reasons. First, it allows us to evaluate to which extent a sentence is connected, in terms of discourse entities, with the other sentences of the text. Second, compared to other centrality measures, the computational complexity of the average outdegree is low ( $\mathcal{O}(\frac{N*(N-1)}{2})$  for a document composed by  $N$  sentences), keeping the local coherence estimation feasible on large documents and on large corpora. Formally, the local coherence of a text  $T$  is equal to

$$\begin{aligned} LocalCoherence(T) &= AvgOutDegree(P) \\ &= \frac{1}{N} \sum_{i=1..N} OutDegree(s_i), \end{aligned}$$

where  $OutDegree(s_i)$  is the sum of the weights associated to edges that leave  $s_i$  and  $N$  is the number of sentences in the text. This value can also be seen as the sum of the values of the adjacency matrix of the projection graph (Figures 1(e) and 1(f)) divided by the number of sentences.

## 4 Experiments

We compare our model with the entity grid approach and evaluate the influence of the different weighting schemes used in the projection graphs, either  $P_W$  or  $P_{Acc}$ , where weights are potentially decreased by distance information  $Dist$ . Our baseline corresponds to local coherence computation based on the unweighted projection graph  $P_U$ .

For graph construction, all nouns in a document are considered as discourse entities, even those which do not head NPs as this is beneficial for the entity grid model as described in Elsner and Charniak (2011). We also propose to use a coreference resolution system and consider coreferent entities to be the same discourse entity. To do so, we use one of the top performing systems from the CoNLL 2012 shared task (Martschat et al., 2012). As the coreference resolution system is trained on well-formed textual documents and expects a correct sentence ordering, we use in all our experiments only features that do not rely on sentence order (e.g. alias relations, string matching, etc.).

Grammatical information associated with each entity is extracted automatically thanks to the Stanford parser using dependency conversion (de Marneffe et al., 2006). Syntactic weights in the bipartite graph are defined following the linguistic intuition that subjects are more important than objects, which are themselves more important than other syntactic roles. Preliminary experiments show that as long as weight assignment follows the scheme  $S > O > X$ , then more coherent documents are associated with a higher local coherence value than less coherent document in 90% of cases (while this value equals 49% when no restriction is given on syntactic weights order). Moreover, as the local coherence computation is a linear combination of the syntactic weights, the function is smooth and no large variations of the local coherence values are observed for small changes of weights' values. For these reasons, weights  $w(e, s_i)$  are set as follows: 3 if  $e$  is subject in  $s_i$ , 2 if  $e$  is an object and 1 otherwise.

We evaluate the ability of our graph-based model to estimate the local coherence of a textual document with three different experiments. First, we perform a sentence ordering task (Section 4.1) as proposed in Barzilay and Lapata (2008). Then, as the first task uses "artificial" documents, we also work on two other tasks that involve "real" documents: summary coherence rating (Section 4.2), and readability assessment (Section 4.3). In these experiments, distance computation and syntactic weights are the same for all tasks and all corpora. However, the model is also flexible and can be adapted to the different tasks by optimizing the parameters on a development data set, which may give better results.

### 4.1 Sentence Ordering

The first experiment consists in ranking alternative sentence orderings of a document, as proposed by Barzilay and Lapata (2008) and Elsner and Charniak (2011).

#### 4.1.1 Experimental Settings

The sentence ordering task can be performed in two ways: discrimination and insertion. Discrimination consists in comparing a document to a random permutation of its sentences. For this, our system associates local coherence values with the original document and its permutation, the output of our system being considered as correct if the score for the original document is higher than the

score of its permutation. In the insertion task, proposed by Elsner and Charniak (2011), we evaluate the ability of our system to retrieve the original position of a sentence previously removed from a document. For this, each sentence is removed in turn and a local coherence score is computed for every possible reinsertion position. The system output is considered as correct if the document associated with the highest local coherence score is the one in which the sentence is reinserted in the correct position.

These two tasks were performed on documents extracted from the English test part of the CoNLL 2012 shared task (Pradhan et al., 2012). This corpus, composed by documents of multiple news sources – spoken or written – was preferred to the ACCIDENTS and EARTHQUAKES corpora used by Barzilay and Lapata (2008) for two reasons. First, as mentioned by Elsner and Charniak (2008), these corpora use a very constrained style and are not typical of normal informative documents<sup>3</sup>. Second, we want to evaluate the influence of automatically performed coreference resolution in a controlled fashion. The coreference resolution system used performs well on the CoNLL 2012 data. In this dataset, documents composed by the concatenation of different news articles or too short to have at least 20 permutations were discarded from the corpus. This filtering results in 61 documents composed of 36.1 sentences or 2064 word tokens on average. In both discrimination and insertion, we compare our system against a random baseline where random values are associated with the different orderings.

#### 4.1.2 Discrimination

Accuracy is used to evaluate the ability of our system to discriminate a document from 20 different permutations. It equals the number of times our system gives the highest score to the original document, divided by the number of comparisons. Since the model can give the same score for a permutation and the original document, we also compute F-measure where recall is *correct/total* and precision equals *correct/decisions*. We test significance using the Student’s t-test that can detect significant differences between paired samples. Moreover, as increasing the number of hypotheses

<sup>3</sup>Our graph-based model obtains for the discrimination task an accuracy of 0.846 and 0.635 on the ACCIDENTS and EARTHQUAKES datasets, respectively, compared to 0.904 and 0.872 as reported by Barzilay and Lapata (2008).

	Acc	F	Acc	F
Random	0.496	0.496		
B&L	0.877	0.877		
E&C	0.915	0.915		
	wo coref		w coref	
$P_U, Dist$	0.830	0.830	0.833	0.833
$P_W, Dist$	0.871	0.871	0.849	0.849
$P_{Acc}, Dist$	0.889	0.889	0.852	0.852

Table 3: Discrimination, reproduced baselines (B&L: Barzilay and Lapata (2008); E&C Elsner and Charniak (2011)) vs. graph-based

in a test can also increase the likelihood of witnessing a rare event, and therefore, the chance to reject the null hypothesis when it is true, we use the Bonferroni correction to adjust the increased random likelihood of apparent significance.

Table 3 presents the values obtained by three baseline systems when applied to our corpus. Results for the entity grid models described by Barzilay and Lapata (2008) and Elsner and Charniak (2011) are obtained by using Micha Elsner’s reimplementation in the Brown Coherence Toolkit<sup>4</sup>. The system was trained on the English training part of the CoNLL 2012 shared task filtered in the same way as the test part.

Table 3 also displays the results for our model. These values show that our system performs comparable to the state-of-the-art. Indeed, the difference between our best results and those of Elsner and Charniak are not statistically significant.

In this experiment, distance information is critical. Without it, it is not possible to distinguish between an original document and one of its permutation as both contain the same number and kind of entities. Distance however can detect changes in the distribution of entities within the document as space between entities is significantly modified when sentence order is permuted. When the number of entities “shared” by two sentences is taken into account ( $P_W$ ), the accuracy of our system grows (from 0.830 to 0.871). Table 3 finally shows that syntactic information improves the performance of our system (yet not significantly) and gives the best results ( $P_{Acc}$ ).

We also evaluated the influence of coreference resolution on the performance of our system. Us-

<sup>4</sup><https://bitbucket.org/melsner/browncoherence>; B&L is Elsner’s “baseline entity grid” (command line option ‘-n’), E&C is Elsner’s “extended entity grid” (‘-f’)

	Acc.	Ins.	Acc.	Ins.
Random	0.028	0.071		
E&C	0.068	0.167		
	wo coref		w coref	
$P_U, Dist$	0.062	0.101	0.068	0.120
$P_W, Dist$	0.075	0.114	0.070	0.138
$P_{Acc}, Dist$	0.071	0.102	0.067	0.097

Table 4: Insertion, reproduced baselines vs. graph-based

ing coreference resolution improves the performance of the system when distance information is used alone in the system (Table 3). However, this improvement is not statistically significant.

### 4.1.3 Insertion

Sentence insertion is much more difficult than discrimination for two reasons. First, in insertion, permutations only differ by one sentence. Second, a document is compared to many more permutations in insertion task than in discrimination.

In complement to accuracy, we use the insertion score introduced by Elsner and Charniak (2011) for evaluation. This score – the higher, the better – computes the proximity between the initial and the proposed position of a sentence, averaged by the number of sentences.

Table 4 shows that, as expected, results for this task are much lower than those obtained for discrimination. However they are still comparable with the results of Elsner and Charniak (2011)<sup>5</sup>.

As previously and for the same reasons, distance information is critical for this task. The best results, that present a statistically significant improvement when compared to the random baseline, are obtained when distance information and the number of entities “shared” by two sentences are taken into account ( $P_W$ ). We can see that the accuracy value obtained with our system is higher than the one provided with the entity grid model. However, the entity grid model reaches a significantly higher insertion score. This means that, if it makes more mistakes than our system, the position chosen by the entity grid model is usually closer to the correct position. Finally, contrary to the discrimination task, syntactic information ( $P_{Acc}$ ) does not improve the performance of our system.

<sup>5</sup>Their results are slightly lower than those presented in their paper, probably because our corpus is composed by documents that can be longer than the ones used in their experiments (Wall Street Journal articles).

When the coreference resolution system is used, the best accuracy value decreases while the insertion score increases from 0.114 to 0.138 (Table 4). Therefore, coreference resolution tends to associate positions that are closer to the original ones.

## 4.2 Summary Coherence Rating

To reconfirm the hypothesis that our model can estimate the local coherence of a textual document, we perform a second experiment, summary coherence rating. To this end, we apply our model on the corpus used and proposed by Barzilay and Lapata (2008). As the objective of our model is to estimate the *coherence* of a summary, we prefer this dataset to other summarization evaluation task corpora, as these account for other dimensions of the summaries: content selection, fluency, etc. Starting with a pair of summaries, one slightly more coherent than the other, the objective of the task is to order the two summaries according to local coherence.

### 4.2.1 Experimental Settings

For the summary coherence rating experiment, pairs to be ordered are composed of summaries extracted from the Document Understanding Conference (DUC 2003). Summaries, provided either by humans or by automatic systems, were judged by seven humans annotators and associated with a coherence score (for more details on this score see Barzilay and Lapata (2008)). 80 pairs were then created, each of these being composed by two summaries of a same document where the score of one of the summaries is significantly higher than the score of the second one. Even though all summaries are of approximately the same length (114.2 words on average), their sentence length can vary considerably. Indeed, more coherent summaries tend to have more sentences and contain less entities.

For evaluation purposes, the accuracy still corresponds to the number of correct ratings divided by the number of comparisons, while the F-measure combines recall and precision measures. As before, significance is tested with the Student’s t-test accounting for the Bonferroni correction.

### 4.2.2 Results

Table 5 compares the results reported by Barzilay and Lapata (2008) on the exact same corpus with the results obtained with our system. It shows that

	Acc.	F	Acc.	F
B&L	0.833			
	wo coref		w coref	
$P_U$	0.800	0.815	0.700	0.718
$P_W$	0.613	0.613	0.538	0.548
$P_{Acc}$	0.700	0.704	0.638	0.638
$P_U, Dist$	0.650	0.658	0.550	0.557
$P_W, Dist$	0.525	0.525	0.513	0.513
$P_{Acc}, Dist$	0.700	0.700	0.588	0.588

Table 5: Summary Coherence Rating, reported results from Barzilay and Lapata (2008) vs. graph-based

our system gives results comparable to those obtained by Barzilay and Lapata (2008).

This table also shows that, contrary to sentence ordering task, accounting for the distance between two sentences (*Dist*) tends to decrease the results. This difference is explained by the fact that a manual summary, usually considered as more coherent by humans annotators, tends to contain more (and shorter) sentences than an automatic one. As adding distance information decreases the value of our local coherence score, our graph-based model gives better results without it.

Moreover, in contrast to the first experiment, when accounting for the number of entities “shared” by two sentences ( $P_W$ ), values of accuracy and F-measure are lower. We explain this behaviour by the number of sentences contained in the less coherent documents. Indeed, they are composed by a smaller number of sentences but contain more entities on average. This means that, in these documents, two sentences tend to share a larger number of entities and therefore have a higher local coherence score when the  $P_W$  projection graph is used.

When combined with distance information, syntactic information still improves the results ( $P_{Acc}$ ), though not significantly, but does not lead to the best results for this task.

Finally, Table 5 also shows that using a coreference resolution system for document representation does not improve the performance of our system. We believe that, as mentioned by Barzilay and Lapata (2008), this degradation is related to the fact that automatic summarization systems do not use anaphoric expressions which makes the coreference resolution system useless in this case.

With our graph-based model, the best results are

obtained by the baseline ( $P_U$ ), and experiments show that adding information about distance or syntax does not help in this context. It seems therefore necessary to integrate information that is more appropriate to summaries. Although making the model more appropriate for a specific task is out of the scope of this paper, our model is flexible and accounting for information about genre differences or sentence length, by adding weights in the graph-based representation of the document, is feasible without any modification of the model.

### 4.3 Readability Assessment

Barzilay and Lapata (2008) argue that grid models are domain and style dependent. Therefore they proposed a readability assessment task to test if the entity grid model can be used for style classification. They combined their model with Schwarm and Ostendorf’s (2005) readability features and use Support Vector Machines to classify documents in two categories. With the same intention, we evaluate the ability of our model to differentiate “easy to read” documents from difficult ones.

#### 4.3.1 Experimental Settings

The objective of the readability assessment task is to evaluate how difficult to read a document is. We perform this task on the data used by Barzilay and Lapata (2008), a corpus collected originally by Barzilay and Elhadad (2003) from the *Encyclopedia Britannica* and its version for children, the *Britannica Elementary*. Both versions contain 107 articles. In *Encyclopedia Britannica*, documents are composed by an average of 83.1 sentences while they contain 36.6 sentences in *Britannica Elementary*. Although these texts are not explicitly annotated with grade levels, they represent two broad readability categories.

In order to estimate the complexity of a document, our model computes the local coherence score for each article in the two categories. The article associated with the higher score is considered to be the more readable as it is more coherent, needing less interpretation from the reader than a document associated with a lower local coherence score. Values presented in the following section correspond to accuracy, where the system is correct if it assigns the higher local coherence score to the most “easy to read” document, and F-measure.

	Acc.	F	Acc.	F
S&O	0.786			
B&L	0.509			
B&L + S&O	0.888			
	wo coref		w coref	
$P_U$	0.589	0.589	0.374	0.374
$P_W$	0.579	0.579	0.383	0.383
$P_{Acc}$	0.645	0.645	0.421	0.421
$P_{U, Dist}$	0.589	0.589	0.280	0.280
$P_{W, Dist}$	0.570	0.570	0.290	0.290
$P_{Acc, Dist}$	0.766	0.766	0.308	0.308

Table 6: Readability, reported results from Barzilay and Lapata (2008) vs. graph-based (S&O: Schwarm and Ostendorf (2005))

### 4.3.2 Results

In order to compare our results with those reported by Barzilay and Lapata (2008), entities used for the graph-based representation are discourse entities that head NPs.

Table 6 shows that, for this task, syntactic information plays a dominant role ( $P_{Acc}$ ). A statistically significant improvement is provided by including syntactic information. It gives more weight to subject entities that are more numerous in the *Britannica Elementary* documents which are composed by simpler and shorter sentences. Finally, when distance is accounted for together with syntactic information, the accuracy is significantly improved ( $p < 0.01$ ) with regard to the results obtained with syntactic information only.

Table 6 also shows that when the number of entities “shared” by two sentences is accounted for ( $P_W$ ), the results are lower. Indeed, *Encyclopedia Britannica* documents are composed by longer sentences, that contain a higher number of entities. This increases the local coherence value of difficult documents more than the value of “easy to read” documents, that contain less entities.

When our graph-based representation used the coreference resolution system, unlike the observation of Barzilay and Lapata (2008), the results of our model decrease significantly. The poor performance of our system in this case can be explained by the fact that the coreference resolution system regroups more entities in *Encyclopedia Britannica* documents than in *Britannica Elementary* ones. Therefore, the number of entities that are “shared” by two sentences increases more importantly in the *Encyclopedia Britannica* corpus, while the dis-

tance between two occurrences of one entity decreases in a more significant manner. For these reasons, the coherence scores associated with “difficult to read” documents tend to be higher when coreference resolution is performed on our data, which reduces the performance of our system. As before, syntactic information leads to the best results, but does not allow the accuracy to be higher than random anymore.

Compared to the results provided by Barzilay and Lapata (2008) with the entity grid model alone, our representation outperforms their model significantly. We believe that this difference is caused by how syntactic information is introduced in the document representation and by the fact that our system can deal with entities that appear throughout the whole document while the entity grid model only looks at entities within a three sentences windows. Our model which captures exclusively local coherence is almost on par with the results reported for Schwarm & Ostendorf’s (2005) system which relies on a wide range of lexical, syntactic and semantic features. Only when Barzilay and Lapata (2008) combine the entity grid with Schwarm & Ostendorf’s features they reach performance considerably better than ours.

In addition to the experiments proposed by Barzilay and Lapata (2008), we used a third readability category, the *Britannica Student*, that contains articles targeted for youths (from 11 to 14 years old). These documents, which are quite similar to the *Encyclopedia Britannica* ones, are composed by an average of 44.1 sentences. As we were only able to find 99 articles out of the 107 original ones in this category, sub corpora of the three categories were used for the comparison with the *Britannica Student* articles.

Table 7 shows the results obtained for the comparisons between the two first categories and the *Britannica Student* articles. As previously, coreference resolution tends to lower the results, therefore only values obtained without coreference resolution are reported in the table.

When articles from *Britannica Student* are compared to articles extracted from *Encyclopedia Britannica*, Table 7 shows that the different parameters have the same influence as for comparing between *Encyclopedia Britannica* and *Britannica Elementary*: statistically significant improvement with syntactic information, higher values when distance is taken into account, etc. However, it

	<i>Brit. vs. Stud.</i>		<i>Stud. vs. Elem.</i>	
	Acc.	F	Acc.	F
$P_U$	0.444	0.444	0.667	0.667
$P_W$	0.434	0.434	0.636	0.636
$P_{Acc}$	0.465	0.465	0.707	0.707
$P_U, Dist$	0.475	0.475	0.646	0.646
$P_W, Dist$	0.485	0.485	0.616	0.616
$P_{Acc, Dist}$	0.556	0.556	0.657	0.657

Table 7: Readability, comparison between *Encyclopedia Britannica*, *Britannica Elementary* and *Britannica Student*

can also be seen that accuracy and F-measure are lower for comparing these two corpora. This is probably due to the stylistic difference between these two kinds of articles, which is less significant than the difference between articles from *Encyclopedia Britannica* and *Britannica Elementary*.

Concerning the comparison between *Britannica Student* and *Britannica Elementary* articles, Table 7 shows that integrating distance information gives slightly different results and tends to decrease the values of accuracy and F-measure. This is explained by the fact that *Britannica Elementary* documents contain fewer entities than *Britannica Student* articles. As the length of the two kinds of articles is similar, distance between entities in *Britannica Elementary* documents is more important. As a result, accounting for distance information lowers the local coherence values for the more coherent document, which reduces the performance of our model. As previously, syntactic information improves the results and, for this comparison, the best result is obtained when syntactic information alone is accounted for. This leads to an accuracy which is almost equal to the one when comparing *Encyclopedia Britannica* and *Britannica Elementary* (0.707 against 0.766).

These two additional experiments show that our model is style dependent. It obtains better results when it has to distinguish between *Encyclopedia Britannica* and *Britannica Elementary* or *Britannica Student* and *Britannica Elementary* articles which present a more important difference from a stylistic point of view than articles from *Encyclopedia Britannica* and *Britannica Elementary*.

## 5 Conclusions

In this paper, we proposed an unsupervised and computationally efficient graph-based local coher-

ence model. Experiments show that our model is robust among tasks and domains, and reaches reasonable results for three tasks with the same parameter values and settings (i.e. accuracy values of 0.889, 0.70 and 0.766 for sentence ordering, summary coherence rating and readability assessment tasks respectively ( $P_{Acc}$ ,  $Dist$ )). Moreover, our model can be optimized and obtains results comparable with entity grid based methods when proper settings are used for each task.

Our model has two main advantages over the entity grid model. First, as the graph used for document representation contains information about entity transitions, our model does not need a learning phase. Second, as it relies only on graph centrality, our model does not suffer from the computational complexity and data sparsity problems mentioned by Barzilay and Lapata (2008).

Our current model leaves space for improvement. Future work should first investigate the integration of information about entities. Indeed, our model only uses entities as indications of sentence connection although it has been shown that distinguishing important from unimportant entities, according to their named-entity category, has a positive impact on local coherence computation (Elsner and Charniak, 2011). Moreover, future work should also examine the use of discourse relation information, as proposed in (Lin et al., 2011). This can be easily done by adding edges in the projection graphs when sentences contain entities related from a discourse point of view while Lin et al.’s approach suffers from complexity and data sparsity problems similar to the entity grid model.

Finally, these promising results on local coherence modeling make us believe that our graph-based representation can be used without much modification for other tasks, e.g. extractive summarization or topic segmentation. This could be achieved with link analysis algorithms such as PageRank, that decide on the importance of a (sentence) node within a graph based on global information recursively drawn from the entire graph.

# Recognizing Rare Social Phenomena in Conversation: Empowerment Detection in Support Group Chatrooms

Elijah Mayfield, David Adamson, and Carolyn Penstein Rosé

Carnegie Mellon University

5000 Forbes Ave, Pittsburgh, PA 15213

{emayfiel, dadamson, cprose}@cs.cmu.edu

## Abstract

Automated annotation of social behavior in conversation is necessary for large-scale analysis of real-world conversational data. Important behavioral categories, though, are often sparse and often appear only in specific subsections of a conversation. This makes supervised machine learning difficult, through a combination of noisy features and unbalanced class distributions. We propose *within-instance content selection*, using cue features to selectively suppress sections of text and biasing the remaining representation towards minority classes. We show the effectiveness of this technique in automated annotation of empowerment language in online support group chatrooms. Our technique is significantly more accurate than multiple baselines, especially when prioritizing high precision.

## 1 Introduction

Quantitative social science research has experienced a recent expansion, out of controlled settings and into natural environments. With this influx of interest comes new methodology, and the inevitable question arises of how to move towards testable hypotheses, using these uncontrolled sources of data as scientific lenses into the real world.

The study of conversational transcripts is a key domain in this new frontier. There are certain social and behavioral phenomena in conversation that cannot be easily identified through questionnaire data, self-reported surveys, or easily extracted user metadata. Examples of these social phenomena in conversation include overt displays of power (Prabhakaran et al., 2012) or indicators of rapport and relationship building (Wang et al.,

2012). Manually annotating these social phenomena cannot scale to large data, so researchers turn to automated annotation of transcripts (Rosé et al., 2008). While machine learning is highly effective for annotation tasks with relatively balanced labels, such as sentiment analysis (Pang and Lee, 2004), more complex social functions are often rarer. This leads to unbalanced class label distributions and a much more difficult machine learning task. Moreover, features indicative of rare social annotations tend to be drowned out in favor of features biased towards the majority class. The net effect is that classification algorithms tend to bias towards the majority class, giving low accuracy for rare class detection.

Automated annotation of social phenomena also brings opportunities for real-world applications. For example, real-time annotation of conversation can power adaptive intervention in collaborative learning settings (Rummel et al., 2008; Adamson and Rosé, 2012). However, with the considerable power of automation comes great responsibility. It is critical to avoid intervening in the case of erroneous annotations, as providing unnecessary or inappropriate support in such a setting has been shown to be harmful to group performance and social cohesion (Dillenbourg, 2002; Stahl, 2012).

We propose adaptations to existing machine learning algorithms which improve recognition of rare annotations in conversational text data. Our primary contribution comes in the form of *within-instance content selection*. We develop a novel algorithm based on textual cues, suppressing information which is likely to be irrelevant to an instance's class label. This allows features which predict minority classes to gain prominence, helping to sidestep the frequency of common features pointing to a majority class label.

Additionally, we propose modifications to existing algorithms. First, we identify a new application of logistic model trees to text data. Next,

we define a modification of confidence-based ensemble voting which encourages minority class labeling. Using these techniques, we demonstrate a significant improvement in classifier performance when recognizing the language of *empowerment* in support group chatrooms, a critical application area for researchers studying conversational interactions in healthcare (Uden-Kraan et al., 2009).

The remainder of this paper is structured as follows. We introduce the domain of empowerment in support contexts, along with previous studies on the challenges that these annotations (and similar others) bring to machine learning. We introduce our new technique for improving the ability to automate this annotation, along with other optimizations to the machine learning workflow which are tailored to this skewed class balance. We present experimental results showing that our method is effective, and provide a detailed analysis of the behavior of our model and the features it uses most. We conclude with a discussion of particularly useful applications of this work.

## 2 Background

We ground this paper’s discussion of machine learning with a real problem, turning to the annotation of empowerment language in chat<sup>1</sup>. The concept of empowerment, while a prolific area of research, lacks a broad definition across professionals, but broadly relates to “the power to act efficaciously to bring about desired results” (Boehm and Staples, 2002) and “experiencing personal growth as a result of developing skills and abilities along with a more positive self-definition” (Staples, 1990). Participants in online support groups feel increased empowerment (Uden-Kraan et al., 2009; Barak et al., 2008). Quantitative studies have shown the effect of empowerment through statistical methods such as structural equation modeling (Vauth et al., 2007), as have qualitative methods such as deductive transcript analysis (Owen et al., 2008) and interview studies (Wahlin et al., 2006).

The transition between these styles of research has been gradual. Pioneering work has demonstrated the ability to distinguish empowerment language in written texts, including prompted writing samples (Pennebaker and Seagal, 1999), nar-

<sup>1</sup>Definitions of empowerment are closely related to the notion of *self-efficacy* (Bandura, 1997). For simplicity, we use the former term exclusively in this paper.

Table 1: Empowerment label distribution in our corpus.

Annotation	Label	#	%
Self-Empowerment	NA	1522	79.3
	POS	202	10.5
	NEG	196	10.2
Other-Empowerment	NA	1560	81.3
	POS	217	11.3
	NEG	143	7.4

ratives in online forums (Hoybye et al., 2005), and some preliminary analysis of synchronous discussion (Ogura et al., 2008; Mayfield et al., 2012b). These transitional works have used limited analysis methodology; in the absence of sophisticated natural language processing, their conclusions often rely on coarse measures, such as word counts and proportions of annotations in a text.

Users, of course, do not express empowerment in every thread in which they participate, which leads to a challenge for machine learning. Threads often focus on a single user’s experiences, in which most participants in a chat are merely commentators, if they participate at all, matching previous research on shifts in speaker salience over time (Hassan et al., 2008). This leads to many user threads which are annotated as not applicable (N/A). We move to our proposed approach with these skewed distributions in mind.

## 3 Data

Our data consists of a set of chatroom conversation transcripts from the Cancer Support Community<sup>2</sup>. Each 90-minute conversation took place in the context of a weekly meeting in a real-time chat, with up to 6 participants in addition to a professional therapist facilitating the discussion. In total, 2,206 conversations were collected from 2007-2011. This data offers potentially rich insight into coping and social support; however, annotating such a dataset by hand would be prohibitively expensive, even when it is already transcribed.

Twenty-one of these conversations have been annotated, as originally described and analyzed in (Mayfield et al., 2012b)<sup>3</sup>. This data was disentangled into *threads* based on common themes or topics, as in prior work (Elsner and Charniak,

<sup>2</sup>[www.cancersupportcommunity.org](http://www.cancersupportcommunity.org)

<sup>3</sup>All annotations were found to be adequately reliable between humans, with thread disentanglement  $f = 0.75$  and empowerment annotation  $\kappa > 0.7$ .

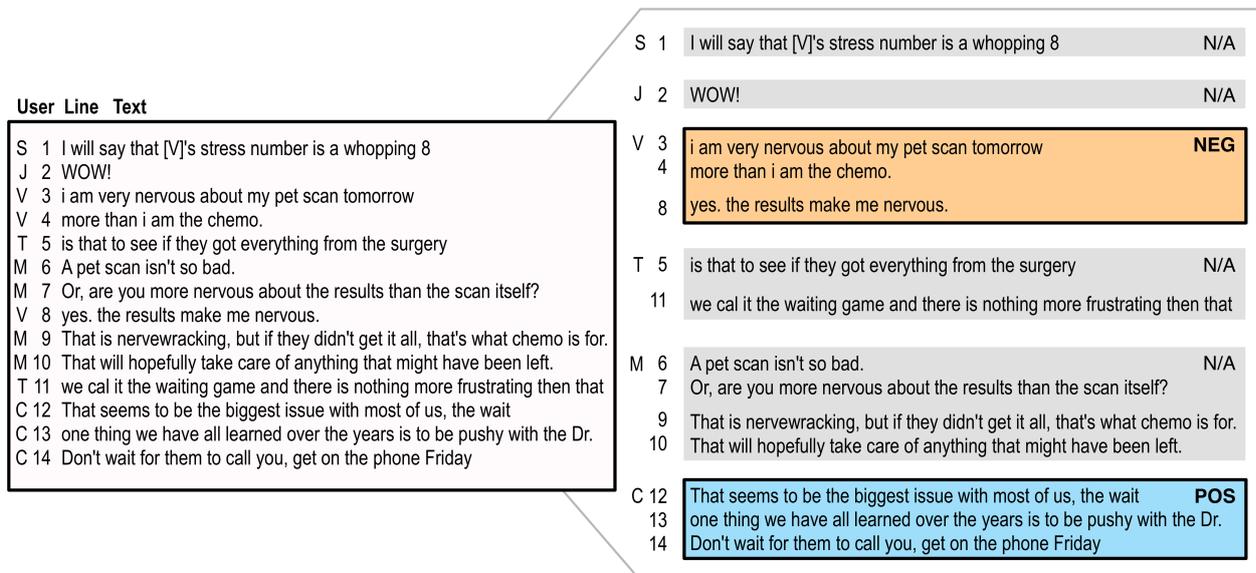

Figure 1: An example mapping from a single thread’s chat lines (left) to the per-user, per-thread instances used for classification in this paper (right), with example annotations for self-empowerment indicated.

2010; Adams and Martel, 2010). A novel *per-user, per-thread* annotation was then employed for empowerment annotation, following a coding manual based on definitions like those in Section 2. Each user was assigned a label of positive or negative empowerment if they exhibited such emotions, or was left blank if they did not do so within the context of that thread. This annotation was performed both for their *self-empowerment* as well as their attitude towards others’ situations (*other-empowerment*). An example of this annotation for self-empowerment is presented in Figure 1 and the distribution of labels is given in Table 1.

Most previous annotation tasks attempt to annotate on a per-utterance basis, such as dialogue act tagging (Popescu-Belis, 2008), or on arbitrary spans of text, such as in the MPQA subjectivity corpus (Wiebe et al., 2005). However, for our task, a per-user, per-thread annotation is more appropriate, because empowerment is often indicated best through narrative (Hoybye et al., 2005). Human annotators are instructed to take this context into account when annotating (Mayfield et al., 2012b). It would therefore be nonsensical to annotate individual lines as “embodying” empowerment. Similar arguments have been made for sentiment, especially as the field moves towards aspect-oriented sentiment (Breck et al., 2007). Assigning labels based on thread boundaries allows for context to be meaningfully taken into account, without crossing topic boundaries.

However, this granularity comes with a price: the distribution of class values in these instances is highly skewed. In our data, the vast majority of users’ threads are marked as not applicable to empowerment. Perhaps more inconveniently, while taking context into account is important for reliable annotation, it leads to extraneous information in many cases. Many threads can have multiple lines of contributions that are topically related to an expression of empowerment (and thus belong in the same thread), but which do not indicate any empowerment themselves. This exacerbates the likelihood of instances being classified as N/A.

We choose to take advantage of these attributes of threads. We know from research in discourse analysis that many sections of conversations are formulaic and rote, like introductions and greetings (Schegloff, 1968). We additionally know that polarity often shifts in dialogue through the use of discourse connectives such as conjunctions and transitional phrases. These issues have been addressed in work in the language technologies community, most notably through the Penn Discourse Treebank (Prasad et al., 2008); however, their applications to noisier synchronous conversation has been rare in computational linguistics.

With these linguistic insights in mind, we examine how we can make best use of them for machine learning performance. While techniques for predicting rare events (Weiss and Hirsh, 1998) and compensating for class imbalance (Frank and

Bouckaert, 2006), these approaches generally focus on statistical properties of large class sets without taking the nature of their datasets into account. In the next section, we propose a new algorithm which takes advantage specifically of the linguistic phenomena in the conversation-based data that we study for empowerment detection. As such, our algorithm is highly suited to this data and task, with the necessary tradeoff in uncertain generality to new domains with unrelated data.

## 4 Cue Discovery for Content Selection

Our algorithm performs content selection by learning a set of cue features. Each of these features indicates some linguistic function within the discourse which should downplay the importance of features either before or after that discourse marker. Our algorithm allows us to evaluate the impact of rules against a baseline, and to iteratively judge each rule atop the changes made by previous rules.

This algorithm fits into existing language technologies research which has attempted to partition documents into sections which are more or less relevant for classification. Many researchers have attempted to make use of cue phrases (Hirschberg and Litman, 1993), especially for segmentation both in prose (Hearst, 1997) and conversation (Galley et al., 2003). The approach of content selection, meanwhile, has been explored for sentiment analysis (Pang and Lee, 2004), where individual sentences may be less subjective and therefore less relevant to the sentiment classification task. It is also similar conceptually to content selection algorithms that have been used for text summarization (Teufel and Moens, 2002) and text generation (Sauper and Barzilay, 2009), both of which rely on finding highly-relevant passages within source texts.

Our work is distinct from these approaches. While we have coarse-grained annotations of empowerment, there is no direct annotation of what makes a good cue for content selection. With our cues, we hope to take advantage of shallow discourse structure in conversation, such as contrastive markers, making use of implicit structure in the conversational domain.

### 4.1 Notation

Before describing extensions to the baseline logistic regression model, we define notation. Our

data is arranged hierarchically. We assume that we have a collection of  $d$  training documents  $\mathbf{Tr} = \{D_1 \dots D_d\}$ , each of which contains many training instances (in our task, an instance consists of all lines of chat from one user in one thread). Our total set of  $n$  instances  $\mathbf{I}$  thus consists of instances  $\{I_1, I_2, \dots I_n\}$ . Each document contains lines of chat  $\mathbf{L}$  and each instance  $I_i$  is comprised of some subset of those lines,  $L_i \subseteq \mathbf{L}$ .

Our feature space  $\mathbf{X} = \{x_1, x_2, \dots x_m\}$  consists of  $m$  unigram features representing the observed vocabulary used in our corpus. Each instance is associated with a feature vector  $\bar{x}$  containing values for each  $x \in \mathbf{X}$ , and each feature  $x$  that is present in the  $i$ -th instance maintains a “memory” of the lines in which it appeared in that instance,  $L_{ix}$ , where  $L_{ix} \subseteq L_i$ . Our potential output labels consist of  $\mathbf{Y} = \{NA, NEG, POS\}$ , though this generalizes to any nominal classification task. Each instance  $I$  is associated with exactly one  $y \in \mathbf{Y}$  for self-empowerment and one for other-empowerment; these two labels do not interact and our tasks are treated as independent in this paper<sup>4</sup>. We define classifiers as functions  $f(\bar{x} \rightarrow y \in \mathbf{Y})$ ; in practice, we use logistic regression via LibLINEAR (Fan et al., 2008).

We define a content selection rule as a pairing  $r = \langle c, t \rangle$  between a cue feature  $c \in \mathbf{X}$  and a selection function  $t \in T$ . We created a list of possible selection functions, given a cue  $c$ , maximizing for generality while being expressive. These are illustrated in Figure 2 and described below:

- **Ignore Local Future (A):** Ignore all features from the two lines after each occurrence of  $c$ .
- **Ignore All Future (B):** Ignore all features occurring after the first occurrence of  $c$ .
- **Ignore Local History (C):** Ignore all features in the two lines preceding each occurrence of  $c$ .
- **Ignore All History (D):** Ignore all features occurring only before the last occurrence of  $c$ .

We define an ensemble member  $E = \langle R, f_R \rangle$  - the ordered list of learned content selection rules  $R = [r_1, r_2, \dots]$  and a classifier  $f_C$  trained on instances transformed by those rules. Our final out-

<sup>4</sup>Future work may examine the interaction of jointly annotating multiple sparse social phenomena.

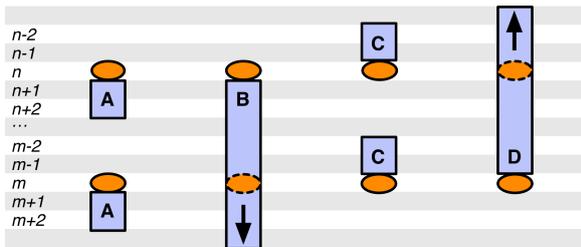

Figure 2: Effects of content selection rules, based on a cue feature (ovals) observed at lines  $m$  and  $n$ .

put of a trained model is a set of ensemble members  $\{E_1, \dots, E_k\}$ .

## 4.2 Algorithm

Our ensemble learning follows the paradigm of cross-validated committees (Parmanto et al., 1996), where  $k$  ensemble members are trained by subdividing our training data into  $k$  subfolds. For each ensemble classifier, cue rules  $R$  are generated on  $k - 1$  subfolds ( $\mathbf{Tr}_k$ ) and evaluated on the remaining subfold ( $\mathbf{Te}_k$ ). In practice, with 21 training documents, 7-fold cross-validation, and  $k = 3$  ensemble members, each generation set consists of 12 documents’ instances, while each evaluation set contains instances from 6 documents.

Our full algorithm is presented in Algorithm 1, and is broken into component parts for clarity. Algorithm 2 begins by measuring the baseline classifier’s ability to recognize minority-class labels. After training on  $\mathbf{Tr}_k$ , we measure the average probability assigned to the correct label of instances in  $\mathbf{Te}_k$ , but only for instances whose correct labels are minority classes (remember, because both  $\mathbf{Tr}_k$  and  $\mathbf{Te}_k$  are drawn from the overall  $\mathbf{Tr}$ , we have access to true class labels). We choose this subset of only minority instances, as we are not interested in optimizing to the majority class.

We next enumerate all rules that we wish to judge. To keep this problem tractable, we ignore features which do not occur in at least 5% of training instances. For the remaining features, we create a candidate rule for each possible pairing of features and selection functions. For each of these candidates, we test its utility by selecting content as if it were an actual rule, then building a new classifier (trained on the generation set) using instances that have been altered in that way. In the evaluation set, we measure the difference in probability of minority class labels being assigned cor-

rectly between the baseline and this altered space. This measure of an individual rule’s impact is described in Algorithm 3.

Once we have evaluated every possible rule once, we select the top-ranked rule and apply it to the feature set. We then iteratively progress through our now-ranked list of candidates, each time treating the newly filtered dataset as our new baseline. We search only top candidates for efficiency, following the fixed-width search methodology for feature selection in very high-dimensionality feature spaces (Gütlein et al., 2009). Each ensemble classifier is finally retrained on all training data, after applying the corresponding content selection rules to that data.

## 5 Prediction

Our prediction algorithm begins with a standard implementation of cross-validated committees (Parmanto et al., 1996), whose results are aggregated with a confidence voting method intended to favor rare labels (Erp et al., 2002). Cross-validated committees are an ensemble technique used to subsample training data to produce multiple hypotheses for classification. Each classifier produced by our cue-based transformation is trained on a subset of our training data. Each makes predictions on all test set instances, producing a distribution of confidence across possible labels. These values serve as inputs to a voting method to produce a final label for each instance.

Compared to other ensemble methods, cross-validated committees as described above are a good fit for our task, because of its unique unit of analysis. As thread-level analysis is the set of individual participants’ turns in a conversation, we risk overfitting if we sample from the same conversations for the training and testing sets. In contrast to standard bagging, hard sampling boundaries never train and test on instances drawn from the same conversation.

To aggregate the votes from members of this ensemble into a final prediction, we employ a variant on Selfridge’s Pandemonium (Selfridge, 1958). If a minority label is selected as the highest-confidence value in any classifier in our ensemble, it is selected. The majority label, by contrast, is only selected if it is the most likely prediction by all classifiers in our ensemble. Thus consensus is required to elect the majority class, and the strongest minority candidate is elected otherwise.

**In** : generation set  $\mathbf{Tr}_k$ , evaluation set  $\mathbf{Te}_k$   
**Out**: ensemble committee  $\{E_1 \dots E_k\}$   
**for**  $i = 1$  **to**  $k$  **do**  
     $R_{final} \leftarrow []$ ;  
     $\mathbf{X}_{freq} \leftarrow \{x \in \mathbf{X} \mid freq(x) \in \mathbf{Tr}_k > 5\%\}$ ;  
     $R \leftarrow \mathbf{X}_{freq} \times T$ ;  
     $R^* \leftarrow R$ ;  
    **repeat**  
         $P_{base} \leftarrow \text{EvaluateClassifier}(\mathbf{Tr}_k, \mathbf{Te}_k)$ ;  
         $\text{EvaluateRules}(P_{base}, \mathbf{Tr}_k, \mathbf{Te}_k, R^*)$ ;  
         $\mathbf{Tr}_k, \mathbf{Te}_k \leftarrow \text{ApplyRule}(R^*[0])$ ;  
         $R \leftarrow R - R^*[0]$ ;  
         $\Delta \leftarrow score(R^*[0])$ ;  
         $R_{final} \leftarrow R_{final} + R^*[0]$ ;  
         $R^* \leftarrow R[0 \dots 50]$ ;  
    **until**  $\Delta < threshold$ ;  
     $\mathbf{Tr}_{final} \leftarrow \mathbf{Tr}_k \cup \mathbf{Te}_k$ ;  
    **foreach**  $r \in R_{final}$  **do**  
         $\mathbf{Tr}_{final} \leftarrow \text{ApplyRule}(\mathbf{Tr}_{final}, r)$ ;  
    **end**  
    Train  $f(\bar{x} \rightarrow y)$  on  $\mathbf{Tr}_{final}$ ;  
**end**

**Algorithm 1:** LearnSelectionCues()

This approach is designed to bias the prediction of our machine learning algorithms in favor of minority classes in a coherent manner. If there is a plausible model that has been trained which recognizes the possibility of a rare label, it is used; the prediction only reverts to the majority class when no plausible minority label could be chosen. As validation of this technique, we compare our “minority pandemonium” approach against both typical pandemonium and standard sum-rule confidence voting (Erp et al., 2002).

### 5.1 Logistic Model Stumps

One characteristic of highly skewed data is that, while minority labels may be expressed in a number of different surface forms, there are many obvious cases in which they do not apply. These cases can actually be harmful to classification of borderline cases. Features that could be given high weight in marginal cases may be undervalued in “low-hanging fruit” easy cases. To remove those obvious instances, a very simple screening heuristic is often enough to eliminate frequent phenotypes of instances where the rare annotation is not present. Prior work has sometimes screened training data through obvious heuristic rules, espe-

**In** : generation set  $\mathbf{Tr}_k$ , evaluation set  $\mathbf{Te}_k$   
**Out**: minority class probability average  $P_{base}$   
Train  $f(\bar{x} \rightarrow y)$  on  $\mathbf{Tr}_k$ ;  
 $\mathbf{Te}_k^{min} \leftarrow \{Instance I \in \mathbf{Te}_k \mid y_I \neq \text{“NA”}\}$   
;  
 $P_{base} \leftarrow 0$ ;  
**foreach**  $Instance I \in \mathbf{Te}_k^{min}$  **do**  
     $P_{base} \leftarrow P_{base} + P(f(\bar{x}_I) = y_I)$   
**end**  
 $P_{base} = P_{base} / size(\mathbf{Te}_k^{min})$   
**Algorithm 2:** EvaluateClassifier()  
  
**In** :  $\mathbf{Tr}_k, \mathbf{Te}_k$ , rules  $R$ , base probability  $P_{base}$   
**Out**:  $R$  sorted on each rule’s improvement score  
**foreach**  $Rule r \in R$  **do**  
     $\mathbf{Tr}'_k, \mathbf{Te}'_k \leftarrow \text{ApplyRule}(\mathbf{Tr}_k, \mathbf{Te}_k, r)$ ;  
     $P_{alter} \leftarrow \text{EvaluateClassifier}(\mathbf{Tr}'_k, \mathbf{Te}'_k)$ ;  
     $score(r) \leftarrow P_{alter} - P_{base}$ ;  
**end**  
Sort  $R$  on  $score(r)$  from high to low;

cially in speech recognition; for instance, training speech recognition for words followed by a pause separately from words followed by another word (Franco et al., 2010), or training separate models based on gender (Jiang et al., 1999).

We achieve this instance screening by learning logistic model tree stumps (Landwehr et al., 2005), which allow us to quickly partition data if there is a particularly easy heuristic that can be learned to eliminate a large number of majority-class labels. One challenge of this approach is our underlying unigram feature space - tree-based algorithms are generally poor classifiers for the high-dimensionality, low-information features in a lexical feature space (Han et al., 2001). To compensate, we employ a smaller, denser set of binary features for tree stump screening: instance length thresholds and LIWC category membership.

First, we define a set of features that split based on the number of lines an instance contains, from 1 to 10 (only a tiny fraction of instances are more than 10 lines long). For example, a feature splitting on instances with lines  $\leq 2$  would be true for one- and two-line instances, and false for all others. Second, we define a feature for each category in the Linguistic Inquiry and Word Count dictionary (Tausczik and Pennebaker, 2010) - these broad classes of words allow for more balanced

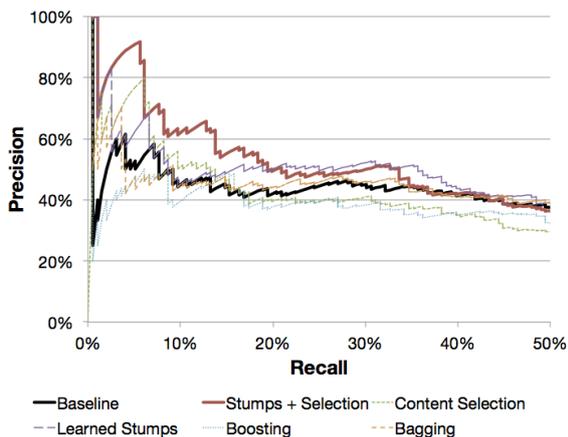

Figure 3: Precision/recall curves for algorithms. After 50% recall all models converge and there are no significant differences in performance.

splits than would unigrams alone. Each category’s feature is true if any word in that category was used at least once in that instance.

We exhaustively sweep this feature space, and report the most successful stump rules for each annotation task. In our other experiments, we report results with and without the best rule for this preprocessing step; we also measure its impact alone.

## 6 Experimental Results

All experiments were performed using LightSIDE (Mayfield and Rosé, 2013). We use a binary unigram feature space, and we perform 7-fold cross-validation. Instances from the same chat transcript never occur in both train and testing folds. Furthermore, we assume that threads have been disentangled already, and our experiments use gold standard thread structure. While this is not a trivial assumption, prior work has shown thread disentanglement to be manageable (Mayfield et al., 2012a); we consider it an acceptable simplifying assumption for our experiments. We compare our methods against baselines including a majority baseline, a baseline logistic regression classifier with L2 regularized features, and two common ensemble methods, AdaBoost (Freund and Schapire, 1996) and bagging (Breiman, 1996) with logistic regression base classifiers<sup>5</sup>.

Table 2 presents the best-performing result from each classification method. For self-empowerment recognition, all methods that we introduce are significant improvements in  $\kappa$ , the

<sup>5</sup>These methods usually use weak, unstable base classifiers; however, in our experiments, those performed poorly.

Table 2: Performance for baselines, common ensemble algorithms, and proposed methods. Statistically significant improvements over baseline are marked ( $p < .01$ , †;  $p < .05$ , \*;  $p < 0.1$ , +).

Method	Self		Other	
	%	$\kappa$	%	$\kappa$
Majority	79.3	.000	81.3	.000
LR Baseline	81.0	.367	81.0	.270
LR + Boosting	78.1	.325	78.5	.275
LR + Bagging	81.2	.352	<b>81.9</b>	.265
LR + Committee	81.0	.367	81.0	.270
Learned Stumps	<b>81.8*</b>	.385†	81.7	<b>.293+</b>
Content Selection	80.9	.389†	80.7	.282
Stumps+Selection	81.3	<b>.406†</b>	79.4	.254

Table 3: Performance of content-selection wrapped learners, for minority voting and two baseline voting methods.

Method	Self		Other	
	%	$\kappa$	%	$\kappa$
Pandemonium	80.3	.283	81.4	.239
Averaged	80.6	.304	<b>81.6</b>	.251
Minority Voting	<b>80.9†</b>	<b>.389†</b>	80.7	<b>.282</b>

measurement of agreement over chance, compared to all baselines. While accuracy remains stable, this is due to predictions shifting away from the majority class and towards minority classes. Our combined model using both logistic model tree stumps and content selection is significantly better than either alone ( $p < .01$ ). To compare the minority pandemonium voting method against baselines of simple pandemonium and summed confidence voting, Table 3 presents the results of content selection wrappers with each voting method. Minority voting is more effective compared to standard confidence voting, improving  $\kappa$  while modestly reducing accuracy; this is typical of a shift towards minority class predictions.

## 7 Discussion

These results show promise for our techniques, which are able to distinguish features of rare labels, previously awash in a sea of irrelevance. Figure 3 shows the impact of our rules as we tune to different levels of recall, with a large boost in precision when recall is not important; our model converges with the baseline for high-recall, low-precision tuning. This suggests that our method is particularly suitable for tasks where confident la-

Table 4: Cue rules commonly selected by the algorithm. Average improvement over the LR baseline is also shown.

<b>Self-Empowerment</b>		
Cue	Transformation	$\Delta\%$
<i>and,but</i>	Ignore Local Future	+5.0
<i>have</i>	Ignore All History	+4.3
<i>!</i>	Ignore All History	+4.2
<i>me,my</i>	Ignore All History	+3.4
<b>Other-Empowerment</b>		
Cue	Transformation	$\Delta\%$

<i>you</i>	Ignore Local History	+5.2
<i>'s</i>	Ignore Local History	+4.1
<i>that</i>	Ignore Local History	+3.9

being of a few instances is more important than labeling as many instances as possible. This is common when tasks have a high cost or carry high risk (for instance, providing real-time conversational supports with an agent, where inappropriate intervention could be disruptive). Other low-recall applications include exploration large corpora for exemplar instances, where the most confident predictions for a given label should be presented first for analyst use. In the rest of this section, we examine notable within-instance and per-instance rules selected by our methods. These rules are summarized in Tables 4 and 5.

For both self- and other-empowerment, we find pronoun rules that match the task (first-person and second-person pronouns for self-Empowerment and other-Empowerment respectively). In both tasks, we find cue rules that suppress the context preceding personal pronouns. These, as well as the possessive suffix *'s*, echo the per-instance effect of the *Self* and *You* splits, anticipating that what follows such a personal reference is likely to bear an evaluation of empowerment. Exclamation marks may indicate strong emotion - we find many instances where what precedes a line with an exclamation is more objective, and what follows includes an assessment. Conjunctions *but* and *and* are selected as cue rules suppressing the two lines that follow the occurrence - suggesting, as suspected, that connective discourse markers play a role in indicating empowerment (Fraser, 1999).

The best-performing stump splits for the Self-Empowerment annotation are *Line Length*  $\leq 1$  and the LIWC word-categories *Article*, *Swear*, and

Table 5: Best decision rules for logistic model stumps. Significant improvement ( $p < 0.05$ ) indicated with \*.

<b>Self-Empowerment</b>				
Split Rule	$\kappa$	$\Delta\kappa$	%	$\Delta\%$
Split $\leq 1$ *	0.385	+0.018	81.8	+0.8
LIWC-Article	0.379	+0.012	81.6	+0.6
LIWC-Swear *	0.376	+0.009	81.4	+0.4
LIWC-Self *	0.376	+0.009	81.5	+0.5
<b>Other-Empowerment</b>				
Split Rule	$\kappa$	$\Delta\kappa$	%	$\Delta\%$
LIWC-You	0.293	+0.023	81.7	+0.7
LIWC-Eating *	0.283	+0.013	81.6	+0.6
LIWC-Negate *	0.282	+0.012	82.3	+1.3
LIWC-Present	0.281	+0.011	81.6	+0.6

*Self*. The split on line length corresponds to the observation that longer instances provide greater opportunity for personal narrative self-assessment to occur (95% of single-line instances are labeled NA). The *Article* category may serve as a proxy for content length - article-less instances in our corpus include one-line social greetings and exchanges of contact information. *Swear* words may be a cue for awareness of self-empowerment - a recent study of women coping with illness reported that swearing in the presence of others, but not alone, was related to potentially harmful outcomes (Robbins et al., 2011). Among *other-* oriented split rules, *Eating* stands out as non-obvious, although medical literature has suggested a link between dietary behavior and empowerment attitudes in a study of women with cancer (Pinto et al., 2002).

## 8 Conclusion

We have demonstrated an algorithm for improving automated classification accuracy on highly skewed tasks for conversational data. This algorithm, particularly its focus on content selection, is rooted in the structural format of our data, which can generalize to many tasks involving conversational data. Our experiments show that this model significantly improves machine learning performance. Our algorithm is taking advantage of structural facets of discourse markers, lending basic sociolinguistic validity to its behavior. Though we have treated each of these rarely-occurring labels as independent thus far, in practice we know that this is not the case. Joint prediction of labels through structured modeling is an obvious next

step for improving classification accuracy.

This is an important step towards large-scale analysis of the impact of support groups on patients and caregivers. Our method can be used to confidently highlight occurrences of rare labels in large data sets. This has real-world implications for professional intervention in social conversational domains, especially in scenarios where such an intervention is likely to be associated with a high cost or high risk. With the construction of more accurate classifiers, we open the possibility of automating annotation on large conversational datasets, enabling new directions for researchers with domain expertise.

# Decentralized Entity-Level Modeling for Coreference Resolution

Greg Durrett, David Hall, and Dan Klein

Computer Science Division

University of California, Berkeley

{gdurrett, dlwh, klein}@cs.berkeley.edu

## Abstract

Efficiently incorporating entity-level information is a challenge for coreference resolution systems due to the difficulty of exact inference over partitions. We describe an end-to-end discriminative probabilistic model for coreference that, along with standard pairwise features, enforces structural agreement constraints between specified properties of coreferent mentions. This model can be represented as a factor graph for each document that admits efficient inference via belief propagation. We show that our method can use entity-level information to outperform a basic pairwise system.

## 1 Introduction

The inclusion of entity-level features has been a driving force behind the development of many coreference resolution systems (Luo et al., 2004; Rahman and Ng, 2009; Haghighi and Klein, 2010; Lee et al., 2011). There is no polynomial-time dynamic program for inference in a model with arbitrary entity-level features, so systems that use such features typically rely on making decisions in a pipelined manner and sticking with them, operating greedily in a left-to-right fashion (Rahman and Ng, 2009) or in a multi-pass, sieve-like manner (Raghunathan et al., 2010). However, such systems may be locked into bad coreference decisions and are difficult to directly optimize for standard evaluation metrics.

In this work, we present a new structured model of entity-level information designed to allow efficient inference. We use a log-linear model that can be expressed as a factor graph. Pairwise features appear in the model as unary factors, adjacent to nodes representing a choice of antecedent (or none) for each mention. Additional nodes model entity-level properties on a per-mention basis, and

structural agreement factors softly drive properties of coreferent mentions to agree with one another. This is a key feature of our model: mentions manage their partial membership in various coreference chains, so that information about entity-level properties is decentralized and propagated across individual mentions, and we never need to explicitly instantiate entities.

Exact inference in this factor graph is intractable, but efficient approximate inference can be carried out with belief propagation. Our model is the first discriminatively-trained model that both makes joint decisions over an entire document and models specific entity-level properties, rather than simply enforcing transitivity of pairwise decisions (Finkel and Manning, 2008; Song et al., 2012).

We evaluate our system on the dataset from the CoNLL 2011 shared task using three different types of properties: synthetic oracle properties, entity phi features (number, gender, animacy, and NER type), and properties derived from unsupervised clusters targeting semantic type information. In all cases, our transitive model of entity properties equals or outperforms our pairwise system and our reimplementation of a previous entity-level system (Rahman and Ng, 2009). Our final system is competitive with the winner of the CoNLL 2011 shared task (Lee et al., 2011).

## 2 Example

We begin with an example motivating our use of entity-level features. Consider the following excerpt concerning two famous auction houses:

*When looking for [art items], [people] go to [Sotheby's and Christie's] because [they]<sub>A</sub> believe [they]<sub>B</sub> can get the best price for [them].*

The first three mentions are all distinct entities, *they<sub>A</sub>* and *they<sub>B</sub>* refer to *people*, and *them* refers to *art items*. The three pronouns are tricky to resolve

automatically because they could at first glance resolve to any of the preceding mentions. We focus in particular on the resolution of *they*<sub>A</sub> and *them*. In order to correctly resolve *they*<sub>A</sub> to *people* rather than *Sotheby's and Christie's*, we must take advantage of the fact that *they*<sub>A</sub> appears as the subject of the verb *believe*, which is much more likely to be attributed to people than to auction houses.

Binding principles prevent *them* from attaching to *they*<sub>B</sub>. But how do we prevent it from choosing as its antecedent the next closest agreeing pronoun, *they*<sub>A</sub>? One way is to exploit the correct coreference decision we have already made, *they*<sub>A</sub> referring to *people*, since people are not as likely to have a price as art items are. This observation argues for enforcing agreement of entity-level semantic properties during inference, specifically properties relating to permitted semantic roles. Because even these six mentions have hundreds of potential partitions into coreference chains, we cannot search over partitions exhaustively, and therefore we must design our model to be able to use this information while still admitting an efficient inference scheme.

### 3 Models

We will first present our BASIC model (Section 3.1) and describe the features it incorporates (Section 3.2), then explain how to extend it to use transitive features (Sections 3.3 and 3.4).

Throughout this section, let  $x$  be a variable containing the words in a document along with any relevant precomputed annotation (such as parse information, semantic roles, etc.), and let  $n$  denote the number of mentions in a given document.

#### 3.1 BASIC Model

Our BASIC model is depicted in Figure 1 in standard factor graph notation. Each mention  $i$  has an associated random variable  $a_i$  taking values in the set  $\{1, \dots, i-1, \langle \text{new} \rangle\}$ ; this variable specifies mention  $i$ 's selected antecedent or indicates that it begins a new coreference chain. Let  $a = (a_1, \dots, a_n)$  be the vector of the  $a_i$ . Note that a set of coreference chains  $C$  (the final desired output) can be uniquely determined from  $a$ , but  $a$  is not uniquely determined by  $C$ .

We use a log linear model of the conditional distribution  $P(a|x)$  as follows:

$$P(a|x) \propto \exp \left( \sum_{i=1}^n \mathbf{w}^T \mathbf{f}_A(i, a_i, x) \right)$$

When looking for [art items], [people] go to [Sotheby's and Christie's] because [they]<sub>A</sub> believe [they]<sub>B</sub> can get the best price for [them].

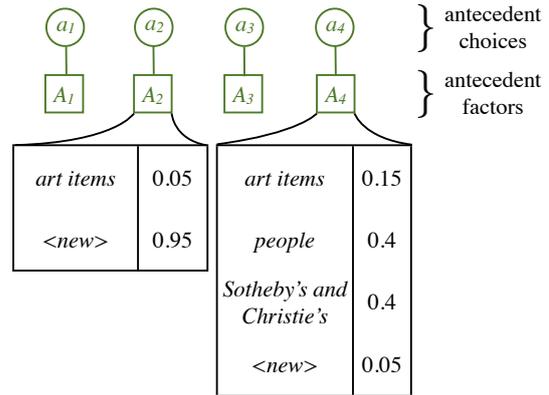

Figure 1: Our BASIC coreference model. A decision  $a_i$  is made independently for each mention about what its antecedent mention should be or whether it should start a new coreference chain. Each unary factor  $A_i$  has a log-linear form with features examining mention  $i$ , its selected antecedent  $a_i$ , and the document context  $x$ .

where  $\mathbf{f}_A(i, a_i, x)$  is a feature function that examines the coreference decision  $a_i$  for mention  $i$  with document context  $x$ ; note that this feature function can include pairwise features based on mention  $i$  and the chosen antecedent  $a_i$ , since information about each mention is contained in  $x$ .

Because the model factors completely over the individual  $a_i$ , these feature functions  $\mathbf{f}_A$  can be expressed as unary factors  $A_i$  (see Figure 1), with  $A_i(j) \propto \exp(\mathbf{w}^T \mathbf{f}_A(i, j, x))$ . Given a setting of  $\mathbf{w}$ , we can determine  $\hat{a} = \arg \max_a P(a|x)$  and then deterministically compute  $C(\hat{a})$ , the final set of coreference chains.

While the features of this model factor over coreference links, this approach differs from classical pairwise systems such as Bengtson and Roth (2008) or Stoyanov et al. (2010). Because potential antecedents compete with each other and with the non-anaphoric hypothesis, the choice of  $a_i$  actually represents a joint decision about  $i-1$  pairwise links, as opposed to systems that use a pairwise binary classifier and a separate agglomeration step, which consider one link at a time during learning. This approach is similar to the mention-ranking model of Rahman and Ng (2009).

#### 3.2 Pairwise Features

We now present the set of features  $\mathbf{f}_A$  used by our unary factors  $A_i$ . Each feature examines the an-

tecedent choice  $a_i$  of the current mention as well as the observed information  $x$  in the document. For each of the features we present, two conjoined versions are included: one with an indicator of the type of the current mention being resolved, and one with an indicator of the types of the current and antecedent mentions. Mention types are either NOMINAL, PROPER, or, if the mention is pronominal, a canonicalized version of the pronoun abstracting away case.<sup>1</sup>

Several features, especially those based on the precise constructs (apposition, etc.) and those incorporating phi feature information, are computed using the machinery in Lee et al. (2011). Other features were inspired by Song et al. (2012) and Rahman and Ng (2009).

**Anaphoricity features:** Indicator of anaphoricity, indicator on definiteness.

**Configurational features:** Indicator on distance in mentions (capped at 10), indicator on distance in sentences (capped at 10), does the antecedent c-command the current mention, are the two mentions in a subject/object construction, are the mentions nested, are the mentions in deterministic appositive/role appositive/predicate nominative/relative pronoun constructions.

**Match features:** Is one mention an acronym of the other, head match, head contained (each way), string match, string contained (each way), relaxed head match features from Lee et al. (2011).

**Agreement features:** Gender, number, animacy, and NER type of the current mention and the antecedent (separately and conjoined).

**Discourse features:** Speaker match conjoined with an indicator of whether the document is an article or conversation.

Because we use conjunctions of these base features together with the antecedent and mention type, our system can capture many relationships that previous systems hand-coded, especially regarding pronouns. For example, our system has access to features such as “*it* is non-anaphoric”, “*it* has as its antecedent a geopolitical entity”, or “*I* has as its antecedent *I* with the same speaker.”

<sup>1</sup>While this canonicalization could theoretically impair our ability to resolve, for example, reflexive pronouns, conjoining features with raw pronoun strings does not improve performance.

We experimented with synonymy and hypernymy features from WordNet (Miller, 1995), but these did not empirically improve performance.

### 3.3 TRANSITIVE Model

The BASIC model can capture many relationships between pairs of mentions, but cannot necessarily capture entity-level properties like those discussed in Section 2. We could of course model entities directly (Luo et al., 2004; Rahman and Ng, 2009), saying that each mention refers to some prior entity rather than to some prior mention. However, inference in this model would require reasoning about all possible partitions of mentions, which is computationally infeasible without resorting to severe approximations like a left-to-right inference method (Rahman and Ng, 2009).

Instead, we would like to try to preserve the tractability of the BASIC model while still being able to exploit entity-level information. To do so, we will allow *each mention* to maintain its own distributions over values for a number of properties; these properties could include gender, named-entity type, or semantic class. Then, we will require each anaphoric mention to agree with its antecedent on the value of each of these properties.

Our TRANSITIVE model which implements this scheme is shown in Figure 2. Each mention  $i$  has been augmented with a single property node  $p_i \in \{1, \dots, k\}$ . The unary  $P_i$  factors encode prior knowledge about the setting of each  $p_i$ ; these factors may be hard (*I* will not refer to a plural entity), soft (such as a distribution over named entity types output by an NER tagger), or practically uniform (e.g. the last name Smith does not specify a particular gender).

To enforce agreement of a particular property, we require a mention to have the same property value as its antecedent. That is, for mentions  $i$  and  $j$ , if  $a_i = j$ , we want to ensure that  $p_i$  and  $p_j$  agree. We can achieve this with the following set of structural equality factors:

$$E_{i-j}(a_i, p_i, p_j) = 1 - \mathbb{I}[a_i = j \wedge p_i \neq p_j]$$

In words, this factor is zero if both  $a_i = j$  and  $p_i$  disagrees with  $p_j$ . These equality factors essentially provide a mechanism by which these priors  $P_i$  can influence the coreference decisions: if, for example, the factors  $P_i$  and  $P_j$  disagree very strongly, choosing  $a_i \neq j$  will be preferred in order to avoid forcing one of  $p_i$  or  $p_j$  to take an undesirable value. Moreover, note that although  $a_i$

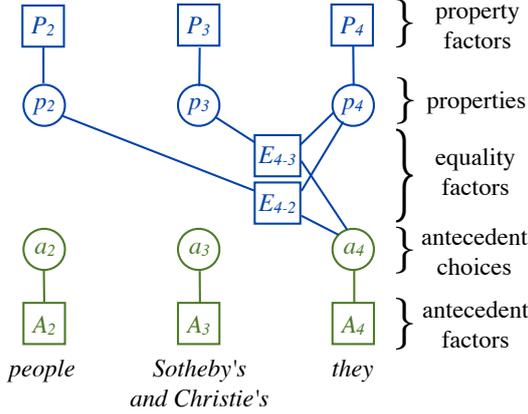

Figure 2: The factor graph for our TRANSITIVE coreference model. Each node  $a_i$  now has a property  $p_i$ , which is informed by its own unary factor  $P_i$ . In our example,  $a_4$  strongly indicates that mentions 2 and 4 are coreferent; the factor  $E_{4-2}$  then enforces equality between  $p_2$  and  $p_4$ , while the factor  $E_{4-3}$  has no effect.

only indicates a single antecedent, the transitive nature of the  $E$  factors forces  $p_i$  to agree with the  $p$  nodes of all other mentions likely to be in the same entity.

### 3.4 Property Projection

So far, our model as specified ensures agreement of our entity-level properties, but strictly enforcing agreement may not always be correct. Suppose that we are using named entity type as an entity-level property. Organizations and geo-political entities are two frequently confused and ambiguous tags, and in the gold-standard coreference chains it may be the case that a single chain contains instances of both. We might wish to learn that organizations and geo-political entities are “compatible” in the sense that we should forgive entities for containing both, but without losing the ability to reject a chain containing both organizations and people, for example.

To address these effects, we expand our model as indicated in Figure 3. As before, we have a set of properties  $p_i$  and agreement factors  $E_{ij}$ . On top of that, we introduce the notion of raw property values  $r_i \in \{1, \dots, k\}$  together with priors in the form of the  $R_i$  factors. The  $r_i$  and  $p_i$  could in principle have different domains, but for this work we take them to have the same domain. The  $P_i$  factors now have a new structure: they now represent a featurized projection of the  $r_i$  onto the  $p_i$ , which can now be thought of as “coreference-

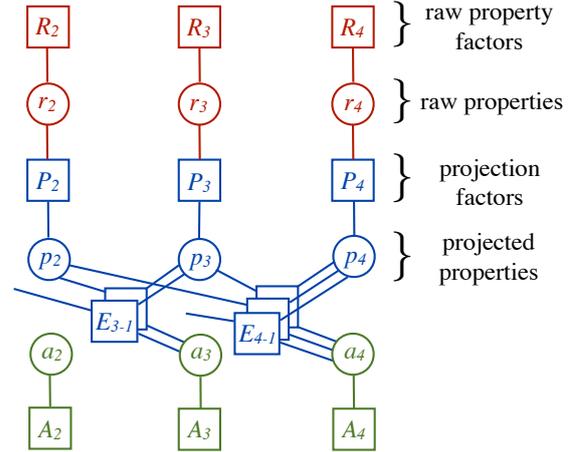

Figure 3: The complete factor graph for our TRANSITIVE coreference model. Compared to Figure 2, the  $R_i$  contain the raw cluster posteriors, and the  $P_i$  factors now project raw cluster values  $r_i$  into a set of “coreference-adapted” clusters  $p_i$  that are used as before. This projection allows mentions with different but compatible raw property values to coexist in the same coreference chain.

adapted” properties. The  $P_i$  factors are defined by  $P_i(p_i, r_i) \propto \exp(\mathbf{w}^T \mathbf{f}_P(p_i, r_i))$ , where  $\mathbf{f}_P$  is a feature vector over the projection of  $r_i$  onto  $p_i$ . While there are many possible choices of  $\mathbf{f}_P$ , we choose it to be an indicator of the values of  $p_i$  and  $r_i$ , so that we learn a fully-parameterized projection matrix.<sup>2</sup> The  $R_i$  are constant factors, and may come from an upstream model or some other source depending on the property being modeled.

Our description thus far has assumed that we are modeling only one type of property. In fact, we can use multiple properties for each mention by duplicating the  $r$  and  $p$  nodes and the  $R$ ,  $P$ , and  $E$  factors across each desired property. We index each of these by  $l \in \{1, \dots, m\}$  for each of  $m$  properties.

The final log-linear model is given by the following formula:

$$P(a|x) \propto \sum_{p,r} \left[ \left( \prod_{i,j,l} E_{l,i-j}(a_i, p_{li}, p_{lj}) \right) \left( \prod_{i,l} R_{li}(r_{li}) \right) \exp \left( \mathbf{w}^T \sum_i \left( \mathbf{f}_A(i, a_i, x) + \sum_l \mathbf{f}_P(p_{li}, r_{li}) \right) \right) \right]$$

where  $i$  and  $j$  range over mentions,  $l$  ranges over

<sup>2</sup>Initialized to zero (or small values), this matrix actually causes the transitive machinery to have no effect, since all posteriors over the  $p_i$  are flat and completely uninformative. Therefore, we regularize the weights of the indicators of  $p_i = r_i$  towards 1 and all other features towards 0 to give each raw cluster a preference for a distinct projected cluster.

each of  $m$  properties, and the outer sum indicates marginalization over all  $p$  and  $r$  variables.

## 4 Learning

Now that we have defined our model, we must decide how to train its weights  $\mathbf{w}$ . The first issue to address is one of the supervision provided. Our model traffics in sets of labels  $a$  which are more specified than gold coreference chains  $C$ , which give cluster membership for each mention but not antecedence. Let  $\mathcal{A}(C)$  be the set of labelings  $a$  that are consistent with a set of coreference chains  $C$ . For example, if  $C = \{\{1, 2, 3\}, \{4\}\}$ , then  $(\langle \text{new} \rangle, 1, 2, \langle \text{new} \rangle) \in \mathcal{A}(C)$  and  $(\langle \text{new} \rangle, 1, 1, \langle \text{new} \rangle) \in \mathcal{A}(C)$  but  $(\langle \text{new} \rangle, 1, \langle \text{new} \rangle, 3) \notin \mathcal{A}(C)$ , since this implies the chains  $C = \{\{1, 2\}, \{3, 4\}\}$

The most natural objective is a variant of standard conditional log-likelihood that treats the choice of  $a$  for the specified  $C$  as a latent variable to be marginalized out:

$$\ell(\mathbf{w}) = \sum_{i=1}^t \log \left( \sum_{a \in \mathcal{A}(C^i)} P(a|x^i) \right) \quad (1)$$

where  $(x^i, C^i)$  is the  $i$ th labeled training example. This optimizes for the 0-1 loss; however, we are much more interested in optimizing with respect to a coreference-specific loss function.

To this end, we will use softmax-margin (Gimpel and Smith, 2010), which augments the probability of each example with a term proportional to its loss, pushing the model to assign less mass to highly incorrect examples. We modify Equation 1 to use a new probability distribution  $P'$  instead of  $P$ , where  $P'(a|x^i) \propto P(a|x^i) \exp(l(a, C))$  and  $l(a, C)$  is a loss function. In order to perform inference efficiently,  $l(a, C)$  must decompose linearly across mentions:  $l(a, C) = \sum_{i=1}^n l(a_i, C)$ . Commonly-used coreference metrics such as MUC (Vilain et al., 1995) and  $B^3$  (Bagga and Baldwin, 1998) do not have this property, so we instead make use of a parameterized loss function that does and fit the parameters to give good performance. Specifically, we take

$$l(a, C) = \sum_{i=1}^n [c_1 \mathbb{I}(K_1(a_i, C)) + c_2 \mathbb{I}(K_2(a_i, C)) + c_3 \mathbb{I}(K_3(a_i, C))]$$

where  $c_1$ ,  $c_2$ , and  $c_3$  are real-valued weights,  $K_1$  denotes the event that  $a_i$  is falsely anaphoric when

it should be non-anaphoric,  $K_2$  denotes the event that  $a_i$  is falsely non-anaphoric when it should be anaphoric, and  $K_3$  denotes the event that  $a_i$  is correctly determined to be anaphoric but . These can be computed based on only  $a_i$  and  $C$ . By setting  $c_1$  low and  $c_2$  high relative to  $c_3$ , we can force the system to be less conservative about making anaphoricity decisions and achieve a better balance with the final coreference metrics.

Finally, we incorporate  $L_1$  regularization, giving us our final objective:

$$\ell(\mathbf{w}) = \sum_{i=1}^t \log \left( \sum_{a \in \mathcal{A}(C^i)} P'(a|x^i) \right) + \lambda \|\mathbf{w}\|_1$$

We optimize this objective using AdaGrad (Duchi et al., 2011); we found this to be faster and give higher performance than L-BFGS using  $L_2$  regularization (Liu and Nocedal, 1989). Note that because of the marginalization over  $\mathcal{A}(C^i)$ , even the objective for the BASIC model is not convex.

## 5 Inference

Inference in the BASIC model is straightforward. Given a set of weights  $\mathbf{w}$ , we can predict

$$\hat{a} = \arg \max_a P(a|x)$$

We then report the corresponding chains  $C(a)$  as the system output.<sup>3</sup> For learning, the gradient takes the standard form of the gradient of a log-linear model, a difference of expected feature counts under the gold annotation and under no annotation. This requires computing marginals  $P'(a_i|x)$  for each mention  $i$ , but because the model already factors this way, this step is easy.

The TRANSITIVE model is more complex. Exact inference is intractable due to the  $E$  factors that couple all of the  $a_i$  by way of the  $p_i$  nodes. However, we can compute approximate marginals for the  $a_i$ ,  $p_i$ , and  $r_i$  using belief propagation. BP has been effectively used on other NLP tasks (Smith and Eisner, 2008; Burkett and Klein, 2012), and is effective in cases such as this where the model is largely driven by non-loopy factors (here, the  $A_i$ ).

From marginals over each node, we can compute the necessary gradient and decode as before:

$$\hat{a} = \arg \max_a \hat{P}(a|x)$$

<sup>3</sup>One could use ILP-based decoding in the style of Finkel and Manning (2008) and Song et al. (2012) to attempt to explicitly find the optimal  $C$  with choice of  $a$  marginalized out, but we did not explore this option.

This corresponds to minimum-risk decoding with respect to the Hamming loss over antecedence predictions.

**Pruning.** The TRANSITIVE model requires instantiating a factor for each potential setting of each  $a_i$ . This factor graph grows quadratically in the size of the document, and even approximate inference becomes slow when a document contains over 200 mentions. Therefore, we use our BASIC model to prune antecedent choices for each  $a_i$  in order to reduce the size of the factor graph that we must instantiate. Specifically, we prune links between pairs of mentions that are of mention distance more than 100, as well as values for  $a_i$  that fall below a particular odds ratio threshold with respect to the best setting of that  $a_i$  in the BASIC model; that is, those for which

$$\log \left( \frac{P_{\text{BASIC}}(a_i|x)}{\max_j P_{\text{BASIC}}(a_i=j|x)} \right)$$

is below a cutoff  $\gamma$ .

## 6 Related Work

Our BASIC model is a mention-ranking approach resembling models used by Denis and Baldrige (2008) and Rahman and Ng (2009), though it is trained using a novel parameterized loss function. It is also similar to the MLN-JOINT(BF) model of Song et al. (2012), but we enforce the single-parent constraint at a deeper structural level, allowing us to treat non-anaphoricity symmetrically with coreference as in Denis and Baldrige (2007) and Stoyanov and Eisner (2012). The model of Fernandes et al. (2012) also uses the single-parent constraint structurally, but with learning via latent perceptron and ILP-based one-best decoding rather than logistic regression and BP-based marginal computation.

Our TRANSITIVE model is novel; while McCallum and Wellner (2004) proposed the idea of using attributes for mentions, they do not actually implement a model that does so. Other systems include entity-level information via handwritten rules (Raghunathan et al., 2010), induced rules (Yang et al., 2008), or features with learned weights (Luo et al., 2004; Rahman and Ng, 2011), but all of these systems freeze past coreference decisions in order to compute their entities.

Most similar to our entity-level approach is the system of Haghghi and Klein (2010), which

also uses approximate global inference; however, theirs is an unsupervised, generative system and they attempt to directly model multinomials over words in each mention. Their system could be extended to handle property information like we do, but our system has many other advantages, such as freedom from a pre-specified list of entity types, the ability to use multiple input clusterings, and discriminative projection of clusters.

## 7 Experiments

We use the datasets, experimental setup, and scoring program from the CoNLL 2011 shared task (Pradhan et al., 2011), based on the OntoNotes corpus (Hovy et al., 2006). We use the standard automatic parses and NER tags for each document. Our mentions are those output by the system of Lee et al. (2011); we also use their postprocessing to remove appositives, predicate nominatives, and singletons before evaluation. For each experiment, we report MUC (Vilain et al., 1995),  $B^3$  (Bagga and Baldwin, 1998), and CEAF<sub>e</sub> (Luo, 2005), as well as their average.

**Parameter settings.** We take the regularization constant  $\lambda = 0.001$  and the parameters of our surrogate loss  $(c_1, c_2, c_3) = (0.15, 2.5, 1)$  for all models.<sup>4</sup> All models are trained for 20 iterations. We take the pruning threshold  $\gamma = -2$ .

### 7.1 Systems

Besides our BASIC and TRANSITIVE systems, we evaluate a strictly pairwise system that incorporates property information by way of indicator features on the current mention’s most likely property value and the proposed antecedent’s most likely property value. We call this system PAIRPROPERTY; it is simply the BASIC system with an expanded feature set.

Furthermore, we compare against a LEFT-TORIGHT entity-level system like that of Rahman and Ng (2009).<sup>5</sup> Decoding now operates in a sequential fashion, with BASIC features computed as before and entity features computed for each mention based on the coreference decisions made thus far. Following Rahman and Ng (2009), features for each property indicate whether the cur-

<sup>4</sup>Additional tuning of these hyper parameters did not significantly improve any of the models under any of the experimental conditions.

<sup>5</sup>Unfortunately, their publicly-available system is closed-source and performs poorly on the CoNLL shared task dataset, so direct comparison is difficult.

rent mention agrees with no mentions in the antecedent cluster, at least one mention, over half of the mentions, or all of the mentions; antecedent clusters of size 1 or 2 fire special-cased features. These additional features beyond those in Rahman and Ng (2009) were helpful, but more involved conjunction schemes and fine-grained features were not. During training, entity features of both the gold and the prediction are computed using the Viterbi clustering of preceding mentions under the current model parameters.<sup>6</sup>

All systems are run in a two-pass manner: first, the BASIC model is run, then antecedent choices are pruned, then our second-round model is trained from scratch on the pruned data.<sup>7</sup>

## 7.2 Noisy Oracle Features

We first evaluate our model’s ability to exploit synthetic entity-level properties. For this experiment, mention properties are derived from corrupted oracle information about the true underlying coreference cluster. Each coreference cluster is assumed to have one underlying value for each of  $m$  coreference properties, each taking values over a domain  $D$ . Mentions then sample distributions over  $D$  from a Dirichlet distribution peaked around the true underlying value.<sup>8</sup> These posteriors are taken as the  $R_i$  for the TRANSITIVE model.

We choose this setup to reflect two important properties of entity-level information: first, that it may come from a variety of disparate sources, and second, that it may be based on the determinations of upstream models which produce posteriors naturally. A strength of our model is that it can accept such posteriors as input, naturally making use of this information in a model-based way.

Table 1 shows development results averaged across ten train-test splits with  $m = 3$  properties, each taking one of  $|D| = 5$  values. We emphasize that these parameter settings give fairly weak oracle information: a document may have hundreds of clusters, so even in the absence of noise these oracle properties do not have high dis-

<sup>6</sup>Using gold entities for training as in Rahman and Ng (2009) resulted in a lower-performing system.

<sup>7</sup>We even do this for the BASIC model, since we found that performance of the pruned and retrained model was generally higher.

<sup>8</sup>Specifically, the distribution used is a Dirichlet with  $\alpha = 3.5$  for the true underlying cluster and  $\alpha = 1$  for other values, chosen so that 25% of samples from the distribution did not have the correct mode. Though these parameters affect the quality of the oracle information, varying them did not change the relative performance of the different models.

NOISY ORACLE				
	MUC	$B^3$	CEAF <sub>e</sub>	Avg.
BASIC	61.96	70.66	47.30	59.97

LEFTTORIGHT	66.49	73.14	49.46	63.03
TRANSITIVE	<b>67.37</b>	<b>74.05</b>	<b>49.68</b>	<b>63.70</b>

Table 1: CoNLL metric scores for our four different systems incorporating noisy oracle data. This information helps substantially in all cases. Both entity-level models outperform the PAIRPROPERTY model, but we observe that the TRANSITIVE model is more effective than the LEFTTORIGHT model at using this information.

criminating power. Still, we see that all models are able to benefit from incorporating this information; however, our TRANSITIVE model outperforms both the PAIRPROPERTY model and the LEFTTORIGHT model. There are a few reasons for this: first, our model is able to directly use soft posteriors, so it is able to exploit the fact that more peaked samples from the Dirichlet are more likely to be correct. Moreover, our model can propagate information backwards in a document as well as forwards, so the effects of noise can be more easily mitigated. By contrast, in the LEFTTORIGHT model, if the first or second mention in a cluster has the wrong property value, features indicating high levels of property agreement will not fire on the next few mentions in those clusters.

## 7.3 Phi Features

As we have seen, our TRANSITIVE model can exploit high-quality entity-level features. How does it perform using real features that have been proposed for entity-level coreference?

Here, we use hard phi feature determinations extracted from the system of Lee et al. (2011). Named-entity type and animacy are both computed based on the output of a named-entity tagger, while number and gender use the dataset of Bergsma and Lin (2006). Once this information is determined, the PAIRPROPERTY and LEFTTORIGHT systems can compute features over it directly. In the TRANSITIVE model, each of the  $R_i$  factors places  $\frac{3}{4}$  of its mass on the determined label and distributes the remainder uniformly among the possible options.

Table 2 shows results when adding entity-level phi features on top of our BASIC pairwise system (which already contains pairwise features) and on top of an ablated BASIC system without pairwise

PHI FEATURES				
	MUC	$B^3$	CEAF <sub>e</sub>	Avg.
BASIC	61.96	70.66	47.30	59.97
LEFTTORIGHT	61.34	70.41	<b>47.64</b>	59.80
TRANSITIVE	<b>62.66</b>	<b>70.92</b>	46.88	<b>60.16</b>
PHI FEATURES (ABLATED BASIC)				
BASIC-PHI	59.45	69.21	46.02	58.23
PAIRPROPERTY	61.88	70.66	47.14	59.90
LEFTTORIGHT	61.42	70.53	<b>47.49</b>	59.81
TRANSITIVE	<b>62.23</b>	<b>70.78</b>	46.74	<b>59.92</b>

Table 2: CoNLL metric scores for our systems incorporating phi features. Our standard BASIC system already includes phi features, so no results are reported for PAIRPROPERTY. Here, our TRANSITIVE system does not give substantial improvement on the averaged metric. Over a baseline which does not include phi features, all systems are able to incorporate them comparably.

phi features. Our entity-level systems successfully captures phi features when they are not present in the baseline, but there is only slight benefit over pairwise incorporation, a result which has been noted previously (Luo et al., 2004).

#### 7.4 Clustering Features

Finally, we consider mention properties derived from unsupervised clusterings; these properties are designed to target semantic properties of nominals that should behave more like the oracle features than the phi features do.

We consider clusterings that take as input pairs  $(n, r)$  of a noun head  $n$  and a string  $r$  which contains the semantic role of  $n$  (or some approximation thereof) conjoined with its governor. Two different algorithms are used to cluster these pairs: a NAIVEBAYES model, where  $c$  generates  $n$  and  $r$ , and a CONDITIONAL model, where  $c$  is generated conditioned on  $r$  and then  $n$  is generated from  $c$ . Parameters for each can be learned with the expectation maximization (EM) algorithm (Dempster et al., 1977), with symmetry broken by a small amount of random noise at initialization.

Similar models have been used to learn sub-categorization information (Rooth et al., 1999) or properties of verb argument slots (Yao et al., 2011). We choose this kind of clustering for its relative simplicity and because it allows pronouns to have more informed properties (from their verbal context) than would be possible using a model that makes type-level decisions about nominals only. Though these specific cluster features are novel to coreference, previous work has used similar

types of fine-grained semantic class information (Hendrickx and Daelemans, 2007; Ng, 2007; Rahman and Ng, 2010). Other approaches incorporate information from other sources (Ponzetto and Strube, 2006) or compute heuristic scores for real-valued features based on a large corpus or the web (Dagan and Itai, 1990; Yang et al., 2005; Bansal and Klein, 2012).

We use four different clusterings in our experiments, each with twenty clusters: dependency-parse-derived NAIVEBAYES clusters, semantic-role-derived CONDITIONAL clusters, SRL-derived NAIVEBAYES clusters generating a NOVERB token when  $r$  cannot be determined, and SRL-derived NAIVEBAYES clusters with all pronoun tuples discarded. Examples of the latter clusters are shown in Figure 4. Each clustering is learned for 30 iterations of EM over English Gigaword (Graff et al., 2007), parsed with the Berkeley Parser (Petrov et al., 2006) and with SRL determined by Senna (Collobert et al., 2011).

Table 3 shows results of modeling these cluster properties. As in the case of oracle features, the PAIRPROPERTY and LEFTTORIGHT systems use the modes of the cluster posteriors, and the TRANSITIVE system uses the posteriors directly as the  $R_i$ . We see comparable performance from incorporating features in both an entity-level framework and a pairwise framework, though the TRANSI-

## 7.5 Final Results

Table 4 shows expanded results on our development sets for the different types of entity-level information we considered. We also show in Table 5 the results of our system on the CoNLL test set, and see that it performs comparably to the Stanford coreference system (Lee et al., 2011). Here, our TRANSITIVE system provides modest improvements over all our other systems.

Based on Table 4, our TRANSITIVE system appears to do better on MUC and  $B^3$  than on CEAF<sub>e</sub>. However, we found no simple way to change the relative performance characteristics of our various systems; notably, modifying the parameters of the loss function mentioned in Section 4 or changing it entirely did not trade off these three metrics but merely increased or decreased them in lockstep. Therefore, the TRANSITIVE system actually substantially improves over our baselines and is not

merely trading off metrics in a way that could be easily reproduced through other means.

## 8 Conclusion

In this work, we presented a novel coreference architecture that can both take advantage of standard pairwise features as well as use transitivity to enforce coherence of decentralized entity-level properties within coreference clusters. Our transitive system is more effective at using properties than a pairwise system and a previous entity-level system, and it achieves performance comparable to that of the Stanford coreference resolution system, the winner of the CoNLL 2011 shared task.

## Abstract

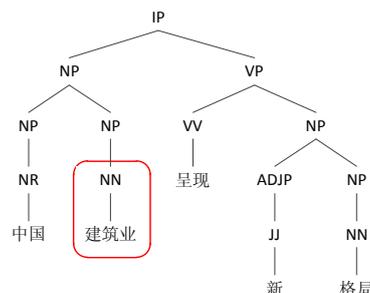

Characters play an important role in the Chinese language, yet computational processing of Chinese has been dominated by word-based approaches, with leaves in syntax trees being words. We investigate Chinese parsing from the character-level, extending the notion of phrase-structure trees by annotating internal structures of words. We demonstrate the importance of character-level information to Chinese processing by building a joint segmentation, part-of-speech (POS) tagging and phrase-structure parsing system that integrates character-structure features. Our joint system significantly outperforms a state-of-the-art word-based baseline on the standard CTB5 test, and gives the best published results for Chinese parsing.

## 1 Introduction

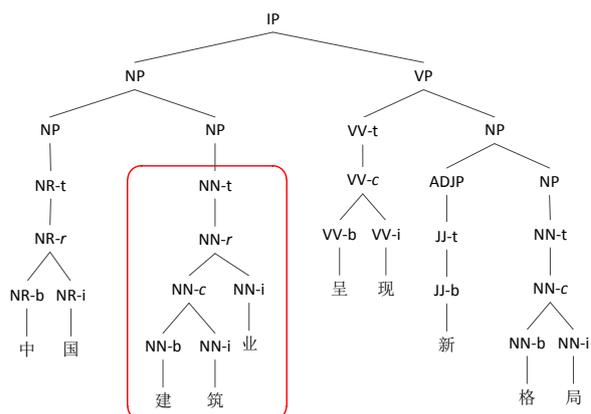

Characters play an important role in the Chinese language. They act as basic phonetic, morpho-syntactic and semantic units in a Chinese sentence. Frequently-occurring character sequences that express certain meanings can be treated as words, while most Chinese words have syntactic structures. For example, Figure 1(b) shows the structure of the word “建筑业 (construction and building industry)”, where the characters “建 (construction)” and “筑 (building)” form a coordination, and modify the character “业 (industry)”.

However, computational processing of Chinese is typically based on words. Words are treated as the atomic units in syntactic parsing, machine translation, question answering and other NLP tasks. Manually annotated corpora, such as the Chinese Treebank (CTB) (Xue et al., 2005), usually have words as the basic syntactic elements

\*Email correspondence.

(a) CTB-style word-based syntax tree for “中国 (China) 建筑业 (architecture industry) 呈现 (show) 新 (new) 格局 (pattern)”.

(b) character-level syntax tree with hierarchal word structures for “中 (middle) 国 (nation) 建 (construction) 筑 (building) 业 (industry) 呈 (present) 现 (show) 新 (new) 格 (style) 局 (situation)”.

Figure 1: Word-based and character-level phrase-structure trees for the sentence “中国建筑业呈现新格局 (China’s architecture industry shows new patterns)”, where “l”, “r”, “c” denote the directions of head characters (see section 2).

(Figure 1(a)). This form of annotation does not give character-level syntactic structures for words, a source of linguistic information that is more fundamental and less sparse than atomic words.

In this paper, we investigate Chinese syntactic parsing with character-level information by extending the notation of phrase-structure

(constituent) trees, adding recursive structures of characters for words. We manually annotate the structures of 37,382 words, which cover the entire CTB5. Using these annotations, we transform CTB-style constituent trees into character-level trees (Figure 1(b)). Our word structure corpus, together with a set of tools to transform CTB-style trees into character-level trees, is released at <https://github.com/zhangmeishan/wordstructures>. Our annotation work is in line with the work of Vadas and Curran (2007) and Li (2011), which provide extended annotations of Penn Treebank (PTB) noun phrases and CTB words (on the morphological level), respectively.

We build a character-based Chinese parsing model to parse the character-level syntax trees. Given an input Chinese sentence, our parser produces its character-level syntax trees (Figure 1(b)). With richer information than word-level trees, this form of parse trees can be useful for all the aforementioned Chinese NLP applications.

With regard to task of parsing itself, an important advantage of the character-level syntax trees is that they allow word segmentation, part-of-speech (POS) tagging and parsing to be performed jointly, using an efficient CKY-style or shift-reduce algorithm. Luo (2003) exploited this advantage by adding flat word structures without manually annotation to CTB trees, and building a generative character-based parser. Compared to a pipeline system, the advantages of a joint system include reduction of error propagation, and the integration of segmentation, POS tagging and syntax features. With hierarchical structures and head character information, our annotated words are more informative than flat word structures, and hence can bring further improvements to phrase-structure parsing.

To analyze word structures in addition to phrase structures, our character-based parser naturally performs joint word segmentation, POS tagging and parsing jointly. Our model is based on the discriminative shift-reduce parser of Zhang and Clark (2009; 2011), which is a state-of-the-art word-based phrase-structure parser for Chinese. We extend their shift-reduce framework, adding more transition actions for word segmentation and POS tagging, and defining novel features that capture character information. Even when trained using character-level syntax trees with flat word structures, our joint parser outperforms a strong pipelined baseline that consists of a state-of-the-

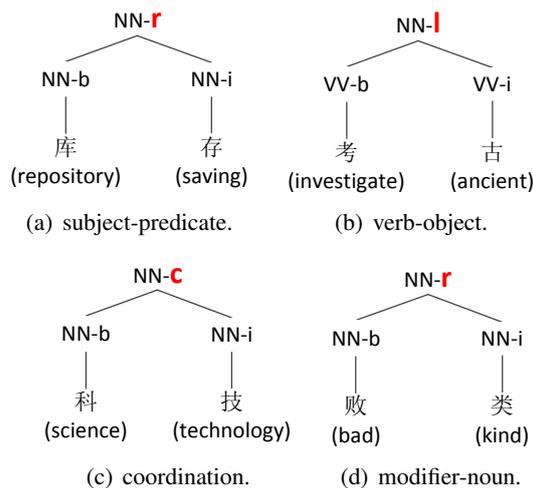

Figure 2: Inner word structures of “库存 (repository)”, “考古 (archaeology)”, “科技 (science and technology)” and “败类 (degenerate)”.

art joint segmenter and POS tagger, and our baseline word-based parser. Our word annotations lead to further improvements to the joint system, especially for phrase-structure parsing accuracy.

Our parser work falls in line with recent work of joint segmentation, POS tagging and parsing (Hatori et al., 2012; Li and Zhou, 2012; Qian and Liu, 2012). Compared with related work, our model gives the best published results for joint segmentation and POS tagging, as well as joint phrase-structure parsing on standard CTB5 evaluations. With linear-time complexity, our parser is highly efficient, processing over 30 sentences per second with a beam size of 16. An open release of the parser is freely available at <http://sourceforge.net/projects/zpar/>, version 0.6.

## 2 Word Structures and Syntax Trees

The Chinese language is a character-based language. Unlike alphabetical languages, Chinese characters convey meanings, and the meaning of most Chinese words takes roots in their character. For example, the word “计算机 (computer)” is composed of the characters “计 (count)”, “算 (calculate)” and “机 (machine)”. An informal name of “computer” is “电脑”, which is composed of “电 (electronic)” and “脑 (brain)”.

Chinese words have internal structures (Xue, 2001; Ma et al., 2012). The way characters interact within words can be similar to the way words interact within phrases. Figure 2 shows the structures of the four words “库存 (repository)”, “考古

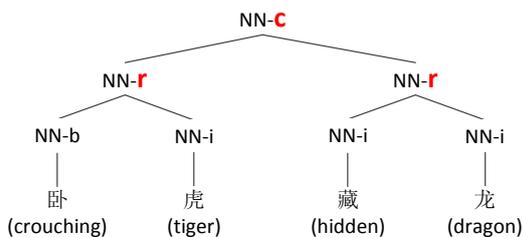

Figure 3: Character-level word structure of “卧虎藏龙 (crouching tiger hidden dragon)”.

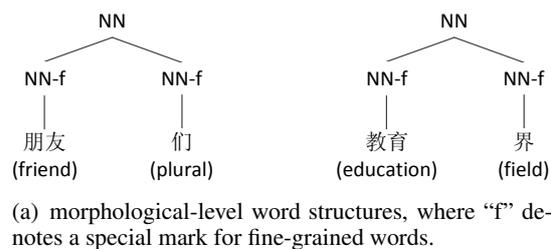

(archaeology)”, “科技 (science and technology)” and “败类 (degenerate)”, which demonstrate four typical syntactic structures of two-character words, including subject-predicate, verb-object, coordination and modifier-noun structures. Multi-character words can also have recursive syntactic structures. Figure 3 illustrates the structure of the word “卧虎藏龙 (crouching tiger hidden dragon)”, which is composed of two subwords “卧虎 (crouching tiger)” and “藏龙 (hidden dragon)”, both having a modifier-noun structure.

The meaning of characters can be a useful source of information for computational processing of Chinese, and some recent work has started to exploit this information. Zhang and Clark (2010) found that the first character in a Chinese word is a useful indicator of the word’s POS. They made use of this information to help joint word segmentation and POS tagging.

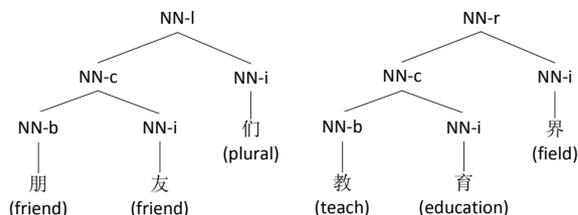

Li (2011) studied the morphological structures of Chinese words, showing that 35% percent of the words in CTB5 can be treated as having morphemes. Figure 4(a) illustrates the morphological structures of the words “朋友们 (friends)” and “教育界 (educational world)”, in which the characters “们 (plural)” and “界 (field)” can be treated as suffix morphemes. They studied the influence of such morphology to Chinese dependency parsing (Li and Zhou, 2012).

The aforementioned work explores the influence of particular types of characters to Chinese processing, yet not the full potentials of complete word structures. We take one step further in this line of work, annotating the full syntactic structures of 37,382 Chinese words in the form of Figure 2 and Figure 3. Our annotation covers the entire vocabulary of CTB5. In addition to difference in coverage (100% vs 35%), our annotation is structurally more informative than that of Li (2011), as illustrated in Figure 4(b).

Our annotations are binarized recursive word

(a) morphological-level word structures, where “f” denotes a special mark for fine-grained words.

(b) character-level word structures.

Figure 4: Comparison between character-level and morphological-level word structures.

structures. For each word or subword, we specify its POS and head direction. We use “l”, “r” and “c” to indicate the “left”, “right” and “coordination” head directions, respectively. The “coordination” direction is mostly used in coordination structures, while a very small number of transliteration words, such as “奥巴马 (Obama)” and “洛杉矶 (Los Angeles)”, have flat structures, and we use “coordination” for their left binarization. For leaf characters, we follow previous work on word segmentation (Xue, 2003; Ng and Low, 2004), and use “b” and “i” to indicate the beginning and non-beginning characters of a word, respectively.

The vast majority of words do not have structural ambiguities. However, the structures of some words may vary according to different POS. For example, “制服” means “dominate” when it is tagged as a verb, of which the head is the left character; the same word means “uniform dress” when tagged as a noun, of which the head is the right character. Thus the input of the word structure annotation is a word together with its POS. The annotation work was conducted by three persons, with one person annotating the entire corpus, and the other two checking the annotations.

Using our annotations, we can extend CTB-style syntax trees (Figure 1(a)) into *character-level* trees (Figure 1(b)). In particular, we mark the original nodes that represent POS tags in CTB-style trees with “-t”, and insert our word structures as unary subnodes of the “-t” nodes. For the rest of the paper, we refer to the “-t” nodes as *full-word nodes*, all nodes above full-word nodes as *phrase*

nodes, and all nodes below full-word nodes as *subword nodes*.

Our character-level trees contain additional syntactic information, which are potentially useful to Chinese processing. For example, the head characters of words can be populated up to phrase-level nodes, and serve as an additional source of information that is less sparse than head words. In this paper, we build a parser that yields character-level trees from raw character sequences. In addition, we use this parser to study the effects of our annotations to character-based statistical Chinese parsing, showing that they are useful in improving parsing accuracies.

### 3 Character-based Chinese Parsing

To produce character-level trees for Chinese NLP tasks, we develop a character-based parsing model, which can jointly perform word segmentation, POS tagging and *phrase-structure* parsing. To our knowledge, this is the first work to develop a transition-based system that jointly performs the above three tasks. Trained using annotated word structures, our parser also analyzes the internal structures of Chinese words.

Our character-based Chinese parsing model is based on the work of Zhang and Clark (2009), which is a transition-based model for lexicalized constituent parsing. They use a beam-search decoder so that the transition action sequence can be globally optimized. The averaged perceptron with early-update (Collins and Roark, 2004) is used to train the model parameters. Their transition system contains four kinds of actions: (1) *SHIFT*, (2) *REDUCE-UNARY*, (3) *REDUCE-BINARY* and (4) *TERMINATE*. The system can provide binarized CFG trees in Chomsky Norm Form, and they present a reversible conversion procedure to map arbitrary CFG trees into binarized trees.

In this work, we remain consistent with their work, using the head-finding rules of Zhang and Clark (2008), and the same binarization algorithm.<sup>1</sup> We apply the same beam-search algorithm for decoding, and employ the averaged perceptron with early-update to train our model.

We make two extensions to their work to enable joint segmentation, POS tagging and phrase-structure parsing from the character level. First, we modify the actions of the transition system for

<sup>1</sup>We use a left-binarization process for flat word structures that contain more than two characters.

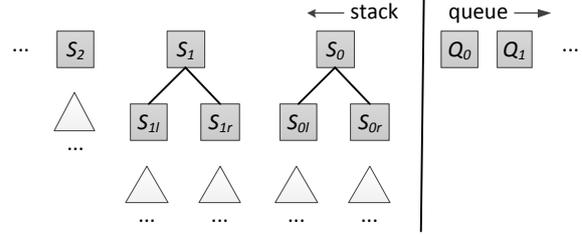

Figure 5: A state in a transition-based model.

parsing the inner structures of words. Second, we extend the feature set for our parsing problem.

#### 3.1 The Transition System

In a transition-based system, an input sentence is processed in a linear left-to-right pass, and the output is constructed by a state-transition process. We learn a model for scoring the transition  $A_i$  from one state  $ST_i$  to the next  $ST_{i+1}$ . As shown in Figure 5, a state  $ST$  consists of a stack  $S$  and a queue  $Q$ , where  $S = (\dots, S_1, S_0)$  contains partially constructed parse trees, and  $Q = (Q_0, Q_1, \dots, Q_{n-j}) = (c_j, c_{j+1}, \dots, c_n)$  is the sequence of input characters that have not been processed. The candidate transition action  $A$  at each step is defined as follows:

- *SHIFT-SEPARATE* ( $t$ ): remove the head character  $c_j$  from  $Q$ , pushing a subword node  $\frac{S'.2}{c_j}$  onto  $S$ , assigning  $S'.t = t$ . Note that the parse tree  $S_0$  must correspond to a full-word or a phrase node, and the character  $c_j$  is the first character of the next word. The argument  $t$  denotes the POS of  $S'$ .
- *SHIFT-APPEND*: remove the head character  $c_j$  from  $Q$ , pushing a subword node  $\frac{S'}{c_j}$  onto  $S$ .  $c_j$  will eventually be combined with all the subword nodes on top of  $S$  to form a word, and thus we must have  $S'.t = S_0.t$ .
- *REDUCE-SUBWORD* ( $d$ ): pop the top two nodes  $S_0$  and  $S_1$  off  $S$ , pushing a new subword node  $\frac{S'}{S_1 S_0}$  onto  $S$ . The argument  $d$  denotes the head direction of  $S'$ , of which the value can be “left”, “right” or “coordination”.<sup>3</sup> Both  $S_0$  and  $S_1$  must be subword nodes and  $S'.t = S_0.t = S_1.t$ .

<sup>2</sup>We use this notation for a compact representation of a tree node, where the numerator represents a father node, and the denominator represents the children.

<sup>3</sup>For the head direction “coordination”, we extract the head character from the left node.

Category	Feature templates	When to Apply
Structure features	$S_{0ntl} S_{0nwl} S_{1ntl} S_{1nwl} S_{2ntl} S_{2nwl} S_{3ntl} S_{3nwl}$ , $Q_0c Q_1c Q_2c Q_3c Q_0c \cdot Q_1c Q_1c \cdot Q_2c Q_2c \cdot Q_3c$ , $S_{0l}twl S_{0r}twl S_{0u}twl S_{1l}twl S_{1r}twl S_{1u}twl$ , $S_{0nw} \cdot S_{1nw} S_{0nw} \cdot S_{1nl} S_{0nl} \cdot S_{1nw} S_{0nl} \cdot S_{1nl}$ , $S_{0nw} \cdot Q_0c S_{0nl} \cdot Q_0c S_{1nw} \cdot Q_0c S_{1nl}Q_0c$ , $S_{0nl} \cdot S_{1nl} \cdot S_{2nl} S_{0nw} \cdot S_{1nl} \cdot S_{2nl} S_{0nl} \cdot S_{1nw} \cdot S_{2nl} S_{0nl} \cdot S_{1nl} \cdot S_{2nw}$ , $S_{0nw} \cdot S_{1nl} \cdot Q_0c S_{0nl} \cdot S_{1nw} \cdot Q_0c S_{0nl} \cdot S_{1nl} \cdot Q_0c$ , $S_{0ncl} S_{0nctl} S_{0nct} S_{1ncl} S_{1nctl} S_{1nct}$ , $S_{2ncl} S_{2nctl} S_{2nct} S_{3ncl} S_{3nctl} S_{3nct}$ , $S_{0nc} \cdot S_{1nc} S_{0ncl} \cdot S_{1nl} S_{0nl} \cdot S_{1ncl} S_{0ncl} \cdot S_{1ncl}$ , $S_{0nc} \cdot Q_0c S_{0nl} \cdot Q_0c S_{1nc} \cdot Q_0c S_{1nl} \cdot Q_0c$ , $S_{0nc} \cdot S_{1nc} \cdot Q_0c S_{0ncl} \cdot S_{1nc} \cdot Q_0c \cdot Q_1c$	All
	$\text{start}(S_0w) \cdot \text{start}(S_1w) \text{ start}(S_0w) \cdot \text{end}(S_1w)$ , $\text{indict}(S_1wS_0w) \cdot \text{len}(S_1wS_0w) \text{ indict}(S_1wS_0w, S_0t) \cdot \text{len}(S_1wS_0w)$	REDUCE-SUBWORD
String features	$t_{-1} \cdot t_0 \quad t_{-2} \cdot t_{-1}t_0 \quad w_{-1} \cdot t_0 \quad c_0 \cdot t_0 \quad \text{start}(w_{-1}) \cdot t_0 \quad c_{-1} \cdot c_0 \cdot t_{-1} \cdot t_0$ ,	SHIFT-SEPARATE
	$w_{-1} \quad w_{-2} \cdot w_{-1} \quad w_{-1}$ , where $\text{len}(w_{-1}) = 1 \quad \text{end}(w_{-1}) \cdot c_0$ , $\text{start}(w_{-1}) \cdot \text{len}(w_{-1}) \quad \text{end}(w_{-1}) \cdot \text{len}(w_{-1}) \quad \text{start}(w_{-1}) \cdot \text{end}(w_{-1})$ , $w_{-1} \cdot c_0 \quad \text{end}(w_{-2}) \cdot w_{-1} \quad \text{start}(w_{-1}) \cdot c_0 \quad \text{end}(w_{-2}) \cdot \text{end}(w_{-1})$ , $w_{-1} \cdot \text{len}(w_{-2}) \quad w_{-2} \cdot \text{len}(w_{-1}) \quad w_{-1} \cdot t_{-1} \quad w_{-1} \cdot t_{-2} \quad w_{-1} \cdot t_{-1} \cdot c_0$ , $w_{-1} \cdot t_{-1} \cdot \text{end}(w_{-2}) \quad c_{-2} \cdot c_{-1} \cdot c_0 \cdot t_{-1}$ , where $\text{len}(w_{-1}) = 1 \quad \text{end}(w_{-1}) \cdot t_{-1}$ , $c \cdot t_{-1} \cdot \text{end}(w_{-1})$ , where $c \in w_{-1}$ and $c \neq \text{end}(w_{-1})$	REDUCE-WORD
	$c_0 \cdot t_{-1} \quad c_{-1} \cdot c_0 \quad \text{start}(w_{-1}) \cdot c_0t_{-1} \quad c_{-1} \cdot c_0 \cdot t_{-1}$	SHIFT-APPEND

Table 1: Feature templates for the character-level parser. The function  $\text{start}(\cdot)$ ,  $\text{end}(\cdot)$  and  $\text{len}(\cdot)$  denote the first character, the last character and the length of a word, respectively.

- REDUCE-WORD: pop the top node  $S_0$  off  $S$ , pushing a full-word node  $\frac{S'}{S_0}$  onto  $S$ . This reduce action generates a full-word node from  $S_0$ , which must be a subword node.
- REDUCE-BINARY ( $d, l$ ): pop the top two nodes  $S_0$  and  $S_1$  off  $S$ , pushing a binary phrase node  $\frac{S'}{S_1 S_0}$  onto  $S$ . The argument  $l$  denotes the constituent label of  $S'$ , and the argument  $d$  specifies the lexical head direction of  $S'$ , which can be either “left” or “right”. Both  $S_0$  and  $S_1$  must be a full-word node or a phrase node.
- REDUCE-UNARY ( $l$ ): pop the top node  $S_0$  off  $S$ , pushing a unary phrase node  $\frac{S'}{S_0}$  onto  $S$ .  $l$  denotes the constituent label of  $S'$ .
- TERMINATE: mark parsing complete.

Compared to set of actions in our baseline transition-based phrase-structure parser, we have made three major changes. First, we split the original SHIFT action into SHIFT-SEPARATE ( $t$ ) and SHIFT-APPEND, which jointly perform the word segmentation and POS tagging tasks. Second, we add an extra REDUCE-SUBWORD ( $d$ ) operation, which is used for parsing the inner struc-

tures of words. Third, we add REDUCE-WORD, which applies a unary rule to mark a completed subword node as a full-word node. The new node corresponds to a unary “-t” node in Figure 1(b).

### 3.2 Features

Table 1 shows the feature templates of our model. The feature set consists of two categories: (1) structure features, which encode the structural information of subwords, full-words and phrases. (2) string features, which encode the information of neighboring characters and words.

For the structure features, the symbols  $S_0, S_1, S_2, S_3$  represent the top four nodes on the stack;  $Q_0, Q_1, Q_2, Q_3$  denote the first four characters in the queue;  $S_{0l}, S_{0r}, S_{0u}$  represent the left, right child for a binary branching  $S_0$ , and the single child for a unary branching  $S_0$ , respectively;  $S_{1l}, S_{1r}, S_{1u}$  represent the left, right child for a binary branching  $S_1$ , and the single child for a unary branching  $S_1$ , respectively;  $n$  represents the type for a node; it is a binary value that indicates whether the node is a subword node;  $c, w, t$  and  $l$  represent the head character, word (or subword), POS tag and constituent label of a node, respectively. The structure features are mostly taken

from the work of Zhang and Clark (2009). The feature templates in bold are novel, are designed to encode head character information. In particular, the **indict** function denotes whether a word is in a tag dictionary, which is collected by extracting all multi-character subwords that occur more than five times in the training corpus.

For string features,  $c_0$ ,  $c_{-1}$  and  $c_{-2}$  represent the current character and its previous two characters, respectively;  $w_{-1}$  and  $w_{-2}$  represent the previous two words to the current character, respectively;  $t_0$ ,  $t_{-1}$  and  $t_{-2}$  represent the POS tags of the current word and the previous two words, respectively. The string features are used for word segmentation and POS tagging, and are adapted from a state-of-the-art joint segmentation and tagging model (Zhang and Clark, 2010).

In summary, our character-based parser contains the word-based features of constituent parser presented in Zhang and Clark (2009), the word-based and shallow character-based features of joint word segmentation and POS tagging presented in Zhang and Clark (2010), and additionally the deep character-based features that encode word structure information, which are the first presented by this paper.

## 4 Experiments

### 4.1 Setting

We conduct our experiments on the CTB5 corpus, using the standard split of data, with sections 1–270,400–931 and 1001–1151 for training, sections 301–325 for system development, and sections 271–300 for testing. We apply the same pre-processing step as Harper and Huang (2011), so that the non-terminal yield unary chains are collapsed to single unary rules.

Since our model can jointly process word segmentation, POS tagging and phrase-structure parsing, we evaluate our model for the three tasks, respectively. For word segmentation and POS tagging, standard metrics of word precision, recall and F-score are used, where the tagging accuracy is the joint accuracy of word segmentation and POS tagging. For phrase-structure parsing, we use the standard `parseval` evaluation metrics on bracketing precision, recall and F-score. As our constituent trees are based on characters, we follow previous work and redefine the boundary of a constituent span by its start and end characters. In addition, we evaluate the performance of word

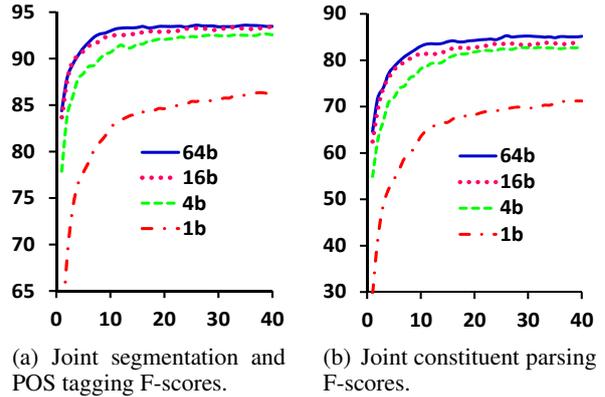

Figure 6: Accuracies against the training epoch for joint segmentation and tagging as well as joint phrase-structure parsing using beam sizes 1, 4, 16 and 64, respectively.

structures, using the word precision, recall and F-score metrics. A word structure is correct only if the word and its internal structure are both correct.

### 4.2 Development Results

Figure 6 shows the accuracies of our model using different beam sizes with respect to the training epoch. The performance of our model increases as the beam size increases. The amount of increases becomes smaller as the size of the beam grows larger. Tested using gcc 4.7.2 and Fedora 17 on an Intel Core i5-3470 CPU (3.20GHz), the decoding speeds are 318.2, 98.0, 30.3 and 7.9 sentences per second with beam size 1, 4, 16 and 64, respectively. Based on this experiment, we set the beam size 64 for the rest of our experiments.

The character-level parsing model has the advantage that deep character information can be extracted as features for parsing. For example, the head character of a word is exploited in our model. We conduct feature ablation experiments to evaluate the effectiveness of these features. We find that the parsing accuracy decreases about 0.6% when the head character related features (the bold feature templates in Table 1) are removed, which demonstrates the usefulness of these features.

### 4.3 Final Results

In this section, we present the final results of our model, and compare it to two baseline systems, a pipelined system and a joint system that is trained with automatically generated flat words structures.

The baseline pipelined system consists of the joint segmentation and tagging model proposed by

	Task	P	R	F
Pipeline	Seg	97.35	98.02	97.69
	Tag	93.51	94.15	93.83
	Parse	81.58	82.95	82.26
Flat word structures	Seg	97.32	98.13	97.73
	Tag	94.09	94.88	94.48
	Parse	83.39	83.84	83.61
Annotated word structures	Seg	97.49	98.18	<b>97.84</b>
	Tag	94.46	95.14	<b>94.80</b>
	Parse	84.42	84.43	<b>84.43</b>
	WS	94.02	94.69	94.35

Table 2: Final results on test corpus.

Zhang and Clark (2010), and the phrase-structure parsing model of Zhang and Clark (2009). Both models give state-of-the-art performances, and are freely available.<sup>4</sup> The model for joint segmentation and POS tagging is trained with a 16-beam, since it achieves the best performance. The phrase-structure parsing model is trained with a 64-beam. We train the parsing model using the automatically generated POS tags by 10-way jackknifing, which gives about 1.5% increases in parsing accuracy when tested on automatic segmented and POS tagged inputs.

The joint system trained with flat word structures serves to test the effectiveness of our joint parsing system over the pipelined baseline, since flat word structures do not contain additional sources of information over the baseline. It is also used to test the usefulness of our annotation in improving parsing accuracy.

Table 2 shows the final results of our model and the two baseline systems on the test data. We can see that both character-level joint models outperform the pipelined system; our model with annotated word structures gives an improvement of 0.97% in tagging accuracy and 2.17% in phrase-structure parsing accuracy. The results also demonstrate that the annotated word structures are highly effective for syntactic parsing, giving an absolute improvement of 0.82% in phrase-structure parsing accuracy over the joint model with flat word structures.

Row “WS” in Table 2 shows the accuracy of hierarchical word-structure recovery of our joint system. This figure can be useful for high-level applications that make use of character-level trees by

<sup>4</sup><http://sourceforge.net/projects/zpar/>, version 0.5.

our parser, as it reflects the capability of our parser in analyzing word structures. In particular, the performance of parsing OOV word structure is an important metric of our parser. The recall of OOV word structures is 60.43%, while if we do not consider the influences of segmentation and tagging errors, counting only the correctly segmented and tagged words, the recall is 87.96%.

#### 4.4 Comparison with Previous Work

In this section, we compare our model to previous systems on the performance of joint word segmentation and POS tagging, and the performance of joint phrase-structure parsing.

Table 3 shows the results. Kruengkrai+ ’09 denotes the results of Kruengkrai et al. (2009), which is a lattice-based joint word segmentation and POS tagging model; Sun ’11 denotes a subword based stacking model for joint segmentation and POS tagging (Sun, 2011), which uses a dictionary of idioms; Wang+ ’11 denotes a semi-supervised model proposed by Wang et al. (2011), which additionally uses the Chinese Gigaword Corpus; Li ’11 denotes a generative model that can perform word segmentation, POS tagging and phrase-structure parsing jointly (Li, 2011); Li+ ’12 denotes a unified dependency parsing model that can perform joint word segmentation, POS tagging and dependency parsing (Li and Zhou, 2012); Li ’11 and Li+ ’12 exploited annotated morphological-level word structures for Chinese; Hatori+ ’12 denotes an incremental joint model for word segmentation, POS tagging and dependency parsing (Hatori et al., 2012); they use external dictionary resources including HowNet Word List and page names from the Chinese Wikipedia; Qian+ ’12 denotes a joint segmentation, POS tagging and parsing system using a unified framework for decoding, incorporating a word segmentation model, a POS tagging model and a phrase-structure parsing model together (Qian and Liu, 2012); their word segmentation model is a combination of character-based model and word-based model. Our model achieved the best performance on both joint segmentation and tagging as well as joint phrase-structure parsing.

Our final performance on constituent parsing is by far the best that we are aware of for the Chinese data, and even better than some state-of-the-art models with gold segmentation. For example, the un-lexicalized PCFG model of Petrov and Klein

System	Seg	Tag	Parse
Kruengkrai+ '09	97.87	93.67	–
Sun '11	98.17*	94.02*	–
Wang+ '11	98.11*	94.18*	–
Li '11	97.3	93.5	79.7
Li+ '12	97.50	93.31	–
Hatori+ '12	<b>98.26*</b>	94.64*	–
Qian+ '12	97.96	93.81	82.85
Ours pipeline	97.69	93.83	82.26
Ours joint flat	97.73	94.48	83.61
Ours joint annotated	97.84	<b>94.80</b>	<b>84.43</b>

Table 3: Comparisons of our final model with state-of-the-art systems, where “\*” denotes that external dictionary or corpus has been used.

(2007) achieves 83.45%<sup>5</sup> in parsing accuracy on the test corpus, and our pipeline constituent parsing model achieves 83.55% with gold segmentation. They are lower than the performance of our character-level model, which is 84.43% without gold segmentation. The main differences between word-based and character-level parsing models are that character-level model can exploit character features. This further demonstrates the effectiveness of characters in Chinese parsing.

## 5 Related Work

Recent work on using the internal structure of words to help Chinese processing gives important motivations to our work. Zhao (2009) studied character-level dependencies for Chinese word segmentation by formalizing segmentation task in a dependency parsing framework. Their results demonstrate that annotated word dependencies can be helpful for word segmentation. Li (2011) pointed out that the word’s internal structure is very important for Chinese NLP. They annotated morphological-level word structures, and a unified generative model was proposed to parse the Chinese morphological and phrase-structures. Li and Zhou (2012) also exploited the morphological-level word structures for Chinese dependency parsing. They proposed a unified transition-based model to parse the morphological and dependency structures of a Chinese sentence in a unified framework. The morphological-level word struc-

<sup>5</sup>We rerun the parser and evaluate it using the publicly-available code on <http://code.google.com/p/berkeleyparser> by ourselves, since we have a preprocessing step for the CTB5 corpus.

tures concern only prefixes and suffixes, which cover only 35% of entire words in CTB. According to their results, the final performances of their model on word segmentation and POS tagging are below the state-of-the-art joint segmentation and POS tagging models. Compared to their work, we consider the character-level word structures for Chinese parsing, presenting a unified framework for segmentation, POS tagging and phrase-structure parsing. We can achieve improved segmentation and tagging performance.

Our character-level parsing model is inspired by the work of Zhang and Clark (2009), which is a transition-based model with a beam-search decoder for word-based constituent parsing. Our work is based on the shift-reduce operations of their work, while we introduce additional operations for segmentation and POS tagging. By such an extension, our model can include all the features in their work, together with the features for segmentation and POS tagging. In addition, we propose novel features related to word structures and interactions between word segmentation, POS tagging and word-based constituent parsing.

Luo (2003) was the first work to introduce the character-based syntax parsing. They use it as a joint framework to perform Chinese word segmentation, POS tagging and syntax parsing. They exploit a generative maximum entropy model for character-based constituent parsing, and find that POS information is very useful for Chinese word segmentation, but high-level syntactic information seems to have little effect on segmentation. Compared to their work, we use a transition-based discriminative model, which can benefit from large amounts of flexible features. In addition, instead of using flat structures, we manually annotate hierarchical tree structures of Chinese words for converting word-based constituent trees into character-based constituent trees.

Hatori et al. (2012) proposed the first joint work for the word segmentation, POS tagging and dependency parsing. They used a single transition-based model to perform the three tasks. Their work demonstrates that a joint model can improve the performance of the three tasks, particularly for POS tagging and dependency parsing. Qian and Liu (2012) proposed a joint decoder for word segmentation, POS tagging and word-based constituent parsing, although they trained models for the three tasks separately. They reported better

performances when using a joint decoder. In our work, we employ a single character-based discriminative model to perform segmentation, POS tagging and phrase-structure parsing jointly, and study the influence of annotated word structures.

## 6 Conclusions and Future Work

We studied the internal structures of more than 37,382 Chinese words, analyzing their structures as the recursive combinations of characters. Using these word structures, we extended the CTB into character-level trees, and developed a character-based parser that builds such trees from raw character sequences. Our character-based parser performs segmentation, POS tagging and parsing simultaneously, and significantly outperforms a pipelined baseline. We make both our annotations and our parser available online.

In summary, our contributions include:

- We annotated the internal structures of Chinese words, which are potentially useful to character-based studies of Chinese NLP. We extend CTB-style constituent trees into character-level trees using our annotations.
- We developed a character-based parsing model that can produce our character-level constituent trees. Our parser jointly performs word segmentation, POS tagging and syntactic parsing.
- We investigated the effectiveness of our joint parser over pipelined baseline, and the effectiveness of our annotated word structures in improving parsing accuracies.

Future work includes investigations of our parser and annotations on Chinese NLP tasks.

## Abstract

We present a novel transition-based, greedy dependency parser which implements a flexible mix of bottom-up and top-down strategies. The new strategy allows the parser to postpone difficult decisions until the relevant information becomes available. The novel parser has a  $\sim 12\%$  error reduction in unlabeled attachment score over an arc-eager parser, with a slow-down factor of 2.8.

## 1 Introduction

Dependency-based methods for syntactic parsing have become increasingly popular during the last decade or so. This development is probably due to many factors, such as the increased availability of dependency treebanks and the perceived usefulness of dependency structures as an interface to downstream applications, but a very important reason is also the high efficiency offered by dependency parsers, enabling web-scale parsing with high throughput. The most efficient parsers are greedy transition-based parsers, which only explore a single derivation for each input and relies on a locally trained classifier for predicting the next parser action given a compact representation of the derivation history, as pioneered by Yamada and Matsumoto (2003), Nivre (2003), Attardi (2006), and others. However, while these parsers are capable of processing tens of thousands of tokens per second with the right choice of classifiers, they are also known to perform slightly below the state-of-the-art because of search errors and subsequent error propagation (McDonald and Nivre, 2007), and recent research on transition-based dependency parsing has therefore explored different ways of improving their accuracy.

The most common approach is to use beam search instead of greedy decoding, in combination

with a globally trained model that tries to minimize the loss over the entire sentence instead of a locally trained classifier that tries to maximize the accuracy of single decisions (given no previous errors), as first proposed by Zhang and Clark (2008). With these methods, transition-based parsers have reached state-of-the-art accuracy for a number of languages (Zhang and Nivre, 2011; Bohnet and Nivre, 2012). However, the drawback with this approach is that parsing speed is proportional to the size of the beam, which means that the most accurate transition-based parsers are not nearly as fast as the original greedy transition-based parsers. Another line of research tries to retain the efficiency of greedy classifier-based parsing by instead improving the way in which classifiers are learned from data. While the classical approach limits training data to parser states that result from oracle predictions (derived from a treebank), these novel approaches allow the classifier to explore states that result from its own (sometimes erroneous) predictions (Choi and Palmer, 2011; Goldberg and Nivre, 2012).

In this paper, we explore an orthogonal approach to improving the accuracy of transition-based parsers, without sacrificing their advantage in efficiency, by introducing a new type of transition system. While all previous transition systems assume a static parsing strategy with respect to top-down and bottom-up processing, our new system allows a dynamic strategy for ordering parsing decisions. This has the advantage that the parser can postpone difficult decisions until the relevant information becomes available, in a way that is not possible in existing transition systems. A second advantage of dynamic parsing is that we can extend the feature inventory of previous systems. Our experiments show that these advantages lead to significant improvements in parsing accuracy, compared to a baseline parser that uses the arc-eager transition system of Nivre (2003), which is one of the most

widely used static transition systems.

## 2 Static vs. Dynamic Parsing

The notions of bottom-up and top-down parsing strategies do not have a general mathematical definition; they are instead specified, often only informally, for individual families of grammar formalisms. In the context of dependency parsing, a parsing strategy is called purely **bottom-up** if every dependency  $h \rightarrow d$  is constructed only after all dependencies of the form  $d \rightarrow i$  have been constructed. Here  $h \rightarrow d$  denotes a dependency with  $h$  the head node and  $d$  the dependent node. In contrast, a parsing strategy is called purely **top-down** if  $h \rightarrow d$  is constructed before any dependency of the form  $d \rightarrow i$ .

If we consider transition-based dependency parsing (Nivre, 2008), the purely bottom-up strategy is implemented by the arc-standard model of Nivre (2004). After building a dependency  $h \rightarrow d$ , this model immediately removes from its stack node  $d$ , preventing further attachment of dependents to this node. A second popular parser, the arc-eager model of Nivre (2003), instead adopts a mixed strategy. In this model, a dependency  $h \rightarrow d$  is constructed using a purely bottom-up strategy if it represents a left-arc, that is, if the dependent  $d$  is placed to the left of the head  $h$  in the input string. In contrast, if  $h \rightarrow d$  represents a right-arc (defined symmetrically), then this dependency is constructed before any right-arc  $d \rightarrow i$  (top-down) but after any left-arc  $d \rightarrow i$  (bottom-up).

What is important to notice about the above transition-based parsers is that the adopted parsing strategies are **static**. By this we mean that each dependency is constructed according to some *fixed* criterion, depending on structural conditions such as the fact that the dependency represents a left or a right arc. This should be contrasted with **dynamic** parsing strategies in which several parsing options are *simultaneously* available for the dependencies being constructed.

In the context of left-to-right, transition-based parsers, dynamic strategies are attractive for several reasons. One argument is related to the well-known PP-attachment problem, illustrated in Figure 1. Here we have to choose whether to attach node P as a dependent of V (arc  $\alpha_2$ ) or else as a dependent of N1 (arc  $\alpha_3$ ). The purely bottom-up arc-standard model has to take a decision as soon as N1 is placed into the stack. This is so

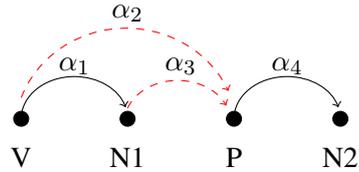

Figure 1: PP-attachment example, with dashed arcs identifying two alternative choices.

because the construction of  $\alpha_1$  excludes  $\alpha_3$  from the search space, while the alternative decision of shifting P into the stack excludes  $\alpha_2$ . This is bad, because the information about the correct attachment could come from the lexical content of node P. The arc-eager model performs slightly better, since it can delay the decision up to the point in which  $\alpha_1$  has been constructed and P is read from the buffer. However, at this point it must make a commitment and either construct  $\alpha_3$  or pop N1 from the stack (implicitly committing to  $\alpha_2$ ) before N2 is read from the buffer. In contrast with this scenario, in the next sections we implement a dynamic parsing strategy that allows a transition system to decide between the attachments  $\alpha_2$  and  $\alpha_3$  after it has seen all of the four nodes V, N1, P and N2.

Other additional advantages of dynamic parsing strategies with respect to static strategies are related to the increase in the feature inventory that we apply to parser states, and to the increase of spurious ambiguity. However, these arguments are more technical than the PP-attachment argument above, and will be discussed later.

## 3 Dependency Parser

In this section we present a novel transition-based parser for projective dependency trees, implementing a dynamic parsing strategy.

### 3.1 Preliminaries

For non-negative integers  $i$  and  $j$  with  $i \leq j$ , we write  $[i, j]$  to denote the set  $\{i, i+1, \dots, j\}$ . When  $i > j$ ,  $[i, j]$  is the empty set.

We represent an input sentence as a string  $w = w_0 \cdots w_n$ ,  $n \geq 1$ , where token  $w_0$  is a special root symbol and, for each  $i \in [1, n]$ , token  $w_i = (i, a_i, t_i)$  encodes a lexical element  $a_i$  and a part-of-speech tag  $t_i$  associated with the  $i$ -th word in the sentence.

A **dependency tree** for  $w$  is a directed, ordered tree  $T_w = (V_w, A_w)$ , where  $V_w = \{w_i \mid i \in$

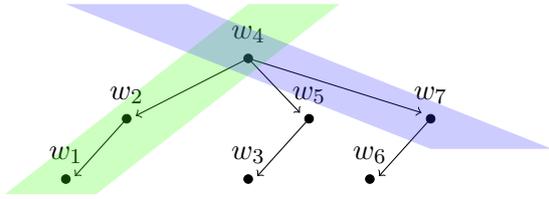

Figure 2: A dependency tree with left spine  $\langle w_4, w_2, w_1 \rangle$  and right spine  $\langle w_4, w_7 \rangle$ .

$[0, n]$  is the set of nodes, and  $A_w \subseteq V_w \times V_w$  is the set of arcs. Arc  $(w_i, w_j)$  encodes a dependency  $w_i \rightarrow w_j$ . A sample dependency tree (excluding  $w_0$ ) is displayed in Figure 2. If  $(w_i, w_j) \in A_w$  for  $j < i$ , we say that  $w_j$  is a left child of  $w_i$ ; a right child is defined in a symmetrical way.

The **left spine** of  $T_w$  is an ordered sequence  $\langle u_1, \dots, u_p \rangle$  with  $p \geq 1$  and  $u_i \in V_w$  for  $i \in [1, p]$ , consisting of all nodes in a descending path from the root of  $T_w$  taking the leftmost child node at each step. More formally,  $u_1$  is the root node of  $T_w$  and  $u_i$  is the leftmost child of  $u_{i-1}$ , for  $i \in [2, p]$ . The **right spine** of  $T_w$  is defined symmetrically; see again Figure 2. Note that the left and the right spines share the root node and no other node.

### 3.2 Basic Idea

Transition-based dependency parsers use a stack data structure, where each stack element is associated with a tree spanning some (contiguous) substring of the input  $w$ . The parser can combine two trees  $T$  and  $T'$  through attachment operations, called left-arc or right-arc, under the condition that  $T$  and  $T'$  appear at the two topmost positions in the stack. Crucially, only the roots of  $T$  and  $T'$  are available for attachment; see Figure 3(a).

In contrast, a stack element in our parser records the *entire* left spine and right spine of the associated tree. This allows us to extend the inventory of the attachment operations of the parser by including the attachment of tree  $T$  as a dependent of any node in the left or in the right spine of a second tree  $T'$ , provided that this does not violate projectivity.<sup>1</sup> See Figure 3(b) for an example.

The new parser implements a mix of bottom-up and top-down strategies, since after any of the attachments in Figure 3(b) is performed, additional dependencies can still be created for the root of  $T$ . Furthermore, the new parsing strategy is clearly dy-

<sup>1</sup>A dependency tree for  $w$  is projective if every subtree has a contiguous yield in  $w$ .

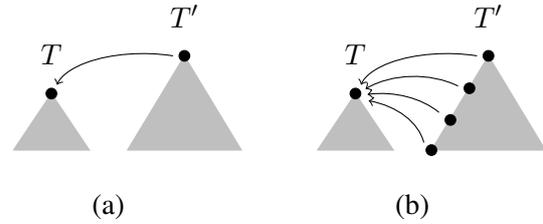

Figure 3: Left-arc attachment of  $T$  to  $T'$  in case of (a) standard transition-based parsers and (b) our parser.

namic, due to the free choice in the timing for these attachments. The new strategy is more powerful than the strategy of the arc-eager model, since we can use top-down parsing at left arcs, which is not allowed in arc-eager parsing, and we do not have the restrictions of parsing right arcs ( $h \rightarrow d$ ) before the attachment of right dependents at node  $d$ .

To conclude this section, let us resume our discussion of the PP-attachment example in Figure 1. We observe that the new parsing strategy allows the construction of a tree  $T'$  consisting of the only dependency  $V \rightarrow N1$  and a tree  $T$ , placed at the right of  $T'$ , consisting of the only dependency  $P \rightarrow N2$ . Since the right spine of  $T'$  consists of nodes  $V$  and  $N1$ , we can freely choose between attachment  $V \rightarrow P$  and attachment  $N1 \rightarrow P$ . Note that this is done after we have seen node  $N2$ , as desired.

### 3.3 Transition-based Parser

We assume the reader is familiar with the formal framework of transition-based dependency parsing originally introduced by Nivre (2003); see Nivre (2008) for an introduction. To keep the notation at a simple level, we only discuss here the unlabeled version of our parser; however, a labeled extension is used in §5 for our experiments.

Our transition-based parser uses a **stack** data structure to store partial parses for the input string  $w$ . We represent the stack as an ordered sequence  $\sigma = [\sigma_d, \dots, \sigma_1]$ ,  $d \geq 0$ , of stack elements, with the topmost element placed at the right. When  $d = 0$ , we have the empty stack  $\sigma = []$ . Sometimes we use the vertical bar to denote the append operator for  $\sigma$ , and write  $\sigma = \sigma' | \sigma_1$  to indicate that  $\sigma_1$  is the topmost element of  $\sigma$ .

A **stack element** is a pair

$$\sigma_k = (\langle u_{k,1}, \dots, u_{k,p} \rangle, \langle v_{k,1}, \dots, v_{k,q} \rangle)$$

where the ordered sequences  $\langle u_{k,1}, \dots, u_{k,p} \rangle$  and

$\langle v_{k,1}, \dots, v_{k,q} \rangle$  are the left and the right spines, respectively, of the tree associated with  $\sigma_k$ . Recall that  $u_{k,1} = v_{k,1}$ , since the root node of the associated tree is shared by the two spines.

The parser also uses a **buffer** to store the portion of the input string still to be processed. We represent the buffer as an ordered sequence  $\beta = [w_i, \dots, w_n]$ ,  $i \geq 0$ , of tokens from  $w$ , with the first element placed at the left. Note that  $\beta$  always represents a (non-necessarily proper) suffix of  $w$ . When  $i > n$ , we have the empty buffer  $\beta = []$ . Sometimes we use the vertical bar to denote the append operator for  $\beta$ , and write  $\beta = w_i | \beta'$  to indicate that  $w_i$  is the first token of  $\beta$ ; consequently, we have  $\beta' = [w_{i+1}, \dots, w_n]$ .

When processing  $w$ , the parser reaches several states, technically called configurations. A **configuration** of the parser relative to  $w$  is a triple  $c = (\sigma, \beta, A)$ , where  $\sigma$  and  $\beta$  are a stack and a buffer, respectively, and  $A \subseteq V_w \times V_w$  is a set of arcs. The initial configuration for  $w$  is  $([], [w_0, \dots, w_n], \emptyset)$ . The set of terminal configurations consists of all configurations of the form  $([\sigma_1], [], A)$ , where  $\sigma_1$  is associated with a tree having root  $w_0$ , that is,  $u_{1,1} = v_{1,1} = w_0$ , and  $A$  is any set of arcs.

The core of a transition-based parser is the set of its transitions. Each **transition** is a binary relation defined over the set of configurations of the parser. Since the set of configurations is infinite, a transition is infinite as well, when viewed as a set. However, transitions can always be specified by some finite means. Our parser uses three types of transitions, defined in what follows.

- **SHIFT**, or **sh** for short. This transition removes the first node from the buffer and pushes into the stack a new element, consisting of the left and right spines of the associated tree. More formally

$$(\sigma, w_i | \beta, A) \vdash_{\text{sh}} (\sigma | (\langle w_i \rangle, \langle w_i \rangle), \beta, A)$$

- **LEFT-ARC<sub>k</sub>**,  $k \geq 1$ , or **la<sub>k</sub>** for short. Let  $h$  be the  $k$ -th node in the left spine of the topmost tree in the stack, and let  $d$  be the root node of the second topmost tree in the stack. This transition creates a new arc  $h \rightarrow d$ . Furthermore, the two topmost stack elements are replaced by a new element associated with the tree resulting from the  $h \rightarrow d$  attachment. The transition does not advance with the reading

of the buffer. More formally

$$(\sigma' | \sigma_2 | \sigma_1, \beta, A) \vdash_{\text{la}_k} (\sigma' | \sigma_{\text{la}}, \beta, A \cup \{h \rightarrow d\})$$

where

$$\begin{aligned} \sigma_1 &= (\langle u_{1,1}, \dots, u_{1,p} \rangle, \langle v_{1,1}, \dots, v_{1,q} \rangle), \\ \sigma_2 &= (\langle u_{2,1}, \dots, u_{2,r} \rangle, \langle v_{2,1}, \dots, v_{2,s} \rangle), \\ \sigma_{\text{la}} &= (\langle u_{1,1}, \dots, u_{1,k}, u_{2,1}, \dots, u_{2,r} \rangle, \\ &\quad \langle v_{1,1}, \dots, v_{1,q} \rangle), \end{aligned}$$

and where we have set  $h = u_{1,k}$  and  $d = u_{2,1}$ .

- **RIGHT-ARC<sub>k</sub>**,  $k \geq 1$ , or **ra<sub>k</sub>** for short. This transition is defined symmetrically with respect to **la<sub>k</sub>**. We have

$$(\sigma' | \sigma_2 | \sigma_1, \beta, A) \vdash_{\text{ra}_k} (\sigma' | \sigma_{\text{ra}}, \beta, A \cup \{h \rightarrow d\})$$

where  $\sigma_1$  and  $\sigma_2$  are as in the **la<sub>k</sub>** case,

$$\begin{aligned} \sigma_{\text{ra}} &= (\langle u_{2,1}, \dots, u_{2,r} \rangle, \\ &\quad \langle v_{2,1}, \dots, v_{2,k}, v_{1,1}, \dots, v_{1,q} \rangle), \end{aligned}$$

and we have set  $h = v_{2,k}$  and  $d = v_{1,1}$ .

Transitions **la<sub>k</sub>** and **ra<sub>k</sub>** are parametric in  $k$ , where  $k$  is bounded by the length of the input string and not by a fixed constant (but see also the experimental findings in §5). Thus our system uses an unbounded number of transition relations, which has an apparent disadvantage for learning algorithms. We will get back to this problem in §4.3.

A **complete computation** relative to  $w$  is a sequence of configurations  $c_1, c_2, \dots, c_t$ ,  $t \geq 1$ , such that  $c_1$  and  $c_t$  are initial and final configurations, respectively, and for each  $i \in [2, t]$ ,  $c_i$  is produced by the application of some transition to  $c_{i-1}$ . It is not difficult to see that the transition-based parser specified above is sound, meaning that the set of arcs constructed in any complete computation on  $w$  is always a dependency tree for  $w$ . The parser is also complete, meaning that every (projective) dependency tree for  $w$  is constructed by some complete computation on  $w$ . A mathematical proof of this statement is beyond the scope of this paper, and will not be provided here.

### 3.4 Deterministic Parsing Algorithm

The transition-based parser of the previous section is a nondeterministic device, since several transitions can be applied to a given configuration. This might result in several complete computations

---

**Algorithm 1** Parsing Algorithm

---

**Input:** string  $w = w_0 \cdots w_n$ , function  $\text{score}()$ **Output:** dependency tree  $T_w$  $c = (\sigma, \beta, A) \leftarrow ([], [w_0, \dots, w_n], \emptyset)$ **while**  $|\sigma| > 1 \vee |\beta| > 0$  **do**    **while**  $|\sigma| < 2$  **do**        update  $c$  with sh     $p \leftarrow$  length of left spine of  $\sigma_1$      $s \leftarrow$  length of right spine of  $\sigma_2$      $\mathcal{T} \leftarrow \{\text{la}_k \mid k \in [1, p]\} \cup$          $\{\text{ra}_k \mid k \in [1, s]\} \cup \{\text{sh}\}$      $\text{best}T \leftarrow \text{argmax}_{t \in \mathcal{T}} \text{score}(t, c)$     update  $c$  with  $\text{best}T$ **return**  $T_w = (V_w, A)$ 

---

for  $w$ . We present here an algorithm that runs the parser in pseudo-deterministic mode, greedily choosing at each configuration the transition that maximizes some score function. Algorithm 1 takes as input a string  $w$  and a scoring function  $\text{score}()$  defined over parser transitions and parser configurations. The scoring function will be the subject of §4 and is not discussed here. The output of the parser is a dependency tree for  $w$ .

At each iteration the algorithm checks whether there are at least two elements in the stack and, if this is not the case, it shifts elements from the buffer to the stack. Then the algorithm uses the function  $\text{score}()$  to evaluate all transitions that can be applied under the current configuration  $c = (\sigma, \beta, A)$ , and it applies the transition with the highest score, updating the current configuration.

To parse a sentence of length  $n$  (excluding the root token  $w_0$ ) the algorithm applies exactly  $2n + 1$  transitions. In the worst case, each transition application involves  $1 + p + s$  transition evaluations. We therefore conclude that the algorithm always reaches a configuration with an empty buffer and a stack which contains only one element. Then the algorithm stops, returning the dependency tree whose arc set is defined as in the current configuration.

## 4 Model and Training

In this section we introduce the adopted learning algorithm and discuss the model parameters.

### 4.1 Learning Algorithm

We use a linear model for the score function in Algorithm 1, and define  $\text{score}(t, c) = \vec{w} \cdot \phi(t, c)$ . Here  $\vec{w}$  is a weight vector and function  $\phi$  provides

---

a feature vector representation for a transition  $t$  applying to a configuration  $c$ . The function  $\phi$  will be discussed at length in §4.3. The vector  $\vec{w}$  is trained using the perceptron algorithm in combination with the averaging method to avoid overfitting; see Freund and Schapire (1999) and Collins and Duffy (2002) for details.

The training data set consists of pairs  $(w, A_g)$ , where  $w$  is a sentence and  $A_g$  is the set of arcs of the gold (desired) dependency tree for  $w$ . At training time, each pair  $(w, A_g)$  is processed using the learning algorithm described as Algorithm 2. The algorithm is based on the notions of correct and incorrect transitions, discussed at length in §4.2.

Algorithm 2 parses  $w$  following Algorithm 1 and using the current  $\vec{w}$ , until the highest score selected transition  $\text{best}T$  is incorrect according to  $A_g$ . When this happens,  $\vec{w}$  is updated by decreasing the weights of the features associated with the incorrect  $\text{best}T$  and by increasing the weights of the features associated with the transition  $\text{bestCorrect}T$  having the highest score among all possible correct transitions. After each update, the learning algorithm resumes parsing from the current configuration by applying  $\text{bestCorrect}T$ , and moves on using the updated weights.

### 4.2 Correct and Incorrect Transitions

Standard transition-based dependency parsers are trained by associating each gold tree with a canonical complete computation. This means that, for each configuration of interest, only one transition

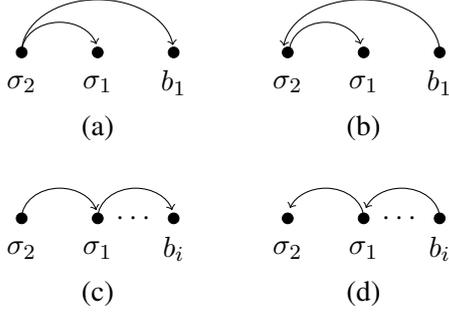

Figure 4: Graphical representation of configurations; drawn arcs are in  $A_g$  but have not yet been added to the configuration. Transition  $sh$  is incorrect for configuration (a) and (b);  $sh$  and  $ra_1$  are correct for (c);  $sh$  and  $la_1$  are correct for (d).

leading to the gold tree is considered as correct. In this paper we depart from such a methodology, and follow Goldberg and Nivre (2012) in allowing more than one correct transition for each configuration, as explained in detail below.

Let  $(w, A_g)$  be a pair in the training set. In §3.3 we have mentioned that there is always a complete computation on  $w$  that results in the construction of the set  $A_g$ . In general, there might be more than one computation for  $A_g$ . This means that the parser shows **spurious ambiguity**.

Observe that all complete computations for  $A_g$  share the same initial configuration  $c_{I,w}$  and final configuration  $c_{F,A_g}$ . Consider now the set  $\mathcal{C}(w)$  of all configurations  $c$  that are reachable from  $c_{I,w}$ , meaning that there exists a sequence of transitions that takes the parser from  $c_{I,w}$  to  $c$ . A configuration  $c \in \mathcal{C}(w)$  is **correct** for  $A_g$  if  $c_{F,A_g}$  is reachable from  $c$ ; otherwise,  $c$  is **incorrect** for  $A_g$ .

Let  $c \in \mathcal{C}(w)$  be a correct configuration for  $A_g$ . A transition  $t$  is correct for  $c$  and  $A_g$  if  $c \vdash_t c'$  and  $c'$  is correct for  $A_g$ ; otherwise,  $t$  is incorrect for  $c$  and  $A_g$ . The next lemma provides a characterization of correct and incorrect transitions; see Figure 4 for examples. We use this characterization in the implementation of predicate  $isCorrect()$  in Algorithm 2.

**Lemma 1** *Let  $(w, A_g)$  be a pair in the training set and let  $c \in \mathcal{C}(w)$  with  $c = (\sigma, \beta, A)$  be a correct configuration for  $A_g$ . Let also  $v_{1,k}$ ,  $k \in [1, q]$ , be the nodes in the right spine of  $\sigma_1$ .*

- (i)  $la_k$  and  $ra_k$  are incorrect for  $c$  and  $A_g$  if and only if they create a new arc  $(h \rightarrow d) \notin A_g$ ;
- (ii)  $sh$  is incorrect for  $c$  and  $A_g$  if and only if the

following conditions are both satisfied:

- (a) there exists an arc  $(h \rightarrow d)$  in  $A_g$  such that  $h$  is in  $\sigma$  and  $d = v_{1,1}$ ;
- (b) there is no arc  $(h' \rightarrow d')$  in  $A_g$  with  $h' = v_{1,k}$ ,  $k \in [1, q]$ , and  $d'$  in  $\beta$ .  $\square$

**PROOF (SKETCH)** To prove part (i) we focus on transition  $ra_k$ ; a similar argument applies to  $la_k$ . The ‘if’ statement in part (i) is self-evident.

‘Only if’. Assuming that transition  $ra_k$  creates a new arc  $(h \rightarrow d) \in A_g$ , we argue that from configuration  $c'$  with  $c \vdash_{ra_k} c'$  we can still reach the final configuration associated with  $A_g$ . We have  $h = v_{2,k}$  and  $d = u_{1,1}$ . The tree fragments in  $\sigma$  with roots  $v_{2,k+1}$  and  $u_{1,1}$  must be adjacent siblings in the tree associated with  $A_g$ , since  $c$  is a correct configuration for  $A_g$  and  $(v_{2,k} \rightarrow u_{1,1}) \in A_g$ . This means that each of the nodes  $v_{2,k+1}, \dots, v_{2,s}$  in the right spine in  $\sigma_2$  in  $c$  must have already acquired all of its right dependents, since the tree is projective. Therefore it is safe for transition  $ra_k$  to eliminate the nodes  $v_{2,k+1}, \dots, v_{2,s}$  from the right spine in  $\sigma_2$ .

We now deal with part (ii). Let  $c \vdash_{sh} c'$ ,  $c' = (\sigma', \beta', A)$ .

‘If’. Assuming (ii)a and (ii)b, we argue that  $c'$  is incorrect. Node  $d$  is the head of  $\sigma'_2$ . Arc  $(h \rightarrow d)$  is not in  $A$ , and the only way we could create  $(h \rightarrow d)$  from  $c'$  is by reaching a new configuration with  $d$  in the topmost stack symbol, which amounts to say that  $\sigma'_1$  can be reduced by a correct transition. Node  $h$  is in some  $\sigma'_i$ ,  $i > 2$ , by (ii)a. Then reduction of  $\sigma'_1$  implies that the root of  $\sigma'_1$  is reachable from the root of  $\sigma'_2$ , which contradicts (ii)b.

‘Only if’. Assuming (ii)a is not satisfied, we argue that  $sh$  is correct for  $c$  and  $A_g$ . There must be an arc  $(h \rightarrow d)$  not in  $A$  with  $d = v_{1,1}$  and  $h$  is some token  $w_i$  in  $\beta$ . From stack  $\sigma' = \sigma''|\sigma'_2|\sigma'_1$  it is always possible to construct  $(h \rightarrow d)$  consuming the substring of  $\beta$  up to  $w_i$  and ending up with stack  $\sigma''|\sigma_{red}$ , where  $\sigma_{red}$  is a stack element with root  $w_i$ . From there, the parser can move on to the final configuration  $c_{F,A_g}$ . A similar argument applies if we assume that (ii)b is not satisfied.  $\blacksquare$

From condition (i) in Lemma 1 and from the fact that there are no cycles in  $A_g$ , it follows that there is at most one correct transition among the transitions of type  $la_k$  or  $ra_k$ . From condition (ii) in the lemma we can also see that the existence of a correct transition of type  $la_k$  or  $ra_k$  for some configuration does not imply that the  $sh$  transition is incorrect

for the same configuration; see Figures 4(c,d) for examples. It follows that for a correct configuration there might be at most 2 correct transitions. In our training experiments for English in §5 we observe 2 correct transitions for 42% of the reached configurations. This nondeterminism is a byproduct of the adopted dynamic parsing strategy, and eventually leads to the spurious ambiguity of the parser.

As already mentioned, we do not impose any canonical form on complete computations that would hardwire a preference for some correct transition and get rid of spurious ambiguity. Following Goldberg and Nivre (2012), we instead regard spurious ambiguity as an additional resource of our parsing strategy. Our main goal is that the training algorithm learns to prefer a *sh* transition in a configuration that does not provide enough information for the choice of the correct arc. In the context of dependency parsing, the strategy of delaying arc construction when the current configuration is not informative is called the *easy-first* strategy, and has been first explored by Goldberg and Elhadad (2010).

### 4.3 Feature Extraction

In existing transition-based parsers a set of atomic features is statically defined and extracted from each configuration. These features are then combined together into complex features, according to some feature template, and joined with the available transition types. This is not possible in our system, since the number of transitions  $la_k$  and  $ra_k$  is not bounded by a constant. Furthermore, it is not meaningful to associate transitions  $la_k$  and  $ra_k$ , for any  $k \geq 1$ , always with the same features, since the constructed arcs impinge on nodes at different depths in the involved spines. It seems indeed more significant to extract information that is local to the arc  $h \rightarrow d$  being constructed by each transition, such as for instance the grandparent and the great grandparent nodes of  $d$ . This is possible if we introduce a higher level of abstraction than in existing transition-based parsers. We remark here that this abstraction also makes the feature representation more similar to the ones typically found in graph-based parsers, which are centered on arcs or subgraphs of the dependency tree.

We index the nodes in the stack  $\sigma$  relative to the head node of the arc being constructed, in case of the transitions  $la_k$  or  $ra_k$ , or else relative to the root node of  $\sigma_1$ , in case of the transition

*sh*. More precisely, let  $c = (\sigma, \beta, A)$  be a configuration and let  $t$  be a transition. We define the **context** of  $c$  and  $t$  as the tuple  $C(c, t) = (s_3, s_2, s_1, q_1, q_2, gp, gg)$ , whose components are placeholders for word tokens in  $\sigma$  or in  $\beta$ . All these placeholders are specified in Table 1, for each  $c$  and  $t$ . Figure 5 shows an example of feature extraction for the displayed configuration  $c = (\sigma, \beta, A)$  and the transition  $la_2$ . In this case we have  $s_3 = u_{3,1}$ ,  $s_2 = u_{2,1}$ ,  $s_1 = u_{1,2}$ ,  $q_1 = gp = u_{1,1}$ ,  $q_2 = b_1$ ;  $gp = none$  because the head of  $gp$  is not available in  $c$ .

Note that in Table 1 placeholders are dynamically assigned in such a way that  $s_1$  and  $s_2$  refer to the nodes in the constructed arc  $h \rightarrow d$ , and  $gp, gg$  refer to the grandparent and the great grandparent nodes, respectively, of  $d$ . Furthermore, the node assigned to  $s_3$  is the parent node of  $s_2$ , if such a node is defined; otherwise, the node assigned to  $s_3$  is the root of the tree fragment in the stack underneath  $\sigma_2$ . Symmetrically, placeholders  $q_1$  and  $q_2$  refer to the parent and grandparent nodes of  $s_1$ , respectively, when these nodes are defined; otherwise, these placeholders get assigned tokens from the buffer. See again Figure 5.

Finally, from the placeholders in  $C(c, t)$  we extract a standard set of atomic features and their complex combinations, to define the function  $\phi$ . Our feature template is an extended version of the feature template of Zhang and Nivre (2011), originally developed for the arc-eager model. The extension is obtained by adding top-down features for left-arcs (based on placeholders  $gp$  and  $gg$ ), and by adding right child features for the first stack element. The latter group of features is usually exploited for the arc-standard model, but is undefined for the arc-eager model.

## 5 Experimental Assessment

Performance evaluation is carried out on the Penn Treebank (Marcus et al., 1993) converted to Stanford basic dependencies (De Marneffe et al., 2006). We use sections 2-21 for training, 22 as development set, and 23 as test set. The part-of-speech tags are assigned by an automatic tagger with accuracy 97.1%. The tagger used on the training set is trained on the same data set by using four-way jackknifing, while the tagger used on the development and test sets is trained on all the training set. We train an arc-labeled version of our parser.

In the first three lines of Table 2 we compare

context placeholder	sh	la <sub>k</sub>			ra <sub>k</sub>		
		k = 1	k = 2	k > 2	k = 1	k = 2	k > 2
s <sub>1</sub>	u <sub>1,1</sub> = v <sub>1,1</sub>	u <sub>1,k</sub>			u <sub>1,1</sub> = v <sub>1,1</sub>		
s <sub>2</sub>	u <sub>2,1</sub> = v <sub>2,1</sub>	u <sub>2,1</sub> = v <sub>2,1</sub>			v <sub>2,k</sub>		
s <sub>3</sub>	u <sub>3,1</sub> = v <sub>3,1</sub>	u <sub>3,1</sub> = v <sub>3,1</sub>			u <sub>3,1</sub> = v <sub>3,1</sub>	v <sub>2,k-1</sub>	
q <sub>1</sub>	b <sub>1</sub>	b <sub>1</sub>	u <sub>1,k-1</sub>		b <sub>1</sub>		
q <sub>2</sub>	b <sub>2</sub>	b <sub>2</sub>	b <sub>2</sub>	u <sub>1,k-2</sub>	b <sub>2</sub>		
gp	none	none	u <sub>1,k-1</sub>		none	v <sub>2,k-1</sub>	
gg	none	none	none	u <sub>1,k-2</sub>	none	none	v <sub>2,k-2</sub>

Table 1: Definition of  $C(c, t) = (s_3, s_2, s_1, q_1, q_2, gp, gg)$ , for  $c = (\sigma'|\sigma_3|\sigma_2|\sigma_1, b_1|b_2|\beta, A)$  and  $t$  of type sh or la<sub>k</sub>, ra<sub>k</sub>,  $k \geq 1$ . Symbols  $u_{j,k}$  and  $v_{j,k}$  are the  $k$ -th nodes in the left and right spines, respectively, of stack element  $\sigma_j$ , with  $u_{j,1} = v_{j,1}$  being the shared root of  $\sigma_j$ ; none is an artificial element used when some context’s placeholder is not available.

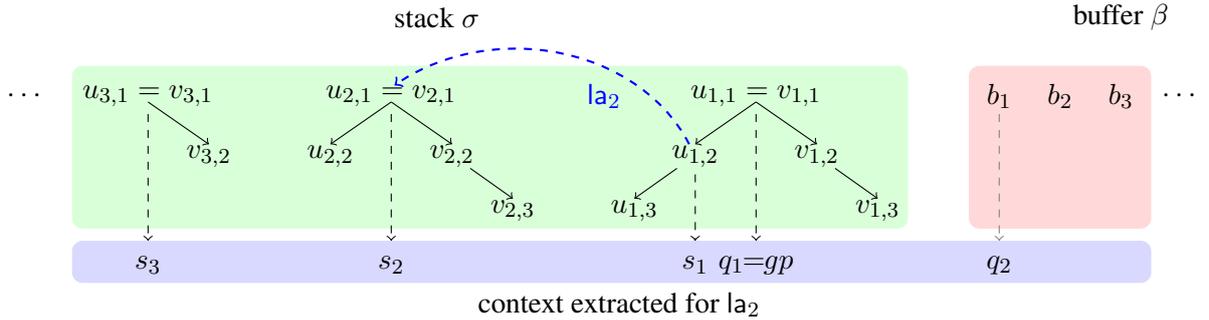

Figure 5: Extraction of atomic features for context  $C(c, la_2) = (s_3, s_2, s_1, q_1, q_2, gp, gg)$ ,  $c = (\sigma, \beta, A)$ .

parser	iter	UAS	LAS	UEM
arc-standard	23	90.02	87.69	38.33
arc-eager	12	90.18	87.83	40.02
this work	30	91.33	89.16	42.38
arc-standard + easy-first	21	90.49	88.22	39.61
arc-standard + spine	27	90.44	88.23	40.27

Table 2: Accuracy on test set, excluding punctuation, for unlabeled attachment score (UAS), labeled attachment score (LAS), unlabeled exact match (UEM).

the accuracy of our parser against our implementation of the arc-eager and arc-standard parsers. For the arc-eager parser, we use the feature template of Zhang and Nivre (2011). The same template is adapted to the arc-standard parser, by removing the top-down parent features and by adding the right child features for the first stack element. It turns out that our feature template, described in §4.3, is the exact merge of the templates used for the arc-eager and the arc-standard parsers.

We train all parsers up to 30 iterations, and for each parser we select the weight vector  $\vec{w}$  from the iteration with the best accuracy on the development set. All our parsers attach the root node at the end of the parsing process, following the ‘None’ ap-

proach discussed by Ballesteros and Nivre (2013). Punctuation is excluded in all evaluation metrics. Considering UAS, our parser provides an improvement of 1.15 over the arc-eager parser and an improvement of 1.31 over the arc-standard parser, that is an error reduction of  $\sim 12\%$  and  $\sim 13\%$ , respectively. Considering LAS, we achieve improvements of 1.33 and 1.47, with an error reduction of  $\sim 11\%$  and  $\sim 12\%$ , over the arc-eager and the arc-standard parsers, respectively.

We speculate that the observed improvement of our parser can be ascribed to two distinct components. The first component is the left-/right-spine representation for stack elements, introduced in §3.3. The second component is the easy-first strategy, implemented on the basis of the spurious ambiguity of our parser and the definition of correct/incorrect transitions in §4.2. In this perspective, we observe that our parser can indeed be viewed as an arc-standard model *augmented* with (i) the spine representation, and (ii) the easy-first strategy. More specifically, (i) generalizes the la/ra transitions to the la<sub>k</sub>/ra<sub>k</sub> transitions, introducing a top-down component into the purely bottom-up arc-standard. On the other hand, (ii) drops the limitation of canonical computations for the arc-standard, and leverages

on the spurious ambiguity of the parser to enlarge the search space.

The two components above are mutually independent, meaning that we can individually implement each component on top of an arc-standard model. More precisely, the arc-standard + spine model uses the transitions  $la_k/ra_k$  but retains the definition of canonical computation, defined by applying each  $la_k/ra_k$  transition as soon as possible. On the other hand, the arc-standard + easy-first model retains the original  $la/ra$  transitions but is trained allowing any correct transition at each configuration. In this case the characterization of correct and incorrect configurations in Lemma 1 has been adapted to transitions  $la/ra$ , taking into account the bottom-up constraint.

With the purpose of incremental comparison, we report accuracy results for the two ‘incremental’ models in the last two lines of Table 2. Analyzing these results, and comparing with the plain arc-standard, we see that the spine representation and the easy-first strategy individually improve accuracy. Moreover, their combination into our model (third line of Table 2) works very well, with an overall improvement larger than the sum of the individual contributions.

We now turn to a computational analysis. At each iteration our parser evaluates a number of transitions bounded by  $\gamma + 1$ , with  $\gamma$  the maximum value of the sum of the lengths of the left spine in  $\sigma_1$  and of the right spine in  $\sigma_2$ . Quantity  $\gamma$  is bounded by the length  $n$  of the input sentence. Since the parser applies exactly  $2n + 1$  transitions, worst case running time is  $\mathcal{O}(n^2)$ . We have computed the average value of  $\gamma$  on our English data set, resulting in 2.98 (variance 2.15) for training set, and 2.95 (variance 1.96) for development set. We conclude that, in the expected case, running time is  $\mathcal{O}(n)$ , with a slow down constant which is rather small, in comparison to standard transition-based parsers. Accordingly, when running our parser against our implementation of the arc-eager and arc-standard models, we measured a slow-down of 2.8 and 2.2, respectively. Besides the change in representation, this slow-down is also due to the increase in the number of features in our system. We have also checked the worst case value of  $\gamma$  in our data set. Interestingly, we have seen that for strings of length smaller than 40 this value linearly grows with  $n$ , and for longer strings the growth stops, with a maximum worst case observed value

of 22.

## 6 Concluding Remarks

We have presented a novel transition-based parser using a dynamic parsing strategy, which achieves a  $\sim 12\%$  error reduction in unlabeled attachment score over the static arc-eager strategy and even more over the (equally static) arc-standard strategy, when evaluated on English.

The idea of representing the right spine of a tree within the stack elements of a shift-reduce device is quite old in parsing, predating empirical approaches. It has been mainly exploited to solve the PP-attachment problem, motivated by psycholinguistic models. The same representation is also adopted in applications of discourse parsing, where right spines are usually called right frontiers; see for instance Subba and Di Eugenio (2009). In the context of transition-based dependency parsers, right spines have also been exploited by Kitagawa and Tanaka-Ishii (2010) to decide where to attach the next word from the buffer. In this paper we have generalized their approach by introducing the symmetrical notion of left spine, and by allowing attachment of full trees rather than attachment of a single word.<sup>2</sup>

Since one can regard a spine as a stack in itself, whose elements are tree nodes, our model is reminiscent of the embedded pushdown automata of Schabes and Vijay-Shanker (1990), used to parse tree adjoining grammars (Joshi and Schabes, 1997) and exploiting a stack of stacks. However, by imposing projectivity, we do not use the extra-power of the latter class.

An interesting line of future research is to combine our dynamic parsing strategy with a training method that allows the parser to explore transitions that apply to incorrect configurations, as in Goldberg and Nivre (2012).

## Acknowledgments

We wish to thank Liang Huang and Marco Kuhlmann for discussion related to the ideas reported in this paper, and the anonymous reviewers for their useful suggestions. The second author has been partially supported by MIUR under project PRIN No. 2010LYA9RH\_006.

---

<sup>2</sup>Accuracy comparison of our work with Kitagawa and Tanaka-Ishii (2010) is not meaningful, since these authors have evaluated their system on the same data set but based on gold part-of-speech tags (personal communication).

## Abstract

Binarization of grammars is crucial for improving the complexity and performance of parsing and translation. We present a versatile binarization algorithm that can be tailored to a number of grammar formalisms by simply varying a formal parameter. We apply our algorithm to binarizing tree-to-string transducers used in syntax-based machine translation.

## 1 Introduction

Binarization amounts to transforming a given grammar into an equivalent grammar of rank 2, i.e., with at most two nonterminals on any right-hand side. The ability to binarize grammars is crucial for efficient parsing, because for many grammar formalisms the parsing complexity depends exponentially on the rank of the grammar. It is also critically important for tractable statistical machine translation (SMT). Syntax-based SMT systems (Chiang, 2007; Graehl et al., 2008) typically use some type of *synchronous grammar* describing a binary translation relation between strings and/or trees, such as synchronous context-free grammars (SCFGs) (Lewis and Stearns, 1966; Chiang, 2007), synchronous tree-substitution grammars (Eisner, 2003), synchronous tree-adjointing grammars (Nesson et al., 2006; DeNeefe and Knight, 2009), and tree-to-string transducers (Yamada and Knight, 2001; Graehl et al., 2008). These grammars typically have a large number of rules, many of which have rank greater than two.

The classical approach to binarization, as known from the Chomsky normal form transformation for context-free grammars (CFGs), proceeds rule by rule. It replaces each rule of rank greater than 2 by an equivalent collection of rules of rank 2. All CFGs can be binarized in this

way, which is why their recognition problem is cubic. In the case of linear context-free rewriting systems (LCFRSs, (Weir, 1988)) the rule-by-rule technique also applies to every grammar, as long as an increased fanout is permitted (Rambow and Satta, 1999).

There are also grammar formalisms for which the rule-by-rule technique is not complete. In the case of SCFGs, not every grammar has an equivalent representation of rank 2 in the first place (Aho and Ullman, 1969). Even when such a representation exists, it is not always possible to compute it rule by rule. Nevertheless, the rule-by-rule binarization algorithm of Huang et al. (2009) is very useful in practice.

In this paper, we offer a generic approach for transferring the rule-by-rule binarization technique to new grammar formalisms. At the core of our approach is a binarization algorithm that can be adapted to a new formalism by changing a parameter at runtime. Thus it only needs to be implemented once, and can then be reused for a variety of formalisms. More specifically, our algorithm requires the user to (i) encode the grammar formalism as a subclass of *interpreted regular tree grammars* (IRTGs, (Koller and Kuhlmann, 2011)) and (ii) supply a collection of *b-rules*, which represent equivalence of grammars syntactically. Our algorithm then replaces, in a given grammar, each rule of rank greater than 2 by an equivalent collection of rules of rank 2, if such a collection is licensed by the b-rules. We define completeness of b-rules in a way that ensures that if any equivalent collection of rules of rank 2 exists, the algorithm finds one. As a consequence, the algorithm binarizes every grammar that can be binarized rule by rule. Step (i) is possible for all the grammar formalisms mentioned above. We show Step (ii) for SCFGs and tree-to-string transducers.

We will use SCFGs as our running example throughout the paper. We will also apply the algo-

rithm to tree-to-string transducers (Graehl et al., 2008; Galley et al., 2004), which describe relations between strings in one language and parse trees of another, which means that existing methods for binarizing SCFGs and LCFRSs cannot be directly applied to these systems. To our knowledge, our binarization algorithm is the first to binarize such transducers. We illustrate the effectiveness of our system by binarizing a large tree-to-string transducer for English-German SMT.

**Plan of the paper.** We start by defining IRTGs in Section 2. In Section 3, we define the general outline of our approach to rule-by-rule binarization for IRTGs, and then extend this to an efficient binarization algorithm based on b-rules in Section 4. In Section 5 we show how to use the algorithm to perform rule-by-rule binarization of SCFGs and tree-to-string transducers, and relate the results to existing work.

## 2 Interpreted regular tree grammars

Grammar formalisms employed in parsing and SMT, such as those mentioned in the introduction, differ in the the derived objects—e.g., strings, trees, and graphs—and the operations involved in the derivation—e.g., concatenation, substitution, and adjoining. Interpreted regular tree grammars (IRTGs) permit a uniform treatment of many of these formalisms. To this end, IRTGs combine two ideas, which we explain here.

**Algebras** IRTGs represent the objects and operations symbolically using terms; the object in question is obtained by interpreting each symbol in the term as a function. As an example, Table 1 shows terms for a string and a tree, together with the denoted object. In the string case, we describe complex strings as concatenation ( $\text{con}^2$ ) of elementary symbols (e.g.,  $a, b$ ); in the tree case, we alternate the construction of a sequence of trees ( $\text{con}^2$ ) with the construction of a single tree by placing a symbol (e.g.,  $\alpha, \beta, \sigma$ ) on top of a (possibly empty) sequence of trees. Whenever a term contains variables, it does not denote an object, but rather a function. In the parlance of universal-algebra theory, we are employing *initial-algebra semantics* (Goguen et al., 1977).

An *alphabet* is a nonempty finite set. Throughout this paper, let  $X = \{x_1, x_2, \dots\}$  be a set, whose elements we call *variables*. We let  $X_k$  denote the set  $\{x_1, \dots, x_k\}$  for every  $k \geq 0$ . Let  $\Sigma$

be an alphabet and  $V \subseteq X$ . We write  $T_\Sigma(V)$  for the set of all terms over  $\Sigma$  with variables  $V$ , i.e., the smallest set  $T$  such that (i)  $V \subseteq T$  and (ii) for every  $\sigma \in \Sigma$ ,  $k \geq 0$ , and  $t_1, \dots, t_k \in T$ , we have  $\sigma(t_1, \dots, t_k) \in T$ . Alternatively, we view  $T_\Sigma(V)$  as the set of all (rooted, labeled, ordered, unranked) *trees over  $\Sigma$  and  $V$* , and draw them as usual. By  $T_\Sigma$  we abbreviate  $T_\Sigma(\emptyset)$ . The *set  $C_\Sigma(V)$  of contexts over  $\Sigma$  and  $V$*  is the set of all trees over  $\Sigma$  and  $V$  in which each variable in  $V$  occurs exactly once.

A *signature* is an alphabet  $\Sigma$  where each symbol is equipped with an *arity*. We write  $\Sigma|_k$  for the subset of all  $k$ -ary symbols of  $\Sigma$ , and  $\sigma|_k$  to denote  $\sigma \in \Sigma|_k$ . We denote the signature by  $\Sigma$  as well. A signature is *binary* if the arities do not exceed 2. Whenever we use  $T_\Sigma(V)$  with a signature  $\Sigma$ , we assume that the trees are ranked, i.e., each node labeled by  $\sigma \in \Sigma|_k$  has exactly  $k$  children.

Let  $\Delta$  be a signature. A  $\Delta$ -*algebra*  $\mathcal{A}$  consists of a nonempty set  $A$  called the *domain* and, for each symbol  $f \in \Delta$  with rank  $k$ , a total function  $f^{\mathcal{A}}: A^k \rightarrow A$ , the *operation* associated with  $f$ . We can *evaluate* any term  $t$  in  $T_\Delta(X_k)$  in  $\mathcal{A}$ , to obtain a  $k$ -ary operation  $t^{\mathcal{A}}$  over the domain. In particular, terms in  $T_\Delta$  evaluate to elements of  $A$ . For instance, in the string algebra shown in Table 1, the term  $\text{con}^2(a, b)$  evaluates to  $ab$ , and the term  $\text{con}^2(\text{con}^2(x_2, a), x_1)$  evaluates to a binary operation  $f$  such that, e.g.,  $f(b, c) = cab$ .

**Bimorphisms** IRTGs separate the finite control (state behavior) of a derivation from its derived object (in its term representation; generational behavior); the former is captured by a regular tree language, while the latter is obtained by applying a tree homomorphism. This idea goes back to the *tree bimorphisms* of Arnold and Dauchet (1976).

Let  $\Sigma$  be a signature. A *regular tree grammar* (RTG)  $G$  over  $\Sigma$  is a triple  $(Q, q_0, R)$  where  $Q$  is a finite set (of *states*),  $q_0 \in Q$ , and  $R$  is a finite set of rules of the form  $q \rightarrow \alpha(q_1, \dots, q_k)$ , where  $q \in Q$ ,  $\alpha \in \Sigma|_k$  and  $q, q_1, \dots, q_k \in Q$ . We call  $\alpha$  the *terminal symbol* and  $k$  the *rank* of the rule. Rules of rank greater than two are called *suprabinary*. For every  $q \in Q$  we define the *language  $L^q(G)$  derived from  $q$*  as the set  $\{\alpha(t_1, \dots, t_k) \mid q \rightarrow \alpha(q_1, \dots, q_k) \in R, t_j \in L^{q_j}(G)\}$ . If  $q = q_0$ , we drop the superscript and write  $L(G)$  for the *tree language of  $G$* . In the literature, there is a definition of RTG which also permits more than one terminal symbol per rule,

or none. This does not increase the generative capacity (Brainerd, 1969).

A (*linear, nondeleting*) *tree homomorphism* is a mapping  $h: T_\Sigma(X) \rightarrow T_\Delta(X)$  that satisfies the following condition: there is a mapping  $g: \Sigma \rightarrow T_\Delta(X)$  such that (i)  $g(\sigma) \in C_\Delta(X_k)$  for every  $\sigma \in \Sigma|_k$ , (ii)  $h(\sigma(t_1, \dots, t_k))$  is the tree obtained from  $g(\sigma)$  by replacing the occurrence of  $x_j$  by  $h(t_j)$ , and (iii)  $h(x_j) = x_j$ . This extends the usual definition of linear and nondeleting homomorphisms (Gécseg and Steinby, 1997) to trees with variables. We abuse notation and write  $h(\sigma)$  for  $g(\sigma)$  for every  $\sigma \in \Sigma$ .

Let  $n \geq 1$  and  $\Delta_1, \dots, \Delta_n$  be signatures. A (*generalized*) *bimorphism* over  $(\Delta_1, \dots, \Delta_n)$  is a tuple  $\mathcal{B} = (G, h_1, \dots, h_n)$  where  $G$  is an RTG over some signature  $\Sigma$  and  $h_i$  is a tree homomorphism from  $T_\Sigma(X)$  into  $T_{\Delta_i}(X)$ . The *language*  $L(\mathcal{B})$  induced by  $\mathcal{B}$  is the tree relation  $\{(h_1(t), \dots, h_n(t)) \mid t \in L(G)\}$ .

An IRTG is a bimorphism whose derived trees are viewed as terms over algebras; see Fig. 1. Formally, an *IRTG*  $\mathbb{G}$  over  $(\Delta_1, \dots, \Delta_n)$  is a tuple  $(\mathcal{B}, \mathcal{A}_1, \dots, \mathcal{A}_n)$  such that  $\mathcal{B}$  is a bimorphism over  $(\Delta_1, \dots, \Delta_n)$  and  $\mathcal{A}_i$  is a  $\Delta_i$ -algebra. The *language*  $L(\mathbb{G})$  induced by  $\mathbb{G}$  is the relation  $\{(t_1^{\mathcal{A}_1}, \dots, t_n^{\mathcal{A}_n}) \mid (t_1, \dots, t_n) \in L(\mathcal{B})\}$ . We call the trees in  $L(G)$  *derivation trees* and the terms in  $L(\mathcal{B})$  *semantic terms*. We say that two IRTGs  $\mathbb{G}$  and  $\mathbb{G}'$  are *equivalent* if  $L(\mathbb{G}) = L(\mathbb{G}')$ . IRTGs were first defined in (Koller and Kuhlmann, 2011).

For example, Fig. 2 is an IRTG that encodes a synchronous context-free grammar (SCFG). It contains a bimorphism  $\mathcal{B} = (G, h_1, h_2)$  consisting of an RTG  $G$  with four rules and homomor-

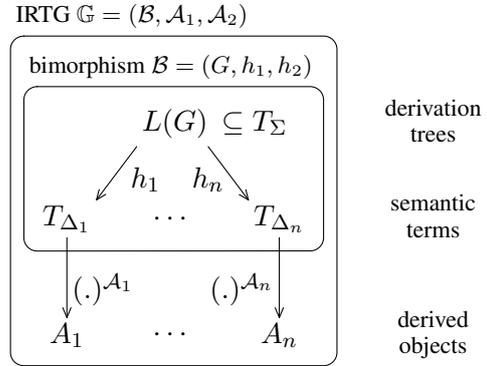

Figure 1: IRTG, bimorphism overview.

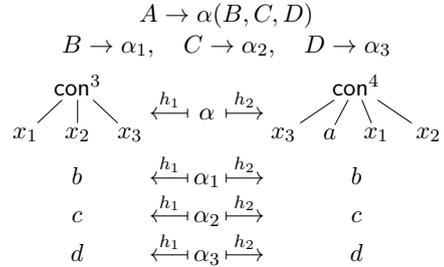

Figure 2: An IRTG encoding an SCFG.

phisms  $h_1$  and  $h_2$  which map derivation trees to trees over the signature of the string algebra in Table 1. By evaluating these trees in the algebra, the symbols  $\text{con}^3$  and  $\text{con}^4$  are interpreted as concatenation, and we see that the first rule encodes the SCFG rule  $A \rightarrow \langle BCD, DaBC \rangle$ . Figure 3 shows a derivation tree with its two homomorphic images, which evaluate to the strings  $bcd$  and  $dabc$ .

IRTGs can be tailored to the expressive capacity of specific grammar formalisms by selecting suitable algebras. The string algebra in Table 1 yields context-free languages, more complex string al-

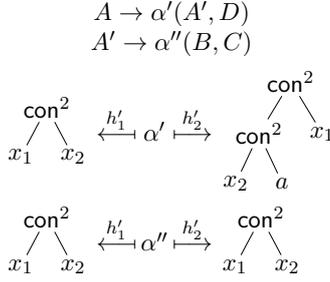

Figure 4: Binary rules corresponding to the  $\alpha$ -rule in Fig. 2.

gebras yield tree-adjointing languages (Koller and Kuhlmann, 2012), and algebras over other domains can yield languages of trees, graphs, or other objects. Furthermore, IRTGs with  $n = 1$  describe languages that are subsets of the algebra's domain,  $n = 2$  yields synchronous languages or tree transductions, and so on.

### 3 IRTG binarization

We will now show how to apply the rule-by-rule binarization technique to IRTGs. We start in this section by defining the binarization of a rule in an IRTG, and characterizing it in terms of *binarization terms* and *variable trees*. We derive the actual binarization algorithm from this in Section 4.

For the remainder of this paper, let  $\mathbb{G} = (\mathcal{B}, \mathcal{A}_1, \dots, \mathcal{A}_n)$  be an IRTG over  $(\Delta_1, \dots, \Delta_n)$  with  $\mathcal{B} = (G, h_1, \dots, h_n)$ .

#### 3.1 An introductory example

We start with an example to give an intuition of our approach. Consider the first rule in Fig. 2, which has rank three. This rule derives (in one step) the fragment  $\alpha(x_1, x_2, x_3)$  of the derivation tree in Fig. 3, which is mapped to the semantic terms  $h_1(\alpha)$  and  $h_2(\alpha)$  shown in Fig. 2. Now consider the rules in Fig. 4. These rules can be used to derive (in two steps) the derivation tree fragment  $\xi$  in Fig. 5e. Note that the terms  $h'_1(\xi)$  and  $h_1(\alpha)$  are *equivalent* in that they denote the same function over the string algebra, and so are the terms  $h'_2(\xi)$  and  $h_2(\alpha)$ . Thus, replacing the  $\alpha$ -rule by the rules in Fig. 4 does not change the language of the IRTG. However, since the new rules are binary,

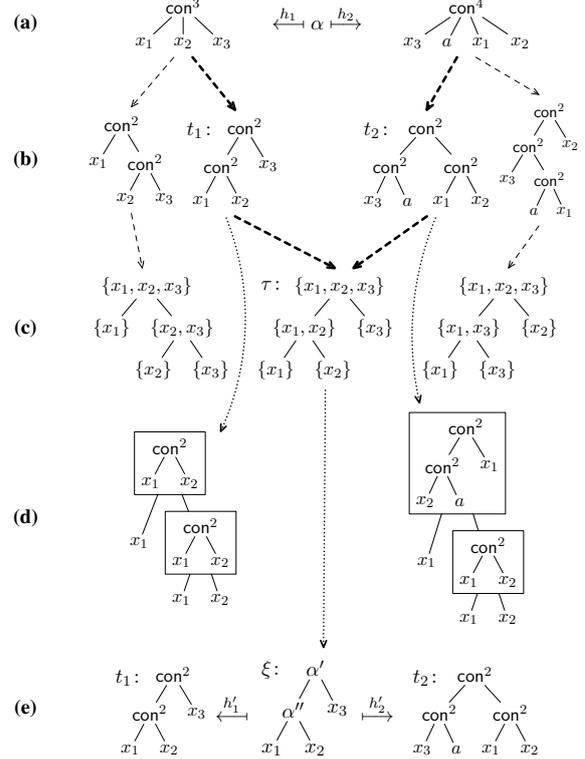

Figure 5: Outline of the binarization algorithm.

parsing and translation will be cheaper.

Now we want to construct the binary rules systematically. In the example, we proceed as follows (cf. Fig. 5). For each of the terms  $h_1(\alpha)$  and  $h_2(\alpha)$  (Fig. 5a), we consider all terms that satisfy two properties (Fig. 5b): (i) they are equivalent to  $h_1(\alpha)$  and  $h_2(\alpha)$ , respectively, and (ii) at each node at most two subtrees contain variables. As Fig. 5 suggests, there may be many different terms of this kind. For each of these terms, we analyze the bracketing of variables, obtaining what we call a *variable tree* (Fig. 5c). Now we pick terms  $t_1$  and  $t_2$  corresponding to  $h_1(\alpha)$  and  $h_2(\alpha)$ , respectively, such that (iii) they have the same variable tree, say  $\tau$ . We construct a tree  $\xi$  from  $\tau$  by a simple relabeling, and we read off the tree homomorphisms  $h'_1$  and  $h'_2$  from a decomposition we perform on  $t_1$  and  $t_2$ , respectively; see Fig. 5, dotted arrows, and compare the boxes in Fig. 5d with the homomorphisms in Fig. 4. Now the rules in Fig. 4 are easily extracted from  $\xi$ .

These rules are equivalent to  $r$  because of (i); they are binary because  $\xi$  is binary, which in turn holds because of (ii); finally, the decompositions of  $t_1$  and  $t_2$  are compatible with  $\xi$  because of (iii). We call terms  $t_1$  and  $t_2$  *binarization terms* if they satisfy (i)–(iii). We will see below that we can con-

struct binary rules equivalent to  $r$  from any given sequence of binarization terms  $t_1, t_2$ , and that binarization terms exist whenever equivalent binary rules exist. The majority of this paper revolves around the question of finding binarization terms.

Rule-by-rule binarization of IRTGs follows the intuition laid out in this example closely: it means processing each suprabinary rule, attempting to replace it with an equivalent collection of binary rules.

### 3.2 Binarization terms

We will now make this intuition precise. To this end, we assume that  $r = q \rightarrow \alpha(q_1, \dots, q_k)$  is a suprabinary rule of  $G$ . As we have seen, binarizing  $r$  boils down to constructing:

- a tree  $\xi$  over some binary signature  $\Sigma'$  and
- tree homomorphisms  $h'_1, \dots, h'_n$  of type  $h'_i: T_{\Sigma'}(X) \rightarrow T_{\Delta_i}(X)$ ,

such that  $h'_i(\xi)$  and  $h_i(\alpha)$  are equivalent, i.e., they denote the same function over  $\mathcal{A}_i$ . We call such a tuple  $(\xi, h'_1, \dots, h'_n)$  a *binarization* of the rule  $r$ . Note that a binarization of  $r$  need not exist. The problem of *rule-by-rule binarization* consists in computing a binarization of each suprabinary rule of a grammar. If such a binarization does not exist, the problem does not have a solution.

In order to define variable trees, we assume a mapping  $\text{seq}$  that maps each finite set  $U$  of pairwise disjoint variable sets to a sequence over  $U$  which contains each element exactly once. Let  $t \in C_{\Delta}(X_k)$ . The *variable set* of  $t$  is the set of all variables that occur in  $t$ . The *set  $S(t)$  of subtree variables* of  $t$  consists of the nonempty variable sets of all subtrees of  $t$ . We represent  $S(t)$  as a tree  $v(t)$ , which we call *variable tree* as follows. Any two elements of  $S(t)$  are either comparable (with respect to the subset relation) or disjoint. We extend this ordering to a tree structure by ordering disjoint elements via  $\text{seq}$ . We let  $v(L) = \{v(t) \mid t \in L\}$  for every  $L \subseteq C_{\Delta}(X_k)$ .

In the example of Fig. 5,  $t_1$  and  $t_2$  have the same set of subtree variables; it is  $\{\{x_1\}, \{x_2\}, \{x_3\}, \{x_1, x_2\}, \{x_1, x_2, x_3\}\}$ . If we assume that  $\text{seq}$  orders sets of variables according to the least variable index, we arrive at the variable tree in the center of Fig. 5.

Now let  $t_1 \in T_{\Delta_1}(X_k), \dots, t_n \in T_{\Delta_n}(X_k)$ . We call the tuple  $t_1, \dots, t_n$  *binarization terms* of  $r$  if the following properties hold: (i)  $h_i(\alpha)$  and  $t_i$  are equivalent; (ii) at each node the tree  $t_i$  contains

at most two subtrees with variables; and (iii) the terms  $t_1, \dots, t_n$  have the same variable tree.

Assume for now that we have found binarization terms  $t_1, \dots, t_n$ . We show how to construct a binarization  $(\xi, h'_1, \dots, h'_n)$  of  $r$  with  $t_i = h'_i(\xi)$ .

First, we construct  $\xi$ . Since  $t_1, \dots, t_n$  are binarization terms, they have the same variable tree, say,  $\tau$ . We obtain  $\xi$  from  $\tau$  by replacing every label of the form  $\{x_j\}$  with  $x_j$ , and every other label with a fresh symbol. Because of condition (ii) in the definition of binarization terms,  $\xi$  is binary.

In order to construct  $h'_i(\sigma)$  for each symbol  $\sigma$  in  $\xi$ , we transform  $t_i$  into a tree  $t'_i$  with labels from  $C_{\Delta_i}(X)$  and the same structure as  $\xi$ . Then we read off  $h'_i(\sigma)$  from the node of  $t'_i$  that corresponds to the  $\sigma$ -labeled node of  $\xi$ . The transformation proceeds as illustrated in Fig. 6: first, we apply the *maximal decomposition operation*  $\rightsquigarrow_d$ ; it replaces every label  $f \in \Delta_i|_k$  by the tree  $f(x_1, \dots, x_k)$ , represented as a box. After that, we keep applying the *merge operation*  $\rightsquigarrow_m$  as often as possible; it merges two boxes that are in a parent-child relation, given that one of them has at most one child. Thus the number of variables in any box can only decrease. Finally, the *reorder operation*  $\rightsquigarrow_o$  orders the children of each box according to the  $\text{seq}$  of their variable sets. These operations do not change the variable tree; one can use this to show that  $t'_i$  has the same structure as  $\xi$ .

Thus, if we can find binarization terms, we can construct a binarization of  $r$ . Conversely, for any given binarization  $(\xi, h'_1, \dots, h'_n)$  the semantic terms  $h'_1(\xi), \dots, h'_n(\xi)$  are binarization terms. This proves the following lemma.

**Lemma 1** *There is a binarization of  $r$  if and only if there are binarization terms of  $r$ .*

### 3.3 Finding binarization terms

It remains to show how we can find binarization terms of  $r$ , if there are any.

Let  $b_i: T_{\Delta_i}(X_k) \rightarrow \mathcal{P}(T_{\Delta_i}(X_k))$  the mapping with  $b_i(t) = \{t' \in T_{\Delta_i}(X_k) \mid t \text{ and } t' \text{ are equivalent, and at each node } t' \text{ has at most two children with variables}\}$ . Figure 5b shows some elements of  $b_1(h_1(\alpha))$  and  $b_2(h_2(\alpha))$  for our example. Terms  $t_1, \dots, t_n$  are binarization terms precisely when  $t_i \in b_i(h_i(\alpha))$  and  $t_1, \dots, t_n$  have the same variable tree. Thus we can characterize binarization terms as follows.

**Lemma 2** *There are binarization terms if and only if  $\bigcap_i v(b_i(h_i(\alpha))) \neq \emptyset$ .*

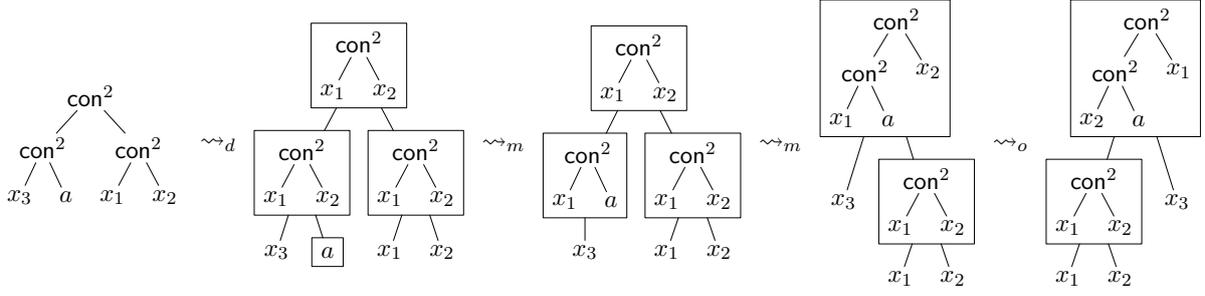

Figure 6: Transforming  $t_2$  into  $t'_2$ .

This result suggests the following procedure for obtaining binarization terms. First, determine whether the intersection in Lemma 2 is empty. If it is, then there is no binarization of  $r$ . Otherwise, select a variable tree  $\tau$  from this set. We know that there are trees  $t_1, \dots, t_n$  such that  $t_i \in b_i(h_i(\alpha))$  and  $v(t_i) = \tau$ . We can therefore select arbitrary concrete trees  $t_i \in b_i(h_i(\alpha)) \cap v^{-1}(\tau)$ . The terms  $t_1, \dots, t_n$  are then binarization terms.

#### 4 Effective IRTG binarization

In this section we develop our binarization algorithm. Its key task is finding binarization terms  $t_1, \dots, t_n$ . This task involves deciding term equivalence, as  $t_i$  must be equivalent to  $h_i(\alpha)$ . In general, equivalence is undecidable, so the task cannot be solved. We avoid deciding equivalence by requiring the user to specify an explicit approximation of  $b_i$ , which we call a *b-rule*. This parameter gives rise to a restricted version of the rule-by-rule binarization problem, which is efficiently computable while remaining practically relevant.

Let  $\Delta$  be a signature. A *binarization rule (b-rule)* over  $\Delta$  is a mapping  $\mathfrak{b}: \Delta \rightarrow \mathcal{P}(T_\Delta(X))$  where for every  $f \in \Delta|_k$  we have that  $\mathfrak{b}(f) \subseteq C_\Delta(X_k)$ , at each node of a tree in  $\mathfrak{b}(f)$  only two children contain variables, and  $\mathfrak{b}(f)$  is a regular tree language. We extend  $\mathfrak{b}$  to  $T_\Delta(X)$  by setting  $\mathfrak{b}(x_j) = \{x_j\}$  and  $\mathfrak{b}(f(t_1, \dots, t_k)) = \{t[x_j/t'_j \mid 1 \leq j \leq k] \mid t \in \mathfrak{b}(f), t'_j \in \mathfrak{b}(t_j)\}$ , where  $[x_j/t'_j]$  denotes substitution of  $x_j$  by  $t'_j$ . Given an algebra  $\mathcal{A}$  over  $\Delta$ , a b-rule  $\mathfrak{b}$  over  $\Delta$  is called a *b-rule over  $\mathcal{A}$*  if, for every  $t \in T_\Delta(X_k)$  and  $t' \in \mathfrak{b}(t)$ ,  $t'$  and  $t$  are equivalent in  $\mathcal{A}$ . Such a b-rule encodes equivalence in  $\mathcal{A}$ , and it does so in an explicit and compact way: because  $\mathfrak{b}(f)$  is a regular tree language, a b-rule can be specified by a finite collection of RTGs, one for each symbol  $f \in \Delta$ . We will look at examples (for the string and tree algebras shown earlier) in Section 5.

From now on, we assume that  $\mathfrak{b}_1, \dots, \mathfrak{b}_n$  are b-rules over  $\mathcal{A}_1, \dots, \mathcal{A}_n$ , respectively. A binarization  $(\xi, h'_1, \dots, h'_n)$  of  $r$  is a *binarization of  $r$  with respect to  $\mathfrak{b}_1, \dots, \mathfrak{b}_n$*  if  $h'_i(\xi) \in \mathfrak{b}_i(h_i(\alpha))$ . Likewise, binarization terms  $t_1, \dots, t_n$  are *binarization terms with respect to  $\mathfrak{b}_1, \dots, \mathfrak{b}_n$*  if  $t_i \in \mathfrak{b}_i(h_i(\alpha))$ . Lemmas 1 and 2 carry over to the restricted notions. The problem of *rule-by-rule binarization with respect to  $\mathfrak{b}_1, \dots, \mathfrak{b}_n$*  consists in computing a binarization with respect to  $\mathfrak{b}_1, \dots, \mathfrak{b}_n$  for each suprabinary rule.

By definition, every solution to this restricted problem is also a solution to the general problem. The converse need not be true. However, we can guarantee that the restricted problem has at least one solution whenever the general problem has one, by requiring  $v(\mathfrak{b}_i(h_i(\alpha))) = v(\mathfrak{b}(h_i(\alpha)))$ . Then the intersection in Lemma 2 is empty in the restricted case if and only if it is empty in the general case. We call the b-rules  $\mathfrak{b}_1, \dots, \mathfrak{b}_1$  *complete* on  $\mathbb{G}$  if the equation holds for every  $\alpha \in \Sigma$ .

Now we show how to effectively compute binarization terms with respect to  $\mathfrak{b}_1, \dots, \mathfrak{b}_n$ , along the lines of Section 3.3. More specifically, we construct an RTG for each of the sets (i)  $\mathfrak{b}_i(h_i(\alpha))$ , (ii)  $\mathfrak{b}'_i = v(\mathfrak{b}_i(h_i(\alpha)))$ , (iii)  $\bigcap_i \mathfrak{b}'_i$ , and (iv)  $\mathfrak{b}''_i = \mathfrak{b}_i(h_i(\alpha)) \cap v^{-1}(\tau)$  (given  $\tau$ ). Then we can select  $\tau$  from (iii) and  $t_i$  from (iv) using a standard algorithm, such as the Viterbi algorithm or Knuth's algorithm (Knuth, 1977; Nederhof, 2003; Huang and Chiang, 2005). The effectiveness of our procedure stems from the fact that we only manipulate RTGs and never enumerate languages.

The construction for (i) is recursive, following the definition of  $\mathfrak{b}_i$ . The base case is a language  $\{x_j\}$ , for which the RTG is easy. For the recursive case, we use the fact that regular tree languages are closed under substitution (Gécseg and Steinby, 1997, Prop. 7.3). Thus we obtain an RTG  $G_i$  with  $L(G_i) = \mathfrak{b}_i(h_i(\alpha))$ .

For (ii) and (iv), we need the following auxiliary

construction. Let  $G_i = (P, p_0, R)$ . We define the mapping  $\text{var}_i: P \rightarrow \mathcal{P}(X_k)$  such that for every  $p \in P$ , every  $t \in L^p(G_i)$  contains exactly the variables in  $\text{var}_i(p)$ . We construct it as follows. We initialize  $\text{var}_i(p)$  to “unknown” for every  $p$ . For every rule  $p \rightarrow x_j$ , we set  $\text{var}_i(p) = \{x_j\}$ . For every rule  $p \rightarrow \sigma(p_1, \dots, p_k)$  such that  $\text{var}_i(p_j)$  is known, we set  $\text{var}_i(p) = \bigcup_j \text{var}_i(p_j)$ . This is iterated; it can be shown that  $\text{var}_i(p)$  is never assigned two different values for the same  $p$ . Finally, we set all remaining unknown entries to  $\emptyset$ .

For (ii), we construct an RTG  $G'_i$  with  $L(G'_i) = b'_i$  as follows. We let  $G'_i = (\{\langle \text{var}_i(p) \rangle \mid p \in P\}, \text{var}_i(p_0), R')$  where  $R'$  consists of the rules

$$\begin{aligned} \langle \{x_j\} \rangle &\rightarrow \{x_j\} && \text{if } p \rightarrow x_i \in R, \\ \langle \text{var}_i(p) \rangle &\rightarrow \text{var}_i(p) \langle \langle U_1 \rangle, \dots, \langle U_l \rangle \rangle \\ &\text{if } p \rightarrow \sigma(p_1, \dots, p_k) \in R, \\ &V = \{\text{var}_i(p_j) \mid 1 \leq j \leq k\} \setminus \{\emptyset\}, \\ &|V| \geq 2, \text{seq}(V) = (U_1, \dots, U_l). \end{aligned}$$

For (iii), we use the standard product construction (Gécseg and Steinby, 1997, Prop. 7.1).

For (iv), we construct an RTG  $G''_i$  such that  $L(G''_i) = b''_i$  as follows. We let  $G''_i = (P, p_0, R'')$ , where  $R''$  consists of the rules

$$\begin{aligned} p &\rightarrow \sigma(p_1, \dots, p_k) \\ &\text{if } p \rightarrow \sigma(p_1, \dots, p_k) \in R, \\ &V = \{\text{var}_i(p_j) \mid 1 \leq j \leq k\} \setminus \{\emptyset\}, \\ &\text{if } |V| \geq 2, \text{ then} \\ &(\text{var}_i(p), \text{seq}(V)) \text{ is a fork in } \tau. \end{aligned}$$

By a fork  $(u, u_1 \dots u_k)$  in  $\tau$ , we mean that there is a node labeled  $u$  with  $k$  children labeled  $u_1$  up to  $u_k$ .

At this point we have all the ingredients for our binarization algorithm, shown in Algorithm 1. It operates directly on a bimorphism, because all the relevant information about the algebras is captured by the b-rules. The following theorem documents the behavior of the algorithm. In short, it solves the problem of rule-by-rule binarization with respect to b-rules  $b_1, \dots, b_n$ .

**Theorem 3** *Let  $\mathbb{G} = (\mathcal{B}, \mathcal{A}_1, \dots, \mathcal{A}_n)$  be an IRTG, and let  $b_1, \dots, b_n$  be b-rules over  $\mathcal{A}_1, \dots, \mathcal{A}_n$ , respectively.*

*Algorithm 1 terminates. Let  $\mathcal{B}'$  be the bimorphism computed by Algorithm 1 on  $\mathcal{B}$  and  $b_1, \dots, b_n$ . Then  $\mathbb{G}' = (\mathcal{B}', \mathcal{A}_1, \dots, \mathcal{A}_n)$  is equivalent to  $\mathbb{G}$ , and  $\mathbb{G}'$  is of rank 2 if and only*

**Input:** bimorphism  $\mathcal{B} = (G, h_1, \dots, h_n)$ ,  
b-rules  $b_1, \dots, b_n$  over  $\Delta_1, \dots, \Delta_n$

**Output:** bimorphism  $\mathcal{B}'$

```

1:  $\mathcal{B}' \leftarrow (G|_{\leq 2}, h_1, \dots, h_n)$ 
2: for rule  $r: q \rightarrow \alpha(q_1, \dots, q_k)$  of  $G|_{>2}$  do
3:   for  $i = 1, \dots, n$  do
4:     compute RTG  $G_i$  for  $b_i(h_i(\alpha))$ 
5:     compute RTG  $G'_i$  for  $v(b_i(h_i(\alpha)))$ 
6:   compute RTG  $G_v$  for  $\bigcap_i L(G'_i)$ 
7:   if  $L(G_v) = \emptyset$  then
8:     add  $r$  to  $\mathcal{B}'$ 
9:   else
10:    select  $t' \in L(G_v)$ 
11:    for  $i = 1, \dots, n$  do
12:      compute RTG  $G''_i$  for
13:         $b''_i = b_i(h_i(\alpha)) \cap v^{-1}(t')$ 
14:      select  $t_i \in L(G''_i)$ 
15:    construct binarization for  $t_1, \dots, t_n$ 
16:    add appropriate rules to  $\mathcal{B}'$ 

```

Algorithm 1: Complete binarization algorithm, where  $G|_{\leq 2}$  and  $G|_{>2}$  is  $G$  restricted to binary and suprabinary rules, respectively.

*if every suprabinary rule of  $\mathbb{G}$  has a binarization with respect to  $b_1, \dots, b_n$ .*

The runtime of Algorithm 1 is dominated by the intersection construction in line 6, which is  $O(m_1 \dots m_n)$  per rule, where  $m_i$  is the size of  $G'_i$ . The quantity  $m_i$  is linear in the size of the terms on the right-hand side of  $h_i$ , and in the number of rules in the b-rule  $b_i$ .

## 5 Applications

Algorithm 1 implements rule-by-rule binarization with respect to given b-rules. If a rule of the given IRTG does not have a binarization with respect to these b-rules, it is simply carried over to the new grammar, which then has a rank higher than 2. The number of remaining suprabinary rules depends on the b-rules (except for rules that have no binarization at all). The user can thus engineer the b-rules according to their current needs, trading off completeness, runtime, and engineering effort.

By contrast, earlier binarization algorithms for formalisms such as SCFG and LCFRS simply attempt to find an equivalent grammar of rank 2; there is no analogue of our b-rules. The problem these algorithms solve corresponds to the general rule-by-rule binarization problem from Section 3.

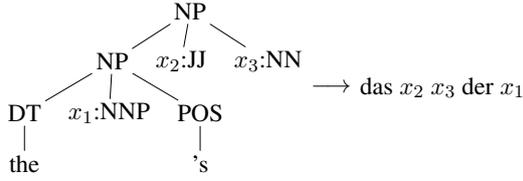

Figure 7: A rule of a tree-to-string transducer.

We show that under certain conditions, our algorithm can be used to solve this problem as well. In the following two subsections, we illustrate this for SCFGs and tree-to-string transducers, respectively. In the final subsection, we discuss how to extend this approach to other grammar formalisms as well.

### 5.1 Synchronous context-free grammars

We have used SCFGs as the running example in this paper. SCFGs are IRTGs with two interpretations into the string algebra of Table 1, as illustrated by the example in Fig. 2. In order to make our algorithm ready to use, it remains to specify a b-rule for the string algebra.

We use the following b-rule for both  $\mathfrak{b}_1$  and  $\mathfrak{b}_2$ . Each symbol  $a \in \Delta_i|_0$  is mapped to the language  $\{a\}$ . Each symbol  $\text{con}^k$ ,  $k \geq 2$ , is mapped to the language induced by the following RTG with states of the form  $[j, j']$  (where  $0 \leq j < j' \leq k$ ) and final state  $[0, k]$ :

$$\begin{aligned}
 [j-1, j] &\rightarrow x_j & (1 \leq j \leq k) \\
 [j, j'] &\rightarrow \text{con}^2([j, j''], [j'', j']) & (0 \leq j < j'' < j' \leq k)
 \end{aligned}$$

This language expresses all possible ways in which  $\text{con}^k$  can be written in terms of  $\text{con}^2$ .

Our definition of rule-by-rule binarization with respect to  $\mathfrak{b}_1$  and  $\mathfrak{b}_2$  coincides with that of Huang et al. (2009): any rule can be binarized by both algorithms or neither. For instance, for the SCFG rule  $A \rightarrow \langle BCDE, CEED \rangle$ , the sets  $v(\mathfrak{b}_1(h_1(\alpha)))$  and  $v(\mathfrak{b}_2(h_2(\alpha)))$  are disjoint, thus no binarization exists. Two strings of length  $N$  can be parsed with a binary IRTG that represents an SCFG in time  $O(N^6)$ .

### 5.2 Tree-to-string transducers

Some approaches to SMT go beyond string-to-string translation models such as SCFG by exploiting known syntactic structures in the source or target language. This perspective on translation naturally leads to the use of tree-to-string transducers

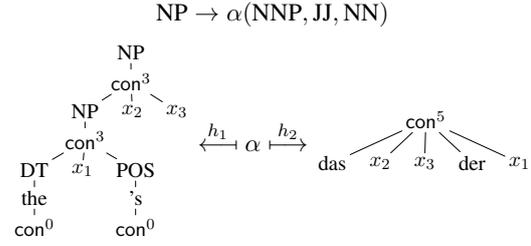

Figure 8: An IRTG rule encoding the rule in Fig. 7.

(Yamada and Knight, 2001; Galley et al., 2004; Huang et al., 2006; Graehl et al., 2008). Figure 7 shows an example of a tree-to-string rule. It might be used to translate “the Commission’s strategic plan” into “das langfristige Programm der Kommission”.

Our algorithm can binarize tree-to-string transducers; to our knowledge, it is the first algorithm to do so. We model the tree-to-string transducer as an IRTG  $\mathbb{G} = ((G, h_1, h_2), \mathcal{A}_1, \mathcal{A}_2)$ , where  $\mathcal{A}_2$  is the string algebra, but this time  $\mathcal{A}_1$  is the tree algebra shown in Table 1. This algebra has operations  $\text{con}^k$  to concatenate sequences of trees and unary  $\gamma$  that maps any sequence  $(t_1, \dots, t_l)$  of trees to the tree  $\gamma(t_1, \dots, t_l)$ , viewed as a sequence of length 1. Note that we exclude the operation  $\text{con}^1$  because it is the identity and thus unnecessary. Thus the rule in Fig. 7 translates to the IRTG rule shown in Fig. 8.

For the string algebra, we reuse the b-rule from Section 5.1; we call it  $\mathfrak{b}_2$  here. For the tree algebra, we use the following b-rule  $\mathfrak{b}_1$ . It maps  $\text{con}^0$  to  $\{\text{con}^0\}$  and each unary symbol  $\gamma$  to  $\{\gamma(x_1)\}$ . Each symbol  $\text{con}^k$ ,  $k \geq 2$ , is treated as in the string case. Using these b-rules, we can binarize the rule in Fig. 8 and obtain the rules in Fig. 9. Parsing of a binary IRTG that represents a tree-to-string transducer is  $O(N^3 \cdot M)$  for a string of length  $N$  and a tree with  $M$  nodes.

We have implemented our binarization algorithm and the b-rules for the string and the tree algebra. In order to test our implementation, we extracted a tree-to-string transducer from about a million parallel sentences of English-German Europarl data, using the GHKM rule extractor (Galley, 2010). Then we binarized the transducer. The results are shown in Fig. 10. Of the 2.15 million rules in the extracted transducer, 460,000 were suprabinary, and 67 % of these could be binarized. Binarization took 4.4 minutes on a single core of an Intel Core i5 2520M processor.

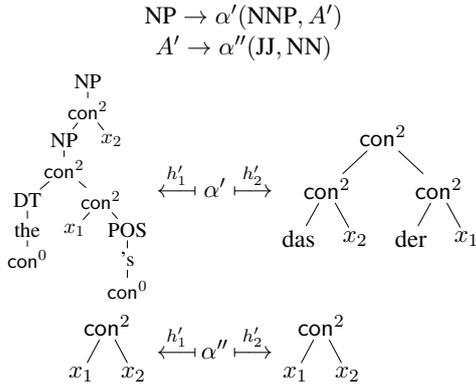

Figure 9: Binarization of the rule in Fig. 8.

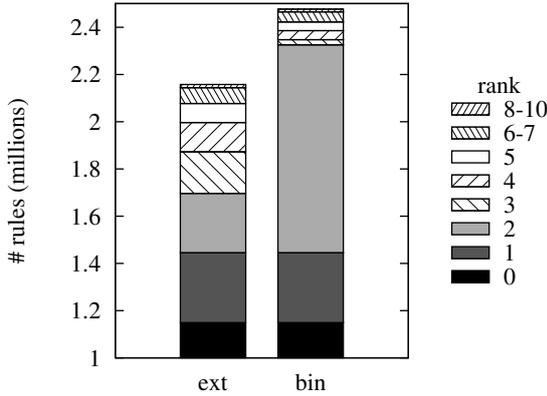

Figure 10: Rules of a transducer extracted from Europarl (ext) vs. its binarization (bin).

### 5.3 General approach

Our binarization algorithm can be used to solve the general rule-by-rule binarization problem for a specific grammar formalism, provided that one can find appropriate b-rules. More precisely, we need to devise a class  $\mathcal{C}$  of IRTGs over the same sequence  $\mathcal{A}_1, \dots, \mathcal{A}_n$  of algebras that encodes the grammar formalism, together with b-rules  $b_1, \dots, b_n$  over  $\mathcal{A}_1, \dots, \mathcal{A}_n$  that are complete on every grammar in  $\mathcal{C}$ , as defined in Section 4.

We have already seen the b-rules for SCFGs and tree-to-string transducers in the preceding subsections; now we have a closer look at the class  $\mathcal{C}$  for SCFGs. We used the class of all IRTGs with two string algebras and in which  $h_i(\alpha)$  contains at most one occurrence of a symbol  $\text{con}^k$  for every  $\alpha \in \Sigma$ . On such a grammar the b-rules are complete. Note that this would not be the case if we allowed several occurrences of  $\text{con}^k$ , as in  $\text{con}^2(\text{con}^2(x_1, x_2), x_3)$ . This term is equivalent to itself and to  $\text{con}^2(x_1, \text{con}^2(x_2, x_3))$ , but the b-

rules only cover the former. Thus they miss one variable tree. For the term  $\text{con}^3(x_1, x_2, x_3)$ , however, the b-rules cover both variable trees.

Generally speaking, given  $\mathcal{C}$  and b-rules  $b_1, \dots, b_n$  that are complete on every IRTG in  $\mathcal{C}$ , Algorithm 1 solves the general rule-by-rule binarization problem on  $\mathcal{C}$ . We can adapt Theorem 3 by requiring that  $\mathbb{G}$  must be in  $\mathcal{C}$ , and replacing each of the two occurrences of “binarization with respect to  $b_1, \dots, b_n$ ” by simply “binarization”. If  $\mathcal{C}$  is such that every grammar from a given grammar formalism can be encoded as an IRTG in  $\mathcal{C}$ , this solves the general rule-by-rule binarization problem of that grammar formalism.

## 6 Conclusion

We have presented an algorithm for binarizing IRTGs rule by rule, with respect to b-rules that the user specifies for each algebra. This improves the complexity of parsing and translation with any monolingual or synchronous grammar that can be represented as an IRTG. A novel algorithm for binarizing tree-to-string transducers falls out as a special case.

In this paper, we have taken the perspective that the binarized IRTG uses the same algebras as the original IRTG. Our algorithm extends to grammars of arbitrary fanout (such as synchronous tree-adjointing grammar (Koller and Kuhlmann, 2012)), but unlike LCFRS-based approaches to binarization, it will not *increase* the fanout to ensure binarizability. In the future, we will explore IRTG binarization with fanout increase. This could be done by binarizing into an IRTG with a more complicated algebra (e.g., of string tuples). We might compute binarizations that are optimal with respect to some measure (e.g., fanout (Gomez-Rodriguez et al., 2009) or parsing complexity (Gildea, 2010)) by keeping track of this measure in the b-rule and taking intersections of weighted tree automata.

## Acknowledgments

We thank the anonymous referees for their insightful remarks, and Sarah Hemmen for implementing an early version of the algorithm. Matthias Büchse was financially supported by DFG VO 1011/6-1.

## Abstract

This paper proposes new distortion models for phrase-based SMT. In decoding, a distortion model estimates the source word position to be translated next (NP) given the last translated source word position (CP). We propose a distortion model that can consider the word at the CP, a word at an NP candidate, and the context of the CP and the NP candidate simultaneously. Moreover, we propose a further improved model that considers richer context by discriminating label sequences that specify spans from the CP to NP candidates. It enables our model to learn the effect of relative word order among NP candidates as well as to learn the effect of distances from the training data. In our experiments, our model improved 2.9 BLEU points for Japanese-English and 2.6 BLEU points for Chinese-English translation compared to the lexical reordering models.

## 1 Introduction

Estimating appropriate word order in a target language is one of the most difficult problems for statistical machine translation (SMT). This is particularly true when translating between languages with widely different word orders.

To address this problem, there has been a lot of research done into word reordering: lexical reordering model (Tillman, 2004), which is one of the distortion models, reordering constraint (Zens et al., 2004), pre-ordering (Xia and McCord, 2004), hierarchical phrase-based SMT (Chiang, 2007), and syntax-based SMT (Yamada and Knight, 2001).

In general, source language syntax is useful for handling long distance word reordering. However,

obtaining syntax requires a syntactic parser, which is not available for many languages. Phrase-based SMT (Koehn et al., 2007) is a widely used SMT method that does not use a parser.

Phrase-based SMT mainly<sup>1</sup> estimates word reordering using distortion models<sup>2</sup>. Therefore, distortion models are one of the most important components for phrase-based SMT. On the other hand, there are methods other than distortion models for improving word reordering for phrase-based SMT, such as pre-ordering or reordering constraints. However, these methods also use distortion models when translating by phrase-based SMT. Therefore, distortion models do not compete against these methods and are commonly used with them. If there is a good distortion model, it will improve the translation quality of phrase-based SMT and benefit to the methods using distortion models.

In this paper, we propose two distortion models for phrase-based SMT. In decoding, a distortion model estimates the source word position to be translated next (NP) given the last translated source word position (CP). The proposed models are *the pair model* and *the sequence model*. The pair model utilizes the word at the CP, a word at an NP candidate site, and the words surrounding the CP and the NP candidates (context) simultaneously. In addition, the sequence model, which is the further improved model, considers richer context by identifying the label sequence that specify the span from the CP to the NP. It enables our model to learn the effect of relative word order among NP candidates as well as to learn the effect of distances from the training data. Our model learns the preference relations among NP

<sup>1</sup>A language model also supports the estimation.

<sup>2</sup>In this paper, reordering models for phrase-based SMT, which are intended to estimate the source word position to be translated next in decoding, are called distortion models. This estimation is used to produce a hypothesis in the target language word order sequentially from left to right.

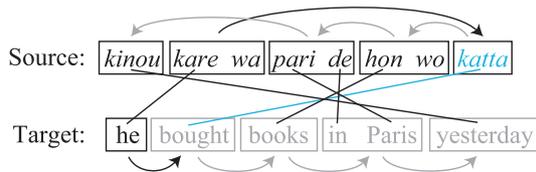

Figure 1: An example of left-to-right translation for Japanese-English. Boxes represent phrases and arrows indicate the translation order of the phrases.

candidates. Our model consists of one probabilistic model and does not require a parser. Experiments confirmed the effectiveness of our method for Japanese-English and Chinese-English translation, using NTCIR-9 Patent Machine Translation Task data sets (Goto et al., 2011).

## 2 Distortion Model for Phrase-Based SMT

A Moses-style phrase-based SMT generates target hypotheses sequentially from left to right. Therefore, the role of the distortion model is to estimate the source phrase position to be translated next whose target side phrase will be located immediately to the right of the already generated hypotheses. An example is shown in Figure 1. In Figure 1, we assume that only the *kare wa* (English side: “he”) has been translated. The target word to be generated next will be “bought” and the source word to be selected next will be its corresponding Japanese word *katta*. Thus, a distortion model should estimate phrases including *katta* as a source phrase position to be translated next.

To explain the distortion model task in more detail, we need to redefine more precisely two terms, the *current position* (CP) and *next position* (NP) in the source sentence. CP is the source sentence position corresponding to the rightmost aligned target word in the generated target word sequence. NP is the source sentence position corresponding to the leftmost aligned target word in the target phrase to be generated next. The task of the distortion model is to estimate the NP<sup>3</sup> from NP candidates (NPCs) for each CP in the source sentence.<sup>4</sup>

<sup>3</sup>NP is not always one position, because there may be multiple correct hypotheses.

<sup>4</sup>This definition is slightly different from that of existing methods such as Moses and (Green et al., 2010). In existing methods, CP is the rightmost position of the last translated source phrase and NP is the leftmost position of the source phrase to be translated next. Note that existing methods do

Figure 2: Examples of CP and NP for Japanese-English translation. The upper sentence is the source sentence and the sentence underneath is a target hypothesis for each example. The NP is in bold, and the CP is in bold italics. The point of an arrow with a  $\times$  mark indicates a wrong NP candidate.

Estimating NP is a difficult task. Figure 2 shows some examples. The superscript numbers indicate the word position in the source sentence.

In Figure 2 (a), the NP is 8. However, in Figure 2 (b), the word (*kare*) at the CP is the same as (a), but the NP is different (the NP is 10). From these examples, we see that distance is not the essential factor in deciding an NP. And it also turns out that the word at the CP alone is not enough to estimate the NP. Thus, not only the word at the CP but also the word at a NP candidate (NPC) should be considered simultaneously.

In (c) and (d) in Figure 2, the word (*kare*) at the CP is the same and *karita* (borrowed) and *katta* (bought) are at the NPCs. *Karita* is the word at the NP and *katta* is not the word at the NP for (c), while *katta* is the word at the NP and *karita* is not the word at the NP for (d). From these examples, considering what the word is at the NP not consider word-level correspondences.

is not enough to estimate the NP. One of the reasons for this difference is the relative word order between words. Thus, considering relative word order is important.

In (d) and (e) in Figure 2, the word (*kare*) at the CP and the word order between *katta* and *karita* are the same. However, the word at the NP for (d) and the word at the NP for (e) are different. From these examples, we can see that selecting a nearby word is not always correct. The difference is caused by the words surrounding the NPCs (context), the CP context, and the words between the CP and the NPC. Thus, these should be considered when estimating the NP.

In summary, in order to estimate the NP, the following should be considered simultaneously: the word at the NP, the word at the CP, the relative word order among the NPCs, the words surrounding NP and CP (context), and the words between the CP and the NPC.

There are distortion models that do not require a parser for phrase-based SMT. The linear distortion cost model used in Moses (Koehn et al., 2007), whose costs are linearly proportional to the reordering distance, always gives a high cost to long distance reordering, even if the reordering is correct. The MSD lexical reordering model (Tillman, 2004; Koehn et al., 2005; Galley and Manning, 2008) only calculates probabilities for the three kinds of phrase reorderings (monotone, swap, and discontinuous), and does not consider relative word order or words between the CP and the NPC. Thus, these models are not sufficient for long distance word reordering.

Al-Onaizan and Papineni (2006) proposed a distortion model that used the word at the CP and the word at an NPC. However, their model did not use context, relative word order, or words between the CP and the NPC.

Ni et al. (2009) proposed a method that adjusts the linear distortion cost using the word at the CP and its context. Their model does not simultaneously consider both the word specified at the CP and the word specified at the NPCs.

Green et al. (2010) proposed distortion models that used context. Their model (the outbound model) estimates how far the NP should be from the CP using the word at the CP and its context.<sup>5</sup> Their model does not simultaneously con-

<sup>5</sup>Their also proposed another model (the inbound model)

sider both the word specified at the CP and the word specified at an NPC. For example, the outbound model considers the word specified at the CP, but does not consider the word specified at an NPC. Their models also do not consider relative word order.

In contrast, our distortion model solves the aforementioned problems. Our distortion models utilize the word specified at the CP, the word specified at an NPC, and also the context of the CP and the NPC simultaneously. Furthermore, our sequence model considers richer context including the relative word order among NPCs and also including all the words between the CP and the NPC. In addition, unlike previous methods, our models learn the preference relations among NPCs.

### 3 Proposed Method

In this section, we first define our distortion model and explain our learning strategy. Then, we describe two proposed models: *the pair model* and *the sequence model* that is the further improved model.

#### 3.1 Distortion Model and Learning Strategy

First, we define our distortion model. Let  $i$  be a CP,  $j$  be an NPC,  $S$  be a source sentence, and  $X$  be the random variable of the NP. In this paper, *distortion probability* is defined as  $P(X = j|i, S)$ , which is the probability of an NPC  $j$  being the NP. Our distortion model is defined as the model calculating the distortion probability.

Next, we explain the learning strategy for our distortion model. We train this model as a discriminative model that discriminates the NP from NPCs. Let  $J$  be a set of word positions in  $S$  other than  $i$ . We train the distortion model subject to

$$\sum_{j \in J} P(X = j|i, S) = 1.$$

The model parameters are learned to maximize the distortion probability of the NP among all of the NPCs  $J$  in each source sentence. This learning strategy is a kind of preference relation learning (Evgeniou and Pontil, 2002). In this learning, the

that estimates reverse direction distance. Each NPC is regarded as an NP, and the inbound model estimates how far the corresponding CP should be from the NP using the word at the NP and its context.

distortion probability of the actual NP will be relatively higher than those of all the other NPCs  $J$ .

This learning strategy is different from that of (Al-Onaizan and Papineni, 2006; Green et al., 2010). For example, Green et al. (2010) trained their outbound model subject to  $\sum_{c \in C} P(Y = c | i, S) = 1$ , where  $C$  is the set of the nine distortion classes<sup>6</sup> and  $Y$  is the random variable of the correct distortion class that the correct distortion is classified into. Distortion is defined as  $j - i - 1$ . Namely, the model probabilities that they learned were the probabilities of distortion classes in all of the training data, not the relative preferences among the NPCs in each source sentence.

### 3.2 Pair Model

The *pair model* utilizes the word at the CP, the word at an NPC, and the context of the CP and the NPC simultaneously to estimate the NP. This can be done by our distortion model definition and the learning strategy described in the previous section.

In this work, we use the maximum entropy method (Berger et al., 1996) as a discriminative machine learning method. The reason for this is that a model based on the maximum entropy method can calculate probabilities. However, if we use scores as an approximation of the distortion probabilities, various discriminative machine learning methods can be applied to build the distortion model.

Let  $s$  be a source word and  $s_1^n = s_1 s_2 \dots s_n$  be a source sentence. We add a beginning of sentence (BOS) marker to the head of the source sentence and an end of sentence (EOS) marker to the end, so the source sentence  $S$  is expressed as  $s_0^{n+1}$  ( $s_0 = \text{BOS}, s_{n+1} = \text{EOS}$ ). Our distortion model calculates the distortion probability for an NPC  $j \in \{j | 1 \leq j \leq n + 1 \wedge j \neq i\}$  for each CP  $i \in \{i | 0 \leq i \leq n\}$

$$P(X = j | i, S) = \frac{1}{Z_i} \exp(\mathbf{w}^T \mathbf{f}(i, j, S, o, d)) \quad (1)$$

where

$$o = \begin{cases} 0 & (i < j) \\ 1 & (i > j) \end{cases}, \quad d = \begin{cases} 0 & (|j - i| = 1) \\ 1 & (2 \leq |j - i| \leq 5) \\ 2 & (6 \leq |j - i|) \end{cases},$$

<sup>6</sup> $(-\infty, -8], [-7, -5], [-4, -3], -2, 0, 1, [2, 3], [4, 6],$  and  $[7, \infty)$ . In (Green et al., 2010),  $-1$  was used as one of distortion classes. However,  $-1$  represents the CP in our definition, and CP is not an NPC. Thus, we shifted all of the distortion classes for negative distortions by  $-1$ .

Template
$\langle o \rangle, \langle o, s_p \rangle^1, \langle o, t_i \rangle, \langle o, t_j \rangle, \langle o, d \rangle, \langle o, s_p, s_q \rangle^2,$
$\langle o, t_i, t_j \rangle, \langle o, t_{i-1}, t_i, t_j \rangle, \langle o, t_i, t_{i+1}, t_j \rangle,$
$\langle o, t_i, t_{j-1}, t_j \rangle, \langle o, t_i, t_j, t_{j+1} \rangle, \langle o, s_i, t_i, t_j \rangle,$
$\langle o, s_j, t_i, t_j \rangle$
<sup>1</sup> $p \in \{p   i - 2 \leq p \leq i + 2 \vee j - 2 \leq p \leq j + 2\}$
<sup>2</sup> $(p, q) \in \{(p, q)   i - 2 \leq p \leq i + 2 \wedge j - 2 \leq q \leq j + 2 \wedge ( p - i  \leq 1 \vee  q - j  \leq 1)\}$

Table 1: Feature templates.  $t$  is the part of speech of  $s$ .

$\mathbf{w}$  is a weight parameter vector, each element of  $\mathbf{f}(\cdot)$  is a binary feature function, and  $Z_i = \sum_{j \in \{j | 1 \leq j \leq n + 1 \wedge j \neq i\}}$  (numerator of Equation 1) is a normalization factor.  $o$  is an orientation of  $i$  to  $j$  and  $d$  is a distance class.

The binary feature function that constitutes an element of  $\mathbf{f}(\cdot)$  returns 1 when its feature is matched and if else, returns 0. Table 1 shows the feature templates used to produce the features. A feature is an instance of a feature template.

In Equation 1,  $i, j$ , and  $S$  are used by the feature functions. Thus, Equation 1 can utilize features consisting of both  $s_i$ , which is the word specified at  $i$ , and  $s_j$ , which is the word specified at  $j$ , or both the context of  $i$  and the context of  $j$  simultaneously. Distance is considered using the distance class  $d$ . Distortion is represented by distance and orientation. The pair model considers distortion using six joint classes of  $d$  and  $o$ .

### 3.3 Sequence Model

The pair model does not consider relative word order among NPCs or all the words between the CP and an NPC. In this section, we propose a further improved model, the *sequence model*, which considers richer context including relative word order among NPCs and also including all the words between the CP and an NPC.

In (c) and (d) in Figure 2, *karita* (borrowed) and *katta* (bought) occur in the source sentences. The pair model considers the effect of distances using only the distance class  $d$ . If these positions are in the same distance class, the pair model cannot consider the differences in distances. In this case, these are conflict instances during training and it is difficult to distinguish the NP for translation.

Now to explain how to consider the relative word order by the sequence model. The sequence model considers the relative word order by discriminating the label sequence corresponding to the NP from the label sequences corresponding to

Label	Description
C	A position is the CP.
I	A position is a position between the CP and the NPC.
N	A position is the NPC.

Table 2: The ‘‘C, I, and N’’ label set.

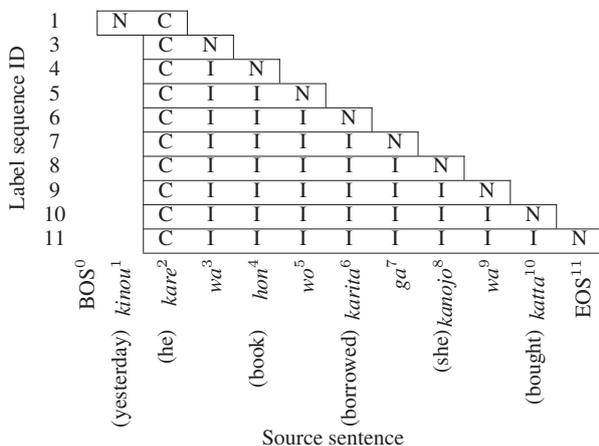

Figure 3: Example of label sequences that specify spans from the CP to each NPC for the case of Figure 2 (c). The labels (C, I, and N) in the boxes are the label sequences.

each NPC in each sentence. Each label sequence corresponds to one NPC. Therefore, if we identify the label sequence that corresponds to the NP, we can obtain the NP. The label sequences specify the spans from the CP to each NPC using three kinds of labels indicating the type of word positions in the spans. The three kinds of labels, ‘‘C, I, and N,’’ are shown in Table 2. Figure 3 shows examples of the label sequences for the case of Figure 2 (c). In Figure 3, the label sequences are represented by boxes and the elements of the sequences are labels. The NPC is used as the label sequence ID for each label sequence.

The label sequence can treat relative word order. For example, the label sequence ID of 10 in Figure 3 knows that *karita* exists to the left of the NPC of 10. This is because *karita*<sup>6</sup> carries a label I while *katta*<sup>10</sup> carries a label N, and a position with label I is defined as relatively closer to the CP than a position with label N. By utilizing the label sequence and corresponding words, the model can reflect the effect of *karita* existing between the CP and the NPC of 10 on the probability.

For the sequence model, *karita* (borrowed) and

*katta* (bought) in (c) and (d) in Figure 2 are not conflict instances in training, whereas they are conflict instances in training for the pair model. The reason is as follows. In order to make the probability of the NPC of 10 smaller than the NPC of 6, instead of making the weight parameters for the features with respect to the word at the position of 10 with label N smaller than the weight parameters for the features with respect to the word at the position of 6 with label N, the sequence model can give negative weight parameters for the features with respect to the word at the position of 6 with label I.

We use a sequence discrimination technique based on CRF (Lafferty et al., 2001) to identify the label sequence that corresponds to the NP. There are two differences between our task and the CRF task. One difference is that CRF discriminates label sequences that consist of labels from all of the label candidates, whereas we constrain the label sequences to sequences where the label at the CP is C, the label at an NPC is N, and the labels between the CP and the NPC are I. The other difference is that CRF is designed for discriminating label sequences corresponding to the same object sequence, whereas we do not assign labels to words outside the spans from the CP to each NPC. However, when we assume that another label such as E has been assigned to the words outside the spans and there are no features involving label E, CRF with our label constraints can be applied to our task. In this paper, the method designed to discriminate label sequences corresponding to the different word sequence lengths is called *partial CRF*.

The sequence model based on partial CRF is derived by extending the pair model. We introduce the label  $l$  and extend the pair model to discriminating the label sequences. There are two extensions to the pair model. One extension uses labels. We suppose that label sequences specify the spans from the CP to each NPC. We conjoined all the feature templates in Table 1 with an additional feature template  $\langle l_i, l_j \rangle$  to include the labels into features where  $l_i$  is the label corresponding to the position of  $i$ . The other extension uses sequence. In the pair model, the position pair of  $(i, j)$  is used to derive features. In contrast, to discriminate label sequences in the sequence model, the position pairs of  $(i, k)$ ,  $k \in \{k | i < k \leq j \vee j \leq k < i\}$

and  $(k, j)$ ,  $k \in \{k | i \leq k < j \vee j < k \leq i\}$  are used to derive features. Note that in the feature templates in Table 1,  $i$  and  $j$  are used to specify two positions. When features are used for the sequence model, one of the positions is regarded as  $k$ .

The distortion probability for an NPC  $j$  being the NP given a CP  $i$  and a source sentence  $S$  is calculated as:

$$P(X = j | i, S) = \frac{1}{Z_i} \exp \left( \sum_{k \in M \cup \{j\}} \mathbf{w}^T \mathbf{f}(i, k, S, o, d, l_i, l_k) + \sum_{k \in M \cup \{i\}} \mathbf{w}^T \mathbf{f}(k, j, S, o, d, l_k, l_j) \right) \quad (2)$$

where

$$M = \begin{cases} \{m | i < m < j\} & (i < j) \\ \{m | j < m < i\} & (i > j) \end{cases}$$

and  $Z_i = \sum_{j \in \{j | 1 \leq j \leq n+1 \wedge j \neq i\}}$  (numerator of Equation 2) is a normalization factor. Since  $j$  is used as the label sequence ID, discriminating  $j$  also means discriminating label sequence IDs.

The first term in  $\exp(\cdot)$  in Equation 2 considers all of the word pairs located at  $i$  and other positions in the sequence, and also their context. The second term in  $\exp(\cdot)$  in Equation 2 considers all of the word pairs located at  $j$  and other positions in the sequence, and also their context.

By designing our model to discriminate among different length label sequences, our model can naturally handle the effect of distances. Many features are derived from a long label sequence because it will contain many labels between the CP and the NPC. On the other hand, fewer features are derived from a short label sequence because a short label sequence will contain fewer labels between the CP and the NPC. The bias from these differences provides important clues for learning the effect of distances.<sup>7</sup>

<sup>7</sup>Note that the sequence model does not only consider larger context than the pair model, but that it also considers labels. The pair model does not discriminate labels, whereas the sequence model uses label N and label I for the positions except for the CP, depending on each situation. For example, in Figure 3, at position 6, label N is used in the label sequence ID of 6, but label I is used in the label sequence IDs of 7 to 11. Namely, even if they are at the same position, the labels in the label sequences are different. The sequence model discriminates the label differences.

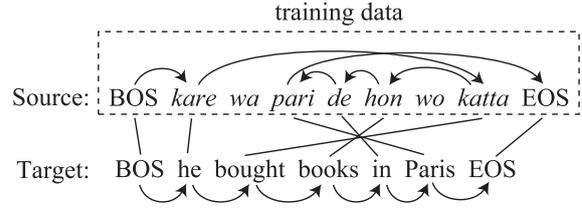

Figure 4: Examples of supervised training data. The lines represent word alignments. The English side arrows point to the nearest word aligned on the right.

### 3.4 Training Data for Discriminative Distortion Model

To train our discriminative distortion model, supervised training data is needed. The training data is built from a parallel corpus and word alignments between corresponding source words and target words. Figure 4 shows examples of training data. We select the target words aligned to the source words sequentially from left to right (target side arrows). Then, the order of the source words in the target word order is decided (source side arrows). The source sentence and the source side arrows are the training data.

## 4 Experiment

In order to confirm the effects of our distortion model, we conducted a series of Japanese to English (JE) and Chinese to English (CE) translation experiments.<sup>8</sup>

### 4.1 Common Settings

We used the patent data for the Japanese to English and Chinese to English translation subtasks from the NTCIR-9 Patent Machine Translation Task (Goto et al., 2011). There were 2,000 sentences for the test data and 2,000 sentences for the development data.

Mecab<sup>9</sup> was used for the Japanese morphological analysis. The Stanford segmenter<sup>10</sup> and tagger<sup>11</sup> were used for Chinese segmentation and POS tagging. The translation model was trained using sentences of 40 words or less from the training data. So approximately 2.05 million sentence pairs consisting of approximately 54 million

<sup>8</sup>We conducted JE and CE translation as examples of language pairs with different word orders and of languages where there is a great need for translation into English.

<sup>9</sup><http://mecab.sourceforge.net/>

<sup>10</sup><http://nlp.stanford.edu/software/segmenter.shtml>

<sup>11</sup><http://nlp.stanford.edu/software/tagger.shtml>

Japanese tokens whose lexicon size was 134k and 50 million English tokens whose lexicon size was 213k were used for JE. And approximately 0.49 million sentence pairs consisting of 14.9 million Chinese tokens whose lexicon size was 169k and 16.3 million English tokens whose lexicon size was 240k were used for CE. GIZA++ and growdiag-final-and heuristics were used to obtain word alignments. In order to reduce word alignment errors, we removed articles {a, an, the} in English and particles {ga, wo, wa} in Japanese before performing word alignments because these function words do not correspond to any words in the other languages. After word alignment, we restored the removed words and shifted the word alignment positions to the original word positions. We used 5-gram language models that were trained using the English side of each set of bilingual training data.

We used an in-house standard phrase-based SMT system compatible with the Moses decoder (Koehn et al., 2007). The SMT weighting parameters were tuned by MERT (Och, 2003) using the development data. To stabilize the MERT results, we tuned three times by MERT using the first half of the development data and we selected the SMT weighting parameter set that performed the best on the second half of the development data based on the BLEU scores from the three SMT weighting parameter sets.

We compared systems that used a common SMT feature set from standard SMT features and different distortion model features. The common SMT feature set consists of: four translation model features, phrase penalty, word penalty, and a language model feature. The compared different distortion model features are: the linear distortion cost model feature (LINEAR), the linear distortion cost model feature and the six MSD bidirectional lexical distortion model (Koehn et al., 2005) features (LINEAR+LEX), the outbound and inbound distortion model features discriminating nine distortion classes (Green et al., 2010) (9-CLASS), the proposed pair model feature (PAIR), and the proposed sequence model feature (SEQUENCE).

## 4.2 Training for the Proposed Models

Our distortion model was trained as follows: We used 0.2 million sentence pairs and their word alignments from the data used to build the translation model as the training data for our distortion models. The features that were selected and used

were the ones that had been counted<sup>12</sup>, using the feature templates in Table 1, at least four times for all of the  $(i, j)$  position pairs in the training sentences. We conjoined the features with three types of label pairs  $\langle C, I \rangle$ ,  $\langle I, N \rangle$ , or  $\langle C, N \rangle$  as instances of the feature template  $\langle l_i, l_j \rangle$  to produce features for SEQUENCE. The L-BFGS method (Liu and Nocedal, 1989) was used to estimate the weight parameters of maximum entropy models. The Gaussian prior (Chen and Rosenfeld, 1999) was used for smoothing.

## 4.3 Training for the Compared Models

For 9-CLASS, we used the same training data as for our distortion models. Let  $t_i$  be the part of speech of  $s_i$ . We used the following feature templates to produce features for the outbound model:  $\langle s_{i-2} \rangle$ ,  $\langle s_{i-1} \rangle$ ,  $\langle s_i \rangle$ ,  $\langle s_{i+1} \rangle$ ,  $\langle s_{i+2} \rangle$ ,  $\langle t_i \rangle$ ,  $\langle t_{i-1}, t_i \rangle$ ,  $\langle t_i, t_{i+1} \rangle$ , and  $\langle s_i, t_i \rangle$ . These feature templates correspond to the components of the feature templates of our distortion models. In addition to these features, we used a feature consisting of the relative source sentence position as the feature used by (Green et al., 2010). The relative source sentence position is discretized into five bins, one for each quintile of the sentence. For the inbound model<sup>13</sup>,  $i$  of the feature templates was changed to  $j$ . Features occurring four or more times in the training sentences were used. The maximum entropy method with Gaussian prior smoothing was used to estimate the model parameters.

The MSD bidirectional lexical distortion model was built using all of the data used to build the translation model.

## 4.4 Results and Discussion

We evaluated translation quality based on the case-insensitive automatic evaluation score BLEU-4 (Papineni et al., 2002). We used distortion limits of 10, 20, 30, and unlimited ( $\infty$ ), which limited the number of words for word reordering to a maximum number. Table 3 presents our main results. The proposed SEQUENCE outperformed the baselines for both Japanese to English and Chinese to English translation. This demonstrates the effectiveness of the proposed SEQUENCE. The scores of the proposed SEQUENCE were higher than those

<sup>12</sup>When we counted features for selection, we only counted features that were from the feature templates of  $\langle s_i, s_j \rangle$ ,  $\langle t_i, t_j \rangle$ ,  $\langle s_i, t_i, t_j \rangle$ , and  $\langle s_j, t_i, t_j \rangle$  in Table 1 when  $j$  was not the NP, in order to avoid increasing the number of features.

<sup>13</sup>The inbound model is explained in footnote 5.

Distortion limit	Japanese-English				Chinese-English			
	10	20	30	$\infty$	10	20	30	$\infty$
LINEAR	27.98	27.74	27.75	27.30	29.18	28.74	28.31	28.33
LINEAR+LEX	30.25	30.37	30.17	29.98	30.81	30.24	30.16	30.13
9-CLASS	30.74	30.98	30.92	30.75	31.80	31.56	31.31	30.84
PAIR	31.62	32.36	31.96	32.03	32.51	32.30	32.25	32.32
SEQUENCE	32.02	32.96	<b>33.29</b>	32.81	<b>33.41</b>	<b>33.44</b>	<b>33.35</b>	<b>33.41</b>

Table 3: Evaluation results for each method. The values are case-insensitive BLEU scores. Bold numbers indicate no significant difference from the best result in each language pair using the bootstrap resampling test at a significance level  $\alpha = 0.01$  (Koehn, 2004).

	Japanese-English	Chinese-English
HIER	30.47	32.66

Table 4: Evaluation results for hierarchical phrase-based SMT.

of the proposed PAIR. This confirms the effectiveness for considering relative word order and words between the CP and an NPC. The proposed PAIR outperformed 9-CLASS, confirming that considering both the word specified at the CP and the word specified at the NPC simultaneously was more effective than that of 9-CLASS.

For translating between languages with widely different word orders such as Japanese and English, a small distortion limit is undesirable because there are cases where correct translations cannot be produced with a small distortion limit, since the distortion limit prunes the search space that does not meet the constraint. Therefore, a large distortion limit is required to translate correctly. For JE translation, our SEQUENCE achieved significantly better results at distortion limits of 20 and 30 than that at a distortion limit of 10, while the baseline systems of LINEAR, LINEAR+LEX, and 9-CLASS did not achieve this. This indicates that SEQUENCE could treat long distance reordering candidates more appropriately than the compared methods.

We also tested hierarchical phrase-based SMT (Chiang, 2007) (HIER) using the Moses implementation. The common data was used to train HIER. We used unlimited max-chart-span for the system setting. Results are given in Table 4. Our SEQUENCE outperformed HIER. The gain for JE was large but the gain for CE was modest. Since phrase-based SMT is generally faster in decoding speed than hierarchical phrase-based SMT, achieving better or comparable scores is worth-

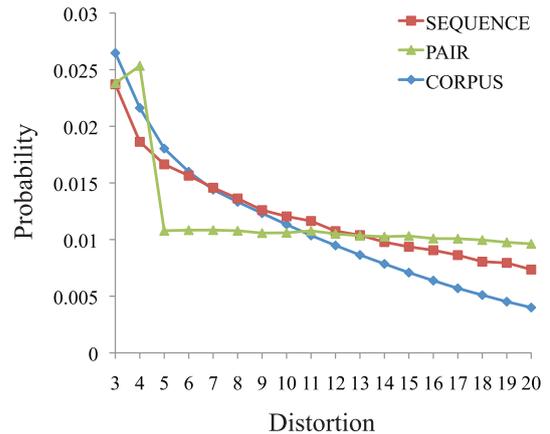

Figure 5: Average probabilities for large distortion for Japanese-English translation.

while.

To investigate the tolerance for sparsity of the training data, we reduced the training data for the sequence model to 20,000 sentences for JE translation.<sup>14</sup> SEQUENCE using this model with a distortion limit of 30 achieved a BLEU score of 32.22.<sup>15</sup> Although the score is lower than the score of SEQUENCE with a distortion limit of 30 in Table 3, the score was still higher than those of LINEAR, LINEAR+LEX, and 9-CLASS for JE in Table 3. This indicates that the sequence model also works even when the training data is not large. This is because the sequence model considers not only the word at the CP and the word at an NPC but also rich context, and rich context would be effective even for a smaller set of training data.

<sup>14</sup>We did not conduct experiments using larger training data because there would have been a very high computational cost to build models using the L-BFGS method.

<sup>15</sup>To avoid effects from differences in the SMT weighting parameters, we used the same SMT weighting parameters for SEQUENCE, with a distortion limit of 30, in Table 3.

To investigate how well SEQUENCE learns the effect of distance, we checked the average distortion probabilities for large distortions of  $j - i - 1$ . Figure 5 shows three kinds of probabilities for distortions from 3 to 20 for Japanese-English translation. One is the average distortion probabilities in the Japanese test sentences for each distortion for SEQUENCE, and another is this for PAIR. The third (CORPUS) is the probabilities for the actual distortions in the training data that were obtained from the word alignments used to build the translation model. The probability for a distortion for CORPUS was calculated by the number of the distortion divided by the total number of distortions in the training data.

Figure 5 shows that when a distance class feature used in the model was the same (e.g., distortions from 5 to 20 were the same distance class feature), PAIR produced average distortion probabilities that were almost the same. In contrast, the average distortion probabilities for SEQUENCE decreased when the lengths of the distortions increased, even if the distance class feature was the same, and this behavior was the same as that of CORPUS. This confirms that the proposed SEQUENCE could learn the effect of distances appropriately from the training data.<sup>16</sup>

## 5 Related Works

We discuss related works other than discussed in Section 2. Xiong et al. (2012) proposed a model predicting the orientation of an argument with respect to its verb using a parser. Syntactic structures and predicate-argument structures are useful for reordering. However, orientations do not handle distances. Thus, our distortion model does not compete against the methods predicting orientations using a parser and would assist them if used

<sup>16</sup>We also checked the average distortion probabilities for the 9-CLASS outbound model in the Japanese test sentences for Japanese-English translation. We averaged the average probabilities for distortions in a distortion span of [4, 6] and also averaged those in a distortion span of [7, 20], where the distortions in each span are in the same distortion class. The average probability for [4, 6] was 0.058 and that for [7, 20] was 0.165. From CORPUS, the average probabilities in the training data for each distortion in [4, 6] were higher than those for each distortion in [7, 20]. However, the converse was true for the comparison between the two average probabilities for the outbound model. This is because the sum of probabilities for distortions from 7 and above was larger than the sum of probabilities for distortions from 4 to 6 in the training data. This comparison indicates that the 9-CLASS outbound model could not appropriately learn the effects of large distances for JE translation.

together.

There are word reordering constraint methods using ITG (Wu, 1997) for phrase-based SMT (Zens et al., 2004; Yamamoto et al., 2008; Feng et al., 2010). These methods consider sentence level consistency with respect to ITG. The ITG constraint does not consider distances of reordering and was used with other distortion models. Our distortion model does not consider sentence level consistency, so our distortion model and ITG constraint methods are thought to be complementary.

There are tree-based SMT methods (Chiang, 2007; Galley et al., 2004; Liu et al., 2006). In many cases, tree-based SMT methods do not use the distortion models that consider reordering distance apart from translation rules because it is not trivial to use distortion scores considering the distances for decoders that do not generate hypotheses from left to right. If it could be applied to these methods, our distortion model might contribute to tree-based SMT methods. Investigating the effects will be for future work.

## 6 Conclusion

This paper described our distortion models for phrase-based SMT. Our sequence model simply consists of only one probabilistic model, but it can consider rich context. Experiments indicate that our models achieved better performance and the sequence model could learn the effect of distances appropriately. Since our models do not require a parser, they can be applied to many languages. Future work includes application to other language pairs, incorporation into ITG constraint methods and other reordering methods, and application to tree-based SMT methods.

## Abstract

In this paper, we explore a novel bilingual word alignment approach based on DNN (Deep Neural Network), which has been proven to be very effective in various machine learning tasks (Collobert et al., 2011). We describe in detail how we adapt and extend the CD-DNN-HMM (Dahl et al., 2012) method introduced in speech recognition to the HMM-based word alignment model, in which bilingual word embedding is discriminatively learnt to capture lexical translation information, and surrounding words are leveraged to model context information in bilingual sentences. While being capable to model the rich bilingual correspondence, our method generates a very compact model with much fewer parameters. Experiments on a large scale English-Chinese word alignment task show that the proposed method outperforms the HMM and IBM model 4 baselines by 2 points in F-score.

## 1 Introduction

Recent years research communities have seen a strong resurgent interest in modeling with deep (multi-layer) neural networks. This trending topic, usually referred under the name *Deep Learning*, is started by ground-breaking papers such as (Hinton et al., 2006), in which innovative training procedures of deep structures are proposed. Unlike shallow learning methods, such as Support Vector Machine, Conditional Random Fields, and Maximum Entropy, which need hand-craft features as input, DNN can learn suitable features (representations) automatically with raw input data, given a training objective.

DNN did not achieve expected success until 2006, when researchers discovered a proper way

to initialize and train the deep architectures, which contains two phases: layer-wise unsupervised pre-training and supervised fine tuning. For pre-training, Restricted Boltzmann Machine (RBM) (Hinton et al., 2006), auto-encoding (Bengio et al., 2007) and sparse coding (Lee et al., 2007) are proposed and popularly used. The unsupervised pre-training trains the network one layer at a time, and helps to guide the parameters of the layer towards better regions in parameter space (Bengio, 2009). Followed by fine tuning in this region, DNN is shown to be able to achieve state-of-the-art performance in various area, or even better (Dahl et al., 2012) (Kavukcuoglu et al., 2010). DNN also achieved breakthrough results on the ImageNet dataset for objective recognition (Krizhevsky et al., 2012). For speech recognition, (Dahl et al., 2012) proposed context-dependent neural network with large vocabulary, which achieved 16.0% relative error reduction.

DNN has also been applied in Natural Language Processing (NLP) field. Most works convert atomic lexical entries into a dense, low dimensional, real-valued representation, called *word embedding*; Each dimension represents a latent aspect of a word, capturing its semantic and syntactic properties (Bengio et al., 2006). Word embedding is usually first learned from huge amount of monolingual texts, and then fine-tuned with task-specific objectives. (Collobert et al., 2011) and (Socher et al., 2011) further apply Recursive Neural Networks to address the structural prediction tasks such as tagging and parsing, and (Socher et al., 2012) explores the compositional aspect of word representations.

Inspired by successful previous works, we propose a new DNN-based word alignment method, which exploits contextual and semantic similarities between words. As shown in example (a) of Figure 1, in word pair {“juda”  $\Rightarrow$  “mammoth”}, the Chinese word “juda” is a common word, but

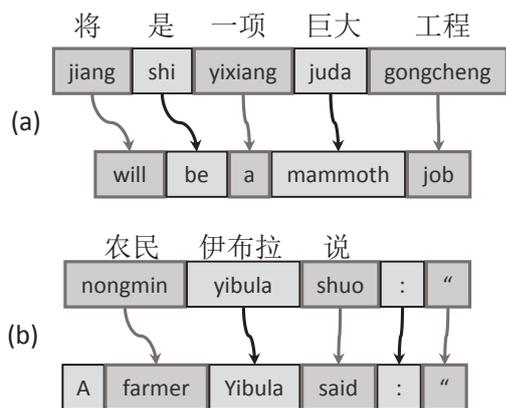

Figure 1: Two examples of word alignment

the English word “mammoth” is not, so it is very hard to align them correctly. If we know that “mammoth” has the similar meaning with “big”, or “huge”, it would be easier to find the corresponding word in the Chinese sentence. As we mentioned in the last paragraph, *word embedding* (trained with huge monolingual texts) has the ability to map a word into a vector space, in which, similar words are near each other.

For example (b) in Figure 1, for the word pair {“yibula”  $\Rightarrow$  “Yibula”}, both the Chinese word “yibula” and English word “Yibula” are rare name entities, but the words around them are very common, which are {“nongmin”, “shuo”} for Chinese side and {“farmer”, “said”} for the English side. The pattern of the context {“nongmin  $X$  shuo”  $\Rightarrow$  “farmer  $X$  said”} may help to align the word pair which fill the variable  $X$ , and also, the pattern {“yixiang  $X$  gongcheng”  $\Rightarrow$  “a  $X$  job”} is helpful to align the word pair {“juda”  $\Rightarrow$  “mammoth”} for example (a).

Based on the above analysis, in this paper, both the words in the source and target sides are firstly mapped to a vector via a discriminatively trained word embeddings, and word pairs are scored by a multi-layer neural network which takes rich contexts (surrounding words on both source and target sides) into consideration; and a HMM-like distortion model is applied on top of the neural network to characterize structural aspect of bilingual sentences.

In the rest of this paper, related work about DNN and word alignment are first reviewed in Section 2, followed by a brief introduction of DNN in Section 3. We then introduce the details of leveraging DNN for word alignment, including the details of our network structure in Section 4

and the training method in Section 5. The merits of our approach are illustrated with the experiments described in Section 6, and we conclude our paper in Section 7.

## 2 Related Work

DNN with unsupervised pre-training was firstly introduced by (Hinton et al., 2006) for MNIST digit image classification problem, in which, RBM was introduced as the layer-wise pre-trainer. The layer-wise pre-training phase found a better local maximum for the multi-layer network, thus led to improved performance. (Krizhevsky et al., 2012) proposed to apply DNN to do object recognition task (ImageNet dataset), which brought down the state-of-the-art error rate from 26.1% to 15.3%. (Seide et al., 2011) and (Dahl et al., 2012) apply Context-Dependent Deep Neural Network with HMM (CD-DNN-HMM) to speech recognition task, which significantly outperforms traditional models.

Most methods using DNN in NLP start with a word embedding phase, which maps words into a fixed length, real valued vectors. (Bengio et al., 2006) proposed to use multi-layer neural network for language modeling task. (Collobert et al., 2011) applied DNN on several NLP tasks, such as part-of-speech tagging, chunking, name entity recognition, semantic labeling and syntactic parsing, where they got similar or even better results than the state-of-the-art on these tasks. (Niehues and Waibel, 2012) shows that machine translation results can be improved by combining neural language model with n-gram traditional language. (Son et al., 2012) improves translation quality of n-gram translation model by using a bilingual neural language model. (Titov et al., 2012) learns a context-free cross-lingual word embeddings to facilitate cross-lingual information retrieval.

For the related works of word alignment, the most popular methods are based on generative models such as IBM Models (Brown et al., 1993) and HMM (Vogel et al., 1996). Discriminative approaches are also proposed to use hand crafted features to improve word alignment. Among them, (Liu et al., 2010) proposed to use phrase and rule pairs to model the context information in a log-linear framework. Unlike previous discriminative methods, in this work, we do not resort to any hand crafted features, but use DNN to induce “features” from raw words.

### 3 DNN structures for NLP

The most important and prevalent features available in NLP are the words themselves. To apply DNN to NLP task, the first step is to transform a discrete word into its *word embedding*, a low dimensional, dense, real-valued vector (Bengio et al., 2006). Word embeddings often implicitly encode syntactic or semantic knowledge of the words. Assuming a finite sized vocabulary  $V$ , word embeddings form a  $(L \times |V|)$ -dimension embedding matrix  $W_V$ , where  $L$  is a pre-determined embedding length; mapping words to embeddings is done by simply looking up their respective columns in the embedding matrix  $W_V$ . The lookup process is called a *lookup layer LT*, which is usually the first layer after the input layer in neural network.

After words have been transformed to their embeddings, they can be fed into subsequent classical network layers to model highly non-linear relations:

$$z^l = f_l(M^l z^{l-1} + b^l) \quad (1)$$

where  $z^l$  is the output of  $l$ th layer,  $M^l$  is a  $|z^l| \times |z^{l-1}|$  matrix,  $b^l$  is a  $|z^l|$ -length vector, and  $f_l$  is an *activation* function. Except for the last layer,  $f_l$  must be non-linear. Common choices for  $f_l$  include sigmoid function, hyperbolic function, “hard” hyperbolic function etc. Following (Collobert et al., 2011), we choose “hard” hyperbolic function as our activation function in this work:

$$htanh(x) = \begin{cases} 1 & \text{if } x \text{ is greater than } 1 \\ -1 & \text{if } x \text{ is less than } -1 \\ x & \text{otherwise} \end{cases} \quad (2)$$

If probabilistic interpretation is desired, a *softmax* layer (Bridle, 1990) can be used to do normalization:

$$z_i^l = \frac{e^{z_i^{l-1}}}{\sum_{j=1}^{|z^l|} e^{z_j^{l-1}}} \quad (3)$$

The above layers can only handle fixed sized input and output. If input must be of variable length, *convolution* layer and *max* layer can be used, (Collobert et al., 2011) which transform variable length input to fixed length vector for further processing.

Multi-layer neural networks are trained with the standard *back propagation* algorithm (LeCun, 1985). As the networks are non-linear and the task specific objectives usually contain many local maximums, special care must be taken in the

optimization process to obtain good parameters. Techniques such as *layerwise pre-training* (Bengio et al., 2007) and many tricks (LeCun et al., 1998) have been developed to train better neural networks. Besides that, neural network training also involves some hyperparameters such as learning rate, the number of hidden layers. We will address these issues in section 4.

### 4 DNN for word alignment

Our DNN word alignment model extends classic HMM word alignment model (Vogel et al., 1996). Given a sentence pair  $(\mathbf{e}, \mathbf{f})$ , HMM word alignment takes the following form:

$$P(\mathbf{a}, \mathbf{e}|\mathbf{f}) = \prod_{i=1}^{|\mathbf{e}|} P_{lex}(e_i|f_{a_i})P_d(a_i - a_{i-1}) \quad (4)$$

where  $P_{lex}$  is the lexical translation probability and  $P_d$  is the jump distance distortion probability.

One straightforward way to integrate DNN into HMM is to use neural network to compute the emission (lexical translation) probability  $P_{lex}$ . Such approach requires a softmax layer in the neural network to normalize over all words in source vocabulary. As vocabulary for natural languages is usually very large, it is prohibitively expensive to do the normalization. Hence we give up the probabilistic interpretation and resort to a non-probabilistic, discriminative view:

$$s_{NN}(\mathbf{a}|\mathbf{e}, \mathbf{f}) = \prod_{i=1}^{|\mathbf{e}|} t_{lex}(e_i, f_{a_i}|\mathbf{e}, \mathbf{f})t_d(a_i, a_{i-1}|\mathbf{e}, \mathbf{f}) \quad (5)$$

where  $t_{lex}$  is a lexical translation score computed by neural network, and  $t_d$  is a distortion score.

In the classic HMM word alignment model, context is not considered in the lexical translation probability. Although we can rewrite  $P_{lex}(e_i|f_{a_i})$  to  $P_{lex}(e_i|\text{context of } f_{a_i})$  to model context, it introduces too many additional parameters and leads to serious over-fitting problem due to data sparseness. As a matter of fact, even without any contexts, the lexical translation table in HMM already contains  $O(|V_e| * |V_f|)$  parameters, where  $|V_e|$  and  $V_f$  denote source and target vocabulary sizes. In contrast, our model does not maintain a separate translation score parameters for every source-target word pair, but computes  $t_{lex}$  through a multi-layer network, which naturally handles contexts on both sides without explosive growth of number of parameters.

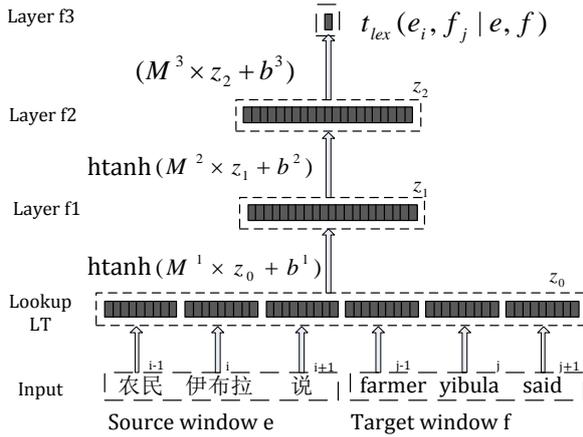

Figure 2: Network structure for computing context dependent lexical translation scores. The example computes translation score  $b^3$  for word pair  $(yibula, yibulayin)$  given its surrounding context.

Figure 2 shows the neural network we used to compute context dependent lexical translation score  $t_{lex}$ . For word pair  $(e_i, f_j)$ , we take fixed length windows surrounding both  $e_i$  and  $f_j$  as input:  $(e_{i-\frac{sw}{2}}, \dots, e_{i+\frac{sw}{2}}, f_{j-\frac{tw}{2}}, \dots, f_{j+\frac{tw}{2}})$ , where  $sw, tw$  stand window sizes on source and target side respectively. Words are converted to embeddings using the lookup table  $LT$ , and the catenation of embeddings are fed to a classic neural network with two hidden-layers, and the output of the network is the our lexical translation score:

$$t_{lex}(e_i, f_j | \mathbf{e}, \mathbf{f}) = f_3 \circ f_2 \circ f_1 \circ LT(window(e_i), window(f_j)) \quad (6)$$

$f_1$  and  $f_2$  layers use  $htanh$  as activation functions, while  $f_3$  is only a linear transformation with no activation function.

For the distortion  $t_d$ , we could use a lexicalized distortion model:

$$t_d(a_i, a_{i-1} | \mathbf{e}, \mathbf{f}) = t_d(a_i - a_{i-1} | window(f_{a_{i-1}})) \quad (7)$$

which can be computed by a neural network similar to the one used to compute lexical translation scores. If we map jump distance  $(a_i - a_{i-1})$  to  $B$  buckets, we can change the length of the output layer to  $B$ , where each dimension in the output stands for a different bucket of jump distances. But we found in our initial experiments on small scale data, lexicalized distortion does not produce better alignment over the simple jump-distance based model. So we drop the lexicalized

distortion and reverse to the simple version:

$$t_d(a_i, a_{i-1} | \mathbf{e}, \mathbf{f}) = t_d(a_i - a_{i-1}) \quad (8)$$

Vocabulary  $V$  of our alignment model consists of a source vocabulary  $V_e$  and a target vocabulary  $V_f$ . As in (Collobert et al., 2011), in addition to real words, each vocabulary contains a special unknown word symbol  $\langle unk \rangle$  to handle unseen words; two sentence boundary symbols  $\langle s \rangle$  and  $\langle /s \rangle$ , which are filled into surrounding window when necessary; furthermore, to handle null alignment, we must also include a special null symbol  $\langle null \rangle$ . When  $f_j$  is null word, we simply fill the surrounding window with the identical null symbols.

To decode our model, the lexical translation scores are computed for each source-target word pair in the sentence pair, which requires going through the neural network  $(|\mathbf{e}| \times |\mathbf{f}|)$  times; after that, the *forward-backward* algorithm can be used to find the viterbi path as in the classic HMM model.

The majority of tunable parameters in our model resides in the lookup table  $LT$ , which is a  $(L \times (|V_e| + |V_f|))$ -dimension matrix. For a reasonably large vocabulary, the number is much smaller than the number of parameters in classic HMM model, which is in the order of  $(|V_e| \times |V_f|)$ .<sup>1</sup>

The ability to model context is not unique to our model. In fact, discriminative word alignment can model contexts by deploying arbitrary features (Moore, 2005). Different from previous discriminative word alignment, our model does not use manually engineered features, but learn “features” automatically from raw words by the neural network. (Berger et al., 1996) use a maximum entropy model to model the bag-of-words context for word alignment, but their model treats each word as a distinct feature, which can not leverage the similarity between words as our model.

## 5 Training

Although unsupervised training technique such as *Contrastive Estimation* as in (Smith and Eisner, 2005), (Dyer et al., 2011) can be adapted to train

<sup>1</sup>In practice, the number of non-zero parameters in classic HMM model would be much smaller, as many words do not co-occur in bilingual sentence pairs. In our experiments, the number of non-zero parameters in classic HMM model is about 328 millions, while the NN model only has about 4 millions.

our model from raw sentence pairs, they are too computational demanding as the lexical translation probabilities must be computed from neural networks. Hence, we opt for a simpler supervised approach, which learns the model from sentence pairs with word alignment. As we do not have a large manually word aligned corpus, we use traditional word alignment models such as HMM and IBM model 4 to generate word alignment on a large parallel corpus. We obtain bi-directional alignment by running the usual *grow-diag-final* heuristics (Koehn et al., 2003) on unidirectional results from both directions, and use the results as our training data. Similar approach has been taken in speech recognition task (Dahl et al., 2012), where training data for neural network model is generated by forced decoding with traditional Gaussian mixture models.

Tunable parameters in neural network alignment model include: word embeddings in lookup table  $LT$ , parameters  $W^l, b^l$  for linear transformations in the hidden layers of the neural network, and distortion parameters  $s_d$  of jump distance. We take the following ranking loss with margin as our training criteria:

$$loss(\theta) = \sum_{\text{every } (\mathbf{e}, \mathbf{f})} \max\{0, 1 - s_\theta(\mathbf{a}^+ | \mathbf{e}, \mathbf{f}) + s_\theta(\mathbf{a}^- | \mathbf{e}, \mathbf{f})\} \quad (9)$$

where  $\theta$  denotes all tunable parameters,  $\mathbf{a}^+$  is the gold alignment path,  $\mathbf{a}^-$  is the highest scoring incorrect alignment path under  $\theta$ , and  $s_\theta$  is model score for alignment path defined in Eq. 5. One nuance here is that the gold alignment after *grow-diag-final* contains many-to-many links, which cannot be generated by any path. Our solution is that for each source word alignment multiple target, we randomly choose one link among all candidates as the golden link.

Because our multi-layer neural network is inherently non-linear and is non-convex, directly training against the above criteria is unlikely to yield good results. Instead, we take the following steps to train our model.

### 5.1 Pre-training initial word embedding with monolingual data

Most parameters reside in the word embeddings. To get a good initial value, the usual approach is to pre-train the embeddings on a large monolingual corpus. We replicate the work in (Collobert

et al., 2011) and train word embeddings for source and target languages from their monolingual corpus respectively. Our vocabularies  $V_s$  and  $V_t$  contain the most frequent 100,000 words from each side of the parallel corpus, and all other words are treated as unknown words. We set word embedding length to 20, window size to 5, and the length of the only hidden layer to 40. Follow (Turian et al., 2010), we randomly initialize all parameters to  $[-0.1, 0.1]$ , and use stochastic gradient descent to minimize the ranking loss with a fixed learning rate 0.01. Note that embedding for null word in either  $V_e$  and  $V_f$  cannot be trained from monolingual corpus, and we simply leave them at the initial value untouched.

Word embeddings from monolingual corpus learn strong syntactic knowledge of each word, which is not always desirable for word alignment between some language pairs like English and Chinese. For example, many Chinese words can act as a verb, noun and adjective without any change, while their English counter parts are distinct words with quite different word embeddings due to their different syntactic roles. Thus we have to modify the word embeddings in subsequent steps according to bilingual data.

### 5.2 Training neural network based on local criteria

Training the network against the sentence level criteria Eq. 5 directly is not efficient. Instead, we first ignore the distortion parameters and train neural networks for lexical translation scores against the following local pairwise loss:

$$\max\{0, 1 - t_\theta((e, f)^+ | \mathbf{e}, \mathbf{f}) + t_\theta((e, f)^- | \mathbf{e}, \mathbf{f})\} \quad (10)$$

where  $(e, f)^+$  is a correct word pair,  $(e, f)^-$  is a wrong word pair in the same sentence, and  $t_\theta$  is as defined in Eq. 6. This training criteria essentially means our model suffers loss unless it gives correct word pairs a higher score than random pairs from the same sentence pair with some margin.

We initialize the lookup table with embeddings obtained from monolingual training, and randomly initialize all  $W^l$  and  $b^l$  in linear layers to  $[-0.1, 0.1]$ . We minimize the loss using stochastic gradient descent as follows. We randomly cycle through all sentence pairs in training data; for each correct word pair (including null alignment), we generate a positive example, and generate two negative examples by randomly corrupting either

side of the pair with another word in the sentence pair. We set learning rate to 0.01. As there is no clear stopping criteria, we simply run the stochastic optimizer through parallel corpus for  $N$  iterations. In this work,  $N$  is set to 50.

To make our model concrete, there are still hyper-parameters to be determined: the window size  $sw$  and  $tw$ , the length of each hidden layer  $L_l$ . We empirically set  $sw$  and  $tw$  to 11,  $L_1$  to 120, and  $L_2$  to 10, which achieved a minimal loss on a small held-out data among several settings we tested.

### 5.3 Training distortion parameters

We fix neural network parameters obtained from the last step, and tune the distortion parameters  $s_d$  with respect to the sentence level loss using standard stochastic gradient descent. We use a separate parameter for jump distance from -7 and 7, and another two parameters for longer forward/backward jumps. We initialize all parameters in  $s_d$  to 0, set the learning rate for the stochastic optimizer to 0.001. As there are only 17 parameters in  $s_d$ , we only need to run the optimizer over a small portion of the parallel corpus.

### 5.4 Tuning neural network based on sentence level criteria

Up-to-now, parameters in the lexical translation neural network have not been trained against the sentence level criteria Eq. 5. We could achieve this by re-using the same online training method used to train distortion parameters, except that we now fix the distortion parameters and let the loss back-propagate through the neural networks. Sentence level training does not take larger context in modeling word translations, but only to optimize the parameters regarding to the sentence level loss. This tuning is quite slow, and it did not improve alignment on an initial small scale experiment; so, we skip this step in all subsequent experiment in this work.

## 6 Experiments and Results

We conduct our experiment on Chinese-to-English word alignment task. We use the manually aligned Chinese-English alignment corpus (Haghighi et al., 2009) which contains 491 sentence pairs as test set. We adapt the segmentation on the Chinese side to fit our word segmentation standard.

### 6.1 Data

Our parallel corpus contains about 26 million unique sentence pairs in total which are mined from web.

The monolingual corpus to pre-train word embeddings are also crawled from web, which amounts to about 1.1 billion unique sentences for English and about 300 million unique sentences for Chinese. As pre-processing, we lowercase all English words, and map all numbers to one special token; and we also map all email addresses and URLs to another special token.

### 6.2 Settings

We use classic HMM and IBM model 4 as our baseline, which are generated by Giza++ (Och and Ney, 2000). We train our proposed model from results of classic HMM and IBM model 4 separately. Since classic HMM, IBM model 4 and our model are all uni-directional, we use the standard *grow-diag-final* to generate bi-directional results for all models.

Models are evaluated on the manually aligned test set using standard metric: precision, recall and F1-score.

### 6.3 Alignment Result

It can be seen from Table 1, the proposed model consistently outperforms its corresponding baseline whether it is trained from alignment of classic HMM or IBM model 4. It is also clear that the

setting	prec.	recall	F-1
HMM	0.768	0.786	0.777
HMM+NN	0.810	0.790	0.798
IBM4	0.839	0.805	0.822
IBM4+NN	<b>0.885</b>	<b>0.812</b>	<b>0.847</b>

Table 1: Word alignment result. The first row and third row show baseline results obtained by classic HMM and IBM4 model. The second row and fourth row show results of the proposed model trained from HMM and IBM4 respectively.

results of our model also depends on the quality of baseline results, which is used as training data of our model. In future we would like to explore whether our method can improve other word alignment models.

We also conduct experiment to see the effect on end-to-end SMT performance. We train hier-

archical phrase model (Chiang, 2007) from different word alignments. Despite different alignment scores, we do not obtain significant difference in translation performance. In our C-E experiment, we tuned on NIST-03, and tested on NIST-08. Case-insensitive BLEU-4 scores on NIST-08 test are 0.305 and 0.307 for models trained from IBM-4 and NN alignment results. The result is not surprising considering our parallel corpus is quite large, and similar observations have been made in previous work as (DeNero and Macherey, 2011) that better alignment quality does not necessarily lead to better end-to-end result.

## 6.4 Result Analysis

### 6.4.1 Error Analysis

From Table 1 we can see higher F-1 score of our model mainly comes from higher precision, with recall similar to baseline. By analyzing the results, we found out that for both baseline and our model, a large part of missing alignment links involves stop words like English words “the”, “a”, “it” and Chinese words “de”. Stop words are inherently hard to align, which often requires grammatical judgment unavailable to our models; as they are also extremely frequent, our model fully learns their alignment patterns of the baseline models, including errors. On the other hand, our model performs better on low-frequency words, especially proper nouns. Take person names for example. Most names are low-frequency words, on which baseline HMM and IBM4 models show the “garbage collector” phenomenon. In our model, different person names have very similar word embeddings on both English side and Chinese side, due to monolingual pre-training; what is more, different person names often appear in similar contexts. As our model considers both word embeddings and contexts, it learns that English person names should be aligned to Chinese person names, which corrects errors of baseline models and leads to better precision.

### 6.4.2 Effect of context

To examine how context contribute to alignment quality, we re-train our model with different window size, all from result of IBM model 4. From Figure 3, we can see introducing context increase the quality of the learned alignment, but the benefit is diminished for window size over 5. On the other hand, the results are quite stable even with large window size 13, without noticeable over-

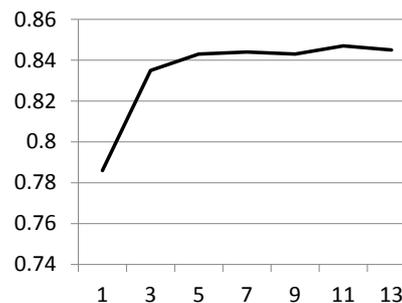

Figure 3: Effect of different window sizes on word alignment F-score.

fitting problem. This is not surprising considering that larger window size only requires slightly more parameters in the linear layers. Lastly, it is worth noticing that our model with no context (window size 1) performs much worse than settings with larger window size and baseline IBM4. Our explanation is as follows. Our model uses the simple jump distance based distortion, which is weaker than the more sophisticated distortions in IBM model 4; thus without context, it does not perform well compared to IBM model 4. With larger window size, our model is able to produce more accurate translation scores based on more contexts, which leads to better alignment despite the simpler distortions.

IBM4+NN	F-1
1-hidden-layer	0.834
2-hidden-layer	0.847
3-hidden-layer	0.843

Table 3: Effect of different number of hidden layers. Two hidden layers outperform one hidden layer, while three hidden layers do not bring further improvement.

### 6.4.3 Effect of number of hidden layers

Our neural network contains two hidden layers besides the lookup layer. It is natural to ask whether adding more layers would be beneficial. To answer this question, we train models with 1, 2 and 3 layers respectively, all from result of IBM model 4. For 1-hidden-layer setting, we set the hidden layer length to 120; and for 3-hidden-layer setting, we set hidden layer lengths to 120, 100, 10 respectively. As can be seen from Table 3, 2-hidden-layer outperforms the 1-hidden-layer setting, while another hidden layer does not bring

improvement. Due to time constraint, we have not tuned the hyper-parameters such as length of hidden layers in 1 and 3-hidden-layer settings, nor have we tested settings with more hidden-layers. It would be wise to test more settings to verify whether more layers would help.

#### 6.4.4 Word Embedding

Following (Collobert et al., 2011), we show some words together with its nearest neighbors using the Euclidean distance between their embeddings. As we can see from Table 2, after bilingual training, “bad” is no longer in the nearest neighborhood of “good” as they hold opposite semantic meanings; the nearest neighbor of “history” is now changed to its related adjective “historical”. Neighbors of proper nouns such as person names are relatively unchanged. For example, neighbors of word “zetian” are all Chinese names in both settings. As Chinese language lacks morphology, the single form and plural form of a noun in English often correspond to the same Chinese word, thus it is desirable that the two English words should have similar word embeddings. While this is true for relatively frequent nouns such as “lab” and “labs”, rarer nouns still remain near their monolingual embeddings as they are only modified a few times during the bilingual training. As shown in last column, neighborhood of “laggards” still consists of other plural forms even after bilingual training.

## 7 Conclusion

In this paper, we explore applying deep neural network for word alignment task. Our model

integrates a multi-layer neural network into an HMM-like framework, where context dependent lexical translation score is computed by neural network, and distortion is modeled by a simple jump-distance scheme. Our model is discriminatively trained on bilingual corpus, while huge monolingual data is used to pre-train word-embeddings. Experiments on large-scale Chinese-to-English task show that the proposed method produces better word alignment results, compared with both classic HMM model and IBM model 4.

For future work, we will investigate more settings of different hyper-parameters in our model. Secondly, we want to explore the possibility of unsupervised training of our neural word alignment model, without reliance of alignment result of other models. Furthermore, our current model use rather simple distortions; it might be helpful to use more sophisticated model such as ITG (Wu, 1997), which can be modeled by Recursive Neural Networks (Socher et al., 2011).

## Abstract

In the ever-expanding sea of microblog data, there is a surprising amount of naturally occurring parallel text: some users create post multilingual messages targeting international audiences while others “retweet” translations. We present an efficient method for detecting these messages and extracting parallel segments from them. We have been able to extract over 1M Chinese-English parallel segments from Sina Weibo (the Chinese counterpart of Twitter) using only their public APIs. As a supplement to existing parallel training data, our automatically extracted parallel data yields substantial translation quality improvements in translating microblog text and modest improvements in translating edited news commentary. The resources in described in this paper are available at <http://www.cs.cmu.edu/~lingwang/utopia>.

## 1 Introduction

Microblogs such as Twitter and Facebook have gained tremendous popularity in the past 10 years. In addition to being an important form of communication for many people, they often contain extremely current, even breaking, information about world events. However, the writing style of microblogs tends to be quite colloquial, with frequent orthographic innovation (*R U still with me or what?*) and nonstandard abbreviations (*idk! shm*)—quite unlike the style found in more traditional, edited genres. This poses considerable problems for traditional NLP tools, which were developed with other domains in mind, which often make strong assumptions about orthographic uniformity (i.e., there is just one way to spell *you*). One approach to cope with this problem is to annotate in-domain data (Gimpel et al., 2011).

Machine translation suffers acutely from the domain-mismatch problem caused by microblog text. On one hand, standard models are probably suboptimal since they (like many models) assume orthographic uniformity in the input. However, more acutely, the data used to develop these systems and train their models is drawn from formal and carefully edited domains, such as parallel web pages and translated legal documents. MT training data seldom looks anything like microblog text.

This paper introduces a method for finding naturally occurring parallel microblog text, which helps address the domain-mismatch problem. Our method is inspired by the perhaps surprising observation that a reasonable number of microblog users tweet “in parallel” in two or more languages. For instance, the American entertainer Snoop Dogg regularly posts parallel messages on Sina Weibo (Mainland China’s equivalent of Twitter), for example, *watup Kenny Mayne!! - Kenny Mayne, 最近这么样啊!!*, where an English message and its Chinese translation are in the same post, separated by a dash. Our method is able to identify and extract such translations. Briefly, this requires determining if a tweet contains more than one language, if these multilingual utterances contain translated material (or are due to something else, such as code switching), and what the translated spans are.

The paper is organized as follows. Section 2 describes the related work in parallel data extraction. Section 3 presents our model to extract parallel data within the same document. Section 4 describes our extraction pipeline. Section 5 describes the data we gathered from both Sina Weibo (Chinese-English) and Twitter (Chinese-English and Arabic-English). We then present experiments showing that our harvested data not only substantially improves translations of microblog text with

existing (and arguably inappropriate) translation models, but that it improves the translation of more traditional MT genres, like newswire. We conclude in Section 6.

## 2 Related Work

Automatic collection of parallel data is a well-studied problem. Approaches to finding parallel web documents automatically have been particularly important (Resnik and Smith, 2003; Fukushima et al., 2006; Li and Liu, 2008; Uszkoreit et al., 2010; Ture and Lin, 2012). These broadly work by identifying promising candidates using simple features, such as URL similarity or “gist translations” and then identifying truly parallel segments with more expensive classifiers. More specialized resources were developed using manual procedures to leverage special features of very large collections, such as Europarl (Koehn, 2005).

Mining parallel or comparable messages from microblogs has mainly relied on Cross-Lingual Information Retrieval techniques (CLIR). Jelh et al. (2012) attempt to find pairs of tweets in Twitter using Arabic tweets as search queries in a CLIR system. Afterwards, the model described in (Xu et al., 2001) is applied to retrieve a set of ranked translation candidates for each Arabic tweet, which are then used as parallel candidates.

The work on mining parenthetical translations (Lin et al., 2008), which attempts to find translations within the same document, has some similarities with our work, since parenthetical translations are within the same document. However, parenthetical translations are generally used to translate names or terms, which is more limited than our work which extracts whole sentence translations.

Finally, crowd-sourcing techniques to obtain translations have been previously studied and applied to build datasets for casual domains (Zbib et al., 2012; Post et al., 2012). These approaches require remunerated workers to translate the messages, and the amount of messages translated per day is limited. We aim to propose a method that acquires large amounts of parallel data for free. The drawback is that there is a margin of error in the parallel segment identification and alignment. However, our system can be tuned for precision or for recall.

## 3 Parallel Segment Retrieval

We will first abstract from the domain of Microblogs and focus on the task of retrieving parallel segments from single documents. Prior work on finding parallel data attempts to reason about the probability that pairs of documents  $(\mathbf{x}, \mathbf{y})$  are parallel. In contrast, we only consider one document at a time, defined by  $\mathbf{x} = x_1, x_2, \dots, x_n$ , and consisting of  $n$  tokens, and need to determine whether there is **parallel data** in  $\mathbf{x}$ , and if so, where are the parallel **segments** and their **languages**. For simplicity, we assume that there are at most 2 continuous segments that are parallel.

As representation for the parallel segments within the document, we use the tuple  $([p, q], l, [u, v], r, \mathbf{a})$ . The word indexes  $[p, q]$  and  $[u, v]$  are used to identify the left segment (from  $p$  to  $q$ ) and right segment (from  $u$  to  $v$ ), which are parallel. We shall refer  $[p, q]$  and  $[u, v]$  as the **spans** of the left and right segments. To avoid overlaps, we set the constraint  $p \leq q < u \leq v$ . Then, we use  $l$  and  $r$  to identify the language of the left and right segments, respectively. Finally,  $\mathbf{a}$  represents the word alignment between the words in the left and the right segments.

The main problem we address is to find the parallel data when the boundaries of the parallel segments are not defined explicitly. If we knew the indexes  $[p, q]$  and  $[u, v]$ , we could simply run a language detector for these segments to find  $l$  and  $r$ . Then, we would use an word alignment model (Brown et al., 1993; Vogel et al., 1996), with source  $\mathbf{s} = x_p, \dots, x_q$ , target  $\mathbf{t} = x_u, \dots, x_v$  and lexical table  $\theta_{l,r}$  to calculate the Viterbi alignment  $\mathbf{a}$ . Finally, from the probability of the word alignments, we can determine whether the segments are parallel.

Thus, our model will attempt to find the optimal values for the segments  $[p, q][u, v]$ , languages  $l, r$  and word alignments  $\mathbf{a}$  jointly. However, there are two problems with this approach. Firstly, word alignment models generally attribute higher probabilities to smaller segments, since these are the result of a smaller product chain of probabilities. In fact, because our model can freely choose the segments to align, choosing only one word as the left segment that is well aligned to a word in the right segment would be the best choice. This is obviously not our goal, since we would not obtain any useful sentence pairs. Secondly, inference must be performed over the combination of all latent variables, which is intractable using

a brute force algorithm. We shall describe our model to solve the first problem in 3.1 and our dynamic programming approach to make the inference tractable in 3.2.

### 3.1 Model

We propose a simple (non-probabilistic) three-factor model that models the spans of the parallel segments, their languages, and word alignments jointly. This model is defined as follows:

$$S([u, v], r, [p, q], l, \mathbf{a} \mid \mathbf{x}) = S_S^\alpha([p, q], [u, v] \mid \mathbf{x}) \times S_L^\beta(l, r \mid [p, q], [u, v], \mathbf{x}) \times S_T^\gamma(\mathbf{a} \mid [p, q], l, [u, v], r, \mathbf{x})$$

Each of the components is weighted by the parameters  $\alpha$ ,  $\beta$  and  $\gamma$ . We set these values empirically  $\alpha = 0.3$ ,  $\beta = 0.3$  and  $\gamma = 0.4$ , and leave the optimization of these parameters as future work. We discuss the components of this model in turn.

**Span score  $S_S$ .** We define the score of hypothesized pair of spans  $[p, q]$ ,  $[u, v]$  as:

$$S_S([p, q], [u, v] \mid \mathbf{x}) = \frac{(q - p + 1) + (v - u + 1)}{\sum_{0 < p' \leq q' < u' \leq v' \leq n} (q' - p' + 1) + (v' - u' + 1)} \times \psi([p, q], [u, v], \mathbf{x})$$

The first factor is a distribution over all spans that assigns higher probability to segmentations that cover more words in the document. It is highest for segmentations that cover all the words in the document (this is desirable since there are many sentence pairs that can be extracted but we want to find the largest sentence pair in the document). The function  $\psi$  takes on values of 0 or 1 depending on whether certain constraints are violated, these include: parenthetical constraints that enforce that spans must not break text within parenthetical characters and language constraints that ensure that we do not break a sequence of Mandarin characters, Arabic words or Latin words.

**Language score  $S_L$ .** The language score  $S_L(l, r \mid [p, q], [u, v], \mathbf{x})$  indicates whether the language labels  $l, r$  are appropriate to the document contents:

$$S_L(l, r \mid [p, q], [u, v], \mathbf{x}) = \frac{\sum_{i=p}^q L(l, x_i) + \sum_{i=u}^v L(r, x_i)}{n}$$

where  $L(l, x)$  is a language detection function that yields 1 if the word  $x_i$  is in language  $l$ , and 0 otherwise. We build the function simply by considering all words that are composed of Latin characters as English, Arabic characters as Arabic and Han characters as Mandarin. This approach is not perfect, but it is simple and works reasonably well for our purposes.

**Translation score  $S_T$ .** The translation score  $S_T(\mathbf{a} \mid [p, q], l, [u, v], r)$  indicates whether  $[p, q]$  is a reasonable translation of  $[u, v]$  with the alignment  $\mathbf{a}$ . We rely on IBM Model 1 probabilities for this score:

$$S_T(\mathbf{a} \mid [p, q], l, [u, v], r, \mathbf{x}) = \frac{1}{(q - p + 1)^{v-u+2}} \prod_{i=u}^v P_{M1}(x_i \mid x_{a_i}).$$

The lexical tables  $P_{M1}$  for the various language pairs are trained a priori using available parallel corpora. While IBM Model 1 produces worse alignments than other models, in our problem, we need to efficiently consider all possible spans, language pairs and word alignments, which makes the problem intractable. We will show that dynamic programming can be used to make this problem tractable, using Model 1. Furthermore, IBM Model 1 has shown good performance for sentence alignment systems previously (Xu et al., 2005; Braune and Fraser, 2010).

### 3.2 Inference

Our goal is to find the spans, language pair and alignments such that:

$$\arg \max_{[p, q], l, [u, v], r, \mathbf{a}} S([p, q], l, [u, v], r, \mathbf{a} \mid \mathbf{x}) \quad (1)$$

A high score indicates that the predicted bispan is likely to correspond to a valid parallel span, so we set a constant threshold  $\tau$  to determine whether a document has parallel data, i.e., the value of  $z$ :

$$z^* = \max_{[u, v], r, [p, q], l, \mathbf{a}} S([u, v], r, [p, q], l, \mathbf{a} \mid \mathbf{x}) > \tau$$

Naively maximizing Eq. 1 would require  $O(|\mathbf{x}|^6)$  operations, which is too inefficient to be practical on large datasets. To process millions of documents, this process would need to be optimized.

The main bottleneck of the naive algorithm is finding new Viterbi Model 1 word alignments every time we change the spans. Thus, we propose

an iterative approach to compute the Viterbi word alignments for IBM Model 1 using dynamic programming.

**Dynamic programming search.** The insight we use to improve the runtime is that the Viterbi word alignment of a bispan can be reused to calculate the Viterbi word alignments of larger bispans. The algorithm operates on a 4-dimensional chart of bispans. It starts with the minimal valid span (i.e.,  $[0, 0], [1, 1]$ ) and progressively builds larger spans from smaller ones. Let  $A_{p,q,u,v}$  represent the Viterbi alignment (under  $S_T$ ) of the bispan  $[p, q], [u, v]$ . The algorithm uses the following recursions defined in terms of four operations  $\lambda_{\{+v,+u,+p,+q\}}$  that manipulate a single dimension of the bispan to construct larger spans:

- $A_{p,q,u,v+1} = \lambda_{+v}(A_{p,q,u,v})$  adds one token to the end of the right span with index  $v + 1$  and find the viterbi alignment for that token. This requires iterating over all the tokens in the left span,  $[p, q]$  and possibly updating their alignments. See Fig. 1 for an illustration.
- $A_{p,q,u+1,v} = \lambda_{+u}(A_{p,q,u,v})$  removes the first token of the right span with index  $u$ , so we only need to remove the alignment from  $u$ , which can be done in time  $O(1)$ .
- $A_{p,q+1,u,v} = \lambda_{+q}(A_{p,q,u,v})$  adds one token to the end of the left span with index  $q + 1$ , we need to check for each word in the right span, if aligning to the word in index  $q+1$  yields a better translation probability. This update requires  $n - q + 1$  operations.
- $A_{p+1,q,u,v} = \lambda_{+p}(A_{p,q,u,v})$  removes the first token of the left span with index  $p$ . After removing the token, we need to find new alignments for all tokens that were aligned to  $p$ . Thus, the number of operations for this update is  $K \times (q - p + 1)$ , where  $K$  is the number of words that were aligned to  $p$ . In the best case, no words are aligned to the token in  $p$ , and we can simply remove it. In the worst case, if all target words were aligned to  $p$ , this update will result in the recalculation of all Viterbi Alignments.

The algorithm proceeds until all valid cells have been computed. One important aspect is that the update functions differ in complexity, so the sequence of updates we apply will impact the performance of the system. Most spans are reachable using any of the four update functions. For instance, the span  $A_{2,3,4,5}$  can be reached using  $\lambda_{+v}(A_{2,3,4,4})$ ,  $\lambda_{+u}(A_{2,3,3,5})$ ,  $\lambda_{+q}(A_{2,2,4,5})$  or  $\lambda_{+p}(A_{1,3,4,5})$ . However, we want to use  $\lambda_{+u}$

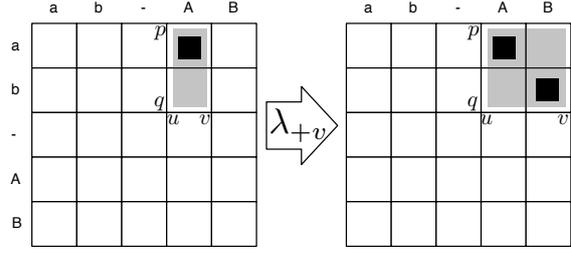

Figure 1: Illustration of the  $\lambda_{+v}$  operator. The light gray boxes show the parallel span and the dark boxes show the span’s Viterbi alignment. In this example, the parallel message contains a “translation” of a b to A B.

whenever possible, since it only requires one operation, although that is not always possible. For instance, the state  $A_{2,2,2,4}$  cannot be reached using  $\lambda_{+u}$ , since the state  $A_{2,2,1,4}$  is not valid, because the spans overlap. If this happens, incrementally more expensive updates need to be used, such as  $\lambda_{+v}$ , then  $\lambda_{+q}$ , which are in the same order of complexity. Finally, we want to minimize the use of  $\lambda_{+p}$ , which is quadratic in the worst case. Thus, we use the following recursive formulation that guarantees the optimal outcome:

$$A_{p,q,u,v} = \begin{cases} \lambda_{+u}(A_{p,q,u-1,v}) & \text{if } u > q + 1 \\ \lambda_{+v}(A_{p,q,u,v-1}) & \text{else if } v > q + 1 \\ \lambda_{+p}(A_{p-1,q,u,v}) & \text{else if } q = p + 1 \\ \lambda_{+q}(A_{p,q-1,u,v}) & \text{otherwise} \end{cases}$$

This transition function applies the cheapest possible update to reach state  $A_{p,q,u,v}$ .

**Complexity analysis.** We can see that  $\lambda_{+u}$  is only needed in the following the cases  $[0, 1][2, 2], [1, 2][3, 3], \dots, [n - 2, n - 1][n, n]$ . Since, this update is quadratic in the worst case, the complexity of this operations is  $O(n^3)$ . The update  $\lambda_{+q}$ , is applied to the cases  $[*, 1][2, 2], [*, 2][3, 3], \dots, [*, n - 1], [n, n]$ , where  $*$  denotes any number within the span constraints but not present in previous updates. Since, the update is linear and we need to iterate through all tokens twice, this update takes  $O(n^3)$  operations. The update  $\lambda_{+v}$  is applied for the cases  $[*, 1][2, *], [*, 2][3, *], \dots, [*, n - 1], [n, *]$ . Thus, with three degrees of freedom and a linear update, it runs in  $O(n^4)$  time. Finally, update  $\lambda_{+u}$  runs in constant time, but is run for all remaining cases, which constitute  $O(n^4)$  space. By summing the

executions of all updates, we observe that the order of magnitude of our exact inference process is  $O(n^4)$ . Note that for exact inference, it is not possible to get a lower order of magnitude, since we need to at least iterate through all possible span values once, which takes  $O(n^4)$  time.

## 4 Parallel Data Extraction

We will now describe our method to extract parallel data from Microblogs. The target domains in this work are Twitter and Sina Weibo, and the main language pair is Chinese-English. Furthermore, we also run the system for the Arabic-English language pair using the Twitter data.

For the Twitter domain, we use a previously crawled dataset from the years 2008 to 2013, where one million tweets are crawled every day. In total, we processed 1.6 billion tweets.

Regarding Sina Weibo, we built a crawler that continuously collects tweets from Weibo. We start from one seed user and collect his posts, and then we find the users he follows that we have not considered, and repeat. Due to the rate limiting established by the Weibo API<sup>1</sup>, we are restricted in terms of number of requests every hour, which greatly limits the amount of messages we can collect. Furthermore, each request can only fetch up to 100 posts from a user, and subsequent pages of 100 posts require additional API calls. Thus, to optimize the number of parallel posts we can collect per request, we only crawl all messages from users that have at least 10 parallel tweets in their first 100 posts. The number of parallel messages is estimated by running our alignment model, and checking if  $\tau > \phi$ , where  $\phi$  was set empirically initially, and optimized after obtaining annotated data, which will be detailed in 5.1. Using this process, we crawled 65 million tweets from Sina Weibo within 4 months.

In both cases, we first filter the collection of tweets for messages containing at least one trigram in each language of the target language pair, determined by their Unicode ranges. This means that for the Chinese-English language pair, we only keep tweets with more than 3 Mandarin characters and 3 latin words. Furthermore, based on the work in (Jelh et al., 2012), if a tweet  $A$  is identified as a retweet, meaning that it references another tweet  $B$ , we also consider the hypothesis that these tweets may be mutual translations. Thus, if  $A$  and  $B$  contain trigrams in different languages,

<sup>1</sup><http://open.weibo.com/wiki/API文档/en>

these are also considered for the extraction of parallel data. This is done by concatenating tweets  $A$  and  $B$ , and adding the constraint that  $[p, q]$  must be within  $A$  and  $[u, v]$  must be within  $B$ . Finally, identical duplicate tweets are removed.

After filtering, we obtained 1124k ZH-EN tweets from Sina Weibo, 868k ZH-EN and 136k AR-EN tweets from Twitter. These language pairs are not definite, since we simply check if there is a trigram in each language.

Finally, we run our alignment model described in section 3, and obtain the parallel segments and their scores, which measure how likely those segments are parallel. In this process, lexical tables for EN-ZH language pair used by Model 1 were built using the FBIS dataset (LDC2003E14) for both directions, a corpus of 300K sentence pairs from the news domain. Likewise, for the EN-AR language pair, we use a fraction of the NIST dataset, by removing the data originated from UN, which leads to approximately 1M sentence pairs.

## 5 Experiments

We evaluate our method in two ways. First, intrinsically, by observing how well our method identifies tweets containing parallel data, the language pair and what their spans are. Second, extrinsically, by looking at how well the data improves a translation task. This methodology is similar to that of Smith et al. (2010).

### 5.1 Parallel Data Extraction

**Data.** Our method needs to determine if a given tweet contains parallel data, and if so, what is the language pair of the data, and what segments are parallel. Thus, we had a native Mandarin speaker, also fluent in English, to annotate 2000 tweets sampled from crawled Weibo tweets. One important question of answer is what portion of the Microblogs contains parallel data. Thus, we also use the random sample Twitter and annotated 1200 samples, identifying whether each sample contains parallel data, for the EN-ZH and AR-EN filtered tweets.

**Metrics.** To test the accuracy of the score  $S$ , we ordered all 2000 samples by score. Then, we calculate the precision, recall and accuracy at increasing intervals of 10% of the top samples. We count as a true positive ( $tp$ ) if we correctly identify a parallel tweet, and as a false positive ( $fp$ ) spuriously detect a parallel tweet. Finally, a true negative ( $tn$ ) occurs when we correctly detect a non-parallel

tweet, and a false negative ( $fn$ ) if we miss a parallel tweet. Then, we set the precision as  $\frac{tp}{tp+fp}$ , recall as  $\frac{tp}{tp+fn}$  and accuracy as  $\frac{tp+tn}{tp+fp+tn+fn}$ . For language identification, we calculate the accuracy based on the number of instances that were identified with the correct language pair. Finally, to evaluate the segment alignment, we use the Word Error Rate (WER) metric, without substitutions, where we compare the left and right spans of our system and the respective spans of the reference. We count an insertion error ( $I$ ) for each word in our system’s spans that is not present in the reference span and a deletion error ( $D$ ) for each word in the reference span that is not present in our system’s spans. Thus, we set  $WER = \frac{D+I}{N}$ , where  $N$  is the number of tokens in the tweet. To compute this score for the whole test set, we compute the average of the  $WER$  for each sample.

**Results.** The precision, recall and accuracy curves are shown in Figure 2. The quality of the parallel sentence detection did not vary significantly with different setups, so we will only show the results for the best setup, which is the baseline model with span constraints.

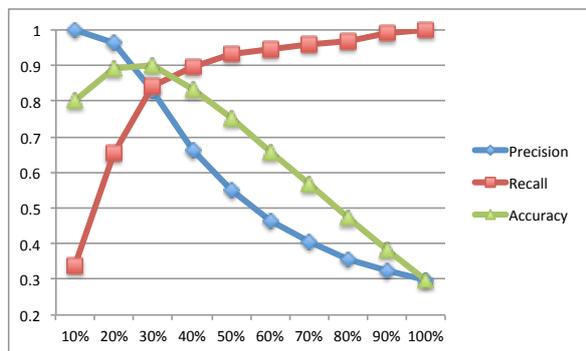

Figure 2: Precision, recall and accuracy curves for parallel data detection. The y-axis denotes the scores for each metric, and the x-axis denotes the percentage of the highest scoring sentence pairs that are kept.

From the precision and recall curves, we observe that most of the parallel data can be found at the top 30% of the filtered tweets, where 5 in 6 tweets are detected correctly as parallel, and only 1 in every 6 parallel sentences is lost. We will denote the score threshold at this point as  $\phi$ , which is a good threshold to estimate on whether the tweet is parallel. However, this parameter can be tuned for precision or recall. We also see that in total,

30% of the filtered tweets are parallel. If we generalize this ratio for the complete set with 1124k tweets, we can expect approximately 337k parallel sentences. Finally, since 65 million tweets were extracted to generate the 337k tweets, we estimate that approximately 1 parallel tweet can be found for every 200 tweets we process using our targeted approach. On the other hand, from the 1200 tweets from Twitter, we found that 27 had parallel data in the ZH-EN pair, if we extrapolate for the whole 868k filtered tweets, we expect that we can find 19530. 19530 parallel sentences from 1.6 billion tweets crawled randomly, represents 0.001% of the total corpora. For AR-EN, a similar result was obtained where we expect 12407 tweets out of the 1.6 billion to be parallel. This shows that targeted approaches can substantially reduce the crawling effort required to find parallel tweets. Still, considering that billions of tweets are posted daily, this is a substantial source of parallel data. The remainder of the tests will be performed on the Weibo dataset, which contains more parallel data. Tests on the Twitter data will be conducted as future work, when we process Twitter data on a larger scale to obtain more parallel sentences.

For the language identification task, we had an accuracy of 99.9%, since distinguishing English and Mandarin is trivial. The small percentage of errors originated from other latin languages (Ex: French) due to our naive language detector.

As for the segment alignment task. Our baseline system with no constraints obtains a WER of 12.86%, and this can be improved to 11.66% by adding constraints to possible spans. This shows that, on average, approximately 1 in 9 words on the parallel segments is incorrect. However, translation models are generally robust to such kinds of errors and can learn good translations even in the presence of imperfect sentence pairs.

Among the 578 tweets that are parallel, 496 were extracted within the same tweet and 82 were extracted from retweets. Thus, we see that the majority of the parallel data comes from within the same tweet.

**Topic analysis.** To give an intuition about the contents of the parallel data we found, we looked at the distribution over topics of the parallel dataset inferred by LDA (Blei et al., 2003). Thus, we grouped the Weibo filtered tweets by users, and ran LDA over the predicted English segments, with 12 topics. The 7 most interpretable topics are shown in Table 1. We see that the data contains a

#	Topic	Most probable words in topic
1	(Dating)	love time girl live mv back word night rt wanna
2	(Entertainment)	news video follow pong image text great day today fans
3	(Music)	cr day tour cn url amazon music full concert alive
4	(Religion)	man god good love life heart would give make lord
5	(Nightlife)	cn url beijing shanqi party adj club dj bejiner vt
6	(Chinese News)	china chinese year people world beijing years passion country government
7	(Fashion)	street fashion fall style photo men model vogue spring magazine

Table 1: Most probable words inferred using LDA in several topics from the parallel data extracted from Weibo. Topic labels (in parentheses) were assigned manually for illustration purposes.

variety of topics, both formal (Chinese news, religion) and informal (entertainment, music).

**Example sentence pairs.** To gain some perspective on the type of sentence pairs we are extracting, we will illustrate some sentence pairs we crawled and aligned automatically. Table 2 contains 5 English-Mandarin and 4 English-Arabic sentence pairs that were extracted automatically. These were chosen, since they contain some aspects that are characteristic of the text present in Microblogs and Social Media. These are:

- **Abbreviations** - In most sentence pairs examples, we can witness the use of abbreviated forms of English words, such as *wanna*, *TMI*, *4* and *imma*. These can be normalized as *want to*, *too much information*, *for* and *I am going to*, respectively. In sentence 5, we observe that this phenomena also occurs in Mandarin. We find that *TMD* is a popular way to write 他妈的 whose Pinyin rendering is *tā mā de*. The meaning of this expression depends on the context it is used, and can convey a similar connotation as adding the intensifier *the hell* to an English sentence.
- **Jargon** - Another common phenomena is the appearance of words that are only used in sub-communities. For instance, in sentence pair 4, we the jargon word *cday* is used, which is a colloquial variant for *birthday*.
- **Emoticons** - In sentence 8, we observe the presence of the emoticon *:)*, which is frequently used in this media. We found that emoticons are either translated as they are or simply removed, in most cases.
- **Syntax errors** - In the domain of microblogs, it is also common that users do not write strictly syntactic sentences, for instance, in sentence pair 7, the sentence *onni this gift only 4 u*, is clearly not syntactically correct. Firstly, *onni* is a named entity, yet it is not capitalized. Secondly, a comma should follow *onni*. Thirdly, the

verb *is* should be used after *gift*. Having examples of these sentences in the training set, with common mistakes (intentional or not), might become a key factor in training MT systems that can be robust to such errors.

- **Dialects** - We can observe a much broader range of dialects in our data, since there are no dialect standards in microblogs. For instance, in sentence pair 6, we observe an arabic word (in bold) used in the spoken Arabic dialect used in some countries along the shores of the Persian Gulf, which means means *the next*. In standard Arabic, a significantly different form is used.

We can also see in sentence pair 9 that our aligner does not always make the correct choice when determining spans. In this case, the segment *RT @MARYAMALKHAWAJA:* was included in the English segment spuriously, since it does not correspond to anything in the Arabic counterpart.

## 5.2 Machine Translation Experiments

We report on machine translation experiments using our harvested data in two domains: edited news and microblogs.

**News translation.** For the news test, we created a new test set from a crawl of the Chinese-English documents on the Project Syndicate website<sup>2</sup>, which contains news commentary articles. We chose to use this data set, rather than more standard NIST test sets to ensure that we had recent documents in the test set (the most recent NIST test sets contain documents published in 2007, well before our microblog data was created). We extracted 1386 parallel sentences for tuning and another 1386 sentences for testing, from the manually aligned segments. For this test set, we used 8 million sentences from the full NIST parallel dataset as the language model training data. We shall call this test set **Syndicate**.

<sup>2</sup><http://www.project-syndicate.org/>

	ENGLISH	MANDARIN

Table 2: Examples of English-Mandarin and English-Arabic sentence pairs. The English-Mandarin sentences were extracted from Sina Weibo and the English-Arabic sentences were extracted from Twitter. Some messages have been shorted to fit into the table. Some interesting aspects of these sentence pairs are marked in bold.

**Microblog translation.** To carry out the microblog translation experiments, we need a high quality parallel test set. Since we are not aware of such a test set, we created one by manually selecting parallel messages from Weibo. Our procedure was as follows. We selected 2000 candidate Weibo posts from users who have a high number of parallel tweets according to our automatic method (at least 2 in every 5 tweets). To these, we added another 2000 messages from our targeted Weibo crawl, but these had no requirement on the proportion of parallel tweets they had produced. We identified 2374 parallel segments, of which we used 1187 for development and 1187 for testing. We refer to this test set as **Weibo**.<sup>3</sup>

Obviously, we removed the development and test sets from our training data. Furthermore, to ensure that our training data was not too similar to the test set in the Weibo translation task, we filtered the *training* data to remove near duplicates by computing edit distance between each parallel sentence in the heldout set and each training instance. If either the source or the target sides of the a training instance had an edit distance of less than 10%, we removed it.<sup>4</sup> As for the language models, we collected a further 10M tweets from Twitter for the English language model and another 10M tweets from Weibo for the Chinese language model.

<sup>3</sup>We acknowledge that self-translated messages are probably not a typically representative sample of all microblog messages. However, we do not have the resources to produce a carefully curated test set with a more broadly representative distribution. Still, we believe these results are informative as long as this is kept in mind.

<sup>4</sup>Approximately 150,000 training instances removed.

	Syndicate		Weibo

NIST+Weibo	<b>13.3</b>	<b>21.5</b>	<b>16.9</b>	<b>17.9</b>

Table 3: BLEU scores for different datasets in different translation directions (left to right), broken with different training corpora (top to bottom).

**Baselines.** We report results on these test sets using different training data. First, we use the FBIS dataset which contains 300K high quality sentence pairs, mostly in the broadcast news domain. Second, we use the full 2012 NIST Chinese-English dataset (approximately 8M sentence pairs, including FBIS). Finally, we use our crawled data (referred as Weibo) by itself and also combined with the two previous training sets.

**Setup.** We use the Moses phrase-based MT system with standard features (Koehn et al., 2003). For reordering, we use the MSD reordering model (Axelrod et al., 2005). As the language model, we use a 5-gram model with Kneser-Ney smoothing. The weights were tuned using MERT (Och, 2003). Results are presented with BLEU-4 (Papineni et al., 2002).

**Results.** The BLEU scores for the different parallel corpora are shown in Table 3 and the top 10 out-of-vocabulary (OOV) words for each dataset are shown in Table 4. We observe that for the **Syndicate** test set, the NIST and FBIS datasets

Syndicate (test)			Weibo (test)

Table 4: The most frequent out-of-vocabulary (OOV) words and their counts for the two English-source test sets with three different training sets.

perform better than our extracted parallel data. This is to be expected, since our dataset was extracted from an extremely different domain. However, by combining the Weibo parallel data with this standard data, improvements in BLEU are obtained. Error analysis indicates that one major factor is that names from current events, such as *Romney* and *Wikileaks* do not occur in the older NIST and FBIS datasets, but they are represented in the Weibo dataset. Furthermore, we also note that the system built on the Weibo dataset does not perform substantially worse than the one trained on the FBIS dataset, a further indication that harvesting parallel microblog data yields a diverse collection of translated material.

For the **Weibo** test set, a significant improvement over the news datasets can be achieved using our crawled parallel data. Once again newer terms, such as *iTunes*, are one of the reasons older datasets perform less well. However, in this case, the top OOV words of the news domain datasets are not the most accurate representation of coverage problems in this domain. This is because many frequent words in microblogs, e.g., nonstandard abbreviations, like *u* and *4* are found in the news domain as words, albeit with different meanings. Thus, the OOV table gives an incomplete picture of the translation problems when using the news domain corpora to translate microblogs. Also, some structural errors occur when training with the news domain datasets, one such example is shown in table 5, where the character 说 is incorrectly translated to *said*. This occurs because this type of constructions is infrequent in news datasets. Furthermore, we can see that compound expressions, such as the translation from 派对时刻 to *party time* are also learned.

Finally, we observe that combining the datasets

Source	对sam farrar 说, 派对时刻
Reference	to sam farrar , party time
FBIS	farrar to sam said , in time
NIST	to sam farrar said , the moment
WEIBO	to sam farrar , party time

Table 5: Translation Examples using different training sets.

yields another gain over individual datasets, both in the **Syndicate** and in the **Weibo** test sets.

## 6 Conclusion

We presented a framework to crawl parallel data from microblogs. We find parallel data from single posts, with translations of the same sentence in two languages. We show that a considerable amount of parallel sentence pairs can be crawled from microblogs and these can be used to improve Machine Translation by updating our translation tables with translations of newer terms. Furthermore, the in-domain data can substantially improve the translation quality on microblog data.

The resources described in this paper and further developments are available to the general public at <http://www.cs.cmu.edu/~lingwang/utopia>.

## Abstract

Supervised topic models with a logistic likelihood have two issues that potentially limit their practical use: 1) response variables are usually over-weighted by document word counts; and 2) existing variational inference methods make strict mean-field assumptions. We address these issues by: 1) introducing a regularization constant to better balance the two parts based on an optimization formulation of Bayesian inference; and 2) developing a simple Gibbs sampling algorithm by introducing auxiliary Polya-Gamma variables and collapsing out Dirichlet variables. Our augment-and-collapse sampling algorithm has analytical forms of each conditional distribution without making any restricting assumptions and can be easily parallelized. Empirical results demonstrate significant improvements on prediction performance and time efficiency.

## 1 Introduction

As widely adopted in supervised latent Dirichlet allocation (sLDA) models (Blei and McAuliffe, 2010; Wang et al., 2009), one way to improve the predictive power of LDA is to define a likelihood model for the widely available document-level response variables, in addition to the likelihood model for document words. For example, the logistic likelihood model is commonly used for binary or multinomial responses. By imposing some priors, posterior inference is done with the Bayes' rule. Though powerful, one issue that could limit the use of existing logistic supervised LDA models is that they treat the document-level response variable as one additional word via a normalized likelihood model. Although some special treatment is carried out on defining the likelihood of the single

response variable, it is normally of a much smaller scale than the likelihood of the usually tens or hundreds of words in each document. As noted by (Halpern et al., 2012) and observed in our experiments, this model imbalance could result in a weak influence of response variables on the topic representations and thus non-satisfactory prediction performance. Another difficulty arises when dealing with categorical response variables is that the commonly used normal priors are no longer conjugate to the logistic likelihood and thus lead to hard inference problems. Existing approaches rely on variational approximation techniques which normally make strict mean-field assumptions.

To address the above issues, we present two improvements. First, we present a general framework of Bayesian logistic supervised topic models with a regularization parameter to better balance response variables and words. Technically, instead of doing standard Bayesian inference via Bayes' rule, which requires a normalized likelihood model, we propose to do regularized Bayesian inference (Zhu et al., 2011; Zhu et al., 2013b) via solving an optimization problem, where the posterior regularization is defined as an expectation of a logistic loss, a surrogate loss of the expected misclassification error; and a regularization parameter is introduced to balance the surrogate classification loss (i.e., the response log-likelihood) and the word likelihood. The general formulation subsumes standard sLDA as a special case.

Second, to solve the intractable posterior inference problem of the generalized Bayesian logistic supervised topic models, we present a simple Gibbs sampling algorithm by exploring the ideas of data augmentation (Tanner and Wong, 1987; van Dyk and Meng, 2001; Holmes and Held, 2006). More specifically, we extend Polson's method for Bayesian logistic regression (Polson et al., 2012) to the generalized logistic supervised topic models, which are much more challeng-

ing due to the presence of non-trivial latent variables. Technically, we introduce a set of Polya-Gamma variables, one per document, to reformulate the generalized logistic pseudo-likelihood model (with the regularization parameter) as a scale mixture, where the mixture component is conditionally normal for classifier parameters. Then, we develop a simple and efficient Gibbs sampling algorithms with analytic conditional distributions without Metropolis-Hastings accept/reject steps. For Bayesian LDA models, we can also explore the conjugacy of the Dirichlet-Multinomial prior-likelihood pairs to collapse out the Dirichlet variables (i.e., topics and mixing proportions) to do collapsed Gibbs sampling, which can have better mixing rates (Griffiths and Steyvers, 2004). Finally, our empirical results on real data sets demonstrate significant improvements on time efficiency. The classification performance is also significantly improved by using appropriate regularization parameters. We also provide a parallel implementation with GraphLab (Gonzalez et al., 2012), which shows great promise in our preliminary studies.

The paper is structured as follows. Sec. 2 introduces logistic supervised topic models as a general optimization problem. Sec. 3 presents Gibbs sampling algorithms with data augmentation. Sec. 4 presents experiments. Sec. 5 concludes.

## 2 Logistic Supervised Topic Models

We now present the generalized Bayesian logistic supervised topic models.

### 2.1 The Generalized Models

We consider binary classification with a training set  $\mathcal{D} = \{(\mathbf{w}_d, y_d)\}_{d=1}^D$ , where the response variable  $Y$  takes values from the output space  $\mathcal{Y} = \{0, 1\}$ . A logistic supervised topic model consists of two parts — an LDA model (Blei et al., 2003) for describing the words  $\mathbf{W} = \{\mathbf{w}_d\}_{d=1}^D$ , where  $\mathbf{w}_d = \{w_{dn}\}_{n=1}^{N_d}$  denote the words within document  $d$ , and a logistic classifier for considering the supervising signal  $\mathbf{y} = \{y_d\}_{d=1}^D$ . Below, we introduce each of them in turn.

**LDA:** LDA is a hierarchical Bayesian model that posits each document as an admixture of  $K$  topics, where each topic  $\Phi_k$  is a multinomial distribution over a  $V$ -word vocabulary. For document  $d$ , the generating process is

1. draw a topic proportion  $\theta_d \sim \text{Dir}(\boldsymbol{\alpha})$
2. for each word  $n = 1, 2, \dots, N_d$ :

- (a) draw a topic<sup>1</sup>  $z_{dn} \sim \text{Mult}(\boldsymbol{\theta}_d)$
- (b) draw the word  $w_{dn} \sim \text{Mult}(\Phi_{z_{dn}})$

where  $\text{Dir}(\cdot)$  is a Dirichlet distribution;  $\text{Mult}(\cdot)$  is a multinomial distribution; and  $\Phi_{z_{dn}}$  denotes the topic selected by the non-zero entry of  $z_{dn}$ . For fully-Bayesian LDA, the topics are random samples from a Dirichlet prior,  $\Phi_k \sim \text{Dir}(\boldsymbol{\beta})$ .

Let  $\mathbf{z}_d = \{z_{dn}\}_{n=1}^{N_d}$  denote the set of topic assignments for document  $d$ . Let  $\mathbf{Z} = \{\mathbf{z}_d\}_{d=1}^D$  and  $\Theta = \{\theta_d\}_{d=1}^D$  denote all the topic assignments and mixing proportions for the entire corpus. LDA infers the posterior distribution  $p(\Theta, \mathbf{Z}, \Phi | \mathbf{W}) \propto p_0(\Theta, \mathbf{Z}, \Phi) p(\mathbf{W} | \mathbf{Z}, \Phi)$ , where  $p_0(\Theta, \mathbf{Z}, \Phi) = (\prod_d p(\theta_d | \boldsymbol{\alpha}) \prod_n p(z_{dn} | \theta_d)) \prod_k p(\Phi_k | \boldsymbol{\beta})$  is the joint distribution defined by the model. As noticed in (Jiang et al., 2012), the posterior distribution by Bayes' rule is equivalent to the solution of an information theoretical optimization problem

$$\min_{q(\Theta, \mathbf{Z}, \Phi)} \text{KL}(q(\Theta, \mathbf{Z}, \Phi) \| p_0(\Theta, \mathbf{Z}, \Phi)) - \mathbb{E}_q[\log p(\mathbf{W} | \mathbf{Z}, \Phi)]$$

s.t. :  $q(\Theta, \mathbf{Z}, \Phi) \in \mathcal{P}$ ,

(1)

where  $\text{KL}(q \| p)$  is the Kullback-Leibler divergence from  $q$  to  $p$  and  $\mathcal{P}$  is the space of probability distributions.

**Logistic classifier:** To consider binary supervising information, a logistic supervised topic model (e.g., sLDA) builds a logistic classifier using the topic representations as input features

$$p(y = 1 | \boldsymbol{\eta}, \mathbf{z}) = \frac{\exp(\boldsymbol{\eta}^\top \bar{\mathbf{z}})}{1 + \exp(\boldsymbol{\eta}^\top \bar{\mathbf{z}})},$$
(2)

where  $\bar{\mathbf{z}}$  is a  $K$ -vector with  $\bar{z}_k = \frac{1}{N} \sum_{n=1}^N \mathbb{I}(z_n^k = 1)$ , and  $\mathbb{I}(\cdot)$  is an indicator function that equals to 1 if predicate holds otherwise 0. If the classifier weights  $\boldsymbol{\eta}$  and topic assignments  $\mathbf{z}$  are given, the prediction rule is

$$\hat{y} |_{\boldsymbol{\eta}, \mathbf{z}} = \mathbb{I}(p(y = 1 | \boldsymbol{\eta}, \mathbf{z}) > 0.5) = \mathbb{I}(\boldsymbol{\eta}^\top \bar{\mathbf{z}} > 0).$$
(3)

Since both  $\boldsymbol{\eta}$  and  $\mathbf{Z}$  are hidden variables, we propose to infer a posterior distribution  $q(\boldsymbol{\eta}, \mathbf{Z})$  that has the minimal expected log-logistic loss

$$\mathcal{R}(q(\boldsymbol{\eta}, \mathbf{Z})) = - \sum_d \mathbb{E}_q[\log p(y_d | \boldsymbol{\eta}, \mathbf{z}_d)],$$
(4)

which is a good surrogate loss for the expected misclassification loss,  $\sum_d \mathbb{E}_q[\mathbb{I}(\hat{y} |_{\boldsymbol{\eta}, \mathbf{z}_d} \neq y_d)]$ , of a Gibbs classifier that randomly draws a model  $\boldsymbol{\eta}$  from the posterior distribution and makes predictions (McAllester, 2003; Germain et al., 2009). In fact, this choice is motivated from the observation that logistic loss has been widely used as a convex surrogate loss for the misclassification

<sup>1</sup>A  $K$ -binary vector with only one entry equaling to 1.

loss (Rosasco et al., 2004) in the task of fully observed binary classification. Also, note that the logistic classifier and the LDA likelihood are coupled by sharing the latent topic assignments  $\mathbf{z}$ . The strong coupling makes it possible to learn a posterior distribution that can describe the observed words well and make accurate predictions.

**Regularized Bayesian Inference:** To integrate the above two components for hybrid learning, a logistic supervised topic model solves the joint Bayesian inference problem

$$\begin{aligned} \min_{q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})} \mathcal{L}(q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})) + c\mathcal{R}(q(\boldsymbol{\eta}, \mathbf{Z})) \quad (5) \\ \text{s.t.: } q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi}) \in \mathcal{P}, \end{aligned}$$

where  $\mathcal{L}(q) = \text{KL}(q||p_0(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})) - \mathbb{E}_q[\log p(\mathbf{W}|\mathbf{Z}, \boldsymbol{\Phi})]$  is the objective for doing standard Bayesian inference with the classifier weights  $\boldsymbol{\eta}$ ;  $p_0(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi}) = p_0(\boldsymbol{\eta})p_0(\boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})$ ; and  $c$  is a regularization parameter balancing the influence from response variables and words.

In general, we define the pseudo-likelihood for the supervision information

$$\psi(y_d|\mathbf{z}_d, \boldsymbol{\eta}) = p^c(y_d|\boldsymbol{\eta}, \mathbf{z}_d) = \frac{\{\exp(\boldsymbol{\eta}^\top \bar{\mathbf{z}}_d)\}^{cy_d}}{(1 + \exp(\boldsymbol{\eta}^\top \bar{\mathbf{z}}_d))^c}, \quad (6)$$

which is un-normalized if  $c \neq 1$ . But, as we shall see this un-normalization does not affect our subsequent inference. Then, the generalized inference problem (5) of logistic supervised topic models can be written in the ‘‘standard’’ Bayesian inference form (1)

$$\begin{aligned} \min_{q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})} \mathcal{L}(q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})) - \mathbb{E}_q[\log \psi(\mathbf{y}|\mathbf{Z}, \boldsymbol{\eta})] \quad (7) \\ \text{s.t.: } q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi}) \in \mathcal{P}, \end{aligned}$$

where  $\psi(\mathbf{y}|\mathbf{Z}, \boldsymbol{\eta}) = \prod_d \psi(y_d|\mathbf{z}_d, \boldsymbol{\eta})$ . It is easy to show that the optimum solution of problem (5) or the equivalent problem (7) is the posterior distribution with supervising information, i.e.,

$$q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi}) = \frac{p_0(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})p(\mathbf{W}|\mathbf{Z}, \boldsymbol{\Phi})\psi(\mathbf{y}|\boldsymbol{\eta}, \mathbf{Z})}{\phi(\mathbf{y}, \mathbf{W})}.$$

where  $\phi(\mathbf{y}, \mathbf{W})$  is the normalization constant to make  $q$  a distribution. We can see that when  $c = 1$ , the model reduces to the standard sLDA, which in practice has the imbalance issue that the response variable (can be viewed as one additional word) is usually dominated by the words. This imbalance was noticed in (Halpern et al., 2012). We will see that  $c$  can make a big difference later.

**Comparison with MedLDA:** The above formulation of logistic supervised topic models as an instance of regularized Bayesian inference provides a direct comparison with the max-margin

supervised topic model (MedLDA) (Jiang et al., 2012), which has the same form of the optimization problems. The difference lies in the posterior regularization, for which MedLDA uses a hinge loss of an expected classifier while the logistic supervised topic model uses an expected log-logistic loss. Gibbs MedLDA (Zhu et al., 2013a) is another max-margin model that adopts the expected hinge loss as posterior regularization. As we shall see in the experiments, by using appropriate regularization constants, logistic supervised topic models achieve comparable performance as max-margin methods. We note that the relationship between a logistic loss and a hinge loss has been discussed extensively in various settings (Rosasco et al., 2004; Globerson et al., 2007). But the presence of latent variables poses additional challenges in carrying out a formal theoretical analysis of these surrogate losses (Lin, 2001) in the topic model setting.

## 2.2 Variational Approximation Algorithms

The commonly used normal prior for  $\boldsymbol{\eta}$  is non-conjugate to the logistic likelihood, which makes the posterior inference hard. Moreover, the latent variables  $\mathbf{Z}$  make the inference problem harder than that of Bayesian logistic regression models (Chen et al., 1999; Meyer and Laud, 2002; Polson et al., 2012). Previous algorithms to solve problem (5) rely on variational approximation techniques. It is easy to show that the variational method (Wang et al., 2009) is a coordinate descent algorithm to solve problem (5) with the additional fully-factorized constraint  $q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi}) = q(\boldsymbol{\eta})(\prod_d q(\boldsymbol{\theta}_d) \prod_n q(z_{dn})) \prod_k q(\boldsymbol{\Phi}_k)$  and a variational approximation to the expectation of the log-logistic likelihood, which is intractable to compute directly. Note that the non-Bayesian treatment of  $\boldsymbol{\eta}$  as unknown parameters in (Wang et al., 2009) results in an EM algorithm, which still needs to make strict mean-field assumptions together with a variational bound of the expectation of the log-logistic likelihood. In this paper, we consider the full Bayesian treatment, which can principally consider prior distributions and infer the posterior covariance.

## 3 A Gibbs Sampling Algorithm

Now, we present a simple and efficient Gibbs sampling algorithm for the generalized Bayesian logistic supervised topic models.

### 3.1 Formulation with Data Augmentation

Since the logistic pseudo-likelihood  $\psi(\mathbf{y}|\mathbf{Z}, \boldsymbol{\eta})$  is not conjugate with normal priors, it is not easy to derive the sampling algorithms directly. Instead, we develop our algorithms by introducing auxiliary variables, which lead to a scale mixture of Gaussian components and analytic conditional distributions for automatical Bayesian inference without an accept/reject ratio. Our algorithm represents a first attempt to extend Polson's approach (Polson et al., 2012) to deal with highly non-trivial Bayesian latent variable models. Let us first introduce the Polya-Gamma variables.

**Definition 1** (Polson et al., 2012) *A random variable  $X$  has a Polya-Gamma distribution, denoted by  $X \sim \mathcal{PG}(a, b)$ , if*

$$X = \frac{1}{2\pi^2} \sum_{i=1}^{\infty} \frac{g_k}{(i-1)^2/2 + b^2/(4\pi^2)},$$

where  $a, b > 0$  and each  $g_i \sim \mathcal{G}(a, 1)$  is an independent Gamma random variable.

Let  $\omega_d = \boldsymbol{\eta}^\top \bar{\mathbf{z}}_d$ . Then, using the ideas of data augmentation (Tanner and Wong, 1987; Polson et al., 2012), we can show that the generalized pseudo-likelihood can be expressed as

$$\psi(y_d|\mathbf{z}_d, \boldsymbol{\eta}) = \frac{1}{2^c} e^{\kappa_d \omega_d} \int_0^\infty \exp\left(-\frac{\lambda_d \omega_d^2}{2}\right) p(\lambda_d|c, 0) d\lambda_d,$$

where  $\kappa_d = c(y_d - 1/2)$  and  $\lambda_d$  is a Polya-Gamma variable with parameters  $a = c$  and  $b = 0$ . This result indicates that the posterior distribution of the generalized Bayesian logistic supervised topic models, i.e.,  $q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})$ , can be expressed as the marginal of a higher dimensional distribution that includes the augmented variables  $\boldsymbol{\lambda}$ . The complete posterior distribution is

$$q(\boldsymbol{\eta}, \boldsymbol{\lambda}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi}) = \frac{p_0(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi}) p(\mathbf{W}|\mathbf{Z}, \boldsymbol{\Phi}) \phi(\mathbf{y}, \boldsymbol{\lambda}|\mathbf{Z}, \boldsymbol{\eta})}{\psi(\mathbf{y}, \mathbf{W})},$$

where the pseudo-joint distribution of  $\mathbf{y}$  and  $\boldsymbol{\lambda}$  is

$$\phi(\mathbf{y}, \boldsymbol{\lambda}|\mathbf{Z}, \boldsymbol{\eta}) = \prod_d \exp\left(\kappa_d \omega_d - \frac{\lambda_d \omega_d^2}{2}\right) p(\lambda_d|c, 0).$$

### 3.2 Inference with Collapsed Gibbs Sampling

Although we can do Gibbs sampling to infer the complete posterior distribution  $q(\boldsymbol{\eta}, \boldsymbol{\lambda}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})$  and thus  $q(\boldsymbol{\eta}, \boldsymbol{\Theta}, \mathbf{Z}, \boldsymbol{\Phi})$  by ignoring  $\boldsymbol{\lambda}$ , the mixing rate would be slow due to the large sample space. One way to effectively improve mixing rates is to integrate out the intermediate variables  $(\boldsymbol{\Theta}, \boldsymbol{\Phi})$  and build a Markov chain whose equilibrium distribution is the marginal distribution  $q(\boldsymbol{\eta}, \boldsymbol{\lambda}, \mathbf{Z})$ . We propose to use collapsed Gibbs

sampling, which has been successfully used in LDA (Griffiths and Steyvers, 2004). For our model, the collapsed posterior distribution is

$$\begin{aligned} q(\boldsymbol{\eta}, \boldsymbol{\lambda}, \mathbf{Z}) &\propto p_0(\boldsymbol{\eta}) p(\mathbf{W}, \mathbf{Z}|\boldsymbol{\alpha}, \boldsymbol{\beta}) \phi(\mathbf{y}, \boldsymbol{\lambda}|\mathbf{Z}, \boldsymbol{\eta}) \\ &= p_0(\boldsymbol{\eta}) \prod_{k=1}^K \frac{\delta(\mathbf{C}_k + \boldsymbol{\beta})}{\delta(\boldsymbol{\beta})} \prod_{d=1}^D \left[ \frac{\delta(\mathbf{C}_d + \boldsymbol{\alpha})}{\delta(\boldsymbol{\alpha})} \right. \\ &\quad \left. \times \exp\left(\kappa_d \omega_d - \frac{\lambda_d \omega_d^2}{2}\right) p(\lambda_d|c, 0) \right], \end{aligned}$$

where  $\delta(\mathbf{x}) = \frac{\prod_{i=1}^{\dim(\mathbf{x})} \Gamma(x_i)}{\Gamma(\sum_{i=1}^{\dim(\mathbf{x})} x_i)}$ ,  $C_k^t$  is the number of times the term  $t$  being assigned to topic  $k$  over the whole corpus and  $\mathbf{C}_k = \{C_k^t\}_{t=1}^V$ ;  $C_d^k$  is the number of times that terms being associated with topic  $k$  within the  $d$ -th document and  $\mathbf{C}_d = \{C_d^k\}_{k=1}^K$ . Then, the conditional distributions used in collapsed Gibbs sampling are as follows.

**For  $\boldsymbol{\eta}$ :** for the commonly used isotropic Gaussian prior  $p_0(\boldsymbol{\eta}) = \prod_k \mathcal{N}(\eta_k; 0, \nu^2)$ , we have

$$\begin{aligned} q(\boldsymbol{\eta}|\mathbf{Z}, \boldsymbol{\lambda}) &\propto p_0(\boldsymbol{\eta}) \prod_d \exp\left(\kappa_d \omega_d - \frac{\lambda_d \omega_d^2}{2}\right) \\ &= \mathcal{N}(\boldsymbol{\eta}; \boldsymbol{\mu}, \Sigma), \end{aligned} \quad (8)$$

where the posterior mean is  $\boldsymbol{\mu} = \Sigma(\sum_d \kappa_d \bar{\mathbf{z}}_d)$  and the covariance is  $\Sigma = (\frac{1}{\nu^2} I + \sum_d \lambda_d \bar{\mathbf{z}}_d \bar{\mathbf{z}}_d^\top)^{-1}$ . We can easily draw a sample from a  $K$ -dimensional multivariate Gaussian distribution. The inverse can be robustly done using Cholesky decomposition, an  $O(K^3)$  procedure. Since  $K$  is normally not large, the inversion can be done efficiently.

**For  $\mathbf{Z}$ :** The conditional distribution of  $\mathbf{Z}$  is

$$\begin{aligned} q(\mathbf{Z}|\boldsymbol{\eta}, \boldsymbol{\lambda}) &\propto \prod_{k=1}^K \frac{\delta(\mathbf{C}_k + \boldsymbol{\beta})}{\delta(\boldsymbol{\beta})} \prod_{d=1}^D \left[ \frac{\delta(\mathbf{C}_d + \boldsymbol{\alpha})}{\delta(\boldsymbol{\alpha})} \right. \\ &\quad \left. \times \exp\left(\kappa_d \omega_d - \frac{\lambda_d \omega_d^2}{2}\right) \right]. \end{aligned}$$

By canceling common factors, we can derive the local conditional of one variable  $z_{dn}$  as:

$$\begin{aligned} q(z_{dn}^k = 1 | \mathbf{Z}_{-n}, \boldsymbol{\eta}, \boldsymbol{\lambda}, w_{dn} = t) &\propto \frac{(C_{k,-n}^t + \beta_t)(C_{d,-n}^k + \alpha_k)}{\sum_t C_{k,-n}^t + \sum_{t=1}^V \beta_t} \exp\left(\gamma \kappa_d \eta_k \right. \\ &\quad \left. - \lambda_d \frac{\gamma^2 \eta_k^2 + 2\gamma(1-\gamma)\eta_k \Lambda_{dn}^k}{2}\right), \end{aligned} \quad (9)$$

where  $C_{\cdot,-n}$  indicates that term  $n$  is excluded from the corresponding document or topic;  $\gamma = \frac{1}{N_d}$ ; and  $\Lambda_{dn}^k = \frac{1}{N_d - 1} \sum_{k'} \eta_{k'} C_{d,-n}^{k'}$  is the discriminant function value without word  $n$ . We can see that the first term is from the LDA model for observed word counts and the second term is from the supervising signal  $\mathbf{y}$ .

**For  $\boldsymbol{\lambda}$ :** Finally, the conditional distribution of the augmented variables  $\boldsymbol{\lambda}$  is

$$\begin{aligned} q(\lambda_d|\mathbf{Z}, \boldsymbol{\eta}) &\propto \exp\left(-\frac{\lambda_d \omega_d^2}{2}\right) p(\lambda_d|c, 0) \\ &= \mathcal{PG}(\lambda_d; c, \omega_d), \end{aligned} \quad (10)$$

---

**Algorithm 1** for collapsed Gibbs sampling

  - 2: **for**  $m = 1$  **to**  $M$  **do**
  - 3:   draw a classifier from the distribution (8)
  - 4:   **for**  $d = 1$  **to**  $D$  **do**
  - 5:     **for** each word  $n$  in document  $d$  **do**
  - 6:       draw the topic using distribution (9)
  - 7:     **end for**
  - 8:     draw  $\lambda_d$  from distribution (10).
  - 9:   **end for**
  - 10: **end for**
- 

which is a Polya-Gamma distribution. The equality has been achieved by using the construction definition of the general  $\mathcal{PG}(a, b)$  class through an exponential tilting of the  $\mathcal{PG}(a, 0)$  density (Polson et al., 2012). To draw samples from the Polya-Gamma distribution, we adopt the efficient method<sup>2</sup> proposed in (Polson et al., 2012), which draws the samples through drawing samples from the closely related exponentially tilted Jacobi distribution.

With the above conditional distributions, we can construct a Markov chain which iteratively draws samples of  $\eta$  using Eq. (8),  $\mathbf{Z}$  using Eq. (9) and  $\lambda$  using Eq. (10), with an initial condition. In our experiments, we initially set  $\lambda = 1$  and randomly draw  $\mathbf{Z}$  from a uniform distribution. In training, we run the Markov chain for  $M$  iterations (i.e., the burn-in stage), as outlined in Algorithm 1. Then, we draw a sample  $\hat{\eta}$  as the final classifier to make predictions on testing data. As we shall see, the Markov chain converges to stable prediction performance with a few burn-in iterations.

### 3.3 Prediction

To apply the classifier  $\hat{\eta}$  on testing data, we need to infer their topic assignments. We take the approach in (Zhu et al., 2012; Jiang et al., 2012), which uses a point estimate of topics  $\Phi$  from training data and makes prediction based on them. Specifically, we use the MAP estimate  $\hat{\Phi}$  to replace the probability distribution  $p(\Phi)$ . For the Gibbs sampler, an estimate of  $\hat{\Phi}$  using the samples is  $\hat{\phi}_{kt} \propto C_k^t + \beta_t$ . Then, given a testing document  $\mathbf{w}$ , we infer its latent components  $\mathbf{z}$  using  $\hat{\Phi}$  as  $p(z_n = k | \mathbf{z}_{-n}) \propto \hat{\phi}_{kw_n} (C_{-n}^k + \alpha_k)$ , where

---

<sup>2</sup>The basic sampler was implemented in the R package BayesLogit. We implemented the sampling algorithm in C++ together with our topic model sampler.

$C_{-n}^k$  is the times that the terms in this document  $\mathbf{w}$  assigned to topic  $k$  with the  $n$ -th term excluded.

## 4 Experiments

We present empirical results and sensitivity analysis to demonstrate the efficiency and prediction performance<sup>3</sup> of the generalized logistic supervised topic models on the 20Newsgroups (20NG) data set, which contains about 20,000 postings within 20 news groups. We follow the same setting as in (Zhu et al., 2012) and remove a standard list of stop words for both binary and multi-class classification. For all the experiments, we use the standard normal prior  $p_0(\eta)$  (i.e.,  $\nu^2 = 1$ ) and the symmetric Dirichlet priors  $\alpha = \frac{\alpha}{K} \mathbf{1}$ ,  $\beta = 0.01 \times \mathbf{1}$ , where  $\mathbf{1}$  is a vector with all entries being 1. For each setting, we report the average performance and the standard deviation with five randomly initialized runs.

### 4.1 Binary classification

Following the same setting in (Lacoste-Jullien et al., 2009; Zhu et al., 2012), the task is to distinguish postings of the newsgroup *alt.atheism* and those of the group *talk.religion.misc*. The training set contains 856 documents and the test set contains 569 documents. We compare the generalized logistic supervised LDA using Gibbs sampling (denoted by gSLDA) with various competitors, including the standard sLDA using variational mean-field methods (denoted by vSLDA) (Wang et al., 2009), the MedLDA model using variational mean-field methods (denoted by vMedLDA) (Zhu et al., 2012), and the MedLDA model using collapsed Gibbs sampling algorithms (denoted by gMedLDA) (Jiang et al., 2012). We also include the unsupervised LDA using collapsed Gibbs sampling as a baseline, denoted by gLDA. For gLDA, we learn a binary linear SVM on its topic representations using SVMlight (Joachims, 1999). The results of DiscLDA (Lacoste-Jullien et al., 2009) and linear SVM on raw bag-of-words features were reported in (Zhu et al., 2012). For gSLDA, we compare two versions – the standard sLDA with  $c = 1$  and the sLDA with a well-tuned  $c$  value. To distinguish, we denote the latter by gSLDA+. We set  $c = 25$  for gSLDA+, and set  $\alpha = 1$  and  $M = 100$  for both gSLDA and gSLDA+. As we shall see, gSLDA is insensitive to  $\alpha$ ,

---

<sup>3</sup>Due to space limit, the topic visualization (similar to that of MedLDA) is deferred to a longer version.

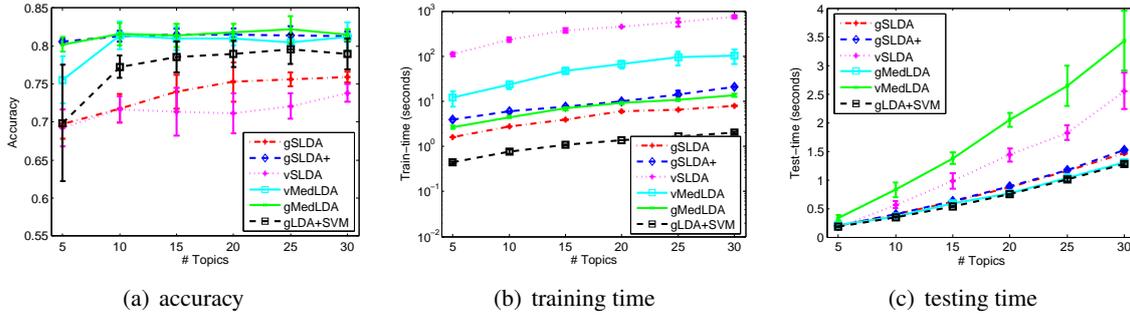

Figure 1: Accuracy, training time (in log-scale) and testing time on the 20NG binary data set.

$c$  and  $M$  in a wide range.

Fig. 1 shows the performance of different methods with various numbers of topics. For accuracy, we can draw two conclusions: 1) without making restricting assumptions on the posterior distributions, gSLDA achieves higher accuracy than vSLDA that uses strict variational mean-field approximation; and 2) by using the regularization constant  $c$  to improve the influence of supervision information, gSLDA+ achieves much better classification results, in fact comparable with those of MedLDA models since they have the similar mechanism to improve the influence of supervision by tuning a regularization constant. The fact that gLDA+SVM performs better than the standard gSLDA is due to the same reason, since the SVM part of gLDA+SVM can well capture the supervision information to learn a classifier for good prediction, while standard sLDA can’t well-balance the influence of supervision. In contrast, the well-balanced gSLDA+ model successfully outperforms the two-stage approach, gLDA+SVM, by performing topic discovery and prediction jointly<sup>4</sup>.

For training time, both gSLDA and gSLDA+ are very efficient, e.g., about 2 orders of magnitudes faster than vSLDA and about 1 order of magnitude faster than vMedLDA. For testing time, gSLDA and gSLDA+ are comparable with gMedLDA and the unsupervised gLDA, but faster than the variational vMedLDA and vSLDA, especially when  $K$  is large.

## 4.2 Multi-class classification

We perform multi-class classification on the 20NG data set with all the 20 categories. For multi-class classification, one possible extension is to use a multinomial logistic regression model for categorical variables  $Y$  by using topic representations  $\bar{z}$  as input features. However, it is non-

<sup>4</sup>The variational sLDA with a well-tuned  $c$  is significantly better than the standard sLDA, but a bit inferior to gSLDA+.

trivial to develop a Gibbs sampling algorithm using the similar data augmentation idea, due to the presence of latent variables and the nonlinearity of the soft-max function. In fact, this is harder than the multinomial Bayesian logistic regression, which can be done via a coordinate strategy (Polson et al., 2012). Here, we apply the binary gSLDA to do the multi-class classification, following the “one-vs-all” strategy, which has been shown effective (Rifkin and Klautau, 2004), to provide some preliminary analysis. Namely, we learn 20 binary gSLDA models and aggregate their predictions by taking the most likely ones as the final predictions. We again evaluate two versions of gSLDA – the standard gSLDA with  $c = 1$  and the improved gSLDA+ with a well-tuned  $c$  value. Since gSLDA is also insensitive to  $\alpha$  and  $c$  for the multi-class task, we set  $\alpha = 5.6$  for both gSLDA and gSLDA+, and set  $c = 256$  for gSLDA+. The number of burn-in is set as  $M = 40$ , which is sufficiently large to get stable results, as we shall see.

Fig. 2 shows the accuracy and training time. We can see that: 1) by using Gibbs sampling without restricting assumptions, gSLDA performs better than the variational vSLDA that uses strict mean-field approximation; 2) due to the imbalance between the single supervision and a large set of word counts, gSLDA doesn’t outperform the decoupled approach, gLDA+SVM; and 3) if we increase the value of the regularization constant  $c$ , supervision information can be better captured to infer predictive topic representations, and gSLDA+ performs much better than gSLDA. In fact, gSLDA+ is even better than the MedLDA that uses mean-field approximation, while is comparable with the MedLDA using collapsed Gibbs sampling. Finally, we should note that the improvement on the accuracy might be due to the different strategies on building the multi-class classifiers. But given the performance gain in the binary task, we believe that the Gibbs sampling algorithm-

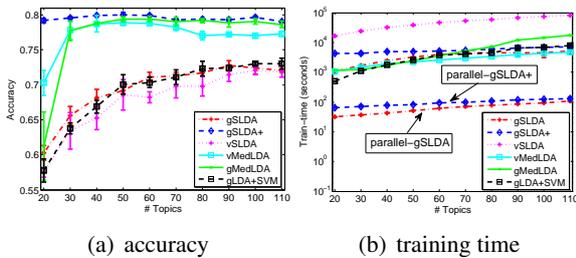

Figure 2: Multi-class classification.

Table 1: Split of training time over various steps.

	SAMPLE $\lambda$	SAMPLE $\eta$	SAMPLE $Z$
K=20	2841.67 (65.80%)	7.70 (0.18%)	1455.25 (34.02%)
K=30	2417.95 (56.10%)	10.34 (0.24%)	1888.78 (43.66%)
K=40	2393.77 (49.00%)	14.66 (0.30%)	2476.82 (50.70%)
K=50	2161.09 (43.67%)	16.33 (0.33%)	2771.26 (56.00%)

m without factorization assumptions is the main factor for the improved performance.

For training time, gSLDA models are about 10 times faster than variational vSLDA. Table 1 shows in detail the percentages of the training time (see the numbers in brackets) spent at each sampling step for gSLDA+. We can see that: 1) sampling the global variables  $\eta$  is very efficient, while sampling local variables ( $\lambda$ ,  $Z$ ) are much more expensive; and 2) sampling  $\lambda$  is relatively stable as  $K$  increases, while sampling  $Z$  takes more time as  $K$  becomes larger. But, the good news is that our Gibbs sampling algorithm can be easily parallelized to speedup the sampling of local variables, following the similar architectures as in LDA.

**A Parallel Implementation:** GraphLab is a graph-based programming framework for parallel computing (Gonzalez et al., 2012). It provides a high-level abstraction of parallel tasks by expressing data dependencies with a distributed graph. GraphLab implements a GAS (gather, apply, scatter) model, where the data required to compute a vertex (edge) are gathered along its neighboring components, and modification of a vertex (edge) will trigger its adjacent components to recompute their values. Since GAS has been successfully applied to several machine learning algorithms<sup>5</sup> including Gibbs sampling of LDA, we choose it as a preliminary attempt to parallelize our Gibbs sampling algorithm. A systematical investigation of the parallel computation with various architectures is interesting, but beyond the scope of this paper.

For our task, since there is no coupling among the 20 binary gSLDA classifiers, we can learn them in parallel. This suggests an efficient hybrid multi-core/multi-machine implementation, which

<sup>5</sup><http://docs.graphlab.org/toolkits.html>

can avoid the time consumption of IPC (i.e., inter-process communication). Namely, we run our experiments on a cluster with 20 nodes where each node is equipped with two 6-core CPUs (2.93GHz). Each node is responsible for learning one binary gSLDA classifier with a parallel implementation on its 12-cores. For each binary gSLDA model, we construct a bipartite graph connecting train documents with corresponding terms. The graph works as follows: 1) the edges contain the token counts and topic assignments; 2) the vertices contain individual topic counts and the augmented variables  $\lambda$ ; 3) the global topic counts and  $\eta$  are aggregated from the vertices periodically, and the topic assignments and  $\lambda$  are sampled asynchronously during the GAS phases. Once started, sampling and signaling will propagate over the graph. One thing to note is that since we cannot directly measure the number of iterations of an asynchronous model, here we estimate it with the total number of topic samplings, which is again aggregated periodically, divided by the number of tokens. We denote the parallel models by parallel-gSLDA ( $c = 1$ ) and parallel-gSLDA+ ( $c = 256$ ). From Fig. 2 (b), we can see that the parallel gSLDA models are about 2 orders of magnitudes faster than their sequential counterpart models, which is very promising. Also, the prediction performance is not sacrificed as we shall see in Fig. 4.

### 4.3 Sensitivity analysis

**Burn-In:** Fig. 3 shows the performance of gSLDA+ with different burn-in steps for binary classification. When  $M = 0$  (see the most left points), the models are built on random topic assignments. We can see that the classification performance increases fast and converges to the stable optimum with about 20 burn-in steps. The training time increases about linearly in general when using more burn-in steps. Moreover, the training time increases linearly as  $K$  increases. In the previous experiments, we set  $M = 100$ .

Fig. 4 shows the performance of gSLDA+ and its parallel implementation (i.e., parallel-gSLDA+) for the multi-class classification with different burn-in steps. We can see when the number of burn-in steps is larger than 20, the performance of gSLDA+ is quite stable. Again, in the log-log scale, since the slopes of the lines in Fig. 4 (b) are close to the constant 1, the training time grows about linearly as the number of

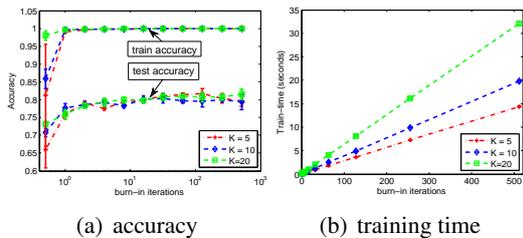

Figure 3: Performance of gSLDA+ with different burn-in steps for binary classification. The most left points are for the settings with no burn in.

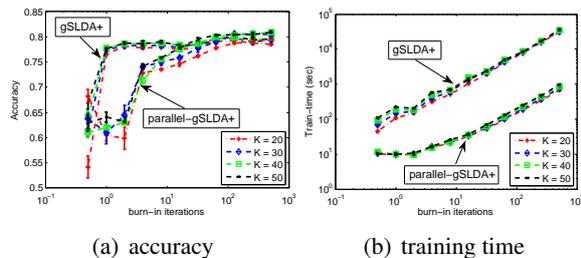

Figure 4: Performance of gSLDA+ and parallel-gSLDA+ with different burn-in steps for multi-class classification. The most left points are for the settings with no burn in.

burn-in steps increases. Even when we use 40 or 60 burn-in steps, the training time is still competitive, compared with the variational vSLDA. For parallel-gSLDA+ using GraphLab, the training is consistently about 2 orders of magnitudes faster. Meanwhile, the classification performance is also comparable with that of gSLDA+, when the number of burn-in steps is larger than 40. In the previous experiments, we have set  $M = 40$  for both gSLDA+ and parallel-gSLDA+.

**Regularization constant  $c$ :** Fig. 5 shows the performance of gSLDA in the binary classification task with different  $c$  values. We can see that in a wide range, e.g., from 9 to 100, the performance is quite stable for all the three  $K$  values. But for the standard sLDA model, i.e.,  $c = 1$ , both the training accuracy and test accuracy are low, which indicates that sLDA doesn't fit the supervision data well. When  $c$  becomes larger, the training accuracy gets higher, but it doesn't seem to over-fit and the generalization performance is stable. In the above experiments, we set  $c = 25$ . For multi-class classification, we have similar observations and set  $c = 256$  in the previous experiments.

**Dirichlet prior  $\alpha$ :** Fig. 6 shows the performance of gSLDA on the binary task with different  $\alpha$  values. We report two cases with  $c = 1$  and  $c = 9$ . We can see that the performance is quite stable in a wide range of  $\alpha$  values, e.g., from 0.1

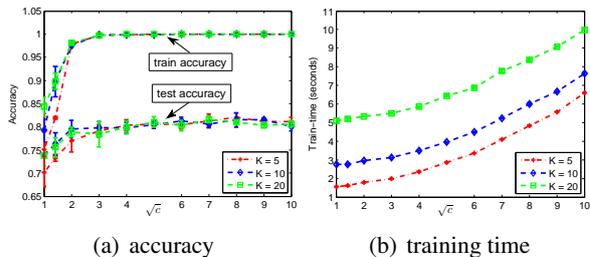

Figure 5: Performance of gSLDA for binary classification with different  $c$  values.

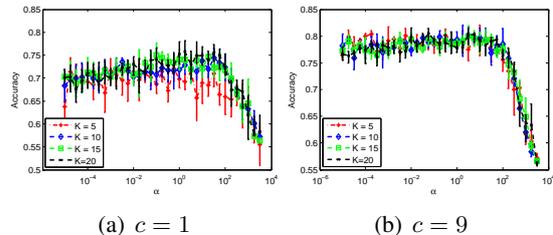

Figure 6: Accuracy of gSLDA for binary classification with different  $\alpha$  values in two settings with  $c = 1$  and  $c = 9$ .

to 10. We also noted that the change of  $\alpha$  does not affect the training time much.

## 5 Conclusions and Discussions

We present two improvements to Bayesian logistic supervised topic models, namely, a general formulation by introducing a regularization parameter to avoid model imbalance and a highly efficient Gibbs sampling algorithm without restricting assumptions on the posterior distributions by exploring the idea of data augmentation. The algorithm can also be parallelized. Empirical results for both binary and multi-class classification demonstrate significant improvements over the existing logistic supervised topic models. Our preliminary results with GraphLab have shown promise on parallelizing the Gibbs sampling algorithm.

For future work, we plan to carry out more careful investigations, e.g., using various distributed architectures (Ahmed et al., 2012; Newman et al., 2009; Smola and Narayanamurthy, 2010), to make the sampling algorithm highly scalable to deal with massive data corpora. Moreover, the data augmentation technique can be applied to deal with other types of response variables, such as count data with a negative-binomial likelihood (Polson et al., 2012).

## Abstract

We present a dual decomposition framework for multi-document summarization, using a model that jointly extracts and compresses sentences. Compared with previous work based on integer linear programming, our approach does not require external solvers, is significantly faster, and is modular in the three qualities a summary should have: conciseness, informativeness, and grammaticality. In addition, we propose a multi-task learning framework to take advantage of existing data for extractive summarization and sentence compression. Experiments in the TAC-2008 dataset yield the highest published ROUGE scores to date, with runtimes that rival those of extractive summarizers.

## 1 Introduction

Automatic text summarization is a seminal problem in information retrieval and natural language processing (Luhn, 1958; Baxendale, 1958; Edmundson, 1969). Today, with the overwhelming amount of information available on the Web, the demand for fast, robust, and scalable summarization systems is stronger than ever.

Up to now, **extractive systems** have been the most popular in multi-document summarization. These systems produce a summary by extracting a representative set of sentences from the original documents (Kupiec et al., 1995; Carbonell and Goldstein, 1998; Radev et al., 2000; Gillick et al., 2008). This approach has obvious advantages: it reduces the search space by letting decisions be made for each sentence as a whole (avoiding fine-grained text generation), and it ensures a grammatical summary, assuming the original sentences are well-formed. The typical trade-offs in these mod-

els (maximizing relevance, and penalizing redundancy) lead to submodular optimization problems (Lin and Bilmes, 2010), which are NP-hard but approximable through greedy algorithms; learning is possible with standard structured prediction algorithms (Sipos et al., 2012; Lin and Bilmes, 2012). Probabilistic models have also been proposed to capture the problem structure, such as determinantal point processes (Gillenwater et al., 2012).

However, extractive systems are rather limited in the summaries they can produce. Long, partly relevant sentences tend not to appear in the summary, or to block the inclusion of other sentences. This has motivated research in **compressive summarization** (Lin, 2003; Zajic et al., 2006; Daumé, 2006), where summaries are formed by compressed sentences (Knight and Marcu, 2000), not necessarily extracts. While promising results have been achieved by models that simultaneously extract and compress (Martins and Smith, 2009; Woodsend and Lapata, 2010; Berg-Kirkpatrick et al., 2011), there are still obstacles that need to be surmounted for these systems to enjoy wide adoption. All approaches above are based on **integer linear programming** (ILP), suffering from slow runtimes, when compared to extractive systems. For example, Woodsend and Lapata (2012) report 55 seconds on average to produce a summary; Berg-Kirkpatrick et al. (2011) report substantially faster runtimes, but fewer compressions are allowed. Having a compressive summarizer which is both fast and expressive remains an open problem. A second inconvenience of ILP-based approaches is that they do not exploit the modularity of the problem, since the declarative specification required by ILP solvers discards important structural information. For example, such solvers are unable to take advantage of efficient dynamic programming routines for sentence compression (McDonald, 2006).

This paper makes progress in two fronts:

- We derive a **dual decomposition** framework for extractive and compressive summarization (§2–3). Not only is this framework orders of magnitude more efficient than the ILP-based approaches, it also allows the three well-known metrics of summaries—conciseness, informativeness, and grammaticality—to be treated separately in a modular fashion (see Figure 1). We also contribute with a novel **knapsack factor**, along with a linear-time algorithm for the corresponding dual decomposition subproblem.
- We propose **multi-task learning** (§4) as a principled way to train compressive summarizers, using auxiliary data for extractive summarization and sentence compression. To this end, we adapt the framework of Evgeniou and Pontil (2004) and Daumé (2007) to train structured predictors that share some of their parts.

Experiments on TAC data (§5) yield state-of-the-art results, with runtimes similar to that of extractive systems. To our best knowledge, this had never been achieved by compressive summarizers.

## 2 Extractive Summarization

In **extractive summarization**, we are given a set of sentences  $\mathcal{D} := \{s_1, \dots, s_N\}$  belonging to one or more documents, and the goal is to extract a subset  $\mathcal{S} \subseteq \mathcal{D}$  that conveys a good summary of  $\mathcal{D}$  and whose total number of words does not exceed a prespecified budget  $B$ .

We use an indicator vector  $\mathbf{y} := \langle y_n \rangle_{n=1}^N$  to represent an extractive summary, where  $y_n = 1$  if  $s_n \in \mathcal{S}$ , and  $y_n = 0$  otherwise. Let  $L_n$  be the number of words of the  $n$ th sentence. By designing a quality score function  $g : \{0, 1\}^N \rightarrow \mathbb{R}$ , this can be cast as a global optimization problem with a knapsack constraint:

$$\begin{aligned} & \text{maximize} && g(\mathbf{y}) \\ & \text{w.r.t.} && \mathbf{y} \in \{0, 1\}^N \\ & \text{s.t.} && \sum_{n=1}^N L_n y_n \leq B. \end{aligned} \quad (1)$$

Intuitively, a good summary is one which selects sentences that individually convey “relevant” information, while collectively having small “redundancy.” This trade-off was explicitly modeled in early works through the notion of **maximal marginal relevance** (Carbonell and Goldstein, 1998; McDonald, 2007). An alternative

are **coverage-based models** (§2.1; Filatova and Hatzivassiloglou, 2004; Yih et al., 2007; Gillick et al., 2008), which seek a set of sentences that covers as many diverse “concepts” as possible; redundancy is automatically penalized since redundant sentences cover fewer concepts. Both models can be framed under the framework of submodular optimization (Lin and Bilmes, 2010), leading to greedy algorithms that have approximation guarantees. However, extending these models to allow for sentence compression (as will be detailed in §3) breaks the diminishing returns property, making submodular optimization no longer applicable.

### 2.1 Coverage-Based Summarization

Coverage-based extractive summarization can be formalized as follows. Let  $\mathcal{C}(\mathcal{D}) := \{c_1, \dots, c_M\}$  be a set of relevant **concept types** which are present in the original documents  $\mathcal{D}$ .<sup>1</sup> Let  $\sigma_m$  be a relevance score assigned to the  $m$ th concept, and let the set  $\mathcal{J}_m \subseteq \{1, \dots, N\}$  contain the indices of the sentences in which this concept occurs. Then, the following quality score function is defined:

$$g(\mathbf{y}) = \sum_{m=1}^M \sigma_m u_m(\mathbf{y}), \quad (2)$$

where  $u_m(\mathbf{y}) := \bigvee_{n \in \mathcal{J}_m} y_n$  is a Boolean function that indicates whether the  $m$ th concept is present in the summary. Plugging this into Eq. 1, one obtains the following Boolean optimization problem:

$$\begin{aligned} & \text{maximize} && \sum_{m=1}^M \sigma_m u_m \\ & \text{w.r.t.} && \mathbf{y} \in \{0, 1\}^N, \mathbf{u} \in \{0, 1\}^M \\ & \text{s.t.} && u_m = \bigvee_{n \in \mathcal{J}_m} y_n, \forall m \in [M] \\ & && \sum_{n=1}^N L_n y_n \leq B, \end{aligned} \quad (3)$$

where we used the notation  $[M] := \{1, \dots, M\}$ . This can be converted into an ILP and addressed with off-the-shelf solvers (Gillick et al., 2008). A drawback of this approach is that solving an ILP exactly is NP-hard. Even though existing commercial solvers can solve most instances with a moderate speed, they still exhibit poor worst-case behaviour; this is exacerbated when there is the need to combine an extractive component with other modules, as in compressive summarization (§3).

<sup>1</sup>Previous work has modeled concepts as events (Filatova and Hatzivassiloglou, 2004), salient words (Lin and Bilmes, 2010), and word bigrams (Gillick et al., 2008). In the sequel, we assume concepts are word  $k$ -grams, but our model can handle other representations, such as phrases or predicate-argument structures.

## 2.2 A Dual Decomposition Formulation

We next describe how the problem in Eq. 3 can be addressed with **dual decomposition**, a class of optimization techniques that tackle the dual of combinatorial problems in a modular, extensible, and parallelizable manner (Komodakis et al., 2007; Rush et al., 2010). In particular, we employ **alternating directions dual decomposition** (AD<sup>3</sup>; Martins et al., 2011a, 2012) for solving a linear relaxation of Eq. 3. AD<sup>3</sup> resembles the subgradient-based algorithm of Rush et al. (2010), but it enjoys a faster convergence rate. Both algorithms split the original problem into several **components**, and then iterate between solving independent **local subproblems** at each component and adjusting multipliers to promote an agreement.<sup>2</sup> The difference between the two methods is that the AD<sup>3</sup> local subproblems, instead of requiring the computation of a locally optimal configuration, require solving a local *quadratic* problem. Martins et al. (2011b) provided linear-time solutions for several logic constraints, with applications to syntax and frame-semantic parsing (Das et al., 2012). We will see that AD<sup>3</sup> can also handle budget and knapsack constraints efficiently.

To tackle Eq. 3 with dual decomposition, we split the coverage-based summarizer into the following  $M + 1$  components (one per constraint):

1. For each of the  $M$  concepts in  $\mathcal{C}(\mathcal{D})$ , one component for imposing the logic constraint in Eq. 3. This corresponds to the OR-WITH-OUTPUT factor described by Martins et al. (2011b); the AD<sup>3</sup> subproblem for the  $m$ th factor can be solved in time  $O(|J_m|)$ .
2. Another component for the knapsack constraint. This corresponds to a (novel) KNAPSACK factor, whose AD<sup>3</sup> subproblem is solvable in time  $O(N)$ . The actual algorithm is described in the appendix (Algorithm 1).<sup>3</sup>

## 3 Compressive Summarization

We now turn to **compressive summarization**, which does not limit the summary sentences to be verbatim extracts from the original documents; in-

<sup>2</sup>For details about dual decomposition and Lagrangian relaxation, see the recent tutorial by Rush and Collins (2012).

<sup>3</sup>The AD<sup>3</sup> subproblem in this case corresponds to computing an Euclidean projection onto the knapsack polytope (Eq. 11). Others addressed the related, but much harder, integer quadratic knapsack problem (McDonald, 2007).

stead, it allows the extraction of *compressed* sentences where some words can be deleted.

Formally, let us express each sentence of  $\mathcal{D}$  as a sequence of word tokens,  $s_n := \langle t_{n,\ell} \rangle_{\ell=0}^{L_n}$ , where  $t_{n,0} \equiv \$$  is a dummy symbol. We represent a **compression** of  $s_n$  as an indicator vector  $z_n := \langle z_{n,\ell} \rangle_{\ell=0}^{L_n}$ , where  $z_{n,\ell} = 1$  if the  $\ell$ th word is included in the compression. By convention, the dummy symbol is included if and only if the remaining compression is non-empty. A compressive summary can then be represented by an indicator vector  $z$  which is the concatenation of  $N$  such vectors,  $z = \langle z_1, \dots, z_N \rangle$ ; each position in this indicator vector is indexed by a sentence  $n \in [N]$  and a word position  $\ell \in \{0\} \cup [L_n]$ .

Models for compressive summarization were proposed by Martins and Smith (2009) and Berg-Kirkpatrick et al. (2011) by combining extraction and compression scores. Here, we follow the latter work, by combining a coverage score function  $g$  with sentence-level compression score functions  $h_1, \dots, h_N$ . This yields the decoding problem:

$$\begin{aligned} & \text{maximize} && g(z) + \sum_{n=1}^N h_n(z_n) \\ & \text{w.r.t.} && z_n \in \{0, 1\}^{L_n}, \forall n \in [N] \\ & \text{s.t.} && \sum_{n=1}^N \sum_{\ell=1}^{L_n} z_{n,\ell} \leq B. \end{aligned} \quad (4)$$

### 3.1 Coverage Model

We use a coverage function similar to Eq. 2, but taking a compressive summary  $z$  as argument:

$$g(z) = \sum_{m=1}^M \sigma_m u_m(z), \quad (5)$$

where we redefine  $u_m$  as follows. First, we parametrize each occurrence of the  $m$ th concept (assumed to be a  $k$ -gram) as a triple  $\langle n, \ell_s, \ell_e \rangle$ , where  $n$  indexes a sentence,  $\ell_s$  indexes a start position within the sentence, and  $\ell_e$  indexes the end position. We denote by  $\mathcal{T}_m$  the set of triples representing all occurrences of the  $m$ th concept in the original text, and we associate an indicator variable  $z_{n,\ell_s:\ell_e}$  to each member of this set. We then define  $u_m(z)$  via the following logic constraints:

- A **concept type** is selected if *some* of its  $k$ -gram tokens are selected:

$$u_m(\mathbf{y}) := \bigvee_{\langle n, \ell_s, \ell_e \rangle \in \mathcal{T}_m} z_{n, \ell_s: \ell_e}. \quad (6)$$

- A  $k$ -gram **concept token** is selected if *all* its words are selected:

$$z_{n, \ell_s: \ell_e} := \bigwedge_{\ell=\ell_s}^{\ell_e} z_{n, \ell}. \quad (7)$$

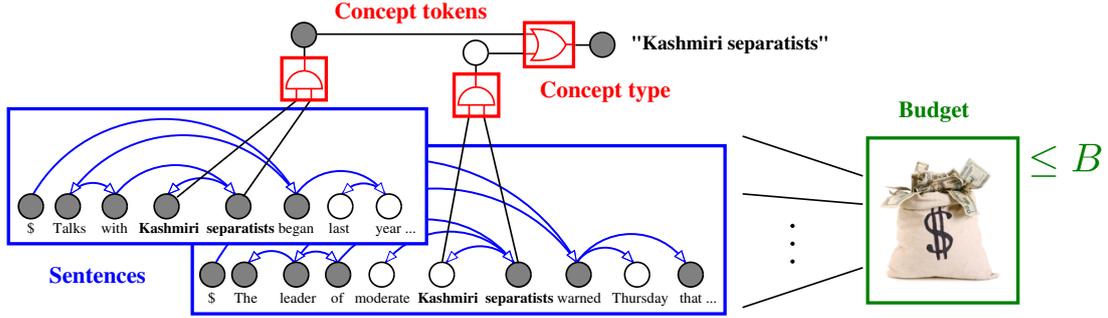

Figure 1: Components of our compressive summarizer. Factors depicted in blue belong to the compression model, and aim to enforce grammaticality. The logic factors in red form the coverage component. Finally, the budget factor, in green, is connected to the word nodes; it ensures that the summary fits the word limit. Shaded circles represent active variables while white circles represent inactive variables.

We set concept scores as  $\sigma_m := \mathbf{w} \cdot \Phi_{\text{cov}}(\mathcal{D}, c_m)$ , where  $\Phi_{\text{cov}}(\mathcal{D}, c_m)$  is a vector of features (described in §3.5) and  $\mathbf{w}$  the corresponding weights.

### 3.2 Compression Model

For the compression score function, we follow Martins and Smith (2009) and decompose it as a sum of local score functions  $\rho_{n,\ell}$  defined on dependency arcs:

$$h_n(\mathbf{z}_n) := \sum_{\ell=1}^{L_n} \rho_{n,\ell}(z_{n,\ell}, z_{n,\pi(\ell)}), \quad (8)$$

where  $\pi(\ell)$  denotes the index of the word which is the parent of the  $\ell$ th word in the dependency tree (by convention, the root of the tree is the dummy symbol). To model the event that an arc is “cut” by disconnecting a child from its head, we define **arc-deletion scores**  $\rho_{n,\ell}(0, 1) := \mathbf{w} \cdot \Phi_{\text{comp}}(s_n, \ell, \pi(\ell))$ , where  $\Phi_{\text{comp}}$  is a feature map, which is described in detail in §3.5. We set  $\rho_{n,\ell}(0, 0) = \rho_{n,\ell}(1, 1) = 0$ , and  $\rho_{n,\ell}(1, 0) = -\infty$ , to allow only the deletion of entire subtrees.

A crucial fact is that one can maximize Eq. 8 efficiently with dynamic programming (using the Viterbi algorithm for trees); the total cost is linear in  $L_n$ . We will exploit this fact in the dual decomposition framework described next.<sup>4</sup>

### 3.3 A Dual Decomposition Formulation

In previous work, the optimization problem in Eq. 4 was converted into an ILP and fed to an off-the-shelf solver (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012). Here, we employ the AD<sup>3</sup> algorithm, in a

<sup>4</sup>The same framework can be readily adapted to other compression models that are efficiently decodable, such as the semi-Markov model of McDonald (2006), which would allow incorporating a language model for the compression.

similar manner as described in §2, but with an additional component for the sentence compressor, and slight modifications in the other components. We have the following  $N + M + \sum_{m=1}^M |\mathcal{T}_m| + 1$  components in total, illustrated in Figure 1:

1. For each of the  $N$  sentences, one component for the **compression model**. The AD<sup>3</sup> quadratic subproblem for this factor can be addressed by solving a *sequence of linear subproblems*, as described by Martins et al. (2012). Each of these subproblems corresponds to maximizing an objective function of the same form as Eq. 8; this can be done in  $O(L_n)$  time with dynamic programming, as discussed in §3.2.
2. For each of the  $M$  concept types in  $\mathcal{C}(\mathcal{D})$ , one OR-WITH-OUTPUT factor for the logic constraint in Eq. 6. This is analogous to the one described for the extractive case.
3. For each  $k$ -gram concept token in  $\mathcal{T}_m$ , one AND-WITH-OUTPUT factor that imposes the constraint in Eq. 7. This factor was described by Martins et al. (2011b) and its AD<sup>3</sup> subproblem can be solved in time linear in  $k$ .
4. Another component linked to all the words imposing that at most  $B$  words can be selected; this is done via a BUDGET factor, a particular case of KNAPSACK. The runtime of this AD<sup>3</sup> subproblem is linear in the number of words.

In addition, we found it useful to add a second BUDGET factor limiting the number of sentences that can be selected to a prescribed value  $K$ . We set  $K = 6$  in our experiments.

### 3.4 Rounding Strategy

Recall that the problem in Eq. 4 is NP-hard, and that AD<sup>3</sup> is solving a linear relaxation. While there are ways of wrapping AD<sup>3</sup> in an exact search algorithm (Das et al., 2012), such strategies work best when the solution of the relaxation has few fractional components, which is typical of parsing and translation problems (Rush et al., 2010; Chang and Collins, 2011), and attractive networks (Taskar et al., 2004). Unfortunately, this is not the case in summarization, where concepts “compete” with each other for inclusion in the summary, leading to frustrated cycles. We chose instead to adopt a fast and simple rounding procedure for obtaining a summary from a fractional solution.

The procedure works as follows. First, solve the LP relaxation using AD<sup>3</sup>, as described above. This yields a solution  $z^*$ , where each component lies in the unit interval  $[0, 1]$ . If these components are all integer, then we have a certificate that this is the optimal solution. Otherwise, we collect the  $K$  sentences with the highest values of  $z_{n,0}^*$  (“posteriors” on sentences), and seek the feasible summary which is the closest (in Euclidean distance) to  $z^*$ , while only containing those sentences. This can be computed exactly in time  $O(B \sum_{k=1}^K L_{n_k})$ , through dynamic programming.<sup>5</sup>

### 3.5 Features and Hard Constraints

As Berg-Kirkpatrick et al. (2011), we used stemmed word bigrams as concepts, to which we associate the following concept features ( $\Phi_{\text{cov}}$ ): indicators for document counts, features indicating if each of the words in the bigram is a stop-word, the earliest position in a document each concept occurs, as well as two and three-way conjunctions of these features.

For the compression model, we include the following arc-deletion features ( $\Phi_{\text{comp}}$ ):

- the dependency label of the arc being deleted, as well as its conjunction with the part-of-speech tag of the head, of the modifier, and of both;
- the dependency labels of the arc being deleted and of its parent arc;
- the modifier tag, if the modifier is a function word modifying a verb ;

<sup>5</sup>Briefly, if we link the roots of the  $K$  sentences to a super-root node, the problem above can be transformed into that of finding the best configuration in the resulting binary tree subject to a budget constraint. We omit details for space.

- a feature indicating whether the modifier or any of its descendants is a negation word;
- indicators of whether the modifier is a temporal word (e.g., *Friday*) or a preposition pointing to a temporal word (e.g., *on Friday*).

In addition, we included hard constraints to prevent the deletion of certain arcs, following previous work in sentence compression (Clarke and Lapata, 2008). We never delete arcs whose dependency label is SUB, OBJ, PMOD, SBAR, VC, or PRD (this makes sure we preserve subjects and objects of verbs, arcs departing from prepositions or complementizers, and that we do not break verb chains or predicative complements); arcs linking to a conjunction word or siblings of such arcs (to prevent inconsistencies in handling coordinative conjunctions); arcs linking verbs to other verbs, to adjectives (e.g., *make available*), to verb particles (e.g., *settle down*), to the word *that* (e.g., *said that*), or to the word *to* if it is a leaf (e.g., *allowed to come*); arcs pointing to negation words, cardinal numbers, or determiners; and arcs connecting two proper nouns or words within quotation marks.

## 4 Multi-Task Learning

We next turn to the problem of learning the model from training data. Prior work in compressive summarization has followed one of two strategies: Martins and Smith (2009) and Woodsend and Lapata (2012) learn the extraction and compression models separately, and then post-combine them, circumventing the lack of fully annotated data. Berg-Kirkpatrick et al. (2011) gathered a small dataset of manually compressed summaries, and trained with full supervision. While the latter approach is statistically more principled, it has the disadvantage of requiring fully annotated data, which is difficult to obtain in large quantities. On the other hand, there is plenty of data containing manually written abstracts (from the DUC and TAC conferences) and user-generated text (from Wikipedia) that may provide useful weak supervision.

With this in mind, we put together a **multi-task learning** framework for compressive summarization (which we name task #1). The goal is to take advantage of existing data for related tasks, such as extractive summarization (task #2), and sentence compression (task #3). The three tasks are instances of **structured predictors** (Bakır et

Tasks	Features	Decoder
Comp. summ. (#1)	$\Phi_{\text{cov}}, \Phi_{\text{comp}}$	AD <sup>3</sup> (solve Eq. 4)
Extr. summ. (#2)	$\Phi_{\text{cov}}$	AD <sup>3</sup> (solve Eq. 3)
Sent. comp. (#3)	$\Phi_{\text{comp}}$	dyn. prg. (max. Eq. 8)

Table 1: Features and decoders used for each task.

al., 2007), and for all of them we assume feature-based models that decompose over “parts”:

- For the compressive summarization task, the parts correspond to **concept features** (§3.1) and to **arc-deletion features** (§3.2).
- For the extractive summarization task, there are parts for **concept features** only.
- For the sentence compression task, the parts correspond to **arc-deletion features** only.

This is summarized in Table 1. Features for the three tasks are populated into feature vectors  $\Phi_1(x, y)$ ,  $\Phi_2(x, y)$ , and  $\Phi_3(x, y)$ , respectively, where  $\langle x, y \rangle$  denotes a task-specific input-output pair. We assume the feature vectors are all  $D$  dimensional, where we place zeros in entries corresponding to parts that are absent. Note that this setting is very general and applies to arbitrary structured prediction problems (not just summarization), the only assumption being that some parts are shared between different tasks.

Next, we associate weight vectors  $\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3 \in \mathbb{R}^D$  to each task, along with a “shared” vector  $\mathbf{w}$ . Each task makes predictions according to the rule:

$$\hat{y} := \arg \max_y (\mathbf{w} + \mathbf{v}_k) \cdot \Phi_k(x, y), \quad (9)$$

where  $k \in \{1, 2, 3\}$ . This setting is equivalent to the approach of Daumé (2007) for domain adaptation, which consists in splitting each feature into task-component features and a shared feature; but here we do not duplicate features explicitly. To learn the weights, we regularize the weight vectors separately, and assume that each task has its own loss function  $\mathcal{L}_k$ , so that the total loss  $\mathcal{L}$  is a weighted sum  $\mathcal{L}(\mathbf{w}, \mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3) := \sum_{k=1}^3 \sigma_k \mathcal{L}_k(\mathbf{w} + \mathbf{v}_k)$ . This yields the following objective function to be minimized:

$$F(\mathbf{w}, \mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3) = \frac{\lambda}{2} \|\mathbf{w}\|^2 + \sum_{k=1}^3 \frac{\lambda_k}{2} \|\mathbf{v}_k\|^2 + \frac{1}{N} \sum_{k=1}^3 \sigma_k \mathcal{L}_k(\mathbf{w} + \mathbf{v}_k), \quad (10)$$

where  $\lambda$  and the  $\lambda_k$ ’s are regularization constants, and  $N$  is the total number of training instances.<sup>6</sup> In our experiments (§5), we let the  $\mathcal{L}_k$ ’s be structured hinge losses (Taskar et al., 2003; Tsochantaridis et al., 2004), where the corresponding cost functions are concept recall (for task #2), precision of arc deletions (for task #3), and a combination thereof (for task #1).<sup>7</sup> These losses were normalized, and we set  $\sigma_k = N/N_k$ , where  $N_k$  is the number of training instances for the  $k$ th task. This ensures all tasks are weighted evenly. We used the same rationale to set  $\lambda = \lambda_1 = \lambda_2 = \lambda_3$ , choosing this value through cross-validation in the dev set.

We optimize Eq. 10 with stochastic subgradient descent. This leads to update rules of the form

$$\begin{aligned} \mathbf{w} &\leftarrow (1 - \eta_t \lambda) \mathbf{w} - \eta_t \sigma_k \tilde{\nabla} \mathcal{L}_k(\mathbf{w} + \mathbf{v}_k) \\ \mathbf{v}_j &\leftarrow (1 - \eta_t \lambda_j) \mathbf{v}_j - \eta_t \delta_{jk} \sigma_k \tilde{\nabla} \mathcal{L}_k(\mathbf{w} + \mathbf{v}_k), \end{aligned}$$

where  $\tilde{\nabla} \mathcal{L}_k$  are stochastic subgradients for the  $k$ th task, that take only a single instance into account, and  $\delta_{jk} = 1$  if and only if  $j = k$ . Stochastic subgradients can be computed via cost-augmented decoding (see footnote 7).

Interestingly, Eq. 10 subsumes previous approaches to train compressive summarizers. The limit  $\lambda \rightarrow \infty$  (keeping the  $\lambda_k$ ’s fixed) forces  $\mathbf{w} \rightarrow 0$ , decoupling all the tasks. In this limit, inference for task #1 (compressive summarization) is based solely on the model learned from that task’s data, recovering the approach of Berg-Kirkpatrick et al. (2011). In the other extreme, setting  $\sigma_1 = 0$  simply ignores task #1’s training data. As a result, the optimal  $\mathbf{v}_1$  will be a vector of zeros; since tasks #2 and #3 have no parts in common, the objective will decouple into a sum of two independent terms

<sup>6</sup>Note that, by substituting  $\mathbf{u}_k := \mathbf{w} + \mathbf{v}_k$  and solving for  $\mathbf{w}$ , the problem in Eq. 10 becomes that of minimizing the sum of the losses with a penalty for the (weighted) variance of the vectors  $\{\mathbf{0}, \mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3\}$ , regularizing the difference towards their average, as in Evgeniou and Pontil (2004). This is similar to the hierarchical joint learning approach of Finkel and Manning (2010), except that our goal is to learn a new task (compressive summarization) instead of combining tasks.

<sup>7</sup>Let  $\mathcal{Y}_k$  denote the output set for the  $k$ th task. Given a task-specific cost function  $\Delta_k : \mathcal{Y}_k \times \mathcal{Y}_k \rightarrow \mathbb{R}$ , and letting  $\langle x_t, y_t \rangle_{t=1}^T$  be the labeled dataset for this task, the structured hinge loss takes the form  $\mathcal{L}_k(\mathbf{u}_k) := \sum_t \max_{y' \in \mathcal{Y}_k} (\mathbf{u}_k \cdot (\Phi_k(x_t, y') - \Phi_k(x_t, y_t)) + \Delta_k(y', y_t))$ . The inner maximization over  $y'$  is called the *cost-augmented decoding problem*: it differs from Eq. 9 by the inclusion of the cost term  $\Delta_k(y', y_t)$ . Our costs decompose over the model’s factors, hence any decoder for Eq. 9 can be used for the maximization above: for tasks #1–#2, we solve a relaxation by running AD<sup>3</sup> without rounding, and for task #3 we use dynamic programming; see Table 1.

involving  $v_2$  and  $v_3$ , which is equivalent to training the two tasks separately and post-combining the models, as Martins and Smith (2009) did.

## 5 Experiments

### 5.1 Experimental setup

We evaluated our compressive summarizers on data from the Text Analysis Conference (TAC) evaluations. We use the same splits as previous work (Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012): the non-update portions of TAC-2009 for training and TAC-2008 for testing. In addition, we reserved TAC-2010 as a devset. The test partition contains 48 multi-document summarization problems; each provides 10 related news articles as input, and asks for a summary with up to 100 words, which is evaluated against four manually written abstracts. We ignored all the query information present in the TAC datasets.

**Single-Task Learning.** In the single-task experiments, we trained a compressive summarizer on the dataset disclosed by Berg-Kirkpatrick et al. (2011), which contains manual compressive summaries for the TAC-2009 data. We trained a structured SVM with stochastic subgradient descent; the cost-augmented inference problems are relaxed and solved with AD<sup>3</sup>, as described in §3.3.<sup>8</sup> We followed the procedure described in Berg-Kirkpatrick et al. (2011) to reduce the number of candidate sentences: scores were defined for each sentence (the sum of the scores of the concepts they cover), and the best-scored sentences were greedily selected up to a limit of 1,000 words. We then tagged and parsed the selected sentences with TurboParser.<sup>9</sup> Our choice of a dependency parser was motivated by our will for a fast system; in particular, TurboParser attains top accuracies at a rate of 1,200 words per second, keeping parsing times below 1 second for each summarization problem.

**Multi-Task Learning.** For the multi-task experiments, we also used the dataset of Berg-Kirkpatrick et al. (2011), but we augmented the training data with extractive summarization and sentence compression datasets, to help train the

compressive summarizer. For extractive summarization, we used the DUC 2003 and 2004 datasets (a total of 80 multi-document summarization problems). We generated oracle extracts by maximizing bigram recall with respect to the manual abstracts, as described in Berg-Kirkpatrick et al. (2011). For sentence compression, we adapted the Simple English Wikipedia dataset of Woodsend and Lapata (2011), containing aligned sentences for 15,000 articles from the English and Simple English Wikipedias. We kept only the 4,481 sentence pairs corresponding to deletion-based compressions.

### 5.2 Results

Table 2 shows the results. The top rows refer to three strong baselines: the ICSI-1 extractive coverage-based system of Gillick et al. (2008), which achieved the best ROUGE scores in the TAC-2008 evaluation; the compressive summarizer of Berg-Kirkpatrick et al. (2011), denoted BGK'11; and the multi-aspect compressive summarizer of Woodsend and Lapata (2012), denoted WL'12. All these systems require ILP solvers. The bottom rows show the results achieved by our implementation of a pure *extractive* system (similar to the learned extractive summarizer of Berg-Kirkpatrick et al., 2011); a system that *post-combines* extraction and compression components trained separately, as in Martins and Smith (2009); and our compressive summarizer trained as a *single task*, and in the *multi-task* setting.

The ROUGE and Pyramid scores show that the compressive summarizers (when properly trained) yield considerable benefits in content coverage over extractive systems, confirming the results of Berg-Kirkpatrick et al. (2011). Comparing the two bottom rows, we see a clear benefit by training in the multi-task setting, with a consistent gain in both coverage and linguistic quality. Our ROUGE-2 score (12.30%) is, to our knowledge, the highest reported on the TAC-2008 dataset, with little harm in grammaticality with respect to an extractive system that preserves the original sentences. Figure 2 shows an example summary.

### 5.3 Runtimes

We conducted another set of experiments to compare the runtime of our compressive summarizer based on AD<sup>3</sup> with the runtimes achieved by GLPK, the ILP solver used by Berg-Kirkpatrick et al. (2011). We varied the maximum number of it-

<sup>8</sup>We use the AD<sup>3</sup> implementation in <http://www.ark.cs.cmu.edu/AD3>, setting the maximum number of iterations to 200 at training time and 1000 at test time. We extended the code to handle the knapsack and budget factors; the modified code will be part of the next release (AD<sup>3</sup> 2.1).

<sup>9</sup><http://www.ark.cs.cmu.edu/TurboParser>

System	R-2	R-SU4	Pyr	LQ
ICSI-1	11.03	13.96	34.5 <sup>†</sup>	–
BGK’11	11.71	14.47	41.3 <sup>†</sup>	–
WL’12	11.37	14.47	–	–
Extractive	11.16	14.07	36.0	<b>4.6</b>
Post-comb.	11.07	13.85	38.4	4.1
Single-task	11.88	14.86	41.0	3.8
Multi-task	<b>12.30</b>	<b>15.18</b>	<b>42.6</b>	4.2

Table 2: Results for compressive summarization. Shown are the ROUGE-2 and ROUGE SU-4 recalls with the default options from the ROUGE toolkit (Lin, 2004); Pyramid scores (Nenkova and Passonneau, 2004); and linguistic quality scores, scored between 1 (very bad) to 5 (very good). For Pyramid, the evaluation was performed by two annotators, each evaluating half of the problems; scores marked with <sup>†</sup> were computed by different annotators and are not directly comparable. Linguistic quality was evaluated by two linguists; we show the average of the reported scores.

Solver	Runtime (sec.)	ROUGE-2
ILP Exact	10.394	12.40
LP-Relax.	2.265	12.38
AD <sup>3</sup> -5000	0.952	12.38
AD <sup>3</sup> -1000	0.406	12.30
AD <sup>3</sup> -200	0.159	12.15
Extractive (ILP)	0.265	11.16

Table 3: Runtimes of several decoders on a Intel Core i7 processor @2.8 GHz, with 8GB RAM. For each decoder, we show the average time taken to solve a summarization problem in TAC-2008. The reported runtimes of AD<sup>3</sup> and LP-Relax include the time taken to round the solution (§3.4), which is 0.029 seconds on average.

erations of AD<sup>3</sup> in {200, 1000, 5000}, and clocked the time spent by GLPK to solve the exact ILPs and their relaxations. Table 3 depicts the results.<sup>10</sup>

We see that our proposed configuration (AD<sup>3</sup>-1000) is orders of magnitude faster than the ILP solver, and 5 times faster than its relaxed variant, while keeping similar accuracy levels.<sup>11</sup> The gain when the number of iterations in AD<sup>3</sup> is increased to 5000 is small, given that the runtime is more

<sup>10</sup>Within dual decomposition algorithms, we verified experimentally that AD<sup>3</sup> is substantially faster than the subgradient algorithm, which is consistent with previous findings (Martins et al., 2011b).

<sup>11</sup>The runtimes obtained with the exact ILP solver seem slower than those reported by Berg-Kirkpatrick et al. (2011). (around 1.5 sec. on average, according to their Fig. 3). We conjecture that this difference is due to the restricted set of subtrees that can be deleted by Berg-Kirkpatrick et al. (2011), which greatly reduces their search space.

Japan dispatched four military ships to help Russia rescue seven crew members aboard a small submarine trapped on the seabed in the Far East. The Russian Pacific Fleet said the crew had 120 hours of oxygen reserves *on board when the submarine submerged at midday Thursday (2300 GMT Wednesday) off the Kamchatka peninsula, the stretch of Far Eastern Russia facing the Bering Sea.* The submarine, *used in rescue, research and intelligence-gathering missions,* became stuck at the bottom of the Bay of Berezovaya off Russia’s Far East coast when its propeller was caught *in a fishing net.* The Russian submarine had been tending an underwater antenna mounted to the sea floor *when it became snagged on a wire helping to stabilize a ventilation cable attached to the antenna.* Rescue crews lowered a British remote-controlled underwater vehicle to a Russian mini-submarine trapped *deep* under the Pacific Ocean, hoping to free the vessel and its seven trapped crewmen *before their air supply ran out.*

Figure 2: Example summary from our compressive system. Removed text is *grayed out*.

than doubled; accuracy starts to suffer, however, if the number of iterations is reduced too much. In practice, we observed that the final rounding procedure was crucial, as only 2 out of the 48 test problems had integral solutions (arguably because of the “repulsive” nature of the network, as hinted in §3.4). For comparison, we also report in the bottom row the average runtime of the learned extractive baseline. We can see that our system’s runtime is competitive with this baseline. To our knowledge, this is the first time a compressive summarizer achieves such a favorable accuracy/speed tradeoff.

## 6 Conclusions

We presented a multi-task learning framework for compressive summarization, leveraging data for related tasks in a principled manner. We decode with AD<sup>3</sup>, a fast and modular dual decomposition algorithm which is orders of magnitude faster than ILP-based approaches. Results show that the state of the art is improved in automatic and manual metrics, with speeds close to extractive systems.

Our approach is modular and easy to extend. For example, a different compression model could incorporate rewriting rules to enable compressions that go beyond word deletion, as in Cohn and Lapata (2008). Other aspects may be added as additional components in our dual decomposition framework, such as query information (Schilder and Kondadadi, 2008), discourse con-

straints (Clarke and Lapata, 2007), or lexical preferences (Woodsend and Lapata, 2012). Our multi-task approach may be used to jointly learn parameters for these aspects; the dual decomposition algorithm ensures that optimization remains tractable even with many components.

## A Projection Onto Knapsack

This section describes a linear-time algorithm (Algorithm 1) for solving the following problem:

$$\begin{aligned} & \text{minimize } \|\mathbf{z} - \mathbf{a}\|^2 \\ & \text{w.r.t. } z_n \in [0, 1], \forall n \in [N], \\ & \text{s.t. } \sum_{n=1}^N L_n z_n \leq B, \end{aligned} \quad (11)$$

where  $\mathbf{a} \in \mathbb{R}^N$  and  $L_n \geq 0, \forall n \in [N]$ . This includes as special cases the problems of projecting onto a budget constraint ( $L_n = 1, \forall n$ ) and onto the simplex (same, plus  $B = 1$ ).

Let  $\text{clip}(t) := \max\{0, \min\{1, t\}\}$ . Algorithm 1 starts by clipping  $\mathbf{a}$  to the unit interval; if that yields a  $\mathbf{z}$  satisfying  $\sum_{n=1}^N L_n z_n \leq B$ , we are done. Otherwise, the solution of Eq. 11 must satisfy  $\sum_{n=1}^N L_n z_n = B$ . It can be shown from the KKT conditions that the solution is of the form  $z_n^* := \text{clip}(a_n + \tau^* L_n)$  for a constant  $\tau^*$  lying in a particular interval of split-points (line 11). To seek this constant, we use an algorithm due to Pardalos and Koor (1990) which iteratively shrinks this interval. The algorithm requires computing medians as a subroutine, which can be done in linear time (Blum et al., 1973). The overall complexity is  $O(N)$  (Pardalos and Koor, 1990).

## Acknowledgments

We thank all reviewers for their insightful comments; Trevor Cohn for helpful discussions about multi-task learning; Taylor Berg-Kirkpatrick for answering questions about their summarizer and for providing code; and Helena Figueira and Pedro Mendes for helping with manual evaluation. This work was partially supported by the EU/FEDER programme, QREN/POR Lisboa (Portugal), under the Discooperio project (contract 2011/18501), and by a FCT grant PTDC/EEI-SII/2312/2012.

# Unsupervised Transcription of Historical Documents

Taylor Berg-Kirkpatrick Greg Durrett Dan Klein

Computer Science Division

University of California at Berkeley

{tberg, gdurrett, klein}@cs.berkeley.edu

## Abstract

We present a generative probabilistic model, inspired by historical printing processes, for transcribing images of documents from the printing press era. By jointly modeling the text of the document and the noisy (but regular) process of rendering glyphs, our unsupervised system is able to decipher font structure and more accurately transcribe images into text. Overall, our system substantially outperforms state-of-the-art solutions for this task, achieving a 31% relative reduction in word error rate over the leading commercial system for historical transcription, and a 47% relative reduction over Tesseract, Google’s open source OCR system.

## 1 Introduction

Standard techniques for transcribing modern documents do not work well on historical ones. For example, even state-of-the-art OCR systems produce word error rates of over 50% on the documents shown in Figure 1. Unsurprisingly, such error rates are too high for many research projects (Arlitsch and Herbert, 2004; Shoemaker, 2005; Holley, 2010). We present a new, generative model specialized to transcribing printing-press era documents. Our model is inspired by the underlying printing processes and is designed to capture the primary sources of variation and noise.

One key challenge is that the fonts used in historical documents are not standard (Shoemaker, 2005). For example, consider Figure 1a. The fonts are not irregular like handwriting – each occurrence of a given character type, e.g. *a*, will use the same underlying glyph. However, the exact glyphs are unknown. Some differences between fonts are minor, reflecting small variations in font design. Others are more severe, like the presence of the archaic long *s* character before 1804. To address the general problem of unknown fonts, our model

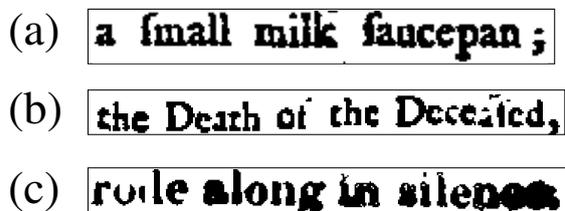

Figure 1: Portions of historical documents with (a) unknown font, (b) uneven baseline, and (c) over-inking.

learns the font in an unsupervised fashion. Font shape and character segmentation are tightly coupled, and so they are modeled jointly.

A second challenge with historical data is that the early typesetting process was noisy. Hand-carved blocks were somewhat uneven and often failed to sit evenly on the mechanical baseline. Figure 1b shows an example of the text’s baseline moving up and down, with varying gaps between characters. To deal with these phenomena, our model incorporates random variables that specifically describe variations in vertical offset and horizontal spacing.

A third challenge is that the actual inking was also noisy. For example, in Figure 1c some characters are thick from over-inking while others are obscured by ink bleeds. To be robust to such rendering irregularities, our model captures both inking levels and pixel-level noise. Because the model is generative, we can also treat areas that are obscured by larger ink blotches as unobserved, and let the model predict the obscured text based on visual and linguistic context.

Our system, which we call *Ocular*, operates by fitting the model to each document in an unsupervised fashion. The system outperforms state-of-the-art baselines, giving a 47% relative error reduction over Google’s open source Tesseract system, and giving a 31% relative error reduction over ABBYY’s commercial FineReader system, which has been used in large-scale historical transcription projects (Holley, 2010).

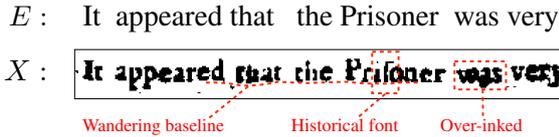

Figure 2: An example image from a historical document ( $X$ ) and its transcription ( $E$ ).

## 2 Related Work

Relatively little prior work has built models specifically for transcribing historical documents. Some of the challenges involved have been addressed (Ho and Nagy, 2000; Huang et al., 2006; Kae and Learned-Miller, 2009), but not in a way targeted to documents from the printing press era. For example, some approaches have learned fonts in an unsupervised fashion but require pre-segmentation of the image into character or word regions (Ho and Nagy, 2000; Huang et al., 2006), which is not feasible for noisy historical documents. Kae and Learned-Miller (2009) jointly learn the font and image segmentation but do not outperform modern baselines.

Work that has directly addressed historical documents has done so using a pipelined approach, and without fully integrating a strong language model (Vamvakas et al., 2008; Kluzner et al., 2009; Kae et al., 2010; Kluzner et al., 2011). The most comparable work is that of Kopec and Lomelin (1996) and Kopec et al. (2001). They integrated typesetting models with language models, but did not model noise. In the NLP community, generative models have been developed specifically for correcting outputs of OCR systems (Kolak et al., 2003), but these do not deal directly with images.

A closely related area of work is automatic decipherment (Ravi and Knight, 2008; Snyder et al., 2010; Ravi and Knight, 2011; Berg-Kirkpatrick and Klein, 2011). The fundamental problem is similar to our own: we are presented with a sequence of symbols, and we need to learn a correspondence between symbols and letters. Our approach is also similar in that we use a strong language model (in conjunction with the constraint that the correspondence be regular) to learn the correct mapping. However, the symbols are not noisy in decipherment problems and in our problem we face a grid of pixels for which the segmentation into symbols is unknown. In contrast, decipherment typically deals only with discrete symbols.

## 3 Model

Most historical documents have unknown fonts, noisy typesetting layouts, and inconsistent ink levels, usually simultaneously. For example, the portion of the document shown in Figure 2 has all three of these problems. Our model must handle them jointly.

We take a generative modeling approach inspired by the overall structure of the historical printing process. Our model generates images of documents line by line; we present the generative process for the image of a single line. Our primary random variables are  $E$  (the text) and  $X$  (the pixels in an image of the line). Additionally, we have a random variable  $T$  that specifies the layout of the bounding boxes of the glyphs in the image, and a random variable  $R$  that specifies aspects of the inking and rendering process. The joint distribution is:

$$\begin{aligned}
 P(E, T, R, X) = & \\
 & P(E) \quad \text{[Language model]} \\
 & \cdot P(T|E) \quad \text{[Typesetting model]} \\
 & \cdot P(R) \quad \text{[Inking model]} \\
 & \cdot P(X|E, T, R) \quad \text{[Noise model]}
 \end{aligned}$$

We let capital letters denote vectors of concatenated random variables, and we denote the individual random variables with lower-case letters. For example,  $E$  represents the entire sequence of text, while  $e_i$  represents  $i$ th character in the sequence.

### 3.1 Language Model $P(E)$

Our language model,  $P(E)$ , is a Kneser-Ney smoothed character  $n$ -gram model (Kneser and Ney, 1995). We generate printed lines of text (rather than sentences) independently, without generating an explicit stop character. This means that, formally, the model must separately generate the character length of each line. We choose not to bias the model towards longer or shorter character sequences and let the line length  $m$  be drawn uniformly at random from the positive integers less than some large constant  $M$ .<sup>1</sup> When  $i < 1$ , let  $e_i$  denote a line-initial null character. We can now write:

$$P(E) = P(m) \cdot \prod_{i=1}^m P(e_i | e_{i-1}, \dots, e_{i-n})$$

<sup>1</sup>In particular, we do not use the kind of “word bonus” common to statistical machine translation models.

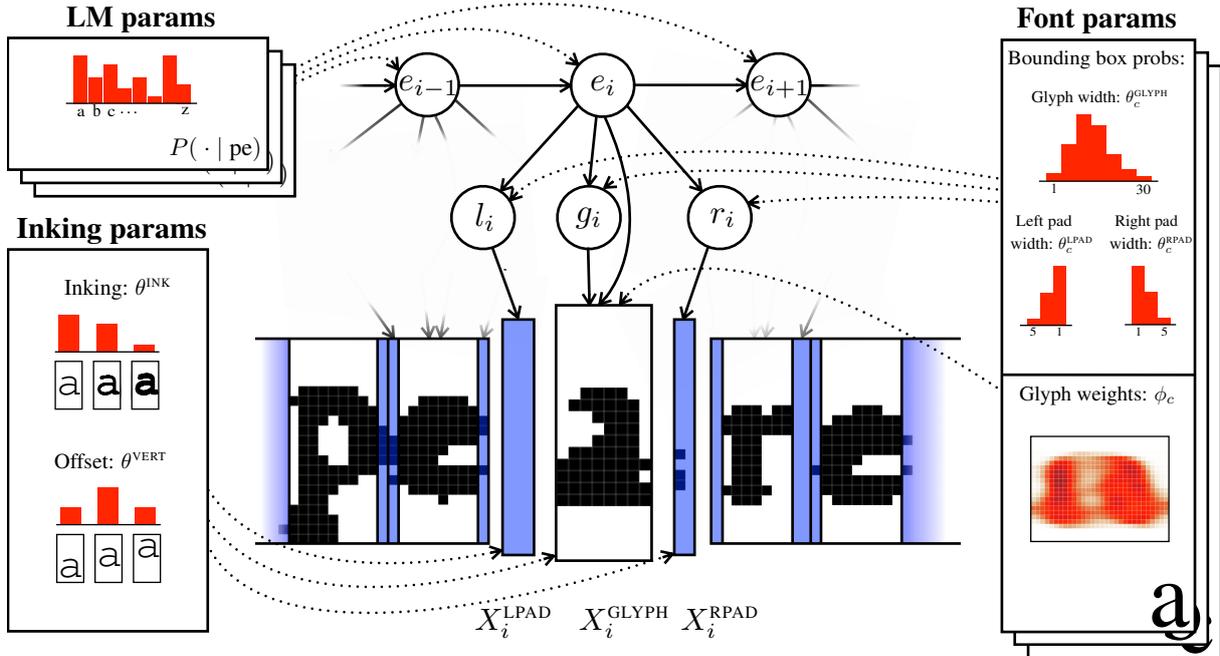

Figure 3: Character tokens  $e_i$  are generated by the language model. For each token index  $i$ , a glyph bounding box width  $g_i$ , left padding width  $l_i$ , and a right padding width  $r_i$ , are generated. Finally, the pixels in each glyph bounding box  $X_i^{\text{GLYPH}}$  are generated conditioned on the corresponding character, while the pixels in left and right padding bounding boxes,  $X_i^{\text{LPAD}}$  and  $X_i^{\text{RPAD}}$ , are generated from a background distribution.

### 3.2 Typesetting Model $P(T|E)$

Generally speaking, the process of typesetting produces a line of text by first tiling bounding boxes of various widths and then filling in the boxes with glyphs. Our generative model, which is depicted in Figure 3, reflects this process. As a first step, our model generates the dimensions of character bounding boxes; for each character token index  $i$  we generate three bounding box widths: a glyph box width  $g_i$ , a left padding box width  $l_i$ , and a right padding box width  $r_i$ , as shown in Figure 3. We let the pixel height of all lines be fixed to  $h$ . Let  $T_i = (l_i, g_i, r_i)$  so that  $T_i$  specifies the dimensions of the character box for token index  $i$ ;  $T$  is then the concatenation of all  $T_i$ , denoting the full layout.

Because the width of a glyph depends on its shape, and because of effects resulting from kerning and the use of ligatures, the components of each  $T_i$  are drawn conditioned on the character token  $e_i$ . This means that, as part of our parameterization of the font, for each character type  $c$  we have vectors of multinomial parameters  $\theta_c^{\text{LPAD}}$ ,  $\theta_c^{\text{GLYPH}}$ , and  $\theta_c^{\text{RPAD}}$  governing the distribution of the dimensions of character boxes of type  $c$ . These parameters are depicted on the right-hand side of

Figure 3. We can now express the typesetting layout portion of the model as:

$$\begin{aligned}
 P(T|E) &= \prod_{i=1}^m P(T_i|e_i) \\
 &= \prod_{i=1}^m [P(l_i; \theta_{e_i}^{\text{LPAD}}) \cdot P(g_i; \theta_{e_i}^{\text{GLYPH}}) \cdot P(r_i; \theta_{e_i}^{\text{RPAD}})]
 \end{aligned}$$

Each character type  $c$  in our font has another set of parameters, a matrix  $\phi_c$ . These are weights that specify the *shape* of the character type's glyph, and are depicted in Figure 3 as part of the font parameters.  $\phi_c$  will come into play when we begin generating pixels in Section 3.3.

#### 3.2.1 Inking Model $P(R)$

Before we start filling the character boxes with pixels, we need to specify some properties of the inking and rendering process, including the amount of ink used and vertical variation along the text baseline. Our model does this by generating, for each character token index  $i$ , a discrete value  $d_i$  that specifies the overall inking level in the character's bounding box, and a discrete value  $v_i$  that specifies the glyph's vertical offset. These variations in the inking and typesetting process are mostly independent of character type. Thus, in

our model, their distributions are not character-specific. There is one global set of multinomial parameters governing inking level ( $\theta^{\text{INK}}$ ), and another governing offset ( $\theta^{\text{VERT}}$ ); both are depicted on the left-hand side of Figure 3. Let  $R_i = (d_i, v_i)$  and let  $R$  be the concatenation of all  $R_i$  so that we can express the inking model as:

$$\begin{aligned} P(R) &= \prod_{i=1}^m P(R_i) \\ &= \prod_{i=1}^m [P(d_i; \theta^{\text{INK}}) \cdot P(v_i; \theta^{\text{VERT}})] \end{aligned}$$

The  $d_i$  and  $v_i$  variables are suppressed in Figure 3 to reduce clutter but are expressed in Figure 4, which depicts the process of rendering a glyph box.

### 3.3 Noise Model $P(X|E, T, R)$

Now that we have generated a typesetting layout  $T$  and an inking context  $R$ , we have to actually generate each of the pixels in each of the character boxes, left padding boxes, and right padding boxes; the matrices that these groups of pixels comprise are denoted  $X_i^{\text{GLYPH}}$ ,  $X_i^{\text{LPAD}}$ , and  $X_i^{\text{RPAD}}$ , respectively, and are depicted at the bottom of Figure 3.

We assume that pixels are binary valued and sample their values independently from Bernoulli distributions.<sup>2</sup> The probability of black (the Bernoulli parameter) depends on the type of pixel generated. All the pixels in a padding box have the same probability of black that depends only on the inking level of the box,  $d_i$ . Since we have already generated this value and the widths  $l_i$  and  $r_i$  of each padding box, we have enough information to generate left and right padding pixel matrices  $X_i^{\text{LPAD}}$  and  $X_i^{\text{RPAD}}$ .

The Bernoulli parameter of a pixel inside a glyph bounding box depends on the pixel’s location inside the box (as well as on  $d_i$  and  $v_i$ , but for simplicity of exposition, we temporarily suppress this dependence) and on the model parameters governing glyph shape (for each character type  $c$ , the parameter matrix  $\phi_c$  specifies the shape of the character’s glyph.) The process by which glyph pixels are generated is depicted in Figure 4.

The dependence of glyph pixels on location complicates generation of the glyph pixel matrix  $X_i^{\text{GLYPH}}$  since the corresponding parameter matrix

<sup>2</sup>We could generate real-valued pixels with a different choice of noise distribution.

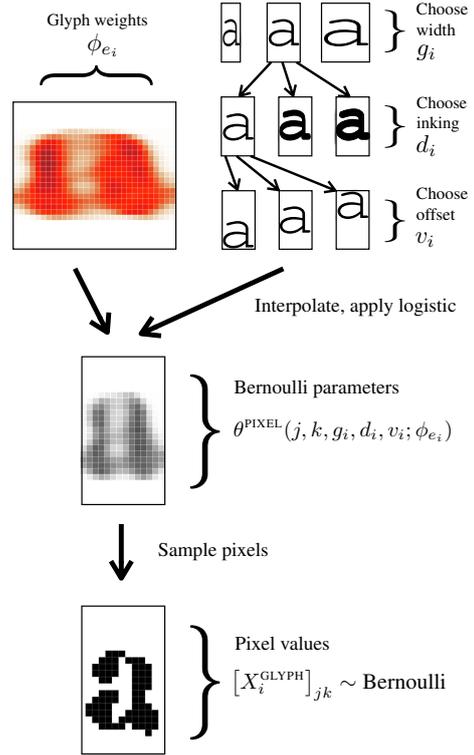

Figure 4: We generate the pixels for the character token  $e_i$  by first sampling a glyph width  $g_i$ , an inking level  $d_i$ , and a vertical offset  $v_i$ . Then we interpolate the glyph weights  $\phi_{e_i}$  and apply the logistic function to produce a matrix of Bernoulli parameters of width  $g_i$ , inking  $d_i$ , and offset  $v_i$ .  $\theta^{\text{PIXEL}}(j, k, g_i, d_i, v_i; \phi_{e_i})$  is the Bernoulli parameter at row  $j$  and column  $k$ . Finally, we sample from each Bernoulli distribution to generate a matrix of pixel values,  $X_i^{\text{GLYPH}}$ .

$\phi_{e_i}$  has some type-level width  $w$  which may differ from the current token-level width  $g_i$ . Introducing distinct parameters for each possible width would yield a model that can learn completely different glyph shapes for slightly different widths of the same character. We, instead, need a parameterization that ties the shapes for different widths together, and at the same time allows mobility in the parameter space during learning.

Our solution is to horizontally interpolate the weights of the shape parameter matrix  $\phi_{e_i}$  down to a smaller set of columns matching the token-level choice of glyph width  $g_i$ . Thus, the type-level matrix  $\phi_{e_i}$  specifies the canonical shape of the glyph for character  $e_i$  when it takes its maximum width  $w$ . After interpolating, we apply the logistic function to produce the individual Bernoulli parameters. If we let  $[X_i^{\text{GLYPH}}]_{jk}$  denote the value of the pixel at the  $j$ th row and  $k$ th column of the glyph pixel matrix  $X_i^{\text{GLYPH}}$  for token  $i$ , and let  $\theta^{\text{PIXEL}}(j, k, g_i; \phi_{e_i})$  denote the token-level

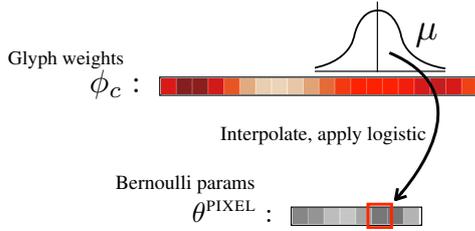

Figure 5: In order to produce Bernoulli parameter matrices  $\theta^{\text{PIXEL}}$  of variable width, we interpolate over columns of  $\phi_c$  with vectors  $\mu$ , and apply the logistic function to each result.

Bernoulli parameter for this pixel, we can write:

$$[X_i^{\text{GLYPH}}]_{jk} \sim \text{Bernoulli}(\theta^{\text{PIXEL}}(j, k, g_i; \phi_{e_i}))$$

The interpolation process for a single row is depicted in Figure 5. We define a constant interpolation vector  $\mu(g_i, k)$  that is specific to the glyph box width  $g_i$  and glyph box column  $k$ . Each  $\mu(g_i, k)$  is shaped according to a Gaussian centered at the relative column position in  $\phi_{e_i}$ . The glyph pixel Bernoulli parameters are defined as follows:

$$\theta^{\text{PIXEL}}(j, k, g_i; \phi_{e_i}) = \text{logistic} \left( \sum_{k'=1}^w [\mu(g_i, k)_{k'} \cdot [\phi_{e_i}]_{jk'}] \right)$$

The fact that the parameterization is log-linear will ensure that, during the unsupervised learning process, updating the shape parameters  $\phi_c$  is simple and feasible.

By varying the magnitude of  $\mu$  we can change the level of smoothing in the logistic model and cause it to permit areas that are over-inked. This is the effect that  $d_i$  controls. By offsetting the rows of  $\phi_c$  that we interpolate weights from, we change the vertical offset of the glyph, which is controlled by  $v_i$ . The full pixel generation process is diagrammed in Figure 4, where the dependence of  $\theta^{\text{PIXEL}}$  on  $d_i$  and  $v_i$  is also represented.

## 4 Learning

We use the EM algorithm (Dempster et al., 1977) to find the maximum-likelihood font parameters:  $\phi_c$ ,  $\theta_c^{\text{LPAD}}$ ,  $\theta_c^{\text{GLYPH}}$ , and  $\theta_c^{\text{RPAD}}$ . The image  $X$  is the only observed random variable in our model. The identities of the characters  $E$  the typesetting layout  $T$  and the inking  $R$  will all be unobserved. We do not learn  $\theta^{\text{INK}}$  and  $\theta^{\text{VERT}}$ , which are set to the uniform distribution.

### 4.1 Expectation Maximization

During the E-step we compute expected counts for  $E$  and  $T$ , but maximize over  $R$ , for which

we compute hard counts. Our model is an instance of a hidden semi-Markov model (HSMM), and therefore the computation of marginals is tractable with the semi-Markov forward-backward algorithm (Levinson, 1986).

During the M-step, we update the parameters  $\theta_c^{\text{LPAD}}$ ,  $\theta_c^{\text{RPAD}}$  using the standard closed-form multinomial updates and use a specialized closed-form update for  $\theta_c^{\text{GLYPH}}$  that enforces unimodality of the glyph width distribution.<sup>3</sup> The glyph weights,  $\phi_c$ , do not have a closed-form update. The noise model that  $\phi_c$  parameterizes is a local log-linear model, so we follow the approach of Berg-Kirkpatrick et al. (2010) and use L-BFGS (Liu and Nocedal, 1989) to optimize the expected likelihood with respect to  $\phi_c$ .

### 4.2 Coarse-to-Fine Learning and Inference

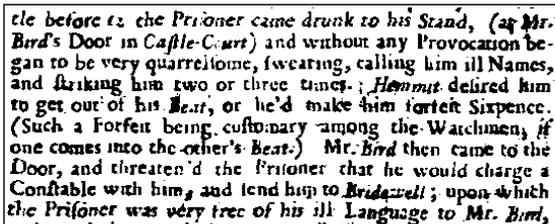

The number of states in the dynamic programming lattice grows exponentially with the order of the language model (Jelinek, 1998; Koehn, 2004). As a result, inference can become slow when the language model order  $n$  is large. To remedy this, we take a coarse-to-fine approach to both learning and inference. On each iteration of EM, we perform two passes: a coarse pass using a low-order language model, and a fine pass using a high-order language model (Petrov et al., 2008; Zhang and Gildea, 2008). We use the marginals<sup>4</sup> from the coarse pass to prune states from the dynamic program of the fine pass.

In the early iterations of EM, our font parameters are still inaccurate, and to prune heavily based on such parameters would rule out correct analyses. Therefore, we gradually increase the aggressiveness of pruning over the course of EM. To ensure that each iteration takes approximately the same amount of computation, we also gradually increase the order of the fine pass, only reaching the full order  $n$  on the last iteration. To produce a decoding of the image into text, on the final iteration we run a Viterbi pass using the pruned fine model.

<sup>3</sup>We compute the weighted mean and weighted variance of the glyph width expected counts. We set  $\theta_c^{\text{GLYPH}}$  to be proportional to a discretized Gaussian with the computed mean and variance. This update is approximate in the sense that it does not necessarily find the unimodal multinomial that maximizes expected log-likelihood, but it works well in practice.

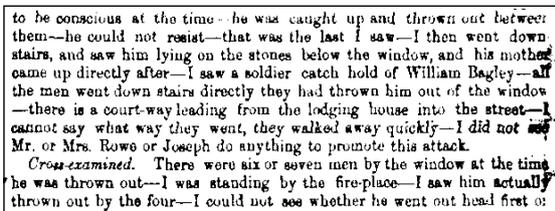

<sup>4</sup>In practice, we use max-marginals for pruning to ensure that there is still a valid path in the pruned lattice.

(a) Old Bailey, 1725:

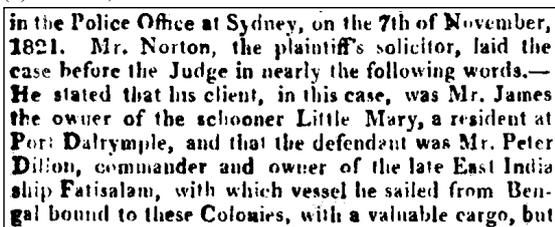

tle before the Prisoner came drunk to his Stand, (at Mr. Bird's Door in Castle-Court) and without any Provocation began to be very quarrelsome, swearing, calling him ill Names, and striking him two or three times; Hemmit delivred him to get out of his Beat, or he'd make him forfeit Sixpence. (Such a Forfeit being customary among the Watchmen, if one comes into the other's Beat.) Mr. Bird then came to the Door, and threaten'd the Prisoner that he would charge a Constable with him, and lend him to Bridewell; upon which the Prisoner was very free of his ill Language to Mr. Bird,

Figure 6: Portions of several documents from our test set representing a range of difficulties are displayed. On document (a), which exhibits noisy typesetting, our system achieves a word error rate (WER) of 25.2. Document (b) is cleaner in comparison, and on it we achieve a WER of 15.4. On document (c), which is also relatively clean, we achieve a WER of 12.5. On document (d), which is severely degraded, we achieve a WER of 70.0.

## 5 Data

We perform experiments on two historical datasets consisting of images of documents printed between 1700 and 1900 in England and Australia. Examples from both datasets are displayed in Figure 6.

### 5.1 Old Bailey

The first dataset comes from a large set of images of the proceedings of the Old Bailey, a criminal court in London, England (Shoemaker, 2005). The Old Bailey curatorial effort, after deciding that current OCR systems do not adequately handle 18th century fonts, manually transcribed the

documents into text. We will use these manual transcriptions to evaluate the output of our system. From the Old Bailey proceedings, we extracted a set of 20 images, each consisting of 30 lines of text to use as our first test set. We picked 20 documents, printed in consecutive decades. The first document is from 1715 and the last is from 1905. We choose the first document in each of the corresponding years, choose a random page in the document, and extracted an image of the first 30 consecutive lines of text consisting of full sentences.<sup>5</sup> The ten documents in the Old Bailey dataset that were printed before 1810 use the long s glyph, while the remaining ten do not.

### 5.2 Trove

Our second dataset is taken from a collection of digitized Australian newspapers that were printed between the years of 1803 and 1954. This collection is called Trove, and is maintained by the the National Library of Australia (Holley, 2010). We extracted ten images from this collection in the same way that we extracted images from Old Bailey, but starting from the year 1803. We manually produced our own gold annotations for these ten images. Only the first document of Trove uses the long s glyph.

### 5.3 Pre-processing

Many of the images in historical collections are bitonal (binary) as a result of how they were captured on microfilm for storage in the 1980s (Arlitsch and Herbert, 2004). This is part of the reason our model is designed to work directly with binarized images. For consistency, we binarized the images in our test sets that were not already binary by thresholding pixel values.

Our model requires that the image be pre-segmented into lines of text. We automatically segment lines by training an HSMM over rows of pixels. After the lines are segmented, each line is resampled so that its vertical resolution is 30 pixels. The line extraction process also identifies pixels that are not located in central text regions, and are part of large connected components of ink, spanning multiple lines. The values of such pixels are treated as unobserved in the model since, more often than not, they are part of ink blotches.

<sup>5</sup>This ruled out portions of the document with extreme structural abnormalities, like title pages and lists. These might be interesting to model, but are not within the scope of this paper.

## 6 Experiments

We evaluate our system by comparing our text recognition accuracy to that of two state-of-the-art systems.

### 6.1 Baselines

Our first baseline is Google’s open source OCR system, Tesseract (Smith, 2007). Tesseract takes a pipelined approach to recognition. Before recognizing the text, the document is broken into lines, and each line is segmented into words. Then, Tesseract uses a classifier, aided by a word-unigram language model, to recognize whole words.

Our second baseline, ABBYY FineReader 11 Professional Edition,<sup>6</sup> is a state-of-the-art commercial OCR system. It is the OCR system that the National Library of Australia used to recognize the historical documents in Trove (Holley, 2010).

### 6.2 Evaluation

We evaluate the output of our system and the baseline systems using two metrics: character error rate (CER) and word error rate (WER). Both these metrics are based on edit distance. CER is the edit distance between the predicted and gold transcriptions of the document, divided by the number of characters in the gold transcription. WER is the word-level edit distance (words, instead of characters, are treated as tokens) between predicted and gold transcriptions, divided by the number of words in the gold transcription. When computing WER, text is tokenized into words by splitting on whitespace.

### 6.3 Language Model

We ran experiments using two different language models. The first language model was trained on the initial one million sentences of the New York Times (NYT) portion of the Gigaword corpus (Graff et al., 2007), which contains about 36 million words. This language model is out of domain for our experimental documents. To investigate the effects of using an in domain language model, we created a corpus composed of the manual annotations of all the documents in the Old Bailey proceedings, excluding those used in our test set. This corpus consists of approximately 32 million words. In all experiments we used a character  $n$ -gram order of six for the final Viterbi de-

Ocular w/ NYT (this work)	<b>14.9</b>	<b>33.0</b>

Table 1: We evaluate the predicted transcriptions in terms of both character error rate (CER) and word error rate (WER), and report macro-averages across documents. We compare with two baseline systems: Google’s open source OCR system, Tesseract, and a state-of-the-art commercial system, ABBYY FineReader. We refer to our system as Ocular w/ NYT and Ocular w/ OB, depending on whether NYT or Old Bailey is used to train the language model.

coding pass and an order of three for all coarse passes.

### 6.4 Initialization and Tuning

We used as a development set ten additional documents from the Old Bailey proceedings and five additional documents from Trove that were not part of our test set. On this data, we tuned the model’s hyperparameters<sup>7</sup> and the parameters of the pruning schedule for our coarse-to-fine approach.

In experiments we initialized  $\theta_c^{\text{RPAD}}$  and  $\theta_c^{\text{LPAD}}$  to be uniform, and initialized  $\theta_c^{\text{GLYPH}}$  and  $\phi_c$  based on the standard modern fonts included with the Ubuntu Linux 12.04 distribution.<sup>8</sup> For documents that use the long  $s$  glyph, we introduce a special character type for the non-word-final  $s$ , and initialize its parameters from a mixture of the modern  $f$  and  $|$  glyphs.<sup>9</sup>

## 7 Results and Analysis

The results of our experiments are summarized in Table 1. We refer to our system as Ocular w/ NYT or Ocular w/ OB, depending on whether the language model was trained using NYT or Old Bailey, respectively. We compute macro-averages

<sup>7</sup>One of the hyperparameters we tune is the exponent of the language model. This balances the contributions of the language model and the typesetting model to the posterior (Och and Ney, 2004).

<sup>8</sup><http://www.ubuntu.com/>

<sup>9</sup>Following Berg-Kirkpatrick et al. (2010), we use a regularization term in the optimization of the log-linear model parameters  $\phi_c$  during the M-step. Instead of regularizing towards zero, we regularize towards the initializer. This slightly improves performance on our development set and can be thought of as placing a prior on the glyph shape parameters.

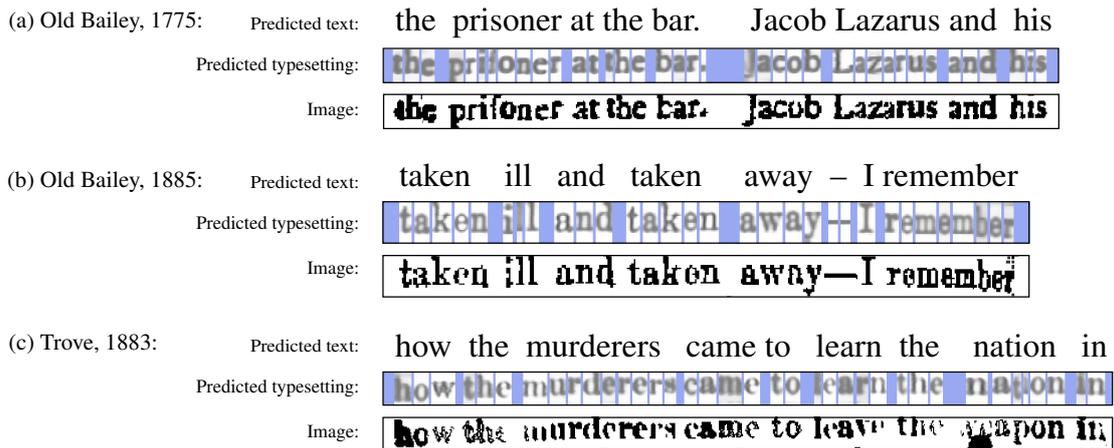

Figure 7: For each of these portions of test documents, the first line shows the transcription predicted by our model and the second line shows a representation of the learned typesetting layout. The grayscale glyphs show the Bernoulli pixel distributions learned by our model, while the padding regions are depicted in blue. The third line shows the input image.

across documents from all years. Our system, using the NYT language model, achieves an average WER of 28.1 on Old Bailey and an average WER of 33.0 on Trove. This represents a substantial error reduction compared to both baseline systems.

If we average over the documents in both Old Bailey and Trove, we find that Tesseract achieved an average WER of 56.3, ABBYY FineReader achieved an average WER of 43.1, and our system, using the NYT language model, achieved an average WER of 29.7. This means that while Tesseract incorrectly predicts more than half of the words in these documents, our system gets more than three-quarters of them right. Overall, we achieve a relative reduction in WER of 47% compared to Tesseract and 31% compared to ABBYY FineReader.

The baseline systems do not have special provisions for the long  $s$  glyph. In order to make sure the comparison is fair, we separately computed average WER on only the documents from after 1810 (which do not use the long  $s$  glyph). We found that using this evaluation our system actually achieves a larger relative reduction in WER: 50% compared to Tesseract and 35% compared to ABBYY FineReader.

Finally, if we train the language model using the Old Bailey corpus instead of the NYT corpus, we see an average improvement of 4 WER on the Old Bailey test set. This means that the domain of the language model is important, but, the results are not affected drastically even when using a language model based on modern corpora (NYT).

### 7.1 Learned Typesetting Layout

Figure 7 shows a representation of the typesetting layout learned by our model for portions of several

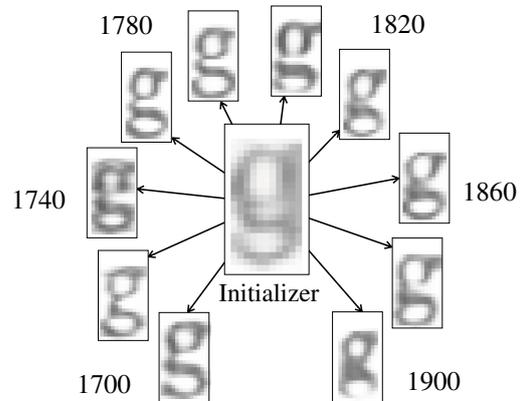

Figure 8: The central glyph is a representation of the initial model parameters for the glyph shape for  $g$ , and surrounding this are the learned parameters for documents from various years.

test documents. For each portion of a test document, the first line shows the transcription predicted by our model, and the second line shows padding and glyph regions predicted by the model, where the grayscale glyphs represent the learned Bernoulli parameters for each pixel. The third line shows the input image.

Figure 7a demonstrates a case where our model has effectively explained both the uneven baseline and over-inked glyphs by using the vertical offsets  $v_i$  and inking variables  $d_i$ . In Figure 7b the model has used glyph widths  $g_i$  and vertical offsets to explain the thinning of glyphs and falling baseline that occurred near the binding of the book. In separate experiments on the Old Bailey test set, using the NYT language model, we found that removing the vertical offset variables from the model increased WER by 22, and removing the inking variables increased WER by 16. This indicates that it is very important to model both these aspects of printing press rendering.

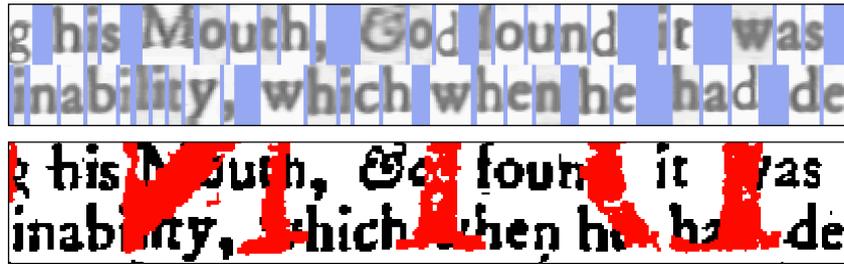

Figure 9: This Old Bailey document from 1719 has severe ink bleeding from the facing page. We annotated these blotches (in red) and treated the corresponding pixels as unobserved in the model. The layout shown is predicted by the model.

Figure 7c shows the output of our system on a difficult document. Here, missing characters and ink blotches confuse the model, which picks something that is reasonable according to the language model, but incorrect.

## 7.2 Learned Fonts

It is interesting to look at the fonts learned by our system, and track how historical fonts changed over time. Figure 8 shows several grayscale images representing the Bernoulli pixel probabilities for the most likely width of the glyph for *g* under various conditions. At the center is the representation of the initial parameter values, and surrounding this are the learned parameters for documents from various years. The learned shapes are visibly different from the initializer, which is essentially an average of modern fonts, and also vary across decades.

We can ask to what extent learning the font structure actually improved our performance. If we turn off learning and just use the initial parameters to decode, WER increases by 8 on the Old Bailey test set when using the NYT language model.

## 7.3 Unobserved Ink Blotches

As noted earlier, one strength of our generative model is that we can make the values of certain pixels unobserved in the model, and let inference fill them in. We conducted an additional experiment on a document from the Old Bailey proceedings that was printed in 1719. This document, a fragment of which is shown in Figure 9, has severe ink bleeding from the facing page. We manually annotated the ink blotches (shown in red), and made them unobserved in the model. The resulting typesetting layout learned by the model is also shown in Figure 9. The model correctly predicted most of the obscured words. Running the model with the manually specified unobserved pixels re-

duced the WER on this document from 58 to 19 when using the NYT language model.

## 7.4 Remaining Errors

We performed error analysis on our development set by randomly choosing 100 word errors from the WER alignment and manually annotating them with relevant features. Specifically, for each word error we recorded whether or not the error contained punctuation (either in the predicted word or the gold word), whether the text in the corresponding portion of the original image was italicized, and whether the corresponding portion of the image exhibited over-inking, missing ink, or significant ink blotches. These last three feature types are subjective in nature but may still be informative. We found that 56% of errors were accompanied by over-inking, 50% of errors were accompanied by ink blotches, 42% of errors contained punctuation, 21% of errors showed missing ink, and 12% of errors contained text that was italicized in the original image.

Our own subjective assessment indicates that many of these error features are in fact causal. More often than not, italicized text is incorrectly transcribed. In cases of extreme ink blotching, or large areas of missing ink, the system usually makes an error.

## 8 Conclusion

We have demonstrated a model, based on the historical typesetting process, that effectively learns font structure in an unsupervised fashion to improve transcription of historical documents into text. The parameters of the learned fonts are interpretable, as are the predicted typesetting layouts. Our system achieves state-of-the-art results, significantly outperforming two state-of-the-art baseline systems.

## Abstract

We adapt discriminative reranking to improve the performance of grounded language acquisition, specifically the task of learning to follow navigation instructions from observation. Unlike conventional reranking used in syntactic and semantic parsing, gold-standard reference trees are not naturally available in a grounded setting. Instead, we show how the weak supervision of response feedback (e.g. successful task completion) can be used as an alternative, experimentally demonstrating that its performance is comparable to training on gold-standard parse trees.

## 1 Introduction

Grounded language acquisition involves learning to comprehend and/or generate language by simply observing its use in a naturally occurring context in which the meaning of a sentence is grounded in perception and/or action (Roy, 2002; Yu and Ballard, 2004; Gold and Scassellati, 2007; Chen et al., 2010). Börschinger et al. (2011) introduced an approach that reduces grounded language learning to unsupervised *probabilistic context-free grammar* (PCFG) induction and demonstrated its effectiveness on the task of sportscasting simulated robot soccer games. Subsequently, Kim and Mooney (2012) extended their approach to make it tractable for the more complex problem of learning to follow natural-language navigation instructions from observations of humans following such instructions in a virtual environment (Chen and Mooney, 2011). The observed sequence of actions provides very weak, ambiguous supervision for learning instructional language since there are many possible ways to describe the same execution path. Although their approach improved accuracy on the navigation task compared

to the original work of Chen and Mooney (2011), it was still far from human performance.

Since their system employs a generative model, *discriminative reranking* (Collins, 2000) could potentially improve its performance. By training a discriminative classifier that uses global features of complete parses to identify correct interpretations, a reranker can significantly improve the accuracy of a generative model. Reranking has been successfully employed to improve syntactic parsing (Collins, 2002b), semantic parsing (Lu et al., 2008; Ge and Mooney, 2006), semantic role labeling (Toutanova et al., 2005), and named entity recognition (Collins, 2002c). Standard reranking requires gold-standard interpretations (e.g. parse trees) to train the discriminative classifier. However, grounded language learning does not provide gold-standard interpretations for the training examples. Only the ambiguous perceptual context of the utterance is provided as supervision. For the navigation task, this supervision consists of the observed sequence of actions taken by a human when following an instruction. Therefore, it is impossible to directly apply conventional discriminative reranking to such problems. We show how to adapt reranking to work with such weak supervision. Instead of using gold-standard annotations to determine the correct interpretations, we simply prefer interpretations of navigation instructions that, when executed in the world, actually reach the intended destination. Additionally, we extensively revise the features typically used in parse reranking to work with the PCFG approach to grounded language learning.

The rest of the paper is organized as follows: Section 2 reviews the navigation task and the PCFG approach to grounded language learning. Section 3 presents our modified approach to reranking and Section 4 describes the novel features used to evaluate parses. Section 5 experimentally evaluates the approach comparing to sev-

est execution success. This requires an external module that evaluates the execution accuracy of the candidate parses. For the navigation task, we use the MARCO (MacMahon et al., 2006) execution module, which is also used to evaluate how well the overall system learns to follow directions (Chen and Mooney, 2011). Since MARCO is nondeterministic when executing underspecified plans, we execute each candidate plan 10 times, and its execution rate is the percentage of trials in which it reaches the correct destination. When there are multiple candidate parses tied for the highest execution rate, the one assigned the largest probability by the baseline model is selected. Our modified averaged perceptron procedure with such a response-based update is shown in Algorithm 1.

One additional issue must be addressed when computing the output of the GEN function. The final plan MRs are produced from parse trees using compositional semantics (see Kim and Mooney (2012) for details). Consequently, the  $n$ -best parse trees for the baseline model do not necessarily produce the  $n$ -best *distinct* plans, since many parses can produce the same plan. Therefore, we adapt the GEN function to produce the  $n$  best distinct plans rather than the  $n$  best parses. This may require examining many more than the  $n$  best parses, because many parses have insignificant differences that do not affect the final plan. The score assigned to a plan is the probability of the most probable parse that generates that plan. In order to efficiently compute the  $n$  best plans, we modify the exact  $n$ -best parsing algorithm developed by Huang and Chiang (2005). The modified algorithm ensures that each plan in the computed  $n$  best list produces a new distinct plan.

### 3.2 Weight Updates Using Multiple Parses

Typically, when used for reranking, the averaged perceptron updates its weights using the feature-vector difference between the current best predicted candidate and the gold-standard reference (line 6 in Algorithm 1). In our initial modified version, we replaced the gold-standard reference parse with the pseudo-gold reference, which has the highest execution rate amongst all candidate parses. However, this ignores all other candidate parses during perceptron training. However, it is not ideal to regard other candidate parses as “useless.” There may be multiple candidate parses with the same maximum execution rate, and even can-

didates with lower execution rates could represent the correct plan for the instruction given the weak, indirect supervision provided by the observed sequence of human actions.

Therefore, we also consider a further modification of the averaged perceptron algorithm which updates its weights using multiple candidate parses. Instead of only updating the weights with the single difference between the predicted and pseudo-gold parses, the weight vector  $\bar{W}$  is updated with the sum of feature-vector differences between the current predicted candidate and *all* other candidates that have a higher execution rate. Formally, in this version, we replace lines 5–6 of Algorithm 1 with:

- 1: **for all**  $y \in \text{GEN}(e_i)$  where  $y \neq y_i$  and  $\text{EXEC}(y) > \text{EXEC}(y_i)$  **do**
- 2:      $\bar{W} = \bar{W} + (\text{EXEC}(y) - \text{EXEC}(y_i)) \times (\Phi(e_i, y) - \Phi(e_i, y_i))$
- 3: **end for**

where  $\text{EXEC}(y)$  is the execution rate of the MR plan  $m$  derived from parse tree  $y$ .

In the experiments below, we demonstrate that, by exploiting multiple reference parses, this new update rule increases the execution accuracy of the final system. Intuitively, this approach gathers additional information from all candidate parses with higher execution accuracy when learning the discriminative reranker. In addition, as shown in line 2 of the algorithm above, it uses the difference in execution rates between a candidate and the currently preferred parse to weight the update to the parameters for that candidate. This allows more effective plans to have a larger impact on the learned model in each iteration.

## 4 Reranking Features

This section describes the features  $\Phi$  extracted from parses produced by the generative model and used to rerank the candidates.

### 4.1 Base Features

The base features adapt those used in previous reranking methods, specifically those of Collins (2002a), Lu et al. (2008), and Ge and Mooney (2006), which are directly extracted from parse trees. In addition, we also include the log probability of the parse tree as an additional feature. Figure 3 shows a sample full parse tree from our baseline model, which is used when explaining the

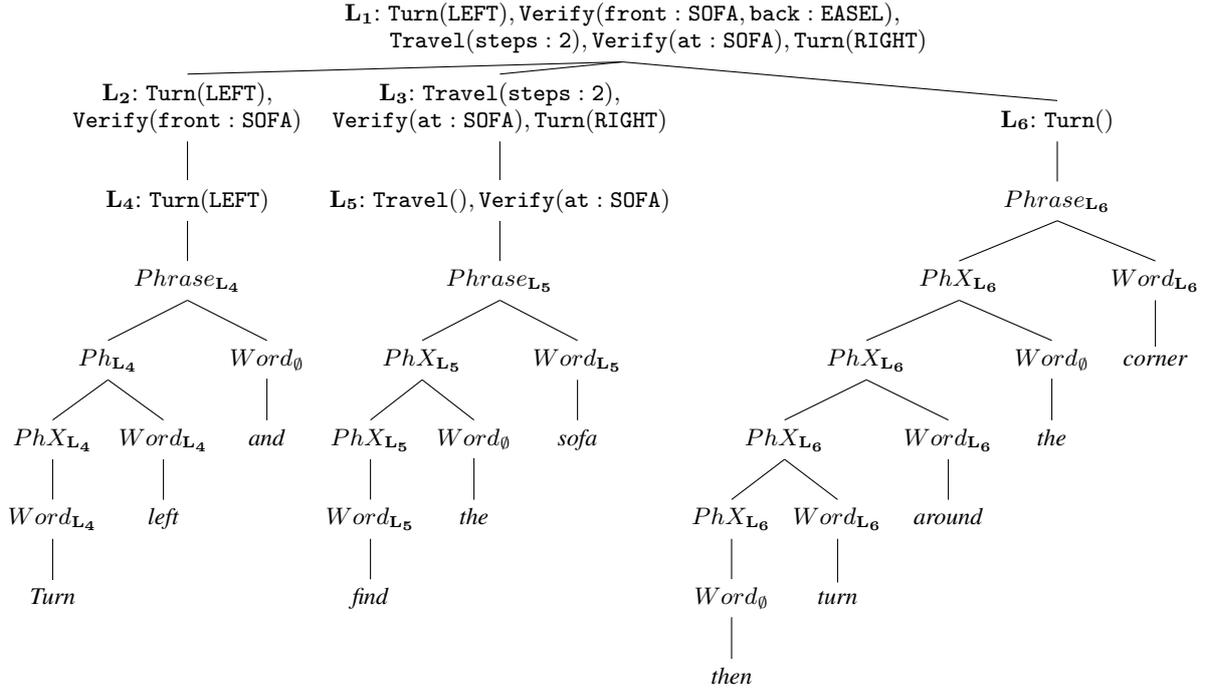

Figure 3: Sample full parse tree for the sentence “Turn left and find the sofa then turn around the corner” used to explain reranking features. Nonterminals representing MR plan components are shown, which are labeled  $L_1$  to  $L_6$  for ease of reference. Additional nonterminals such as *Phrase*, *Ph*, *PhX*, and *Word* are subsidiary ones for generating NL words from MR nonterminals. They are also shown in order to represent the entire process of how parse trees are constructed (for details, refer to Kim and Mooney (2012)).

reranking features below, each illustrated by an example.

- a) PCFG Rule. Indicates whether a particular PCFG rule is used in the parse tree:  $f(L_1 \Rightarrow L_2 L_3) = 1$ .
- b) Grandparent PCFG Rule. Indicates whether a particular PCFG rule *as well as* the nonterminal above it is used in the parse tree:  $f(L_3 \Rightarrow L_5 L_6 | L_1) = 1$ .
- c) Long-range Unigram. Indicates whether a nonterminal has a given NL word below it in the parse tree:  $f(L_2 \rightsquigarrow \text{left}) = 1$  and  $f(L_4 \rightsquigarrow \text{turn}) = 1$ .
- d) Two-level Long-range Unigram. Indicates whether a nonterminal has a child nonterminal which eventually generates a NL word in the parse tree:  $f(L_4 \rightsquigarrow \text{left} | L_2) = 1$
- e) Unigram. Indicates whether a nonterminal produces a given child nonterminal or terminal NL word in the parse tree:  $f(L_1 \rightarrow L_2) = 1$  and  $f(L_1 \rightarrow L_3) = 1$ .

- f) Grandparent Unigram. Indicates whether a nonterminal has a given child nonterminal/terminal below it, as well as a given parent nonterminal:  $f(L_2 \rightarrow L_4 | L_1) = 1$
- g) Bigram. Indicates whether a given bigram of nonterminal/terminals occurs for given a parent nonterminal:  $f(L_1 \rightarrow L_2 : L_3) = 1$ .
- h) Grandparent Bigram. Same as Bigram, but also includes the nonterminal above the parent nonterminal:  $f(L_3 \rightarrow L_5 : L_6 | L_1) = 1$ .
- i) Log-probability of Parse Tree. Certainty assigned by the base generative model.

## 4.2 Predicate-Only Features

The base features above generally include nonterminal symbols used in the parse tree. In the grounded PCFG model, nonterminals are named after components of the semantic representations (MRs), which are complex and numerous. There are  $\simeq 2,500$  nonterminals in the grammar constructed for the navigation data, most of which are very specific and rare. This results in a very large, sparse feature space which can easily lead

the reranking model to over-fit the training data and prevent it from generalizing properly.

Therefore, we also tried constructing more general features that are less sparse. First, we construct generalized versions of the base features in which nonterminal symbols use only predicate names and omit their arguments. In the navigation task, action arguments frequently contain redundant, rarely used information. In particular, the interleaving verification steps frequently include many details that are never actually mentioned in the NL instructions. For instance, a nonterminal for the MR

```
Turn(LEFT),
Verify(at:SOFA, front:EASEL),
Travel(steps:3)
```

is transformed into the predicate-only form

```
Turn(), Verify(), Travel()
```

, and then used to construct more general versions of the base features described in the previous section. Second, another version of the base features are constructed in which nonterminal symbols include action arguments but omit all interleaving verification steps. This is a somewhat more conservative simplification of the nonterminal symbols. Although verification steps sometimes help interpret the actions and their surrounding context, they frequently cause the nonterminal symbols to become unnecessarily complex and specific.

### 4.3 Descended Action Features

Finally, another feature group which we utilize captures whether a particular atomic action in a nonterminal “descends” into one of its child nonterminals or not. An atomic action consists of a predicate and its arguments, e.g. `Turn(LEFT)`, `Travel(steps:2)`, or `Verify(at:SOFA)`. When an atomic action descends into lower nonterminals in a parse tree, it indicates that it is mentioned in the NL instruction and is therefore important. Below are several feature types related to descended actions that are used in our reranking model:

- a) **Descended Action.** Indicates whether a given atomic action in a nonterminal descends to the next level. In Figure 3,  $f(\text{Turn}(\text{LEFT})) = 1$  since it descends into  $L_2$  and  $L_4$ .
- b) **Descended Action Unigram.** Same as Descended Action, but also includes the current nonterminal:  $f(\text{Turn}(\text{LEFT})|L_1) = 1$ .

- c) **Grandparent Descended Action Unigram.** Same as Descended Action Unigram, but additionally includes the parent nonterminal as well as the current one:  $f(\text{Turn}(\text{LEFT})|L_2, L_1) = 1$ .

- d) **Long-range Descended Action Unigram.** Indicates whether a given atomic action in a nonterminal descends to a child nonterminal and this child generates a given NL word below it:  $f(\text{Turn}(\text{LEFT}) \rightsquigarrow \text{left}) = 1$

## 5 Experimental Evaluation

### 5.1 Data and Methodology

The navigation data was collected by MacMahon et al. (2006), and includes English instructions and human follower data.<sup>1</sup> The data contains 706 route instructions for three virtual worlds. The instructions were produced by six instructors for 126 unique starting and ending location pairs over the three maps. Each instruction is annotated with 1 to 15 human follower traces with an average of 10.4 actions per instruction. Each instruction contains an average of 5.0 sentences each with an average of 7.8 words. Chen and Mooney (2011) constructed a version of the data in which each sentence is annotated with the actions taken by the majority of followers when responding to this sentence. This single-sentence version is used for training. Manually annotated “gold standard” formal plans for each sentence are used for evaluation purposes only.

We followed the same experimental methodology as Kim and Mooney (2012) and Chen and Mooney (2011). We performed “leave one environment out” cross-validation, i.e. 3 trials of training on two environments and testing on the third. The baseline model is first trained on data for two environments and then used to generate the  $n = 50$  best plans for both training and testing instructions. As mentioned in Section 3.1, we need to generate many more top parse trees to get 50 distinct formal MR plans. We limit the number of best parse trees to 1,000,000, and even with this high limit, some training examples were left with less than 50 distinct plans.<sup>2</sup> Each candidate

<sup>1</sup>Data is available at <http://www.cs.utexas.edu/users/ml/clamp/navigation/>

<sup>2</sup>9.6% of the examples (310 out of total 3237) produced less than 50 distinct MR plans in the evaluation. This was mostly due to exceeding the parse-tree limit and partly because the baseline model failed to parse some NL sentences.

n		1	2	5	10	25	50
Parse Accuracy	F1	74.81	79.08	82.78	85.32	87.52	88.62
Plan Execution	Single-sentence	57.22	63.86	70.93	76.41	83.59	87.02
	Paragraph	20.17	28.08	35.34	40.64	48.69	53.66

Table 1: Oracle parse and execution accuracy for single sentence and complete paragraph instructions for the  $n$  best parses.

plan is then executed using MARCO and its rate of successfully reaching the goal is recorded. Our reranking model is then trained on the training data using the  $n$ -best candidate parses. We only retain reranking features that appear (i.e. have a value of 1) at least twice in the training data.

Finally, we measure both parse and execution accuracy on the test data. Parse accuracy evaluates how well a system maps novel NL sentences for new environments into correct MR plans (Chen and Mooney, 2011). It is calculated by comparing the system’s MR output to the gold-standard MR. Accuracy is measured using F1, the harmonic mean of precision and recall for individual MR constituents, thereby giving partial credit to approximately correct MRs. We then execute the resulting MR plans in the test environment to see whether they successfully reach the desired destinations. Execution is evaluated both for single sentence and complete paragraph instructions. Successful execution rates are calculated by averaging 10 nondeterministic MARCO executions.

## 5.2 Reranking Results

### Oracle results

As typical in reranking experiments, we first present results for an “oracle” that always returns the best result amongst the top- $n$  candidates produced by the baseline system, thereby providing an upper bound on the improvements possible with reranking. Table 1 shows oracle accuracy for both semantic parsing and plan execution for single sentence and complete paragraph instructions for various values of  $n$ . For oracle parse accuracy, for each sentence, we pick the parse that gives the highest F1 score. For oracle single-sentence execution accuracy, we pick the parse that gives the highest execution success rate. These single-sentence plans are then concatenated to produce a complete plan for each paragraph instruction in order to measure overall execution accuracy. Since making an error in *any* of the sentences in an in-

struction can easily lead to the wrong final destination, paragraph-level accuracies are always much lower than sentence-level ones. In order to balance oracle accuracy and the computational effort required to produce  $n$  distinct plans, we chose  $n = 50$  for the final experiments since oracle performance begins to asymptote at this point.

### Response-based vs. gold-standard reference weight updates

Table 2 presents reranking results for our proposed response-based weight update (*Single*) for the averaged perceptron (cf. Section 3.1) compared to the typical weight update method using gold-standard parses (*Gold*). Since the gold-standard annotation gives the correct MR rather than a parse tree for each sentence, *Gold* selects as a single reference parse the candidate in the top 50 whose resulting MR is most similar to the gold-standard MR as determined by its parse accuracy. Ge and Mooney (2006) employ a similar approach when reranking semantic parses.

The results show that our response-based approach (*Single*) has better execution accuracy than both the baseline *and* the standard approach using gold-standard parses (*Gold*). However, *Gold* does perform best on parse accuracy since it explicitly focuses on maximizing the accuracy of the resulting MR. In contrast, by focusing discriminative training on optimizing performance of the ultimate end task, our response-based approach actually outperforms the traditional approach on the final task. In addition, it only utilizes feedback that is naturally available for the task, rather than requiring an expert to laboriously annotate each sentence with a gold-standard MR. Even though *Gold* captures more elements of the gold-standard MRs, it may miss some critical MR components that are crucial to the final navigation task. The overall result is very promising because it demonstrates how reranking can be applied to grounded language learning tasks where gold-standard parses are not readily available.

	Parse Acc	Plan Execution	
	F1	Single	Para
Baseline	74.81	57.22	20.17
Gold	<b>78.26</b>	52.57	19.33
Single	73.32	59.65	22.62
Multi	73.43	<b>62.81</b>	<b>26.57</b>

Table 2: Reranking results comparing our response-based methods using single (*Single*) or multiple (*Multi*) pseudo-gold parses to the standard approach using a single gold-standard parse (*Gold*). *Baseline* refers to Kim and Mooney (2012)’s system. Reranking results use all features described in Section 4. “*Single*“ means the single-sentence version and “*Para*” means the full paragraph version of the corpus.

### Weight update with single vs. multiple reference parses

Table 2 also shows performance when using multiple reference parse trees to update weights (cf. Section 3.2). Using multiple parses (*Multi*) clearly performs better for all evaluation metrics, particularly execution. As explained in Section 3.2, the single-best pseudo-gold parse provides weak, ambiguous feedback since it only provides a rough estimate of the response feedback from the execution module. Using a variety of preferable parses to update weights provides a greater amount and variety of weak feedback and therefore leads to a more accurate model.<sup>3</sup>

### Comparison of different feature groups

Table 3 compares reranking results using the different feature groups described in Section 4. Compared to the baseline model (Kim and Mooney, 2012), each of the feature groups *Base* (base features), *Pred* (predicate-only and verification-removed features), and *Desc* (descended action features) helps improve the performance of plan execution for both single sentence and complete paragraph navigation instructions. Among them, *Desc* is the most effective group of features. Combinations of the feature groups helps fur-

<sup>3</sup>We also tried extending *Gold* to use multiple reference parses in the same manner, but this actually degraded its performance for all metrics. This indicates that, unlike *Multi*, parses other than the best one do not have useful information in terms of optimizing normal parse accuracy. Instead, additional parses seem to add noise to the training process in this case. Therefore, updating with multiple parses does not appear to be useful in standard reranking.

Features	Parse Acc	Plan Execution	
	F1	Single	Para
Baseline	<b>74.81</b>	57.22	20.17
Base	71.50	60.09	23.20
Pred	71.61	60.87	24.13
Desc	73.90	61.33	25.00
Base+Pred	69.52	61.49	26.24
Base+Desc	73.66	61.72	25.58
Pred+Desc	72.56	62.36	26.04
All	73.43	<b>62.81</b>	<b>26.57</b>

Table 3: Reranking results comparing different sets of features. *Base* refers to base features (cf. Section 4.1), *Pred* refers to predicate-only features and also includes features based on removing interleaving verification steps (cf. Section 4.2), *Desc* refers to descended action features (cf. Section 4.3). *All* refers to all the features including *Base*, *Pred*, and *Desc*. All results use weight update with multiple reference parses (cf. Section 3.2).

ther improve the plan execution performance, and reranking using all of the feature groups (*All*) performs the best, as expected. However, since our model is optimizing plan execution during training, the results for parse accuracy are always worse than the baseline model.

## 6 Related Work

Discriminative reranking is a common machine learning technique to improve the output of generative models. It has been shown to be effective for various natural language processing tasks including syntactic parsing (Collins, 2000; Collins, 2002b; Collins and Koo, 2005; Charniak and Johnson, 2005; Huang, 2008), semantic parsing (Lu et al., 2008; Ge and Mooney, 2006), part-of-speech tagging (Collins, 2002a), semantic role labeling (Toutanova et al., 2005), named entity recognition (Collins, 2002c), machine translation (Shen et al., 2004; Fraser and Marcu, 2006) and surface realization in generation (White and Rajkumar, 2009; Konstas and Lapata, 2012). However, to our knowledge, there has been no previous attempt to apply discriminative reranking to grounded language acquisition, where gold-standard reference parses are not typically available for training reranking models.

Our use of response-based training is similar

to work on learning semantic parsers from execution output such as the answers to database queries (Clarke et al., 2010; Liang et al., 2011). Although the demands of grounded language tasks, such as following navigation instructions, are different, it would be interesting to try adapting these alternative approaches to such problems.

## 7 Future Work

In the future, we would like to explore the construction of better, more-general reranking features that are less prone to over-fitting. Since typical reranking features rely on the combination and/or modification of nonterminals appearing in parse trees, for the large PCFG's produced for grounded language learning, such features are very sparse and rare. Although the current features provide a significant increase in performance, oracle results imply that an even larger benefit may be achievable.

In addition, employing other reranking methodologies, such as kernel methods (Collins, 2002b), and forest reranking exploiting a packed forest of exponentially many parse trees (Huang, 2008), is another area of future work. We also would like to apply our approach to other reranking algorithms such as SVMs (Joachims, 2002) and Max-Ent methods (Charniak and Johnson, 2005).

## 8 Conclusions

In this paper, we have shown how to adapt discriminative reranking to grounded language learning. Since typical grounded language learning problems, such as navigation instruction following, do not provide the gold-standard reference parses required by standard reranking models, we have devised a novel method for using the weaker supervision provided by response feedback (e.g. the execution of inferred navigation plans) when training a perceptron-based reranker. This approach was shown to be very effective compared to the traditional method of using gold-standard parses. In addition, since this response-based supervision is weak and ambiguous, we have also presented a method for using multiple reference parses to perform perceptron weight updates and shown a clear further improvement in end-task performance with this approach.

## Abstract

Syntactic structures, by their nature, reflect first and foremost the formal constructions used for expressing meanings. This renders them sensitive to formal variation both within and across languages, and limits their value to semantic applications. We present UCCA, a novel multi-layered framework for semantic representation that aims to accommodate the semantic distinctions expressed through linguistic utterances. We demonstrate UCCA's portability across domains and languages, and its relative insensitivity to meaning-preserving syntactic variation. We also show that UCCA can be effectively and quickly learned by annotators with no linguistic background, and describe the compilation of a UCCA-annotated corpus.

## 1 Introduction

Syntactic structures are mainly committed to representing the formal patterns of a language, and only indirectly reflect semantic distinctions. For instance, while virtually all syntactic annotation schemes are sensitive to the structural difference between (a) “John took a shower” and (b) “John showered”, they seldom distinguish between (a) and the markedly different (c) “John took my book”. In fact, the annotations of (a) and (c) are identical under the most widely-used schemes for English, the Penn Treebank (PTB) (Marcus et al., 1993) and CoNLL-style dependencies (Surdeanu et al., 2008) (see Figure 1).

\* Omri Abend is grateful to the Azrieli Foundation for the award of an Azrieli Fellowship.

Underscoring the semantic similarity between (a) and (b) can assist semantic applications. One example is machine translation to target languages that do not express this structural distinction (e.g., both (a) and (b) would be translated to the same German sentence “John duschte”). Question Answering applications can also benefit from distinguishing between (a) and (c), as this knowledge would help them recognize “my book” as a much more plausible answer than “a shower” to the question “what did John take?”.

This paper presents a novel approach to grammatical representation that annotates semantic distinctions and aims to abstract away from specific syntactic constructions. We call our approach *Universal Conceptual Cognitive Annotation (UCCA)*. The word “cognitive” refers to the type of categories UCCA uses and its theoretical underpinnings, and “conceptual” stands in contrast to “syntactic”. The word “universal” refers to UCCA's capability to accommodate a highly rich set of semantic distinctions, and its aim to ultimately provide all the necessary semantic information for learning grammar. In order to accommodate this rich set of distinctions, UCCA is built as a multi-layered structure, which allows for its open-ended extension. This paper focuses on the foundational layer of UCCA, a coarse-grained layer that represents some of the most important relations expressed through linguistic utterances, including argument structure of verbs, nouns and adjectives, and the inter-relations between them (Section 2).

UCCA is supported by extensive typological cross-linguistic evidence and accords with the leading Cognitive Linguistics theories. We build primarily on Basic Linguistic Theory (BLT) (Dixon, 2005; 2010a; 2010b; 2012), a typological approach to grammar successfully used for the de-

scription of a wide variety of languages. BLT uses semantic similarity as its main criterion for categorizing constructions both within and across languages. UCCA takes a similar approach, thereby creating a set of distinctions that is motivated cross-linguistically. We demonstrate UCCA’s relative insensitivity to paraphrasing and to cross-linguistic variation in Section 4.

UCCA is exceptional in (1) being a semantic scheme that abstracts away from specific syntactic forms and is not defined relative to a specific domain or language, (2) providing a coarse-grained representation which allows for open-ended extension, and (3) using cognitively-motivated categories. An extensive comparison of UCCA to existing approaches to syntactic and semantic representation, focusing on the major resources available for English, is found in Section 5.

This paper also describes the compilation of a UCCA-annotated corpus. We provide a quantitative assessment of the annotation quality. Our results show a quick learning curve and no substantial difference in the performance of annotators with and without background in linguistics. This is an advantage of UCCA over its syntactic counterparts that usually need annotators with extensive background in linguistics (see Section 3).

We note that UCCA’s approach that advocates automatic learning of syntax from semantic supervision stands in contrast to the traditional view of generative grammar (Clark and Lappin, 2010).

## 2 The UCCA Scheme

### 2.1 The Formalism

UCCA uses directed acyclic graphs (DAGs) to represent its semantic structures. The atomic meaning-bearing units are placed at the leaves of the DAG and are called *terminals*. In the foundational layer, terminals are words and multi-word chunks, although this definition can be extended to include arbitrary morphemes.

The nodes of the graph are called *units*. A unit may be either (i) a terminal or (ii) several elements jointly viewed as a single entity according to some semantic or cognitive consideration. In many cases, a non-terminal unit is comprised of a single relation and the units it applies to (its arguments), although in some cases it may also contain secondary relations. Hierarchy is formed by using units as arguments or relations in other units.

Categories are annotated over the graph’s edges,

and represent the descendant unit’s role in forming the semantics of the parent unit. Therefore, the internal structure of a unit is represented by its outbound edges and their categories, while the roles a unit plays in the relations it participates in are represented by its inbound edges.

We note that UCCA’s structures reflect a single interpretation of the text. Several discretely different interpretations (e.g., high vs. low PP attachments) may therefore yield several different UCCA annotations.

UCCA is a multi-layered formalism, where each layer specifies the relations it encodes. The question of which relations will be annotated (equivalently, which units will be formed) is determined by the layer in question. For example, consider “John kicked his ball”, and assume our current layer encodes the relations expressed by “kicked” and by “his”. In that case, the unit “his” has a single argument<sup>1</sup> (“ball”), while “kicked” has two (“John” and “his ball”). Therefore, the units of the sentence are the terminals (which are always units), “his ball” and “John kicked his ball”. The latter two are units by virtue of expressing a relation along with its arguments. See Figure 2(a) for a graph representation of this example.

For a brief comparison of the UCCA formalism with other dependency annotations see Section 5.

### 2.2 The UCCA Foundational Layer

The foundational layer is designed to cover the entire text, so that each word participates in at least one unit. It focuses on argument structures of verbal, nominal and adjectival predicates and the inter-relations between them. Argument structure phenomena are considered basic by many approaches to semantic and grammatical representation, and have a high applicative value, as demonstrated by their extensive use in NLP.

The foundational layer views the text as a collection of *Scenes*. A Scene can describe some movement or action, or a temporally persistent state. It generally has a temporal and a spatial dimension, which can be specific to a particular time and place, but can also describe a schematized event which refers to many events by highlighting a common meaning component. For example, the Scene “John loves bananas” is a schematized event, which refers to John’s disposition towards bananas without making any temporal or spatial

---

<sup>1</sup>The anaphoric aspects of “his” are not considered part of the current layer (see Section 2.3).

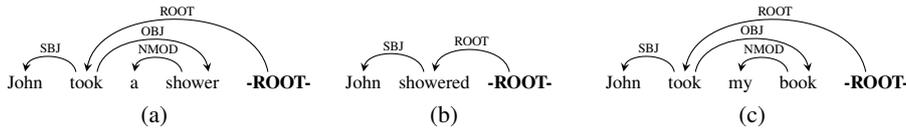

Figure 1: CoNLL-style dependency annotations. Note that (a) and (c), which have different semantics but superficially similar syntax, have the same annotation.

Abb.	Category	Short Definition
<b>Scene Elements</b>		
P	<b>Process</b>	The main relation of a Scene that evolves in time (usually an action or movement).
S	<b>State</b>	The main relation of a Scene that does not evolve in time.
A	<b>Participant</b>	A participant in a Scene in a broad sense (including locations, abstract entities and Scenes serving as arguments).
D	<b>Adverbial</b>	A secondary relation in a Scene (including temporal relations).
<b>Elements of Non-Scene Units</b>		
C	<b>Center</b>	Necessary for the conceptualization of the parent unit.
E	<b>Elaborator</b>	A non-Scene relation which applies to a single Center.
N	<b>Connector</b>	A non-Scene relation which applies to two or more Centers, highlighting a common feature.
R	<b>Relator</b>	All other types of non-Scene relations. Two varieties: (1) Rs that relate a C to some super-ordinate relation, and (2) Rs that relate two Cs pertaining to different aspects of the parent unit.
<b>Inter-Scene Relations</b>		
H	<b>Parallel Scene</b>	A Scene linked to other Scenes by regular linkage (e.g., temporal, logical, purposive).
L	<b>Linker</b>	A relation between two or more Hs (e.g., “when”, “if”, “in order to”).
G	<b>Ground</b>	A relation between the speech event and the uttered Scene (e.g., “surprisingly”, “in my opinion”).
<b>Other</b>		
F	<b>Function</b>	Does not introduce a relation or participant. Required by the structural pattern it appears in.

Table 1: The complete set of categories in UCCA’s foundational layer.

specifications. The definition of a Scene is motivated cross-linguistically and is similar to the semantic aspect of the definition of a “clause” in Basic Linguistic Theory<sup>2</sup>.

Table 1 provides a concise description of the categories used by the foundational layer<sup>3</sup>. We turn to a brief description of them.

**Simple Scenes.** Every Scene contains one main relation, which is the anchor of the Scene, the most important relation it describes (similar to frame-evoking lexical units in FrameNet (Baker et al., 1998)). We distinguish between static Scenes, that describe a temporally persistent state, and processual Scenes that describe a temporally evolving event, usually a movement or an action. The main relation receives the category *State* (*S*) in static and *Process* (*P*) in processual Scenes. We note that the S-P distinction is introduced here mostly for practical purposes, and that both categories can be viewed as sub-categories of the more abstract category Main Relation.

A Scene contains one or more *Participants* (*A*).

<sup>2</sup>As UCCA annotates categories on its edges, Scene nodes bear no special indication. They can be identified by examining the labels on their outgoing edges (see below).

<sup>3</sup>Repeated here with minor changes from (Abend and Rappoport, 2013), which focuses on the categories themselves.

This category subsumes concrete and abstract participants as well as embedded Scenes (see below). Scenes may also contain secondary relations, which are marked as *Adverbials* (*D*).

The above categories are indifferent to the syntactic category of the Scene-evoking unit, be it a verb, a noun, an adjective or a preposition. For instance, in the Scene “The book is in the garden”, “is in” is the *S*, while “the book” and “the garden” are *As*. In “Tomatoes are red”, the main static relation is “are red”, while “Tomatoes” is an *A*.

The foundational layer designates a separate set of categories to units that do not evoke a Scene. *Centers* (*C*) are the sub-units of a non-Scene unit that are necessary for the unit to be conceptualized and determine its semantic type. There can be one or more *Cs* in a non-Scene unit<sup>4</sup>.

Other sub-units of non-Scene units are categorized into three types. First, units that apply to a single *C* are annotated as *Elaborators* (*E*). For instance, “big” in “big dogs” is an *E*, while “dogs” is a *C*. We also mark determiners as *Es* in this coarse-grained layer<sup>5</sup>. Second, relations that relate two or

<sup>4</sup>By allowing several *Cs* we avoid the difficulties incurred by the common single head assumption. In some cases the *Cs* are inferred from context and can be implicit.

<sup>5</sup>Several *Es* that apply to a single *C* are often placed in

more Cs, highlighting a common feature or role (usually coordination), are called *Connectors (N)*. See an example in Figure 2(b).

*Relators (R)* cover all other types of relations between two or more Cs. Rs appear in two main varieties. In one, Rs relate a single entity to a super-ordinate relation. For instance, in “I heard noise in the kitchen”, “in” relates “the kitchen” to the Scene it is situated in. In the other, Rs relate two units pertaining to different aspects of the same entity. For instance, in “bottom of the sea”, “of” relates “bottom” and “the sea”, two units that refer to different aspects of the same entity.

Some units do not introduce a new relation or entity into the Scene, and are only part of the formal pattern in which they are situated. Such units are marked as *Functions (F)*. For example, in the sentence “it is customary for John to come late”, the “it” does not refer to any specific entity or relation and is therefore an F.

Two example annotations of simple Scenes are given in Figure 2(a) and Figure 2(b).

**More complex cases.** UCCA allows units to participate in more than one relation. This is a natural requirement given the wealth of distinctions UCCA is designed to accommodate. Already in the foundational layer of UCCA, the need arises for multiple parents. For instance, in “John asked Mary to join him”, “Mary” is a Participant of both the “asking” and the “joining” Scenes.

In some cases, an entity or relation is prominent in the interpretation of the Scene, but is not mentioned explicitly anywhere in the text. We mark such entities as *Implicit Units*. Implicit units are identical to terminals, except that they do not correspond to a stretch of text. For example, “playing games is fun” has an implicit A which corresponds to the people playing the game.

UCCA annotates inter-Scene relations (linkage) and, following Basic Linguistic Theory, distinguishes between three major types of linkage. First, a Scene can be an A in another Scene. For instance, in “John said he must leave”, “he must leave” is an A inside the Scene evoked by “said”. Second, a Scene may be an E of an entity in another Scene. For instance, in “the film we saw yesterday was wonderful”, “film we saw yesterday” is a Scene that serves as an E of “film”, which is both an A in the Scene and the Center of an A in the

a flat structure. In general, the coarse-grained foundational layer does not try to resolve fine scope issues.

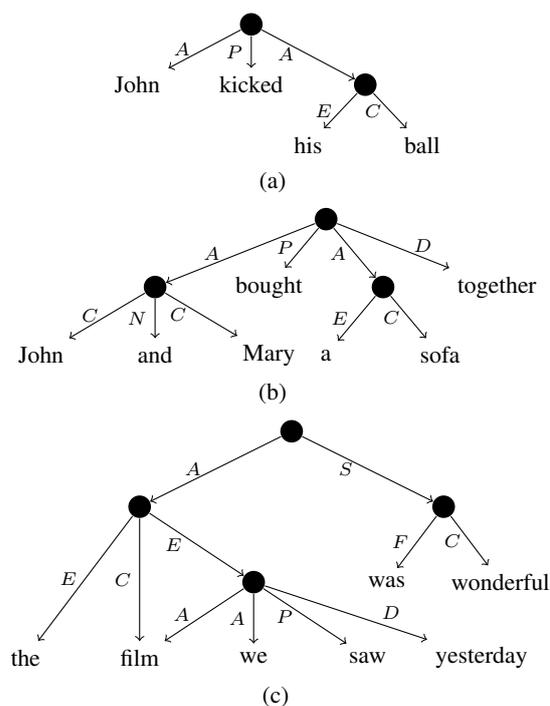

Figure 2: Examples of UCCA annotation graphs.

Scene evoked by “wonderful” (see Figure 2(c)).

A third type of linkage covers all other cases, e.g., temporal, causal and conditional inter-Scene relations. The linked Scenes in such cases are marked as *Parallel Scenes (H)*. The units specifying the relation between Hs are marked as *Linkers (L)*<sup>6</sup>. As with other relations in UCCA, Linkers and the Scenes they link are bound by a unit.

Unlike common practice in grammatical annotation, linkage relations in UCCA can cross sentence boundaries, as can relations represented in other layers (e.g., coreference). UCCA therefore annotates texts comprised of several paragraphs and not individual sentences (see Section 3).

**Example sentences.** Following are complete annotations of two abbreviated example sentences from our corpus (see Section 3).

“Golf became a passion for his oldest daughter: she took daily lessons and became very good, reaching the Connecticut Golf Championship.”

This sentence contains four Scenes, evoked by “became a passion”, “took daily lessons”, “became very good” and “reaching”. The individual Scenes are annotated as follows:

1. “Golf<sub>A</sub> [became<sub>E</sub> a<sub>E</sub> passion<sub>C</sub>]<sub>P</sub> [for<sub>R</sub> his<sub>E</sub> oldest<sub>E</sub> daughter<sub>C</sub>]<sub>A</sub>”

<sup>6</sup>It is equally plausible to include Linkers for the other two linkage types. This is not included in the current layer.

2. “she<sub>A</sub> [took<sub>F</sub> [daily<sub>E</sub> lessons<sub>C</sub>]<sub>C</sub>]<sub>P</sub>”
3. “she<sub>A</sub> ... [became<sub>E</sub> [very<sub>E</sub> good<sub>C</sub>]<sub>C</sub>]<sub>S</sub>”
4. “she<sub>A</sub> ... reaching<sub>P</sub> [the<sub>E</sub> Connecticut<sub>E</sub> Golf<sub>E</sub> Championship<sub>C</sub> ]<sub>A</sub>”

There is only one explicit Linker in this sentence (“and”), which links Scenes (2) and (3). None of the Scenes is an A or an E in the other, and they are therefore all marked as Parallel Scenes. We also note that in the case of the light verb construction “took lessons” and the copula clauses “became good” and “became a passion”, the verb is not the Center of the main relation, but rather the following noun or adjective. We also note that the unit “she” is an A in Scenes (2), (3) and (4).

We turn to our second example:

“Cukor encouraged the studio to  
accept her demands.”

This sentence contains three Scenes, evoked by “encouraged”, “accept” and “demands”:

1. Cukor<sub>A</sub> encouraged<sub>P</sub> [the<sub>E</sub> studio<sub>C</sub>]<sub>A</sub> [to<sub>R</sub> [accept her demands]<sub>C</sub> ]<sub>A</sub>
2. [the studio]<sub>A</sub> ... accept<sub>P</sub> [her demands]<sub>A</sub>
3. her<sub>A</sub> demands<sub>P</sub> **IMP**<sub>A</sub>

Scenes (2) and (3) act as Participants in Scenes (1) and (2) respectively. In Scene (2), there is an implicit Participant which corresponds to whatever was demanded. Note that “her demands” is a Scene, despite being a noun phrase.

### 2.3 UCCA’s Multi-layered Structure

Additional layers may refine existing relations or otherwise annotate a complementary set of distinctions. For instance, a refinement layer can categorize linkage relations according to their semantic types (e.g., temporal, purposive, causal) or provide tense distinctions for verbs. Another immediate extension to UCCA’s foundational layer can be the annotation of coreference relations. Recall the example “John kicked his ball”. A coreference layer would annotate a relation between “John” and “his” by introducing a new node whose descendants are these two units. The fact that this node represents a coreference relation would be represented by a label on the edge connecting them to the coreference node.

There are three common ways to extend an annotation graph. First, by adding a relation that relates previously established units. This is done by introducing a new node whose descendants are the related units. Second, by adding an intermediate

	Passage #					
	1	2	3	4	5	6
# Sents.	8	20	23	14	13	15
# Tokens	259	360	343	322	316	393
ITA	67.3	74.1	71.2	73.5	77.8	81.1
Vs. Gold	72.4	76.7	75.5	75.7	79.5	84.2
Correction	<b>93.7</b>					

Table 2: The upper part of the table presents the number of sentences and the number of tokens in the first passages used for the annotator training. The middle part presents the average F-scores obtained by the annotators throughout these passages. The first row presents the average F-score when comparing the annotations of the different annotators among themselves. The second row presents the average F-score when comparing them to a “gold standard”. The bottom row shows the average F-score between an annotated passage of a trained annotator and its manual correction by an expert. It is higher due to *conforming analyses* (see text). All F-scores are in percents.

unit between a parent unit and some of its sub-units. For instance, consider “he replied foolishly” and “he foolishly replied”. A layer focusing on Adverbial scope may refine the flat Scene structure assigned by the foundational layer, expressing the scope of “foolishly” over the relation “replied” in the first case, and over the entire Scene in the second. Third, by adding sub-units to a terminal. For instance, consider “gave up”, an expression which the foundational layer considers atomic. A layer that annotates tense can break the expression into “gave” and “up”, in order to annotate “gave” as the tense-bearing unit.

Although a more complete discussion of the formalism is beyond the scope of this paper, we note that the formalism is designed to allow different annotation layers to be defined and annotated independently of one another, in order to facilitate UCCA’s construction through a community effort.

### 3 A UCCA-Annotated Corpus

The annotated text is mostly based on English Wikipedia articles for celebrities. We have chosen this genre as it is an inclusive and diverse domain, which is still accessible to annotators from varied backgrounds.

For the annotation process, we designed and implemented a web application tailored for UCCA’s annotation. A sample of the corpus containing roughly 5K tokens, as well as the annotation application can be found in our website<sup>7</sup>.

UCCA’s annotations are not confined to a single sentence. The annotation is therefore carried out in passages of 300-400 tokens. After its an-

<sup>7</sup>[www.cs.huji.ac.il/~omria01](http://www.cs.huji.ac.il/~omria01)

notation, a passage is manually corrected before being inserted into the repository.

The section of the corpus annotated thus far contains 56890 tokens in 148 annotated passages (average length of 385 tokens). Each passage contains 450 units on average and 42.2 Scenes. Each Scene contains an average of 2 Participants and 0.3 Adverbials. 15% of the Scenes are static (contain an S as the main relation) and the rest are dynamic (containing a P). The average number of tokens in a Scene (excluding punctuation) is 10.7. 18.3% of the Scenes are Participants in another Scene, 11.4% are Elaborator Scenes and the remaining are Parallel Scenes. A passage contains an average of 11.2 Linkers.

**Inter-annotator agreement.** We employ 4 annotators with varying levels of background in linguistics. Two of the annotators have no background in linguistics, one took an introductory course and one holds a Bachelor's degree in linguistics. The training process of the annotators lasted 30–40 hours, which includes the time required for them to get acquainted with the web application. As this was the first large-scale trial with the UCCA scheme, some modifications to the scheme were made during the annotator's training. We therefore expect the training process to be even faster in later distributions.

There is no standard evaluation measure for comparing two grammatical annotations in the form of labeled DAGs. We therefore converted UCCA to constituency trees<sup>8</sup> and, following standard practice, computed the number of brackets in both trees that match in both span and label. We derive an F-score from these counts.

Table 2 presents the inter-annotator agreement in the training phase. The four annotators were given the same passage in each of these cases. In addition, a “gold standard” was annotated by the authors of this paper. The table presents the average F-score between the annotators, as well as the average F-score when comparing to the gold standard. Results show that although it represents complex hierarchical structures, the UCCA scheme is learned quickly and effectively.

We also examined the influence of prior linguistic background on the results. In the first passage there was a substantial advantage to the annotators

<sup>8</sup>In cases a unit had multiple parents, we discarded all but one of its incoming edges. This resulted in discarding 1.9% of the edges. We applied a simple normalization procedure to the resulting trees.

who had prior training in linguistics. The obtained F-scores when comparing to a gold standard, ordered decreasingly according to the annotator's acquaintance with linguistics, were 78%, 74.4%, 69.5% and 67.8%. However, this performance gap quickly vanished. Indeed, the obtained F-scores, again compared to a gold standard and averaged over the next five training passages, were (by the same order) 78.6%, 77.3%, 79.2% and 78%.

This is an advantage of UCCA over other syntactic annotation schemes that normally require highly proficient annotators. For instance, both the PTB and the Prague Dependency Treebank (Böhmová et al., 2003) employed annotators with extensive linguistic background. Similar findings to ours were reported in the PropBank project, which successfully employed annotators with various levels of linguistic background. We view this as a major advantage of semantic annotation schemes over their syntactic counterparts, especially given the huge amount of manual labor required for large syntactic annotation projects.

The UCCA interface allows for multiple non-contradictory (“conforming”) analyses of a stretch of text. It assumes that in some cases there is more than one acceptable option, each highlighting a different aspect of meaning of the analyzed utterance (see below). This makes the computation of inter-annotator agreement fairly difficult. It also suggests that the above evaluation is excessively strict, as it does not take into account such conforming analyses. To address this issue, we conducted another experiment where an expert annotator corrected the produced annotations. Comparing the corrected versions to the originals, we found that F-scores are typically in the range of 90%–95%. An average taken over a sample of passages annotated by all four annotators yielded an F-score of 93.7%.

It is difficult to compare the above results to the inter-annotator agreement of other projects for two reasons. First, many existing schemes are based on other annotation schemes or heavily rely on automatic tools for providing partial annotations. Second, some of the most prominent annotation projects do not provide reliable inter-annotator agreement scores (Artstein and Poesio, 2008).

A recent work that did report inter-annotator agreement in terms of bracketing F-score is an annotation project of the PTB's noun phrases with more elaborate syntactic structure (Vadas and Cur-

ran, 2011). They report an agreement of 88.3% in a scenario where their two annotators worked separately. Note that this task is much more limited in scope than UCCA (annotates noun phrases instead of complete passages in UCCA; uses 2 categories instead of 12 in UCCA). Nevertheless, the obtained inter-annotator agreement is comparable.

**Disagreement examples.** Here we discuss two major types of disagreements that recurred in the training process. The first is the distinction between Elaborators and Centers. In most cases this distinction is straightforward, particularly where one sub-unit determines the semantic type of the parent unit, while its siblings add more information to it (e.g., “truck<sub>E</sub> company<sub>C</sub>” is a type of a company and not of a truck). Some structures do not nicely fall into this pattern. One such case is with apposition. In the example “the Fox drama Glory days”, both “the Fox drama” and “Glory days” are reasonable candidates for being a Center, which results in disagreements.

Another case is the distinction between Scenes and non-Scene relations. Consider the example “[John’s portrayal of the character] has been described as ...”. The sentence obviously contains two scenes, one in which John portrays a character and another where someone describes John’s doings. Its internal structure is therefore “John’s<sub>A</sub> portrayal<sub>P</sub> [of the character]<sub>A</sub>”. However, the syntactic structure of this unit leads annotators at times into analyzing the subject as a non-Scene relation whose C is “portrayal”.

Static relations tend to be more ambiguous between a Scene and a non-Scene interpretation. Consider “Jane Smith (née Ross)”. It is not at all clear whether “née Ross” should be annotated as a Scene or not. Even if we do assume it is a Scene, it is not clear whether the Scene it evokes is her Scene of birth, which is dynamic, or a static Scene which can be paraphrased as “originally named Ross”. This leads to several conforming analyses, each expressing a somewhat different conceptualization of the Scene. This central notion will be more elaborately addressed in future work.

We note that all of these disagreements can be easily resolved by introducing an additional layer focusing on the construction in question.

#### 4 UCCA’s Benefits to Semantic Tasks

UCCA’s relative insensitivity to syntactic forms has potential benefits for a wide variety of seman-

tic tasks. This section briefly demonstrates these benefits through a number of examples.

Recall the example “John took a shower” (Section 1). UCCA annotates the sentence as a single Scene, with a single Participant and a processual main relation: “John<sub>A</sub> [took<sub>F</sub> [a<sub>E</sub> shower<sub>C</sub>]<sub>C</sub>]<sub>P</sub>”. The paraphrase “John showered” is annotated similarly: “John<sub>A</sub> showered<sub>P</sub>”. The structure is also preserved under translation to other languages, such as German (“John<sub>A</sub> duschte<sub>P</sub>”, where “duschte” is a verb), or Portuguese “John<sub>A</sub> [tomou<sub>F</sub> banho<sub>C</sub>]<sub>P</sub>” (literally, John took shower). In all of these cases, UCCA annotates the example as a Scene with an A and a P, whose Center is a word expressing the notion of showering.

Another example is the sentence “John does not have any money”. The foundational layer of UCCA annotates negation units as Ds, which yields the annotation “John<sub>A</sub> [does<sub>F</sub>]<sub>S</sub>- not<sub>D</sub> [have<sub>C</sub>]<sub>-S</sub> [any<sub>E</sub> money<sub>C</sub>]<sub>A</sub>” (where “does ... have” is a discontinuous unit)<sup>9</sup>. This sentence can be paraphrased as “John<sub>A</sub> has<sub>P</sub> no<sub>D</sub> money<sub>A</sub>”. UCCA reflects the similarity of these two sentences, as it annotates both cases as a single Scene which has two Participants and a negation. A syntactic scheme would normally annotate “no” in the second sentence as a modifier of “money”, and “not” as a negation of “have”.

The value of UCCA’s annotation can again be seen in translation to languages that have only one of these forms. For instance, the German translation of this sentence, “John<sub>A</sub> hat<sub>S</sub> kein<sub>D</sub> Geld<sub>A</sub>”, is a literal translation of “John has no money”. The Hebrew translation of this sentence is “eyn le john kesef” (literally, “there-is-no to John money”). The main relation here is therefore “eyn” (there-is-no) which will be annotated as *S*. This yields the annotation “eyn<sub>S</sub> [le<sub>R</sub> John<sub>C</sub>]<sub>A</sub> kesef<sub>A</sub>”.

The UCCA annotation in all of these cases is composed of two Participants and a State. In English and German, the negative polarity unit is represented as a D. The negative polarity of the Hebrew “eyn” is represented in a more detailed layer.

As a third example, consider the two sentences “There are children playing in the park” and “Children are playing in the park”. The two sentences have a similar meaning but substantially different syntactic structures. The first contains two clauses, an existential main clause (headed by “there are”)

<sup>9</sup>The foundational layer places “not” in the Scene level to avoid resolving fine scope issues (see Section 2)

and a subordinate clause (“playing in the park”). The second contains a simple clause headed by “playing”. While the parse trees of these sentences are very different, their UCCA annotation in the foundational layer differ only in terms of Function units: “Children<sub>A</sub> [are<sub>F</sub> playing<sub>C</sub>]<sub>P</sub> [in<sub>R</sub> the<sub>E</sub> park<sub>C</sub>]<sub>A</sub>” and “There<sub>F</sub> are<sub>F</sub> children<sub>A</sub> [playing]<sub>P</sub> [in<sub>R</sub> the<sub>E</sub> park<sub>C</sub>]<sub>A</sub>”<sup>10</sup>.

Aside from machine translation, a great variety of semantic tasks can benefit from a scheme that is relatively insensitive to syntactic variation. Examples include text simplification (e.g., for second language teaching) (Siddharthan, 2006), paraphrase detection (Dolan et al., 2004), summarization (Knight and Marcu, 2000), and question answering (Wang et al., 2007).

## 5 Related Work

In this section we compare UCCA to some of the major approaches to grammatical representation in NLP. We focus on English, which is the most studied language and the focus of this paper.

Syntactic annotation schemes come in many forms, from lexical categories such as POS tags to intricate hierarchical structures. Some formalisms focus particularly on syntactic distinctions, while others model the syntax-semantics interface as well (Kaplan and Bresnan, 1981; Pollard and Sag, 1994; Joshi and Schabes, 1997; Steedman, 2001; Sag, 2010, *inter alia*). UCCA diverges from these approaches in aiming to abstract away from specific syntactic forms and to only represent semantic distinctions. Put differently, UCCA advocates an approach that treats syntax as a hidden layer when learning the mapping between form and meaning, while existing syntactic approaches aim to model it manually and explicitly.

UCCA does not build on any other annotation layers and therefore implicitly assumes that semantic annotation can be learned directly. Recent work suggests that indeed structured prediction methods have reached sufficient maturity to allow direct learning of semantic distinctions. Examples include Naradowsky et al. (2012) for semantic role labeling and Kwiatkowski et al. (2010) for semantic parsing to logical forms. While structured prediction for the task of predicting tree structures is already well established (e.g., (Suzuki et al.,

2009)), recent work has also successfully tackled the task of predicting semantic structures in the form of DAGs (Jones et al., 2012).

The most prominent annotation scheme in NLP for English syntax is the Penn Treebank. Many syntactic schemes are built or derived from it. An increasingly popular alternative to the PTB are dependency structures, which are usually represented as trees whose nodes are the words of the sentence (Ivanova et al., 2012). Such representations are limited due to their inability to naturally represent constructions that have more than one head, or in which the identity of the head is not clear. They also face difficulties in representing units that participate in multiple relations. UCCA proposes a different formalism that addresses these problems by introducing a new node for every relation (cf. (Sangati and Mazza, 2009)).

Several annotated corpora offer a joint syntactic and semantic representation. Examples include the Groningen Meaning bank (Basile et al., 2012), Treebank Semantics (Butler and Yoshimoto, 2012) and the Lingo Redwoods treebank (Oepen et al., 2004). UCCA diverges from these projects in aiming to abstract away from syntactic variation, and is therefore less coupled with a specific syntactic theory.

A different strand of work addresses the construction of an interlingual representation, often with a motivation of applying it to machine translation. Examples include the UNL project (Uchida and Zhu, 2001), the IAMTC project (Dorr et al., 2010) and the AMR project (Banarescu et al., 2012). These projects share with UCCA their emphasis on cross-linguistically valid annotations, but diverge from UCCA in three important respects. First, UCCA emphasizes the notion of a multi-layer structure where the basic layers are maximally coarse-grained, in contrast to the above works that use far more elaborate representations. Second, from a theoretical point of view, UCCA differs from these works in aiming to represent conceptual semantics, building on works in Cognitive Linguistics (e.g., (Langacker, 2008)). Third, unlike interlingua that generally define abstract representations that may correspond to several different texts, UCCA incorporates the text into its structure, thereby facilitating learning.

Semantic role labeling (SRL) schemes bear similarity to the foundational layer, due to their focus on argument structure. The leading SRL ap-

<sup>10</sup>The two sentences are somewhat different in terms of their information structure (Van Valin Jr., 2005), which is represented in a more detailed UCCA layer.

proaches are PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004) on the one hand, and FrameNet (Baker et al., 1998) on the other. At this point, all these schemes provide a more fine-grained set of categories than UCCA.

PropBank and NomBank are built on top of the PTB annotation, and provide for each verb (PropBank) and noun (NomBank), a delineation of their arguments and their categorization into semantic roles. Their structures therefore follow the syntax of English quite closely. UCCA is generally less tailored to the syntax of English (e.g., see secondary verbs (Dixon, 2005)).

Furthermore, PropBank and NomBank do not annotate the internal structure of their arguments. Indeed, the construction of the commonly used semantic dependencies derived from these schemes (Surdeanu et al., 2008) required a set of syntactic head percolation rules to be used. These rules are somewhat arbitrary (Schwartz et al., 2011), do not support multiple heads, and often reflect syntactic rather than semantic considerations (e.g., “millions” is the head of “millions of dollars”, while “dollars” is the head of “five million dollars”).

Another difference is that PropBank and NomBank each annotate only a subset of predicates, while UCCA is more inclusive. This difference is most apparent in cases where a single complex predicate contains both nominal and verbal components (e.g., “limit access”, “take a shower”). In addition, neither PropBank nor NomBank address copula clauses, despite their frequency. Finally, unlike PropBank and NomBank, UCCA’s foundational layer annotates linkage relations.

In order to quantify the similarity between UCCA and PropBank, we annotated 30 sentences from the PropBank corpus with their UCCA annotations and converted the outcome to PropBank-style annotations<sup>11</sup>. We obtained an unlabeled F-score of 89.4% when comparing to PropBank, which indicates that PropBank-style annotations are generally derivable from UCCA’s. The disagreement between the schemes reflects both annotation conventions and principle differences, some of which were discussed above.

The FrameNet project (Baker et al., 1998)

<sup>11</sup>The experiment was conducted on the first 30 sentences of section 02. The identity of the predicates was determined according to the PropBank annotation. We applied a simple conversion procedure that uses half a dozen rules that are not conditioned on any lexical item. We used a strict evaluation that requires an exact match in the argument’s boundaries.

proposes a comprehensive approach to semantic roles. It defines a lexical database of Frames, each containing a set of possible frame elements and their semantic roles. It bears similarity to UCCA both in its use of Frames, which are a context-independent abstraction of UCCA’s Scenes, and in its emphasis on semantic rather than distributional considerations. However, despite these similarities, FrameNet focuses on constructing a lexical resource covering specific cases of interest, and does not provide a fully annotated corpus of naturally occurring text. UCCA’s foundational layer can be seen as a complementary effort to FrameNet, as it focuses on high-coverage, coarse-grained annotation, while FrameNet is more fine-grained at the expense of coverage.

## 6 Conclusion

This paper presented Universal Conceptual Cognitive Annotation (UCCA), a novel framework for semantic representation. We described the foundational layer of UCCA and the compilation of a UCCA-annotated corpus. We demonstrated UCCA’s relative insensitivity to paraphrases and cross-linguistic syntactic variation. We also discussed UCCA’s accessibility to annotators with no background in linguistics, which can alleviate the almost prohibitive annotation costs of large syntactic annotation projects.

UCCA’s representation is guided by conceptual notions and has its roots in the Cognitive Linguistics tradition and specifically in Cognitive Grammar (Langacker, 2008). These theories represent the meaning of an utterance according to the mental representations it evokes and not according to its reference in the world. Future work will explore options to further reduce manual annotation, possibly by combining texts with visual inputs during training.

We are currently attempting to construct a parser for UCCA and to apply it to several semantic tasks, notably English-French machine translation. Future work will also discuss UCCA’s portability across domains. We intend to show that UCCA, which is less sensitive to the idiosyncrasies of a specific domain, can be easily adapted to highly dynamic domains such as social media.

**Acknowledgements.** We would like to thank Tomer Eshet for partnering in the development of the web application and to Amit Beka for his help with UCCA’s software and development set.

## Abstract

Many current Natural Language Processing [NLP] techniques work well assuming a large context of text as input data. However they become ineffective when applied to short texts such as Twitter feeds. To overcome the issue, we want to find a related newswire document to a given tweet to provide contextual support for NLP tasks. This requires robust modeling and understanding of the semantics of short texts.

The contribution of the paper is two-fold: 1. we introduce the Linking-Tweets-to-News task as well as a dataset of linked tweet-news pairs, which can benefit many NLP applications; 2. in contrast to previous research which focuses on lexical features within the short texts (text-to-word information), we propose a graph based latent variable model that models the inter short text correlations (text-to-text information). This is motivated by the observation that a tweet usually only covers one aspect of an event. We show that using tweet specific feature (hashtag) and news specific feature (named entities) as well as temporal constraints, we are able to extract text-to-text correlations, and thus completes the semantic picture of a short text. Our experiments show significant improvement of our new model over baselines with three evaluation metrics in the new task.

## 1 Introduction

Recently there has been an increasing interest in language understanding of Twitter messages. Researchers (Speriosui et al., 2011; Brody and Diakopoulos, 2011; Jiang et al., 2011) were in-

terested in sentiment analysis on Twitter feeds, and opinion mining towards political issues or politicians (Tumasjan et al., 2010; Conover et al., 2011). Others (Ramage et al., 2010; Jin et al., 2011) summarized tweets using topic models. Although these NLP techniques are mature, their performance on tweets inevitably degrades, due to the inherent sparsity in short texts. In the case of sentiment analysis, while people are able to achieve 87.5% accuracy (Maas et al., 2011) on a movie review dataset (Pang and Lee, 2004), the performance drops to 75% (Li et al., 2012) on a sentence level movie review dataset (Pang and Lee, 2005). The problem worsens when some existing NLP systems cannot produce any results given the short texts. Considering the following tweet:

*Pray for Mali...*

A typical event extraction/discovery system (Ji and Grishman, 2008) fails to discover the *war* event due to the lack of context information (Benson et al., 2011), and thus fails to shed light on the users focus/interests.

To enable the NLP tools to better understand Twitter feeds, we propose the task of linking a tweet to a news article that is relevant to the tweet, thereby augmenting the context of the tweet. For example, we want to supplement the implicit context of the above tweet with a news article such as the following entitled:

*State of emergency declared in Mali*

where abundant evidence can be fed into an off-the-shelf event extraction/discovery system. To create a gold standard dataset, we download tweets spanning over 18 days, each with a url linking to a news article of CNN or NYTIMES, as well as all the news of CNN and NYTIMES published during the period. The goal is to predict the url referred news article based on the text in each tweet.<sup>1</sup> We

<sup>1</sup>The data and code is publicly available at [www.cs.columbia.edu/~weiwei/](http://www.cs.columbia.edu/~weiwei/)

believe many NLP tasks will benefit from this task. In fact, in the topic modeling research, previous work (Jin et al., 2011) already showed that by incorporating webpages whose urls are contained in tweets, the tweet clustering purity score was boosted from 0.280 to 0.392.

Given the few number of words in a tweet (14 words on average in our dataset), the traditional high dimensional surface word matching is lossy and fails to pinpoint the news article. This constitutes a classic short text semantics impediment (Agirre et al., 2012). Latent variable models are powerful by going beyond the surface word level and mapping short texts into a low dimensional dense vector (Socher et al., 2011; Guo and Diab, 2012b). Accordingly, we apply a latent variable model, namely, the Weighted Textual Matrix Factorization [WTMF] (Guo and Diab, 2012b; Guo and Diab, 2012c) to both the tweets and the news articles. WTMF is a state-of-the-art unsupervised model that was tested on two short text similarity datasets: (Li et al., 2006) and (Agirre et al., 2012), which outperforms Latent Semantic Analysis [LSA] (Landauer et al., 1998) and Latent Dirichlet Allocation [LDA] (Blei et al., 2003) by a large margin. We employ it as a strong baseline in this task as it exploits and effectively models the missing words in a tweet, in practice adding thousands of more features for the tweet, by contrast LDA, for example, only leverages observed words (14 features) to infer the latent vector for a tweet.

Apart from the data sparseness, our dataset proposes another challenge: a tweet usually covers only one aspect of an event. In our previous example, the tweet only contains the location *Mali* while the event is about French army participated in Mali war. In this scenario, we would like to find the missing elements of the tweet such as *French, war* from other short texts, to complete the semantic picture of *Pray in Mali* tweet. One drawback of WTMF for our purposes is that it simply models the text-to-word information without leveraging the correlation between short texts. While this is acceptable on standard short text similarity datasets (data points are independently generated), it ignores some valuable information characteristically present in our dataset: (1) The tweet specific features such as hashtags. Hashtags prove to be a direct indication of the semantics of tweets (Ramage et al., 2010); (2) The news specific features

such as named entities in a document. Named entities acquired from a news document, typically with high accuracy using Named Entity Recognition [NER] tools, may be particularly informative. If two texts mention the same entities then they might describe the same event; (3) The temporal information in both genres (tweets and news articles). We note that there is a higher chance of event description overlap between two texts if their time of publication is similar.

In this paper, we study the problem of mining and exploiting correlations between texts using these features. Two texts may be considered related or complementary if they share a hashtag/NE or satisfies the temporal constraints. Our proposed latent variable model not only models text-to-word information, but also is aware of the text-to-text information (illustrated in Figure 1): two linked texts should have similar latent vectors, accordingly the semantic picture of a tweet is completed by receiving semantics from its related tweets. We incorporate this additional information in the WTMF model. We also show the different impact of the text-to-text relations in the tweet genre and news genre. We are able to achieve significantly better results than with a text-to-words WTMF model. This work can be regarded as a short text modeling approach that extends previous work however with a focus on combining the mining of information within short texts coupled with utilizing extra shared information across the short texts.

## 2 Task and Data

The task is given the text in a tweet, a system aims to find the most relevant news article. For gold standard data, we harvest all the tweets that have a single url link to a CNN or NYTIMES news article, dated from the 11th of Jan to the 27th of Jan, 2013. In evaluation, we consider this url-referred news article as the gold standard – the most relevant document for the tweet, and remove the url from the text of the tweet. We also collect all the news articles from both CNN and NYTIMES from RSS feeds during the same timeframe. Each tweet entry has the **published time, author, text**; each news entry contains **published time, title, news summary, url**. The tweet/news pairs are extracted by matching urls. We manually filtered “trivial” tweets where the tweet content is simply the news title or news summary. The final dataset results in

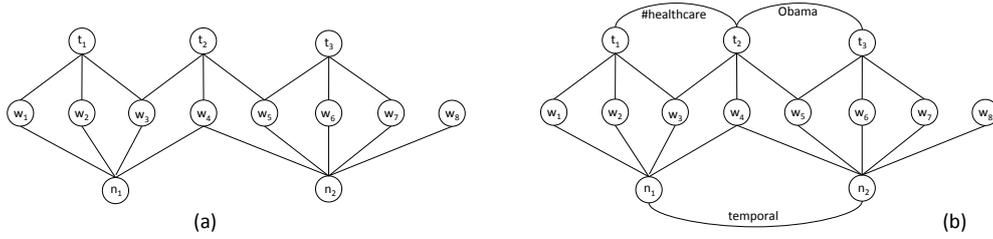

Figure 1: (a) WTMF. (b) WTMF-G: the tweet nodes  $t$  and news nodes  $n$  are connected by hashtags, named entities or temporal edges (for simplicity, the missing tokens are not shown in the figure)

34,888 tweets and 12,704 news articles.

It is worth noting that the news corpus is not restricted to current events. It covers various genres and topics, such as travel guides. e.g. *World’s most beautiful lakes*, and health issues, e.g. *The importance of a ‘stop day’*, etc.

### 2.1 Evaluation metric

For our task evaluation, ideally, we would like the system to be able to identify the news article specifically referred to by the url within each tweet in the gold standard. However, this is very difficult given the large number of potential candidates, especially those with slight variations. Therefore, following the Concept Definition Retrieval task in (Guo and Diab, 2012b) and (Steck, 2010) we use a metric for evaluating the ranking of the correct news article to evaluate the systems, namely,  $ATOP_t$ , *area under the TOPK<sub>t</sub>(k) recall curve for a tweet t*. Basically, it is the normalized ranking  $\in [0, 1]$  of the correct news article among all candidate news articles:  $ATOP_t = 1$  means the url-referred news article has the highest similarity value with the tweet (a correct NARU);  $ATOP_t = 0.95$  means the similarity value with correct news article is larger than 95% of the candidates, i.e. within the top 5% of the candidates.  $ATOP_t$  is calculated as follows:

$$ATOP_t = \int_0^1 TOPK_t(k) dk \quad (1)$$

where  $TOPK_t(k) = 1$  if the url referred news article is in the “top  $k$ ” list, otherwise  $TOPK_t(k) = 0$ . Here  $k \in [0, 1]$  is the relative position (when  $k = 1$ , it means all the candidates).

We also include other metrics to examine if the system is able to rank the url referred news article in the first few returned results: **TOP10** recall hit rate to evaluate whether the correct news is in the top 10 results, and **RR**, Reciprocal Rank=  $1/r$

(i.e.,  $RR = 1/3$  when the correct news article is ranked at the 3rd highest place).

## 3 Weighted Textual Matrix Factorization

The WTMF model (Guo and Diab, 2012a) has been successfully applied to the short text similarity task, achieving state-of-the-art unsupervised performance. This can be attributed to the fact that it models the missing tokens as features, thereby adding many more features for a short text. The missing words of a sentence are defined as all the vocabulary of the training corpus minus the observed words in a sentence. Missing words serve as negative examples for the semantics of a short text: the short text should not be related to the missing words.

As per (Guo and Diab, 2012b), the corpus is represented in a matrix  $X$ , where each cell stores the TF-IDF values of words. The rows of  $X$  are words and columns are short texts. As in Figure 2, matrix  $X$  is approximated by the product of a  $K \times M$  matrix  $P$  and a  $K \times N$  matrix  $Q$ . Accordingly, each sentence  $s_j$  is represented by a  $K$  dimensional latent vector  $Q_{\cdot,j}$ . Similarly a word  $w_i$  is generalized by  $P_{\cdot,i}$ . Therefore, the inner product of a word vector  $P_{\cdot,i}$  and a short text vector  $Q_{\cdot,j}$  is to approximate the cell  $X_{ij}$  (shaded part in Figure 2). In this way, the missing words are modeled by requiring the inner product of a word vector and short text vector to be close to 0 (the word and the short text should be irrelevant).

Since 99% cells in  $X$  are missing tokens (0 value), the impact of observed words is significantly diminished. Therefore a small weight  $w_m$  is assigned for each 0 cell (missing tokens) in the matrix  $X$  in order to preserve the influence of observed words.  $P$  and  $Q$  are optimized by minimize the objective function:

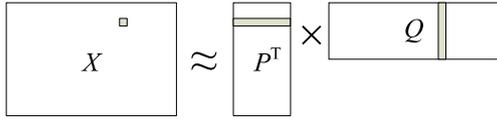

Figure 2: Weighted Textual Matrix Factorization

$$\sum_i \sum_j W_{ij} (P_{\cdot,i} \cdot Q_{\cdot,j} - X_{ij})^2 + \lambda \|P\|_2^2 + \lambda \|Q\|_2^2$$

$$W_{i,j} = \begin{cases} 1, & \text{if } X_{ij} \neq 0 \\ w_m, & \text{if } X_{ij} = 0 \end{cases} \quad (2)$$

where  $\lambda$  is a regularization term.

## 4 Creating Text-to-text Relations via Twitter/News Features

WTMF exploits the text-to-word information in a very nuanced way, while the dependency between texts is ignored. In this Section, we introduce how to create text-to-text relations.

### 4.1 Hashtags and Named Entities

Hashtags highlight the topics in tweets, e.g., *The #flu season has started*. We believe two tweets sharing the same hashtag should be related, hence we place a link between them to explicitly inform the model that these two tweets should be similar.

We find only 8,701 tweets out of 34,888 include hashtags. In fact, we observe many hashtag words are mentioned in tweets without explicitly being tagged with #. To overcome the hashtag sparseness issue, one can resort to keywords recommendation algorithms to mine hashtags for the tweets (Yang et al., 2012). In this paper, we adopt a simple but effective approach: we collect all the hashtags in the dataset, and automatically hashtag any word in a tweet if that word appears hashtagged in any other tweets. This process resulted in 33,242 tweets automatically labeled with hashtags. For each tweet, and for each hashtag it contains, we extract  $k$  tweets that contain this hashtag, assuming they are complementary to the target tweet, and link the  $k$  tweets to the target tweet. If there are more than  $k$  tweets found, we choose the top  $k$  ones that are most chronologically close to the target tweet. The statistics of links can be found in table 2.

Named entities are some of the most salient features in a news article. Directly applying Named Entity Recognition (NER) tools on news titles or

tweets results in many errors (Liu et al., 2011) due to the noise in the data, such as slang and capitalization. Accordingly, we first apply the NER tool on news summaries, then label named entities in the tweets in the same way as labeling the hashtags: if there is a string in the tweet that matches a named entity from the summaries, then it is labeled as a named entity in the tweet. 25,132 tweets are assigned at least one named entity.<sup>2</sup> To create the similar tweet set, we find  $k$  tweets that also contain the named entity.

### 4.2 Temporal Relations

Tweets published in the same time interval have a larger chance of being similar than those are not chronologically close (Wang and McCallum, 2006). However, we cannot simply assume any two tweets are similar only based on the timestamp. Therefore, for a tweet we link it to the  $k$  most similar tweets whose published time is within 24 hours of the target tweet’s timestamp. We use the similarity score returned by WTMF model to measure the similarity of two tweets.

We experimented with other features such as authorship. We note that it was not a helpful feature. While authorship information helps in the task of news/tweets recommendation for a *user* (Corso et al., 2005; Yan et al., 2012), the authorship information is too general for this task where we target on “recommending” a news article for a *tweet*.

### 4.3 Creating Relations on News

We extract the 3 subgraphs (based on hashtags, named entities and temporal) on news articles. However, automatically tagging hashtags or named entities leads to much worse performance (around 93% ATOP values, a 3% decrease from baseline WTMF). There are several reasons for this: 1. When a hashtag-matched word appears in a tweet, it is often related to the central meaning of the tweet, however news articles are generally much longer than tweets, resulting in many more hashtags/named entities matches even though these named entities may not be closely related. 2. The noise introduced during automatic NER accumulates much faster given the large number of named entities in news data. Therefore we only extract temporal relations for news articles.

<sup>2</sup>Note that there are some false positive named entities detected such as *apple*. We plan to address removing noisy named entities and hashtags in future work

## 5 WTMF on Graphs

We propose a novel model to incorporate the links generated as described in the previous section.

If two texts are connected by a link, it means they should be semantically similar. In the WTMF model, we would like the latent vectors of two text nodes  $Q_{\cdot,j_1}, Q_{\cdot,j_2}$  to be as similar as possible, namely that their cosine similarity to be close to 1. To implement this, we add a regularization term in the objective function of WTMF (equation 2) for each linked pairs  $Q_{\cdot,j_1}, Q_{\cdot,j_2}$ :

$$\delta \cdot \left( \frac{Q_{\cdot,j_1} \cdot Q_{\cdot,j_2}}{|Q_{\cdot,j_1}| |Q_{\cdot,j_2}|} - 1 \right)^2 \quad (3)$$

where  $|Q_{\cdot,j}|$  denotes the length of vector  $Q_{\cdot,j}$ . The coefficient  $\delta$  denotes the importance of the text-to-text links. A larger  $\delta$  means we put more weights on the text-to-text links and less on the text-to-word links. We refer to this model as WTMF-G (WTMF on graphs).

### 5.1 Inference

Alternating Least Square [ALS] is used for inference in weighted matrix factorization (Srebro and Jaakkola, 2003). However, ALS is no longer applicable here with the new regularization term (equation 3) involving the length of text vectors  $|Q_{\cdot,j}|$ , which is not in quadratic form. Therefore we approximate the objective function by treating the vector length  $|Q_{\cdot,j}|$  as fixed values during the ALS iterations:

$$\begin{aligned} P_{\cdot,i} &= (Q\tilde{W}^{(i)}Q^\top + \lambda I)^{-1} Q\tilde{W}^{(i)}X_{\cdot,i} \\ Q_{\cdot,j} &= (P\tilde{W}^{(j)}P^\top + \lambda I + \delta L_{(j)}^2 Q_{\cdot,s(j)} \text{diag}(L_{(s(j))}^2) Q_{\cdot,s(j)}^\top)^{-1} \\ &\quad (P\tilde{W}^{(j)}X_{j\cdot}^\top + \delta L_{(j)} Q_{\cdot,s(j)} L_{n(j)}) \end{aligned} \quad (4)$$

We define  $n(j)$  as the linked neighbors of short text  $j$ , and  $Q_{\cdot,n(j)}$  as the set of latent vectors of  $j$ 's neighbors. The reciprocal of length of these vectors in the current iteration are stored in  $L_{s(j)}$ . Similarly, the reciprocal of the length of the short text vector  $Q_{\cdot,j}$  is  $L_j$ .  $\tilde{W}^{(i)} = \text{diag}(W_{\cdot,i})$  is an  $M \times M$  diagonal matrix containing the  $i$ th row of weight matrix  $W$ . Due to limited space, the details of the optimization are not shown in this paper; they can be found in (Steck, 2010).

## 6 Experiments

### 6.1 Experiment Setting

**Corpora:** We use the same corpora as in (Guo and Diab, 2012b): Brown corpus (each sentence is

treated as a document), sense definitions of Wiktionary and Wordnet (Fellbaum, 1998). The tweets and news articles are also included in the corpus, generating 441,258 short texts and 5,149,122 words. The data is tokenized, POS-tagged by Stanford POS tagger (Toutanova et al., 2003), and lemmatized by WordNet::QueryData.pm. The value of each word in matrix  $X$  is its TF-IDF value in the short text.

**Baselines:** We present 4 baselines: 1. Information Retrieval model [IR], which simply treats a tweet as a document, and performs traditional surface word matching. 2. LDA- $\theta$  with Gibbs Sampling as inference method. We use the inferred topic distribution  $\theta$  as a latent vector to represent the tweet/news. 3. LDA-*wvec*. The problem with LDA- $\theta$  is the inferred topic distribution latent vector is very sparse with only a few non-zero values, resulting in many tweet/news pairs receiving a high similarity value as long as they are in the same topic domain. Hence following (Guo and Diab, 2012b), we first compute the latent vector of a word by  $P(z|w)$  (topic distribution per word), then average the word latent vectors weighted by TF-IDF values to represent the short text, which yields much better results. 4. WTMF. In these baselines, hashtags and named entities are simply treated as words.

To curtail variation in results due to randomness, each reported number is the average of 10 runs. For WTMF and WTMF-G, we assign the same initial random values and run 20 iterations. In both systems we fix the missing words weight as  $w_m = 0.01$  and regularization coefficient at  $\lambda = 20$ , which is the best condition of WTMF found in (Guo and Diab, 2012b; Guo and Diab, 2012c). For LDA- $\theta$  and LDA-*wvec*, we run Gibbs Sampling based LDA for 2000 iterations and average the model over the last 10 iterations.

**Evaluation:** The similarity between a tweet and a news article is measured by cosine similarity. A news article is represented as the concatenation of its title and its summary, which yields better performance.<sup>3</sup>

As in (Guo and Diab, 2012b), for each tweet, we collect the 1,000 news articles published prior to the tweet whose dates of publication are closest to that of the tweet.<sup>4</sup> The cosine similarity

<sup>3</sup>While these are separated, WTMF receive ATOP 95.558% for representing news article as titles and 94.385% for representing news article as summaries

<sup>4</sup>Ideally we want to include all the news articles published

Models	Parameters	ATOP		TOP10		RR

Table 1: ATOP Performance (latent dimension  $D = 100$  for LDA/WTMF/WTMF-G)

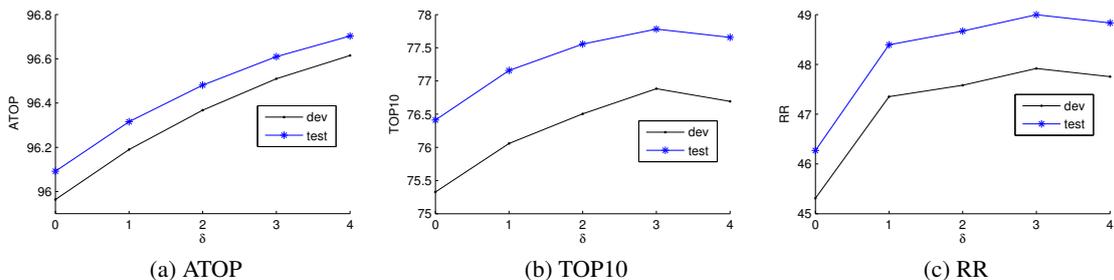

Figure 3: Impact of  $\delta$  ( $D = 100, k = 4$ )

score between the url referred news article and the tweet is compared against the scores of these 1,000 news articles to calculate the metric scores. 1/10 of the tweet/news pairs are used as development set, based on which all the parameters are tuned. The metrics ATOP, TOP10 and RR are used to evaluate the performance of systems.

## 6.2 Results

Table 1 summarizes the performance of the baselines and WTMF-G at latent dimension  $D = 100$ . All the parameters are chosen based on the development set. For WTMF-G, we try different values of  $k$  (the number of neighbors linked to a tweet/news for a hashtag/NE/time constraint) and  $\delta$  (the weight of link information). We choose to model the links in four subgraphs: (a) hashtags in tweet; (b) named entities in tweet; (c) time in tweet; (d) time in news article. For LDA we tune the hyperparameter  $\alpha$  (Dirichlet prior for topic distribution of a document) and  $\beta$  (Dirichlet prior for word distribution given a topic). It is worth noting that ATOP measures the overall ranking in 1000 samples while TOP10/RR focus on whether the aligned news article is in the first few returned results.

Same as reported in (Guo and Diab, 2012b), LDA- $\theta$  has the worst results due to directly using prior to the tweet, however, that will give a bias to some tweets, since the latter tweets have a larger candidate set than the earlier ones

the inferred topic distribution of a text  $\theta$ . The inferred topic vector has only a few non-zero values, hence a lot of information is missing. LDA-*wvec* preserves more information by creating a dense latent vector from the topic distribution of a word  $P(z|w)$ , and thus does much better in ATOP.

It is interesting to see that IR model has a very low ATOP (90.795%) and an acceptable RR (46.281%) score, in contrast to LDA-*wvec* with a high ATOP (94.148%) and a low RR(27.904%) score. This is caused by the nature of the two models. LDA-*wvec* is able to identify global coarse grained topic information (such as *politics* vs. *economics*), hence receiving a high ATOP by excluding the most irrelevant news articles, however it does not distinguish fine grained difference such as *Hillary* vs. *Obama*. IR model exerts the opposite influence via word matching. It ranks a correct news article very high if overlapping words exist (leading to a high RR), or the news article is ranked very low if no overlapping words (hence a low ATOP).

We can conclude WTMF is a very strong baseline given that it achieves high scores with three metrics. As a latent variable model, it is able to capture global topics (+1.89% ATOP over LDA-*wvec*); moreover, by explicitly modeling missing words, the existence of a word is also encoded in the latent vector (+2.31% TOP10 and -0.011% RR over IR model).

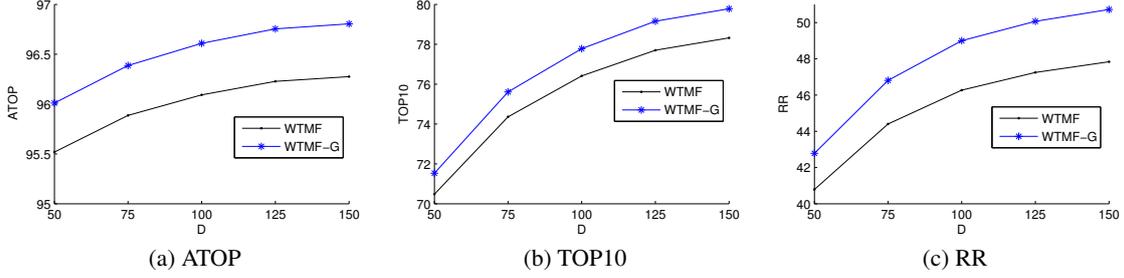

Figure 4: Impact of latent dimension  $D$  ( $k = 4$ )

Table 2: Contribution of subgraphs when  $D = 100$ ,  $k = 4$ ,  $\delta = 3$  (gain over baseline WTMF)

With WTMF being a very challenging baseline, WTMF-G can still significantly improve all 3 metrics. In the case  $k = 4$ ,  $\delta = 3$  compared to WTMF, WTMF-G receives +1.371% TOP10, +2.727% RR, and +0.518% ATOP value (this is a significant improvement of ATOP value considering that it is averaged on 30,000 data points, at an already high level of 96% reducing error rate by 13%). All the improvement of WTMF-G over WTMF is statistically significant at the 99% confidence level with a two-tailed paired t-test.

We also present results using different number of links  $k$  in WTMF-G in table 1. We experiment with  $k = \{3, 4, 5\}$ .  $k = 4$  is found to be the optimal value (although  $k = 5$  has a better ATOP). Figure 3 demonstrates the impact of  $\delta = \{0, 1, 2, 3, 4\}$  on each metric when  $k = 4$ . Note when  $\delta = 0$  no link is used, which is the baseline WTMF. We can see using links is always helpful. When  $\delta = 4$ , we receive a higher ATOP value but lower TOP10 and RR.

Figure 4 illustrates the impact of dimension  $D = \{50, 75, 100, 125, 150\}$  on WTMF and WTMF-G ( $k = 4$ ) on the test set. The trends hold in different  $D$  values with a consistent improvement. Generally a larger  $D$  leads to a better performance. In all conditions WTMF-G outperforms WTMF.

### 6.3 Contribution of Subgraphs

We are interested in the contribution of each feature subgraph. Therefore we list the impact of individual components in table 2. The impact of each subgraph is evaluated in two conditions: (a) the *subgraph-only*; (b) the *full-model-minus* the subgraph. The *full model* is the combination of the 4 subgraphs (which is also the best model  $k = 4$  in table 1). In the last two rows of table 2 we also present the results of using authorship only and the full model plus authorship. The 2nd column lists the number of links in the subgraph. To highlight the difference, we report the gain of each model over the baseline model WTMF.

We have several interesting observations from table 2. It is clear that the hashtag subgraph on tweets is the most useful subgraph: with hashtag\_tweet it has the best ATOP and TOP10 values among *subgraph-only* condition (ATOP: +0.379% vs. 2nd best +0.136%, TOP10: +1.021% vs. 2nd best +0.503%), while in the full-model-minus condition, minus hashtag has the lowest ATOP and TOP10. Observing that it also contains the most links, we believe the coverage is another important reason for the great performance.

It seems the named entity subgraph helps the least. Looking into the extracted named entities and hashtags, we find many popular named enti-

ties are covered by hashtags. That said, adding named entity subgraph into final model has a positive contribution.

It is worth noting that the `time_news` subgraph has the most positive influence on RR. This is because temporal information is very salient in news domain: usually there are several reports to describe an event within a short period, therefore the news latent vector is strengthened by receiving semantics from its neighbors.

At last, we analyze the influence of authorship of tweets. Adding authorship into the full model greatly hurts the scores of TOP10 and RR, whereas it is helpful to ATOP. This is understandable since by introducing author links between tweets, to some degree we are averaging the latent vectors of tweets written by the same person. Therefore, for a tweet whose topic is vague and hard to detect, it will get some prior knowledge of topics through the author links (hence increase ATOP), whereas this prior knowledge becomes noise for the tweets that are already handled very well by the model (hence decrease TOP10 and RR).

#### 6.4 Error Analysis

We look closely into ATOP results to obtain an intuitive feel for what is captured and what is not. For example, the ATOP score of WTMF for the tweet-news pair below is 89.9%:

*Tweet: ...stoked growing speculation that Pakistan's powerful military was quietly supporting moves... @declanwalsh*

*News: Pakistan Supreme Court Orders Arrest of Prime Minister*

By identifying “Pakistan” and “Supreme Court” as hashtags/named entity, WTMF-G is able to propagate the semantics from the following two informative tweets to the original tweet, hence achieving a higher ATOP score of 91.9%.

*#Pakistan Supreme Court orders the arrest of the PM on corruption charges.*

*A discouraging sign from a tumultuous political system: Pakistan's Supreme Court ordered the arrest of PM Ashraf today.*

Below is an example that shows the deficiency of both WTMF and WTMF-G:

*Tweet: Another reason to contemplate moving: an early death*

*News: America flunks its health exam*

In this case WTMF and WTMF-G achieve a

low ATOP of 69.8% and 75.1%, respectively. The only evidence the latent variable models rely on is lexical items (WTMF-G extract additional text-to-text correlation by word matching). To pinpoint the url referred news articles, other advanced NLP features should be exploited. In this case, we believe sentiment information could be helpful – both tweet and the news article contain a negative polarity.

## 7 Related Work

**Short Text Semantics:** The field of short text semantics has progressed immensely in recent years. Early work focus on word pair similarity in the high dimensional space. The word pair similarity is either knowledge based (Mihalcea et al., 2006; Tsatsaronis et al., 2010) or corpus based (Li et al., 2006; Islam and Inkpen, 2008), where co-occurrence information cannot be efficiently exploited. Guo and Diab (2012b; 2012a; 2013) show the superiority of the latent space approach in the WTMF model achieving state-of-the-art performance on two datasets. However, all of them only reply on text-to-word information. In this paper, we focus on modeling inter-text relations induced by Twitter/news features. We extend the WTMF model and adapt it into tweets modeling, achieving significantly better results.

**Modeling Tweets in a Latent Space:** Ramage et al. (2010) also use hashtags to improve the latent representation of tweets in a LDA framework, Labeled-LDA (Ramage et al., 2009), treating each hashtag as a label. Similar to the experiments presented in this paper, the result of using Labeled-LDA alone is worse than the IR model, due to the sparseness in the induced LDA latent vector. Jin et al. (2011) apply an LDA based model on clustering by incorporating url referred documents. The semantics of long documents are transferred to the topic distribution of tweets.

**News recommendation:** A news recommendation system aims to recommend news articles to a user based on the features (e.g., key words, tags, category) in the documents that the user likes (hence these documents form a training set) (Claypool et al., 1999; Corso et al., 2005; Lee and Park, 2007). Our paper resembles it in searching for a related news article. However, we target on recommending news article only based on a tweet, which is a much smaller context than the set of favorite documents chosen by a user .

## Abstract

We propose a computational framework for identifying linguistic aspects of politeness. Our starting point is a new corpus of requests annotated for politeness, which we use to evaluate aspects of politeness theory and to uncover new interactions between politeness markers and context. These findings guide our construction of a classifier with domain-independent lexical and syntactic features operationalizing key components of politeness theory, such as *indirection*, *deference*, *impersonalization* and *modality*. Our classifier achieves close to human performance and is effective across domains. We use our framework to study the relationship between politeness and social power, showing that polite Wikipedia editors are more likely to achieve high status through elections, but, once elevated, they become less polite. We see a similar negative correlation between politeness and power on Stack Exchange, where users at the top of the reputation scale are less polite than those at the bottom. Finally, we apply our classifier to a preliminary analysis of politeness variation by gender and community.

## 1 Introduction

Politeness is a central force in communication, arguably as basic as the pressure to be truthful, informative, relevant, and clear (Grice, 1975; Leech, 1983; Brown and Levinson, 1978). Natural languages provide numerous and diverse means for encoding politeness and, in conversation, we constantly make choices about where and how to use these devices. Kaplan (1999) observes that “people desire to be *paid* respect” and identifies honorifics and other politeness markers, like *please*,

as “the coin of that payment”. In turn, politeness markers are intimately related to the power dynamics of social interactions and are often a decisive factor in whether those interactions go well or poorly (Gyasi Obeng, 1997; Chilton, 1990; Andersson and Pearson, 1999; Rogers and Lee-Wong, 2003; Holmes and Stubbe, 2005).

The present paper develops a computational framework for identifying and characterizing politeness marking in requests. We focus on requests because they involve the speaker imposing on the addressee, making them ideal for exploring the social value of politeness strategies (Clark and Schunk, 1980; Francik and Clark, 1985). Requests also stimulate extensive use of what Brown and Levinson (1987) call *negative politeness*: speaker strategies for minimizing (or appearing to minimize) the imposition on the addressee, for example, by being indirect (*Would you mind*) or apologizing for the imposition (*I’m terribly sorry, but*) (Lakoff, 1973; Lakoff, 1977; Brown and Levinson, 1978).

Our investigation is guided by a new corpus of requests annotated for politeness. The data come from two large online communities in which members frequently make requests of other members: Wikipedia, where the requests involve editing and other administrative functions, and Stack Exchange, where the requests center around a diverse range of topics (e.g., programming, gardening, cycling). The corpus confirms the broad outlines of linguistic theories of politeness pioneered by Brown and Levinson (1987), but it also reveals new interactions between politeness markings and the morphosyntactic context. For example, the politeness of *please* depends on its syntactic position and the politeness markers it co-occurs with.

Using this corpus, we construct a politeness classifier with a wide range of domain-independent lexical, sentiment, and dependency features operationalizing key components of po-

liteness theory, including not only the negative politeness markers mentioned above but also elements of *positive politeness* (gratitude, positive and optimistic sentiment, solidarity, and inclusiveness). The classifier achieves near human-level accuracy across domains, which highlights the consistent nature of politeness strategies and paves the way to using the classifier to study new data.

Politeness theory predicts a negative correlation between politeness and the power of the requester, where power is broadly construed to include social status, authority, and autonomy (Brown and Levinson, 1987). The greater the speaker’s power relative to her addressee, the less polite her requests are expected to be: there is no need for her to incur the expense of paying respect, and failing to make such payments can invoke, and hence reinforce, her power. We support this prediction by applying our politeness framework to Wikipedia and Stack Exchange, both of which provide independent measures of social status. We show that polite Wikipedia editors are more likely to achieve high status through elections; however, once elected, they become less polite. Similarly, on Stack Exchange, we find that users at the top of the reputation scale are less polite than those at the bottom.

Finally, we briefly address the question of how politeness norms vary across communities and social groups. Our findings confirm established results about the relationship between politeness and gender, and they identify substantial variation in politeness across different programming language subcommunities on Stack Exchange.

## 2 Politeness data

Requests involve an imposition on the addressee, making them a natural domain for studying the inter-connections between linguistic aspects of politeness and social variables.

**Requests in online communities** We base our analysis on two online communities where requests have an important role: the Wikipedia community of editors and the Stack Exchange question-answer community.<sup>1</sup> On Wikipedia, to coordinate on the creation and maintenance of the collaborative encyclopedia, editors can interact with each other on user talk-pages;<sup>2</sup> re-

<sup>1</sup><http://stackexchange.com/about>

<sup>2</sup>[http://en.wikipedia.org/wiki/Wikipedia:User\\_pages](http://en.wikipedia.org/wiki/Wikipedia:User_pages)

quests posted on a user talk-page, although public, are generally directed to the owner of the talk-page. On Stack Exchange, users often comment on existing posts requesting further information or proposing edits; these requests are generally directed to the authors of the original posts.

Both communities are not only rich in user-to-user requests, but these requests are also part of consequential conversations, not empty social banter; they solicit specific information or concrete actions, and they expect a response.

**Politeness annotation** Computational studies of politeness, or indeed any aspect of linguistic pragmatics, demand richly labeled data. We therefore label a large portion of our request data (over 10,000 utterances) using Amazon Mechanical Turk (AMT), creating the largest corpus with politeness annotations (see Table 1 for details).<sup>3</sup>

We choose to annotate requests containing exactly two sentences, where the second sentence is the actual request (and ends with a question mark). This provides enough context to the annotators while also controlling for length effects. Each annotator was instructed to read a batch of 13 requests and consider them as originating from a co-worker by email. For each request, the annotator had to indicate how polite she perceived the request to be by using a slider with values ranging from “very impolite” to “very polite”.<sup>4</sup> Each request was labeled by five different annotators.

We vetted annotators by restricting their residence to be in the U.S. and by conducting a linguistic background questionnaire. We also gave them a paraphrasing task shown to be effective for verifying and eliciting linguistic attentiveness (Munro et al., 2010), and we monitored the annotation job and manually filtered out annotators who submitted uniform or seemingly random annotations.

Because politeness is highly subjective and annotators may have inconsistent scales, we applied the standard z-score normalization to each worker’s scores. Finally, we define the politeness score (henceforth *politeness*) of a request as the average of the five scores assigned by the annotators. The distribution of resulting request scores (shown in Figure 1) has an average of 0 and stan-

<sup>3</sup>Publicly available at <http://www.mpi-sws.org/~cristian/Politeness.html>

<sup>4</sup>We used non-categorical ratings for finer granularity and to help account for annotators’ different perception scales.

domain	#requests	#annotated	#annotators
Wiki	35,661	4,353	219
SE	373,519	6,604	212

Table 1: Summary of the request data and its politeness annotations.

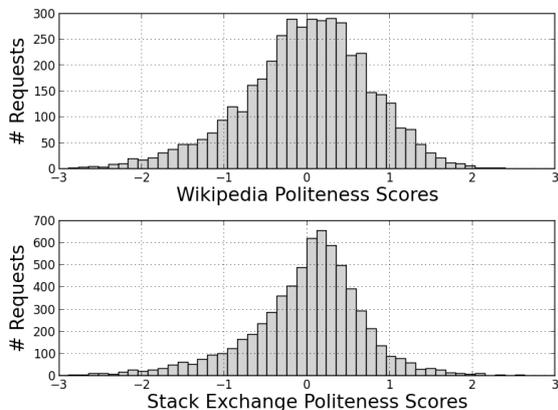

Figure 1: Distribution of politeness scores. Positive scores indicate requests perceived as polite.

standard deviation of 0.7 for both domains; positive values correspond to polite requests (i.e., requests with normalized annotations towards the “very polite” extreme) and negative values to impolite requests. A summary of all our request data is shown in Table 1.

**Inter-annotator agreement** To evaluate the reliability of the annotations we measure the inter-annotator agreement by computing, for each batch of 13 documents that were annotated by the same set of 5 users, the mean pairwise correlation of the respective scores. For reference, we compute the same quantities after randomizing the scores by sampling from the observed distribution of politeness scores. As shown in Figure 2, the labels are coherent and significantly different from the randomized procedure ( $p < 0.0001$  according to a Wilcoxon signed rank test).<sup>5</sup>

**Binary perception** Although we did not impose a discrete categorization of politeness, we acknowledge an implicit binary perception of the phenomenon: whenever an annotator moved a slider in one direction or the other, she made a binary politeness judgment. However, the bound-

<sup>5</sup>The commonly used Cohen/Fleiss Kappa agreement measures are not suitable for this type of annotation, in which labels are continuous rather than categorical.

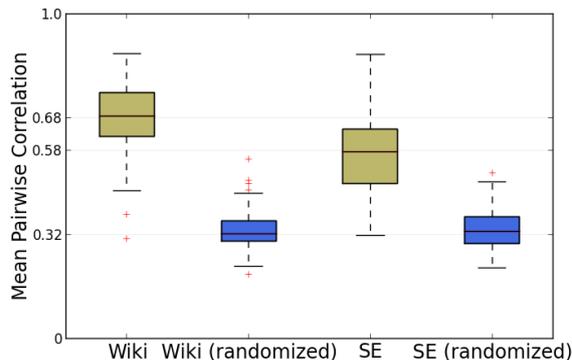

Figure 2: Inter-annotator pairwise correlation, compared to the same measure after randomizing the scores.

Quartile:	1 <sup>st</sup>	2 <sup>nd</sup>	3 <sup>rd</sup>	4 <sup>th</sup>
Wiki	62%	8%	3%	51%
SE	37%	4%	6%	46%

Table 2: The percentage of requests for which all five annotators agree on binary politeness. The 4<sup>th</sup> quartile contains the requests with the top 25% politeness scores in the data. (For reference, randomized scoring yields agreement percentages of <20% for all quartiles.)

ary between somewhat polite and somewhat impolite requests can be blurry. To test this intuition, we break the set of annotated requests into four groups, each corresponding to a politeness score quartile. For each quartile, we compute the percentage of requests for which all five annotators made the same binary politeness judgment. As shown in Table 2, full agreement is much more common in the 1<sup>st</sup> (bottom) and 4<sup>th</sup> (top) quartiles than in the middle quartiles. This suggests that the politeness scores assigned to requests that are only somewhat polite or somewhat impolite are less reliable and less tied to an intuitive notion of binary politeness. This discrepancy motivates our choice of classes in the prediction experiments (Section 4) and our use of the top politeness quartile (the 25% most polite requests) as a reference in our subsequent discussion.

### 3 Politeness strategies

As we mentioned earlier, requests impose on the addressee, potentially placing her in social peril if she is unwilling or unable to comply. Requests therefore naturally give rise to the negative po-

liteness strategies of Brown and Levinson (1987), which are attempts to mitigate these social threats. These strategies are prominent in Table 3, which describes the core politeness markers we analyzed in our corpus of Wikipedia requests. We do not include the Stack Exchange data in this analysis, reserving it as a “test community” for our prediction task (Section 4).

Requests exhibiting politeness markers are automatically extracted using regular expression matching on the dependency parse obtained by the Stanford Dependency Parser (de Marneffe et al., 2006), together with specialized lexicons. For example, for the hedges marker (Table 3, line 19), we match all requests containing a nominal subject dependency edge pointing out from a hedge verb from the hedge list created by Hyland (2005). For each politeness strategy, Table 3 shows the average **politeness** score of the respective requests (as described in Section 2; positive numbers indicate polite requests), and their **top politeness quartile** membership (i.e., what percentage fall within the top quartile of politeness scores). As discussed at the end of Section 2, the top politeness quartile gives a more robust and more intuitive measure of politeness. For reference, a random sample of requests will have a 0 politeness score and a 25% top quartile membership; in both cases, larger numbers indicate higher politeness.

Gratitude and deference (lines 1–2) are ways for the speaker to incur a social cost, helping to balance out the burden the request places on the addressee. Adopting Kaplan (1999)’s metaphor, these are the coin of the realm when it comes to paying the addressee respect. Thus, they are indicators of positive politeness.

Terms from the sentiment lexicon (Liu et al., 2005) are also tools for positive politeness, either by emphasizing a positive relationship with the addressee (line 4), or being impolite by using negative sentiment that damages this positive relationship (line 5). Greetings (line 3) are another way to build a positive relationship with the addressee.

The remainder of the cues in Table 3 are negative politeness strategies, serving the purpose of minimizing, at least in appearance, the imposition on the addressee. Apologizing (line 6) deflects the social threat of the request by attuning to the imposition itself. Being indirect (line 9) is another way to minimize social threat. This strategy allows the speaker to avoid words and phrases convention-

ally associated with requests. First-person plural forms like *we* and *our* (line 15) are also ways of being indirect, as they create the sense that the burden of the request is shared between speaker and addressee (*We really should . . .*). Though indirectness is not invariably interpreted as politeness marking (Blum-Kulka, 2003), it is nonetheless a reliable marker of it, as our scores indicate. What’s more, direct variants (imperatives, statements about the addressee’s obligations) are less polite (lines 10–11).

Indirect strategies also combine with hedges (line 19) conveying that the addressee is unlikely to accept the burden (*Would you by any chance . . . ?*, *Would it be at all possible . . . ?*). These too serve to provide the addressee with a face-saving way to deny the request. We even see subtle effects of modality at work here: the irrealis, counterfactual forms *would* and *could* are more polite than their ability (dispositional) or future-oriented variants *can* and *will*; compare lines 12 and 13. This parallels the contrast between factuality markers (impolite; line 20) and hedging (polite; line 19).

Many of these features are correlated with each other, in keeping with the insight of Brown and Levinson (1987) that politeness markers are often combined to create a cumulative effect of increased politeness. Our corpora also highlight interactions that are unexpected (or at least unaccounted for) on existing theories of politeness. For example, sentence-medial *please* is polite (line 7), presumably because of its freedom to combine with other negative politeness strategies (*Could you please . . .*). In contrast, sentence-initial *please* is impolite (line 8), because it typically signals a more direct strategy (*Please do this*), which can make the politeness marker itself seem insincere. We see similar interactions between pronominal forms and syntactic structure: sentence-initial *you* is impolite (*You need to . . .*), whereas sentence-medial *you* is often part of the indirect strategies we discussed above (*Would/Could you . . .*).

#### 4 Predicting politeness

We now show how our linguistic analysis can be used in a machine learning model for automatically classifying requests according to politeness. A classifier can help verify the predictive power, robustness, and domain-independent generality of the linguistic strategies of Section 3. Also, by providing automatic politeness judgments for large

Strategy	Politeness	In top quartile	Example
1. Gratitude	0.87 <sup>***</sup>	78% <sup>***</sup>	<b>I</b> really <b>appreciate</b> that you’ve done them.
2. Deference	0.78 <sup>***</sup>	70% <sup>***</sup>	<b>Nice work</b> so far on your rewrite.
3. Greeting	0.43 <sup>***</sup>	45% <sup>***</sup>	<b>Hey</b> , I just tried to ...

20. Factuality	-0.38 <sup>***</sup>	13% <sup>***</sup>	<b>In fact</b> you did link, ...

Table 3: Positive (1-5) and negative (6–20) politeness strategies and their relation to human perception of politeness. For each strategy we show the average (human annotated) **politeness** scores for the requests exhibiting that strategy (compare with 0 for a random sample of requests; a positive number indicates the strategy is perceived as being polite), as well as the percentage of requests exhibiting the respective strategy that fall in the **top quartile** of politeness scores (compare with 25% for a random sample of requests). Throughout the paper: for politeness scores, statistical significance is calculated by comparing the set of requests exhibiting the strategy with the rest using a Mann-Whitney-Wilcoxon U test; for top quartile membership a binomial test is used.

amounts of new data on a scale unfeasible for human annotation, it can also enable a detailed analysis of the relation between politeness and social factors (Section 5).

**Task setup** To evaluate the robustness and domain-independence of the analysis from Section 3, we run our prediction experiments on two very different domains. We treat Wikipedia as a “development domain” since we used it for developing and identifying features and for training our models. Stack Exchange is our “test domain” since it was not used for identifying features. We take the model (features and weights) trained on Wikipedia and use them to classify requests from Stack Exchange.

We consider two classes of requests: **polite** and **impolite**, defined as the top and, respectively, bottom quartile of requests when sorted by their politeness score (based on the binary notion of politeness discussed in Section 2). The classes are therefore balanced, with each class consisting of 1,089 requests for the Wikipedia domain and 1,651 requests for the Stack Exchange domain.

We compare two classifiers — a bag of words classifier (BOW) and a linguistically informed classifier (Ling.) — and use human labelers as a reference point. The BOW classifier is an SVM using a unigram feature representation.<sup>6</sup> We consider this to be a strong baseline for this new

<sup>6</sup>Unigrams appearing less than 10 times are excluded.

classification task, especially considering the large amount of training data available. The linguistically informed classifier (Ling.) is an SVM using the linguistic features listed in Table 3 in addition to the unigram features. Finally, to obtain a reference point for the prediction task we also collect three new politeness annotations for each of the requests in our dataset using the same methodology described in Section 2. We then calculate human performance on the task (Human) as the percentage of requests for which the average score from the additional annotations matches the binary politeness class of the original annotations (e.g., a positive score corresponds to the polite class).

**Classification results** We evaluate the classifiers both in an in-domain setting, with a standard leave-one-out cross validation procedure, and in a cross-domain setting, where we train on one domain and test on the other (Table 4). For both our development and our test domains, and in both the in-domain and cross-domain settings, the linguistically informed features give 3-4% absolute improvement over the bag of words model. While the in-domain results are within 3% of human performance, the greater room for improvement in the cross-domain setting motivates further research on linguistic cues of politeness.

The experiments in this section confirm that our theory-inspired features are indeed effective in practice, and generalize well to new domains. In the next section we exploit this insight to automatically annotate a much larger set of requests (about 400,000) with politeness labels, enabling us to relate politeness to several social variables and outcomes. For new requests, we use class probability estimates obtained by fitting a logistic regression model to the output of the SVM (Witten and Frank, 2005) as *predicted politeness scores* (with values between 0 and 1; henceforth *politeness*, by abuse of language).

## 5 Relation to social factors

We now apply our framework to studying the relationship between politeness and social variables, focussing on social power dynamics. Encouraged by the close-to-human performance of our in-domain classifiers, we use them to assign politeness labels to our full dataset and then compare these labels to independent measures of power and status in our data. The results closely match those obtained with human-labeled data alone, thereby

Train Test	In-domain		Cross-domain	
	Wiki	SE	Wiki	SE
BOW	79.84%	74.47%	64.23%	72.17%
Ling.	83.79%	78.19%	67.53%	75.43%
Human	86.72%	80.89%	80.89%	86.72%

Table 4: Accuracies of our two classifiers for Wikipedia (Wiki) and Stack Exchange (SE), for in-domain and cross-domain settings. Human performance is included as a reference point. The random baseline performance is 50%.

supporting the use of computational methods to pursue questions about social variables.

### 5.1 Relation to social outcome

Earlier, we characterized politeness markings as currency used to pay respect. Such language is therefore costly in a social sense, and, relatedly, tends to incur costs in terms of communicative efficiency (Van Rooy, 2003). Are these costs worth paying? We now address this question by studying politeness in the context of the electoral system of the Wikipedia community of editors.

Among Wikipedia editors, status is a salient social variable (Anderson et al., 2012). Administrators (*admins*) are editors who have been granted certain rights, including the ability to block other editors and to protect or delete articles.<sup>7</sup> Admins have a higher status than common editors (*non-admins*), and this distinction seems to be widely acknowledged by the community (Burke and Kraut, 2008b; Leskovec et al., 2010; Danescu-Niculescu-Mizil et al., 2012). Aspiring editors become admins through public elections,<sup>8</sup> so we know when the status change from non-admin to admins occurred and can study users' language use in relation to that time.

To see whether politeness correlates with eventual high status, we compare, in Table 5, the politeness levels of requests made by users who will eventually succeed in becoming administrators (Eventual status: Admins) with requests made by users who are not admins (Non-admins).<sup>9</sup> We observe that admins-to-be are significantly more po-

<sup>7</sup><http://en.wikipedia.org/wiki/Wikipedia:Administrators>

<sup>8</sup>[http://en.wikipedia.org/wiki/Wikipedia:Requests\\_for\\_adminship](http://en.wikipedia.org/wiki/Wikipedia:Requests_for_adminship)

<sup>9</sup>We consider only requests made up to one month before the election, to avoid confusion with pre-election behavior.

Eventual status	Politeness	Top quart.
Admins	0.46**	30%***
Non-admins	0.39***	25%
Failed	0.37**	22%

Table 5: Politeness and status. Editors who will eventually become admins are more polite than non-admins ( $p < 0.001$  according to a Mann-Whitney-Wilcoxon U test) and than editors who will eventually fail to become admins ( $p < 0.001$ ). Out of their requests, 30% are rated in the top politeness quartile (significantly more than the 25% of a random sample;  $p < 0.001$  according to a binomial test). This analysis was conducted on 31k requests (1.4k for Admins, 28.9k for Non-admins, 652 for Failed).

lite than non-admins. One might wonder whether this merely reflects the fact that not all users aspire to become admins, and those that do are more polite. To address this, we also consider users who ran for adminship but did not earn community approval (Eventual status: Failed). These users are also significantly less polite than their successful counterparts, indicating that politeness indeed correlates with a positive social outcome here.

## 5.2 Politeness and power

We expect a rise in status to correlate with a decline in politeness (as predicted by politeness theory, and discussed in Section 1). The previous section does not test this hypothesis, since all editors compared in Table 5 had the same (non-admin) status when writing the requests. However, our data does provide three ways of testing this hypothesis.

First, after the adminship elections, successful editors get a boost in power by receiving admin privileges. Figure 3 shows that this boost is mirrored by a significant decrease in politeness (blue, diamond markers). Losing an election has the opposite effect on politeness (red, circle markers), perhaps as a consequence of reinforced low status.

Second, Stack Exchange allows us to test more situational power effects.<sup>10</sup> On the site, users request, from the community, information they are lacking. This informational asymmetry between the question-asker and his audience puts him at

<sup>10</sup>We restrict all experiments in this section to the largest subcommunity of Stack Exchange, namely Stack Overflow.

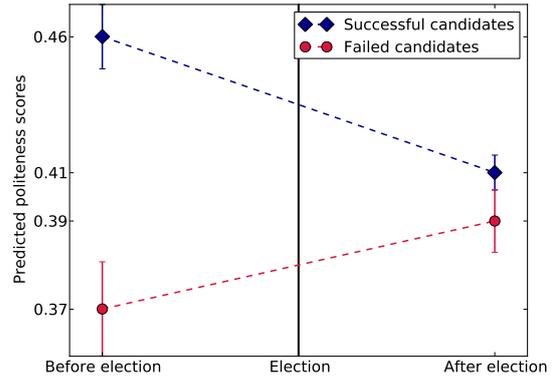

Figure 3: Successful and failed candidates before and after elections. Editors that will eventually succeed (diamond marker) are significantly more polite than those that will fail (circle markers). Following the elections, successful editors become less polite while unsuccessful editors become more polite.

a social disadvantage. We therefore expect the question-asker to be more polite than the people who respond. Table 6 shows that this expectation is born out: comments posted to a thread by the original question-asker are more polite than those posted by other users.

Role	Politeness	Top quart.
Question-asker	0.65***	32%***
Answer-givers	0.52***	20%***

Table 6: Politeness and dependence. Requests made in comments posted by the question-asker are significantly more polite than the other requests. Analysis conducted on 181k requests (106k for question-askers, 75k for answer-givers).

Third, Stack Exchange allows us to examine power in the form of authority, through the community’s reputation system. Again, we see a negative correlation between politeness and power, even after controlling for the role of the user making the requests (i.e., Question-asker or Answer-giver). Table 7 summarizes the results.<sup>11</sup>

**Human validation** The above analyses are based on predicted politeness from our classifier. This allows us to use the entire request data cor-

<sup>11</sup>Since our data does not contain time stamps for reputation scores, we only consider requests that were issued in the six months prior to the available snapshot.

Reputation level	Politeness	Top quart.
Low reputation	0.68***	27%***
Middle reputation	0.66***	25%
High reputation	0.64***	23%***

Table 7: Politeness and Stack Exchange reputation (texts by question-askers only). High-reputation users are less polite. Analysis conducted on 25k requests (4.5k low, 12.5k middle, 8.4k high).

pus to test our hypotheses and to apply precise controls to our experiments (such as restricting our analysis to question-askers in the reputation experiment). In order to validate this methodology, we turned again to human annotation: we collected additional politeness annotation for the types of requests involved in the newly designed experiments. When we re-ran our experiments on human-labeled data alone we obtained the same qualitative results, with statistical significance always lower than 0.01.<sup>12</sup>

**Prediction-based interactions** The human validation of classifier-based results suggests that our prediction framework can be used to explore differences in politeness levels across factors of interest, such as communities, geographical regions and gender, even where gathering sufficient human-annotated data is infeasible. We mention just a few such preliminary results here: (i) Wikipedians from the U.S. Midwest are most polite (when compared to other census-defined regions), (ii) female Wikipedians are generally more polite (consistent with prior studies in which women are more polite in a variety of domains; (Herring, 1994)), and (iii) programming language communities on Stack Exchange vary significantly by politeness (Table 8; full disclosure: our analyses were conducted in Python).

## 6 Related work

Politeness has been a central concern of modern pragmatic theory since its inception (Grice, 1975; Lakoff, 1973; Lakoff, 1977; Leech, 1983; Brown and Levinson, 1978), because it is a source of pragmatic enrichment, social meaning, and cultural variation (Harada, 1976; Matsumoto, 1988;

<sup>12</sup>However, due to the limited size of the human-labeled data, we could not control for the role of the user in the Stack Exchange reputation experiment.

PL name	Politeness	Top quartile
Python	0.47***	23%
Perl	0.49	24%
PHP	0.51	24%
Javascript	0.53**	26%**
Ruby	0.59***	28%*

Table 8: Politeness of requests from different language communities on Stack Exchange.

Ide, 1989; Blum-Kulka and Kasper, 1990; Blum-Kulka, 2003; Watts, 2003; Byon, 2006). The starting point for most research is the theory of Brown and Levinson (1987). Aspects of this theory have been explored from game-theoretic perspectives (Van Rooy, 2003) and implemented in language generation systems for interactive narratives (Walker et al., 1997), cooking instructions, (Gupta et al., 2007), translation (Faruqui and Pado, 2012), spoken dialog (Wang et al., 2012), and subjectivity analysis (Abdul-Mageed and Diab, 2012), among others.

In recent years, politeness has been studied in online settings. Researchers have identified variation in politeness marking across different contexts and media types (Herring, 1994; Brennan and Ohaeri, 1999; Duthler, 2006) and between different social groups (Burke and Kraut, 2008a). The present paper pursues similar goals using orders of magnitude more data, which facilitates a fuller survey of different politeness strategies.

Politeness marking is one aspect of the broader issue of how language relates to power and status, which has been studied in the context of workplace discourse (Bramsen et al., ; Diehl et al., 2007; Peterson et al., 2011; Prabhakaran et al., 2012; Gilbert, 2012; McCallum et al., 2007) and social networking (Scholand et al., 2010). However, this research focusses on domain-specific textual cues, whereas the present work seeks to leverage domain-independent politeness cues, building on the literature on how politeness affects workplace social dynamics and power structures (Gyasi Obeng, 1997; Chilton, 1990; Andersson and Pearson, 1999; Rogers and Lee-Wong, 2003; Holmes and Stubbe, 2005). Burke and Kraut (2008b) study the question of how and why specific individuals rise to administrative positions on Wikipedia, and Danescu-Niculescu-Mizil et al. (2012) show that power differences on Wikipedia

are revealed through aspects of linguistic accommodation. The present paper complements this work by revealing the role of politeness in social outcomes and power relations.

## 7 Conclusion

We construct and release a large collection of politeness-annotated requests and use it to evaluate key aspects of politeness theory. We build a politeness classifier that achieves near-human performance and use it to explore the relation between politeness and social factors such as power, status, gender, and community membership. We hope the publicly available collection of annotated requests enables further study of politeness and its relation to social factors, as this paper has only begun to explore this area.

# Modeling Thesis Clarity in Student Essays

Isaac Persing and Vincent Ng

Human Language Technology Research Institute

University of Texas at Dallas

Richardson, TX 75083-0688

{persingq, vince}@hlt.utdallas.edu

## Abstract

Recently, researchers have begun exploring methods of scoring student essays with respect to particular dimensions of quality such as coherence, technical errors, and relevance to prompt, but there is relatively little work on modeling thesis clarity. We present a new annotated corpus and propose a learning-based approach to scoring essays along the thesis clarity dimension. Additionally, in order to provide more valuable feedback on why an essay is scored as it is, we propose a second learning-based approach to identifying what kinds of errors an essay has that may lower its thesis clarity score.

## 1 Introduction

Automated essay scoring, the task of employing computer technology to evaluate and score written text, is one of the most important educational applications of natural language processing (NLP) (see Shermis and Burstein (2003) and Shermis et al. (2010) for an overview of the state of the art in this task). A major weakness of many existing scoring engines such as the Intelligent Essay Assessor<sup>TM</sup> (Landauer et al., 2003) is that they adopt a holistic scoring scheme, which summarizes the quality of an essay with a single score and thus provides very limited feedback to the writer. In particular, it is not clear which dimension of an essay (e.g., style, coherence, relevance) a score should be attributed to. Recent work addresses this problem by scoring a particular dimension of essay quality such as coherence (Miltsakaki and Kukich, 2004), technical errors, Relevance to Prompt (Higgins et al., 2004), and organization (Persing et al., 2010). Essay grading software that provides feedback along multiple dimensions of essay quality such as E-rater/Criterion (Attali and Burstein, 2006) has also begun to emerge.

Nevertheless, there is an essay scoring dimension for which few computational models have been developed — *thesis clarity*. Thesis clarity refers to how clearly an author explains the *thesis* of her essay, i.e., the position she argues for with respect to the topic on which the essay is written.<sup>1</sup> An essay with a high thesis clarity score presents its thesis in a way that is easy for the reader to understand, preferably but not necessarily directly, as in essays with explicit thesis sentences. It additionally contains no errors such as excessive misspellings that make it more difficult for the reader to understand the writer’s purpose.

Our goals in this paper are two-fold. First, we aim to develop a computational model for scoring the thesis clarity of student essays. Because there are many reasons why an essay may receive a low thesis clarity score, our second goal is to build a system for determining why an essay receives its score. We believe the feedback provided by this system will be more informative to a student than would a thesis clarity score alone, as it will help her understand which aspects of her writing need to be improved in order to better convey her thesis. To this end, we identify five common errors that impact thesis clarity, and our system’s purpose is to determine which of these errors occur in a given essay. We evaluate our thesis clarity scoring model and error identification system on a data set of 830 essays annotated with both thesis clarity scores and errors.

In sum, our contributions in this paper are three-fold. First, we develop a scoring model and error identification system for the thesis clarity dimension on student essays. Second, we use features explicitly designed for each of the identified error

---

<sup>1</sup>An essay’s thesis is the overall message of the *entire* essay. This concept is unbound from the the concept of thesis sentences, as even an essay that never explicitly states its thesis in any of its sentences may still have an overall message that can be inferred from the arguments it makes.

types in order to train our scoring model, in contrast to many existing systems for other scoring dimensions, which use more general features developed without the concept of error classes. Third, we make our data set consisting of thesis clarity annotations of 830 essays publicly available in order to stimulate further research on this task. Since progress in thesis clarity modeling is hindered in part by the lack of a publicly annotated corpus, we believe that our data set will be a valuable resource to the NLP community.

## 2 Corpus Information

We use as our corpus the 4.5 million word International Corpus of Learner English (ICLE) (Granger et al., 2009), which consists of more than 6000 essays written by university undergraduates from 16 countries and 16 native languages who are learners of English as a Foreign Language. 91% of the ICLE texts are argumentative. We select a subset consisting of 830 argumentative essays from the ICLE to annotate and use for training and testing of our models of essay thesis clarity. Table 1 shows three of the thirteen topics selected for annotation. Fifteen native languages are represented in the set of essays selected for annotation.

## 3 Corpus Annotation

For each of the 830 argumentative essays, we ask two native English speakers to (1) score it along the thesis clarity dimension and (2) determine the subset of the five pre-defined errors that detracts from the clarity of its thesis.

**Scoring.** Annotators evaluate the clarity of each essay’s thesis using a numerical score from 1 to 4 at half-point increments (see Table 2 for a description of each score). This contrasts with previous work on essay scoring, where the corpus is

Score	Description of Thesis Clarity
4	essay presents a <b>very clear thesis</b> and requires little or no clarification
3	essay presents a <b>moderately clear thesis</b> but could benefit from some clarification
2	essay presents an <b>unclear thesis</b> and would greatly benefit from further clarification
1	essay presents <b>no thesis of any kind</b> and it is difficult to see what the thesis could be

Table 2: Descriptions of the meaning of scores.

annotated with a binary decision (i.e., *good* or *bad*) for a given scoring dimension (e.g., Higgins et al. (2004)). Hence, our annotation scheme not only provides a finer-grained distinction of thesis clarity (which can be important in practice), but also makes the prediction task more challenging.

To ensure consistency in annotation, we randomly select 100 essays to have graded by both annotators. Analysis of these essays reveals that, though annotators only exactly agree on the thesis clarity score of an essay 36% of the time, the scores they apply are within 0.5 points in 62% of essays and within 1.0 point in 85% of essays. Table 3 shows the number of essays that receive each of the seven scores for thesis clarity.

score	1.0	1.5	2.0	2.5	3.0	3.5	4.0
essays	4	9	52	78	168	202	317

Table 3: Distribution of thesis clarity scores.

**Error identification.** To identify what kinds of errors make an essay’s thesis unclear, we ask one of our annotators to write 1–4 sentence critiques of thesis clarity on 527 essays, and obtain our list of five common error classes by categorizing the things he found to criticize. We present our annotators with descriptions of these five error classes (see Table 4), and ask them to assign zero or more of the error types to each essay.

It is important to note that we ask our annotators to mark an essay with one of these errors only when the error makes the thesis less clear. So for example, an essay whose thesis is irrelevant to the prompt but is explicitly and otherwise clearly stated would not be marked as having a Relevance to Prompt error. If the irrelevant thesis is stated in such a way that its inapplicability to the prompt causes the reader to be confused about what the essay’s purpose is, however, then the essay would be assigned a Relevance to Prompt error.

To measure inter-annotator agreement on error identification, we ask both annotators to identify

<b>Id</b>	<b>Error</b>	<b>Description</b>
CP	<b>Confusing Phrasing</b>	The thesis is phrased oddly, making it hard to understand the writer’s point.
IPR	<b>Incomplete Prompt Response</b>	The thesis seems to leave some part of a multi-part prompt unaddressed.
R	<b>Relevance to Prompt</b>	The apparent thesis’s weak relation to the prompt causes confusion.
MD	<b>Missing Details</b>	The thesis leaves out important detail needed to understand the writer’s point.
WP	<b>Writer Position</b>	The thesis describes a position on the topic without making it clear that this is the position the writer supports.

Table 4: Descriptions of thesis clarity errors.

the errors in the same 100 essays that were doubly-annotated with thesis clarity scores. We then compute Cohen’s Kappa (Carletta, 1996) on each error from the two sets of annotations, obtaining an average Kappa value of 0.75, which indicates fair agreement. Table 5 shows the number of essays assigned to each of the five thesis clarity errors. As we can see, Confusing Phrasing, Incomplete Prompt Response, and Relevance to Prompt are the major error types.

error	CP	IPR	R	MD	WP
essays	152	123	142	47	39

Table 5: Distribution of thesis clarity errors.

**Relationship between clarity scores and error classes.** To determine the relationship between thesis clarity scores and the five error classes, we train a linear SVM regressor using the SVM<sup>light</sup> software package (Joachims, 1999) with the five error types as independent variables and the reduction in thesis clarity score due to errors as the dependent variable. More specifically, each training example consists of a target, which we set to the essay’s thesis clarity score minus 4.0, and six binary features, each of the first five representing the presence or absence of one of the five errors in the essay, and the sixth being a bias feature which we always set to 1. Representing the reduction in an essay’s thesis clarity score with its thesis clarity score minus 4.0 allows us to more easily interpret the error and bias weights of the trained system, as under this setup, each error’s weight should be a negative number reflecting how many points an essay loses due to the presence of that error. The bias feature allows for the possibility that an essay may lose points from its thesis clarity score for problems not accounted for in our five error classes. By setting this bias feature to 1, we tell our learner that an essay’s default score may be less than 4.0 because these other problems may lower the average score of otherwise perfect essays.

After training, we examined the weight parameters of the learned regressor and found that they

were all negative:  $-0.6$  for CP,  $-0.5998$  for IPR,  $-0.8992$  for R,  $-0.6$  for MD,  $-0.8$  for WP, and  $-0.1$  for the bias. These results are consistent with our intuition that each of the enumerated error classes has a negative impact on thesis clarity score. In particular, each has a demonstrable negative impact, costing essays an average of more than 0.59 points when it occurs. Moreover, this set of errors accounts for a large majority of all errors impacting thesis clarity because unenumerated errors cost essays an average of only one-tenth of one point on the four-point thesis clarity scale.

## 4 Error Classification

In this section, we describe in detail our system for identifying thesis clarity errors.

### 4.1 Model Training and Application

We recast the problem of identifying which thesis clarity errors apply to an essay as a multi-label classification problem, wherein each essay may be assigned zero or more of the five pre-defined error types. To solve this problem, we train five binary classifiers, one for each error type, using a one-versus-all scheme. So in the binary classification problem for identifying error  $e_i$ , we create one training instance from each essay in the training set, labeling the instance as positive if the essay has  $e_i$  as one of its labels, and negative otherwise. Each instance is represented by seven types of features, including two types of baseline features (Section 4.2) and five types of features we introduce for error identification (Section 4.3).

After creating training instances for error  $e_i$ , we train a binary classifier,  $b_i$ , for identifying which test essays contain error  $e_i$ . We use SVM<sup>light</sup> for classifier training with the regularization parameter,  $C$ , set to  $c_i$ . To improve classifier performance, we perform feature selection. While we employ seven types of features (see Sections 4.2 and 4.3), only the word n-gram features are subject to feature selection.<sup>2</sup> Specifically, we employ

<sup>2</sup>We do not apply feature selection to the remaining fea-

the top  $n_i$  n-gram features as selected according to information gain computed over the training data (see Yang and Pedersen (1997) for details). Finally, since each classifier assigns a real value to each test essay presented to it indicating its confidence that the essay should be assigned error  $e_i$ , we employ a classification threshold  $t_i$  to decide how high this real value must be in order for our system to conclude that an essay contains error  $e_i$ .

Using held-out validation data, we jointly tune the three parameters in the previous paragraph,  $c_i$ ,  $n_i$ , and  $t_i$ , to optimize the F-score achieved by  $b_i$  for error  $e_i$ .<sup>3</sup> However, an exact solution to this optimization problem is computationally expensive. Consequently, we find a local maximum by employing the simulated annealing algorithm (Kirkpatrick et al., 1983), altering one parameter at a time to optimize F-score by holding the remaining parameters fixed.

After training the classifiers, we use them to classify the test set essays. The test instances are created in the same way as the training instances.

## 4.2 Baseline Features

Our **Baseline** system for error classification employs two types of features. First, since labeling essays with thesis clarity errors can be viewed as a text categorization task, we employ lemmatized word unigram, bigram, and trigram features that occur in the essay that have not been removed by the feature selection parameter  $n_i$ . Because the essays vary greatly in length, we normalize each essay’s set of word features to unit length.

The second type of baseline features is based on random indexing (Kanerva et al., 2000). Random indexing is “an efficient, scalable and incremental alternative” (Sahlgren, 2005) to Latent Semantic Indexing (Deerwester et al., 1990; Landauer

ture types since each of them includes only a small number of overall features that are expected to be useful.

<sup>3</sup>For parameter tuning, we employ the following values.  $c_i$  may be assigned any of the values  $10^2$ ,  $10^3$ ,  $10^4$ ,  $10^5$ , or  $10^6$ .  $n_i$  may be assigned any of the values 3000, 4000, 5000, or ALL, where ALL means all features are used. For  $t_i$ , we split the range of classification values  $b_i$  returns for the test set into tenths.  $t_i$  may take the values 0.0, 0.1, 0.2, . . . , 1.0, and X, where 0.0 classifies all instances as negative, 0.1 classifies only instances  $b_i$  assigned values in the top tenth of the range as positive, and so on, and X is the default threshold, labeling essays as positive instances of  $e_i$  only if  $b_i$  returns for them a value greater than 0. It was necessary to assign  $t_i$  in this way because the range of values classifiers return varies greatly depending on which error type we are classifying and which other parameters we use. This method gives us reasonably fine-grained thresholds without having to try an unreasonably large number of values for  $t_i$ .

and Dutnais, 1997) which allows us to automatically generate a semantic similarity measure between any two words. We train our random indexing model on over 30 million words of the English Gigaword corpus (Parker et al., 2009) using the S-Space package (Jurgens and Stevens, 2010). We expect that features based on random indexing may be particularly useful for the Incomplete Prompt Response and Relevance to Prompt errors because they may help us find text related to the prompt even if some of its components have been rephrased (e.g., an essay may talk about “jail” rather than “prison”, which is mentioned in one of the prompts). For each essay, we therefore generate four random indexing features, one encoding the entire essay’s similarity to the prompt, another encoding the essay’s highest individual sentence’s similarity to the prompt, a third encoding the highest entire essay similarity to one of the prompt sentences, and finally one encoding the highest individual sentence similarity to an individual prompt sentence. Since random indexing does not provide a straightforward way to measure similarity between groups of words such as sentences or essays, we use Higgins and Burstein’s (2007) method to generate these features.

## 4.3 Novel Features

Next, we introduce five types of novel features.

**Spelling.** One problem we note when examining the information gain top-ranked features for the Confusing Phrasing error is that there are very few common confusing phrases that can contribute to this error. Errors of this type tend to be unique, and hence are not very useful for error classification (because we are not likely to see the same error in the training and test sets). We notice, however, that there are a few misspelled words at the top of the list. This makes sense because a thesis sentence containing excessive misspellings may be less clear to the reader. Even the most common spelling errors, however, tend to be rare. Furthermore, we ask our annotators to only annotate an error if it makes the thesis less clear. The mere presence of an awkward phrase or misspelling is not enough to justify the Confusing Phrasing label. Hence, we introduce a **misspelling** feature whose value is the number of spelling errors in an essay’s most-misspelled sentence.<sup>4</sup>

<sup>4</sup>We employ SCOWL (<http://wordlist.sourceforge.net/>) as our dictionary, assuming that a

**Keywords.** Improving the prediction of majority classes can greatly enhance our system’s overall performance. Hence, since we have introduced the misspelling feature to enhance our system’s performance on one of the more frequently occurring errors (Confusing Phrasing), it makes sense to introduce another type of feature to improve performance on the other two most frequent errors, Incomplete Prompt Response and Relevance to Prompt. For this reason, we introduce keyword features. To use this feature, we first examine each of the 13 essay prompts, splitting it into its component pieces. For our purposes, a component of a prompt is a prompt substring such that, if an essay does not address it, it may be assigned the Incomplete Prompt Response label. Then, for each component, we manually select the most important (primary) and second most important (secondary) words that it would be good for a writer to use to address the component. To give an example, the lemmatized version of the third component of the second essay in Table 1 is “it should rehabilitate they”. For this component we selected “rehabilitate” as a primary keyword and “society” as a secondary keyword. To compute one of our keyword features, we compute the random indexing similarity between the essay and each group of primary keywords taken from components of the essay’s prompt and assign the feature the lowest of these values. If this feature has a low value, that suggests that the essay may have an Incomplete Prompt Response error because the essay probably did not respond to the part of the prompt from which this value came. To compute another of the keyword features, we count the numbers of combined primary and secondary keywords the essay contains from each component of its prompt, and divide each number by the total number of primary and secondary features for that component. If the greatest of these fractions has a low value, that indicates the essay’s thesis might not be very Relevant to the Prompt.<sup>5</sup>

**Aggregated word n-gram features.** Other ways we could measure our system’s performance (such as macro F-score) would consider our system’s performance on the less frequent errors no less important than its performance on the

word that does not appear in the dictionary is misspelled.

<sup>5</sup>Space limitations preclude a complete listing of the keyword features. See our website at <http://www.hlt.utdallas.edu/~persingq/ICLE/> for the complete list.

most frequent errors. For this reason, it now makes sense for us to introduce a feature tailored to help our system do better at identifying the least-frequent error types, Missing Details and Writer Position, each of which occurs in fewer than 50 essays. To help with identification of these error classes, we introduce aggregated word n-gram features. While we mention in the previous section one of the reasons regular word n-gram features can be expected to help with these error classes, one of the problems with regular word n-gram features is that it is fairly infrequent for the exact same useful phrase to occur too frequently. Additionally, since there are numerous word n-grams, some infrequent ones may just by chance only occur in positive training set instances, causing the learner to think they indicate the positive class when they do not. To address these problems, for each of the five error classes  $e_i$ , we construct two Aggregated word features  $Aw+_i$  and  $Aw-_i$ . For each essay,  $Aw+_i$  counts the number of word n-grams we believe indicate that an essay is a positive example of  $e_i$ , and  $Aw-_i$  counts the number of word n-grams we believe indicate an essay is not an example of  $e_i$ .  $Aw+$  n-grams for the Missing Details error tend to include phrases like “there is something” or “this statement”, while  $Aw-$  ngrams are often words taken directly from an essay’s prompt. N-grams used for Writer Position’s  $Aw+$  tend to suggest the writer is distancing herself from whatever statement is being made such as “every person”, but n-grams for this error’s  $Aw-$  feature are difficult to find. Since  $Aw+_i$  and  $Aw-_i$  are so error specific, they are only included in an essay’s feature representation when it is presented to learner  $b_i$ . So while aggregated word n-grams introduce ten new features, each learner  $b_i$  only sees two of these ( $Aw+_i$  and  $Aw-_i$ ).

We construct the lists of word n-grams that are aggregated for use as the  $Aw+$  and  $Aw-$  feature values in the following way. For each error class  $e_i$ , we sort the list of all features occurring at least ten times in the training set by information gain. A human annotator then manually inspects the top thousand features in each of the five lists and sorts each list’s features into three categories. The first category for  $e_i$ ’s list consists of features that indicate an essay may be a positive instance. Each word n-gram from this list that occurs in an essay increases the essay’s  $Aw+_i$  value by one.

Similarly, any word n-gram sorted into the second category, which consists of features the annotator thinks indicate a negative instance of  $e_i$ , increases the essay’s  $Aw-$  value by one. The third category just contains all the features the annotator did not believe were useful enough to either class, and we make no further use of those features. For most error types, only about 12% of the top 1000 features get sorted into one of the first two categories.

**POS n-grams.** We might further improve our system’s performance on the Missing Details error type by introducing a feature that aggregates part-of-speech (POS) tag n-grams in the same way that the  $Aw$  features aggregate word n-gram features. For this reason, we include POS tag 1, 2, 3, and 4-grams in the set of features we sort in the previous paragraph. For each error  $e_i$ , we select POS tag n-grams from the top thousand features of the information gain sorted list to count toward the  $Ap+_i$  and  $Ap-_i$  aggregation features. We believe this kind of feature may help improve performance on Missing Details because the list of features aggregated to generate the  $Ap+_i$  feature’s value includes POS n-gram features like CC “NN” (scare quotes). This feature type may also help with Confusing Phrasing because the list of POS tag n-grams our annotator generated for its  $Ap+_i$  contains useful features like DT NNS VBZ VBN (e.g., “these signals has been”), which captures noun-verb disagreement.

**Semantic roles.** Our last aggregated feature is generated using FrameNet-style semantic role labels obtained using SEMAFOR (Das et al., 2010). For each sentence in our data set, SEMAFOR identifies each semantic frame occurring in the sentence as well as each frame element that participates in it. For example, a semantic frame may describe an event that occurs in a sentence, and the event’s frame elements may be the people or objects that participate in the event. For a more concrete example, consider the sentence “They said they do not believe that the prison system is outdated”. This sentence contains a Statement frame because a statement is made in it. One of the frame elements participating in the frame is the Speaker “they”. From this frame, we would extract a feature pairing the frame together with its frame element to get the feature “Statement-Speaker-they”. This feature indicates that the essay it occurs in might be a positive instance of the Writer Position error since it tells us the writer is

attributing some statement being made to someone else. Hence, this feature along with several others like “Awareness-Cognizer-we all” are useful when constructing the lists of frame features for Writer Position’s aggregated frame features  $Af+_i$  and  $Af-_i$ . Like every other aggregated feature,  $Af+_i$  and  $Af-_i$  are generated for every error  $e_i$ .

## 5 Score Prediction

Because essays containing thesis clarity errors tend to have lower thesis clarity scores than essays with fewer errors, we believe that thesis clarity scores can be predicted for essays by utilizing the same features we use for identifying thesis clarity errors. Because our score prediction system uses the same feature types we use for thesis error identification, each essay’s vector space representation remains unchanged. Only its label changes to one of the values in Table 2 in order to reflect its thesis clarity score. To make use of the fact that some pairs of scores are more similar than others (e.g., an essay with a score of 3.5 is more similar to an essay with a score of 4.0 than it is to one with a score of 1.0), we cast thesis clarity score prediction as a regression rather than classification task.

Treating thesis clarity score prediction as a regression problem removes our need for a classification threshold parameter like the one we use in the error identification problem, but if we use SVM<sup>light</sup>’s regression option, it does not remove the need for tuning a regularization parameter,  $C$ , or a feature selection parameter,  $n$ .<sup>6</sup> We jointly tune these two parameters to optimize performance on held-out validation data by performing an exhaustive search in the parameter space.<sup>7</sup>

After we select the features, construct the essay instances, train a regressor on training set essays, and tune parameters on validation set essays, we can use the regressor to obtain thesis clarity scores on test set essays.

<sup>6</sup>Before tuning the feature selection parameter, we have to sort the list of n-gram features occurring the training set. To enable the use of information gain as the sorting criterion, we treat each distinct score as its own class.

<sup>7</sup>The absence of the classification threshold parameter and the fact that we do not need to train multiple learners, one for each score, make it feasible for us to do two things. First, we explore a wider range of values for the two parameters: we allow  $C$  to take any value from  $10^0$ ,  $10^1$ ,  $10^2$ ,  $10^3$ ,  $10^4$ ,  $10^5$ ,  $10^6$ , or  $10^7$ , and we allow  $n$  to take any value from 1000, 2000, 3000, 4000, 5000, or ALL. Second, we exhaustively explore the space defined by these parameters in order to obtain an exact solution to the parameter optimization problem.

## 6 Evaluation

In this section, we evaluate our systems for error identification and scoring. All the results we report are obtained via five-fold cross-validation experiments. In each experiment, we use 3/5 of our labeled essays for model training, another 1/5 for parameter tuning, and the final 1/5 for testing.

### 6.1 Error Identification

**Evaluation metrics.** To evaluate our thesis clarity error type identification system, we compute precision, recall, micro F-score, and macro F-score, which are calculated as follows. Let  $tp_i$  be the number of test essays correctly labeled as positive by error  $e_i$ 's binary classifier  $b_i$ ;  $p_i$  be the total number of test essays labeled as positive by  $b_i$ ; and  $g_i$  be the total number of test essays that belong to  $e_i$  according to the gold standard. Then, the precision ( $P_i$ ), recall ( $R_i$ ), and F-score ( $F_i$ ) for  $b_i$  and the macro F-score ( $\hat{F}$ ) of the combined system for one test fold are calculated by

$$P_i = \frac{tp_i}{p_i}, R_i = \frac{tp_i}{g_i}, F_i = \frac{2P_iR_i}{P_i + R_i}, \hat{F} = \frac{\sum_i F_i}{5}.$$

However, the macro F-score calculation can be seen as giving too much weight to the less frequent errors. To avoid this problem, we also calculate for each system the micro precision, recall, and F-score (P, R, and F), where

$$P = \frac{\sum_i tp_i}{\sum_i p_i}, R = \frac{\sum_i tp_i}{\sum_i g_i}, F = \frac{2PR}{P + R}.$$

Since we perform five-fold cross-validation, each value we report for each of these measures is an average over its values for the five folds.<sup>8</sup>

**Results and discussion.** Results on error identification, expressed in terms of precision, recall, micro F-score, and macro F-score are shown in the first four columns of Table 6. Our **Baseline** system, which only uses word n-gram and random indexing features, seems to perform uniformly poorly across both micro and macro F-scores (F and  $\hat{F}$ ; see row 1). The per-class results<sup>9</sup> show that, since micro F-score places more weight on the correct identification of the most frequent errors, the system's micro F-score (31.1%) is fairly close to the average of the scores obtained on the three most frequent error classes, CP, IPR, and R,

<sup>8</sup>This averaging explains why the formula for F does not exactly hold in the Table 6 results.

<sup>9</sup>Per-class results are not shown due to space limitations.

System	Error Identification				Scoring		
	P	R	F	$\hat{F}$	S1	S2	S3
<b>B</b>	24.8	44.7	31.1	24.0	.658	.517	.403
<b>Bm</b>	24.2	44.2	31.2	25.3	.654	.515	.402
<b>Bmk</b>	29.2	44.2	34.9	26.7	.663	.490	<b>.369</b>
<b>Bmkw</b>	28.5	49.6	35.5	31.4	<b>.651</b>	.484	.374
<b>Bmkwp</b>	<b>34.2</b>	49.6	40.4	34.6	.671	<b>.483</b>	.377
<b>Bmkwpf</b>	33.6	<b>54.4</b>	<b>41.4</b>	<b>37.3</b>	.672	.486	.382

Table 6: Five-fold cross-validation results for the thesis clarity error identification and scoring.

and remains unaffected by very low F-scores on the two remaining infrequent classes.<sup>10</sup>

When we add the **misspelling** feature to the baseline, resulting in the system called **Bm** (row 2), the micro F-score sees a very small, insignificant improvement.<sup>11</sup> What is pleasantly surprising, however, is that, even though the misspelling features were developed for the Confusing Phrasing error type, they actually have more of a positive impact on Missing Details and Writer Position, bumping their individual error F-scores up by about 5 and 3 percent respectively. This suggests that spelling difficulties may be correlated with these other essay-writing difficulties, despite their apparent unrelatedness. This effect is strong enough to generate the small, though insignificant, gain in macro F-score shown in the table.

When we add **keyword** features to the system, micro F-score increases significantly by 3.7 points (row 3). The micro per-class results reveal that, as intended, keyword features improve Incomplete Prompt Response and Relevance to Prompt's F-scores reveals that they do by 6.4 and 9.2 percentage points respectively. The macro F-scores reveal this too, though the macro F-score gains are 3.2 points and 11.5 points respectively. The macro F-score of the overall system would likely have improved more than shown in the table if the addition of keyword features did not simultaneously reduce Missing Details's score by several points.

While we hoped that adding aggregated word n-gram features to the system (row 4) would be able to improve performance on Confusing Phrasing due to the presence of phrases such as "in university be" in the error's  $Aw+_i$  list, there turned out to be few such common phrases in the data set,

<sup>10</sup>Since parameters for optimizing micro F-score and macro F-score are selected independently, the per-class F-scores associated with micro F-score are different than those used for calculating macro F-score. Hence, when we discuss per-class changes influencing micro F-score, we refer to the former set, and otherwise we refer to the latter set.

<sup>11</sup>All significance tests are paired  $t$ -tests, with  $p < 0.05$ .

so performance on this class remains mostly unchanged. This feature type does, however, result in major improvements to micro and macro performance on Missing Details and Writer Position, the other two classes this feature was designed to help. Indeed, the micro F-score versions of Missing Details and Writer Position improve by 15.3 and 10.8 percentage points respectively. Since these are minority classes, however, the large improvements result in only a small, insignificant improvement in the overall system’s micro F-score. The macro F-score results for these classes, however, improve by 6.5% and 17.6% respectively, giving us a nearly 5-point, statistically significant bump in macro F-score after we add this feature.

Confusing Phrasing has up to now stubbornly resisted any improvement, even when we added features explicitly designed to help our system do better on this error type. When we add aggregated part of speech n-gram features on top of the previous system, that changes dramatically. Adding these features makes both our system’s F-scores on Confusing Phrasing shoot up almost 8%, resulting in a significant, nearly 4.9% improvement in overall micro F-score and a more modest but insignificant 3.2% improvement in macro F-score (row 5). The micro F-score improvement can also be partly attributed to a four point improvement in Incomplete Prompt Response’s micro F-score. The 13.7% macro F-score improvement of the Missing Details error plays a larger role in the overall system’s macro F-score improvement than Confusing Phrasing’s improvement, however.

The improvement we see in micro F-score when we add aggregated frame features (row 6) can be attributed almost solely to improvements in classification of the minority classes. This is surprising because, as we mentioned before, minority classes tend to have a much smaller impact on overall micro F-score. Furthermore, the overall micro F-score improvement occurs despite declines in the performances on two of the majority class errors. Missing Details and Writer Position’s micro F-score performances increase by 19.1% and 13.4%. The latter is surprising only because of the magnitude of its improvement, as this feature type was explicitly intended to improve its performance. We did not expect this aggregated feature type to be especially useful for Missing Details error identification because very few of these types of features occur in its  $Af+i$  list, and there are

none in its  $Af-i$  list. The few that are in the former list, however, occur fairly often and look like fairly good indicators of this error (both the examples “Event-Event-it” and “Categorization-Item-that” occur in the positive list, and both do seem vague, indicating more details are to be desired).

Overall, this system improves our baseline’s macro F-score performance significantly by 13.3% and its micro F-score performance significantly by 10.3%. As we progressed, adding each new feature type to the baseline system, there was no definite and consistent pattern to how the precisions and recalls changed in order to produce the universal increases in the F-scores that we observed for each new system. Both just tended to jerkily progress upward as new feature types were added. This confirms our intuition about these features – namely that they do not all uniformly improve our performance in the same way. Some aim to improve precision by telling us when essays are less likely to be positive instances of an error class, such as any of the  $Aw-i$ ,  $Ap-i$ , or  $Af-i$  features, and others aim to tell us when an essay is more likely to be a positive instance of an error.

## 6.2 Scoring

**Scoring metrics.** We design three evaluation metrics to measure the error of our thesis clarity scoring system. The  $S1$  metric measures the frequency at which a system predicts the wrong score out of the seven possible scores. Hence, a system that predicts the right score only 25% of the time would receive an  $S1$  score of 0.75.

The  $S2$  metric measures the average distance between the system’s score and the actual score. This metric reflects the idea that a system that estimates scores close to the annotator-assigned scores should be preferred over a system whose estimations are further off, even if both systems estimate the correct score at the same frequency.

Finally, the  $S3$  metric measures the average square of the distance between a system’s thesis clarity score estimations and the annotator-assigned scores. The intuition behind this metric is that not only should we prefer a system whose estimations are close to the annotator scores, but we should also prefer one whose estimations are not too frequently very far away from the annotator scores. These three scores are given by:

$$\frac{1}{N} \sum_{A_j \neq E'_j} 1, \quad \frac{1}{N} \sum_{i=1}^N |A_j - E_j|, \quad \frac{1}{N} \sum_{i=1}^N (A_j - E_j)^2$$

where  $A_j$ ,  $E_j$ , and  $E'_j$  are the annotator assigned, system estimated, and rounded system estimated scores<sup>12</sup> respectively for essay  $j$ , and  $N$  is the number of essays.

**Results and discussion.** Results on scoring are shown in the last three columns of Table 6. We see that the thesis clarity score predicting variation of the **Baseline** system, which employs as features only word n-grams and random indexing features, predicts the wrong score 65.8% of the time. Its predicted score is on average 0.517 points off of the actual score, and the average squared distance between the predicted and actual scores is 0.403.

We observed earlier that a high number of misspellings may be positively correlated with one or more unrelated errors. Adding the **misspelling** feature to the scoring systems, however, only yields minor, insignificant improvements to their performances under the three scoring metrics.

While adding **keyword** features on top of this system does not improve the frequency with which the right score is predicted, it both tends to move the predictions closer to the actual thesis clarity score value (as evidenced by the significant improvement in  $S2$ ) and ensures that predicted scores will not too often stray too far from the actual value (as evidenced by the significant improvement in  $S3$ ). Overall, the scoring model employing the **Bmk** feature set performs significantly better than the **Baseline** scoring model with respect to two out of three scoring metrics.

The only remaining feature type whose addition yields a significant performance improvement is the aggregated **word** feature type, which improves system **Bmk**'s  $S2$  score significantly while having an insignificant impact on the other  $S$  metrics.

Neither of the remaining aggregative features yields any significant improvements in performance. This is a surprising finding since, up until we introduced aggregated **part-of-speech** tag n-gram features into our regressor, each additional feature that helped with error classification made at least a small but positive contribution to at least two out of the three  $S$  scores. These aggregative features, which proved to be very powerful when assigning error labels, are not as useful for thesis

<sup>12</sup>Since our regressor assigns each essay a real value rather than an actual valid thesis clarity score, it would be difficult to obtain a reasonable  $S1$  score without rounding the system estimated score to one of the possible values. For that reason, we round the estimated score to the nearest of the seven scores the human annotators were permitted to assign (1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0) only when calculating  $S1$ .

Gold	S1 (Bmkw)			S2 (Bmkwp)			S3 (Bmk)		
	.25	.50	.75	.25	.50	.75	.25	.50	.75
1.0	3.5	3.5	3.5	3.0	3.2	3.5	3.1	3.2	3.3
1.5	2.5	3.0	3.0	2.8	3.1	3.2	2.6	3.0	3.2
2.0	3.0	3.0	3.5	3.0	3.2	3.5	3.0	3.1	3.4
2.5	3.0	3.5	3.5	3.0	3.3	3.6	3.0	3.3	3.5
3.0	3.0	3.5	3.5	3.1	3.4	3.5	3.1	3.3	3.5
3.5	3.5	3.5	4.0	3.2	3.4	3.6	3.2	3.4	3.5
4.0	3.5	3.5	4.0	3.4	3.6	3.8	3.4	3.5	3.7

Table 7: Regressor scores for top three systems.

clarity scoring.

To more closely examine the behavior of the best scoring systems, in Table 7 we chart the distributions of scores they predict for each gold standard score. As an example of how to read this table, consider the number 2.8 appearing in row 1.5 in the .25 column of the  $S2$  (**Bmkwp**) region. This means that 25% of the time, when system **Bmkwp** (which obtains the best  $S2$  score) is presented with a test essay having a gold standard score of 1.5, it predicts that the essay has a score less than or equal to 2.8 for the  $S2$  metric.

From this table, we see that each of the best systems has a strong bias toward predicting more frequent scores as there are no numbers less than 3.0 in the 50% columns, and about 82.8% of all essays have gold standard scores of 3.0 or above. Nevertheless, no system relies entirely on bias, as evidenced by the fact that each column in the table has a tendency for its scores to ascend as the gold standard score increases, implying that the systems have some success at predicting lower scores for essays with lower gold standard scores.

Finally, we note that the difference in error weighting between the  $S2$  and  $S3$  scoring metrics appears to be having its desired effect, as there is a strong tendency for each entry in the  $S3$  subtable to be less than or equal to its corresponding entry in the  $S2$  subtable due to the greater penalty the  $S3$  metric imposes for predictions that are very far away from the gold standard scores.

## 7 Conclusion

We examined the problem of modeling thesis clarity errors and scoring in student essays. In addition to developing these models, we proposed novel features for use in our thesis clarity error model and employed these features, each of which was explicitly designed for one or more of the error types, to train our scoring model. We make our thesis clarity annotations publicly available in order to stimulate further research on this task.

## Abstract

We present a corpus analysis of how Italian connectives are translated into LIS, the Italian Sign Language. Since corpus resources are scarce, we propose an alignment method between the syntactic trees of the Italian sentence and of its LIS translation. This method, and clustering applied to its outputs, highlight the different ways a connective can be rendered in LIS: with a corresponding sign, by affecting the location or shape of other signs, or being omitted altogether. We translate these findings into a computational model that will be integrated into the pipeline of an existing Italian-LIS rendering system. Initial experiments to learn the four possible translations with Decision Trees give promising results.

## 1 Introduction

Automatic translation between a spoken language and a signed language gives rise to some of the same difficulties as translation between spoken languages, but adds unique challenges of its own. Contrary to what one might expect, sign languages are not artificial languages, but natural languages that spontaneously arose within deaf communities; although they are typically named after the region where they are used, they are not derived from the local spoken language and tend to bear no similarity to it. Therefore, translation from any spoken language into the signed language of that specific region is at least as complicated as between any pairs of unrelated languages.

The problem of automatic translation is compounded by the fact that the amount of computational resources to draw on is much smaller than is typical for major spoken languages. Moreover, the fact that sign languages employ a different

transmission modality (gestures and expressions instead of sounds) means that existing writing systems are not easily adaptable to them. The resulting lack of a shared written form does nothing to improve the availability of sign language corpora; bilingual corpora, which are of particular importance to a translation system, are especially rare. In fact, various projects around the world are trying to ameliorate this sad state of affairs for specific Sign Languages (Lu and Huenerfauth, 2010; Braffort et al., 2010; Morrissey et al., 2010).

In this paper, we describe the work we performed as concerns the translation of connectives from the Italian language into LIS, the Italian Sign Language (*Lingua Italiana dei Segni*). Because the communities of signers in Italy are relatively small and fragmented, and the language has a relatively short history, there is far less existing research and material to draw on than for, say, ASL (American Sign Language) or BSL (British Sign Language).

Our work was undertaken within the purview of the ATLAS project (Bertoldi et al., 2010; Lombardo et al., 2010; Lombardo et al., 2011; Prinetto et al., 2011; Mazzei, 2012; Ahmad et al., 2012), which developed a full pipeline for translating Italian into LIS. ATLAS is part of a recent crop of projects devoted to developing automatic translation from language  $L$  spoken in geographic area  $G$  into the sign language spoken in  $G$  (Dreuw et al., 2010; López-Ludeña et al., 2011; Almohimeed et al., 2011; Lu and Huenerfauth, 2012). Input is taken in the form of written Italian text, parsed, and converted into a semantic representation of its contents; from this semantic representation, LIS output is produced, using a custom serialization format called AEWLIS (which we will describe later). This representation is then augmented with space positioning information, and fed into a final renderer component that performs the signs using a virtual actor. ATLAS focused on a limited domain for which a bilingual Italian/LIS cor-

pus was available: weather forecasts, for which the Italian public broadcasting corporation (RAI) had long been producing special broadcasts with a signed translation. This yielded a corpus of 376 LIS sentences with corresponding Italian text: this corpus, converted into AEWLIS format, was the main data source for the project. Still, it is a very small corpus, hence the main project shied away from statistical NLP techniques, relying instead on rule-based approaches developed with the help of a native Italian/LIS bilingual speaker; a similar approach is taken e.g. in (Almohimeed et al., 2011) for Arabic.

### 1.1 Why connectives?

The main semantic-bearing elements of an Italian sentence, such as nouns or verbs, typically have a LIS sign as their direct translation. We focus on a different class of elements, comprising conjunctions and prepositions, but also some adverbs and prepositional phrases; collectively, we refer to them as connectives. Since they are mainly structural elements, they are more heavily affected by differences in the syntax and grammar of Italian and LIS (and, presumably, in those of any spoken language and the “corresponding” SL). Specifically, as we will see later, some connectives are translated with a sign, some connectives are dropped, whereas others affect the positioning of other signs, or just their syntactic proximity.

It should be noted that our usage of the term “connectives” is somewhat unorthodox. For example, while prepositions can be seen as connectives (Ferrari, 2008), only a few adverbs can work as connectives. From the Italian Treebank, we extracted all words or phrases that belonged to a syntactic category that can be a connective (conjunction, preposition, adverb or prepositional phrase). We then found that we could better serve the needs of ATLAS by running our analysis on the entire resulting list, without filtering it by eliminating the entries that are not actual connectives. In fact, semantic differences re-emerge through our analysis: e.g., the temporal adverbs “domani” and “dopodomani” are nearly always preserved, as they do carry key information (especially for weather forecasting) and are not structural elements.

In performing our analysis, we pursued a different path from the main project, relying entirely on the bilingual corpus. Although the use of sta-

tistical techniques was hampered by the small size of the corpus, at the same time it presented an interesting opportunity to attack the problem from a different angle. In this paper we describe how we uncovered the translation distributions of the different connectives from Italian to LIS via tree alignment.

## 2 Corpus Analysis

The corpus consists of 40 weather forecasts in Italian and LIS. The Italian spoken utterance and LIS signing were transcribed from the original videos – one example of an Italian sentence and its LIS equivalent are shown in Figure 1. An English word-by-word translation is provided for the Italian sentence, followed by a more fluent translation; the LIS glosses are literally translated. Note that as concerns LIS, this simply includes the gloss for the corresponding sign. The 40 weather forecast comprise 374 Italian sentences and 376 LIS sentences, stored in 372 AEWLIS files. In most cases, a file corresponds to one Italian sentence and one corresponding LIS sentences; however, there are 4 files where an Italian sentence is split into two LIS sentences, and 2 files where two Italian sentences are merged into one LIS sentence.

AEWLIS is an XML-based format (see Figure 2) which represents each sign in the LIS sentence as an element, in the order in which they occur in the sentence. A sign’s lemma is represented by the Italian word with the same meaning, always written in uppercase, and with its part of speech (*tipoAG* in Figure 2); there are also IDs referencing the lemma’s position in a few dictionaries, but these are not always present. The AEWLIS file also stores several additional attributes, such as: a parent reference that represents the syntax of the LIS sentence; the syntactic role “played” by the sign in the LIS sentence; the facial expression accompanying the gesture; the location in the signing space (which may be an absolute location or a reference to a previous sign’s: compare *HR* (High Right) and *atLemma* in Figure 2). These attributes are stored as elements grouped by type, and reference the corresponding sign element by its ordinal position in the sentence. The additional attributes are not always available: morphological variations are annotated only when they differ from an assumed standard form of the sign, while the syntactic structure was annotated for only 89 sentences.

## 2.1 Distributional statistics for connectives

The list of Italian connectives we considered was extracted from the Italian Treebank developed at the Institute for Computational Linguistics in Pisa, Italy (Montemagni et al., 2003) by searching for conjunctions, prepositions and adverbs. This yielded a total of 777 potential connectives. Of those, only 104 occur in our corpus. A simple count of the occurrences of connectives in the Italian and LIS versions of the corpus yields the following results:

- (a) 78 connectives (2068 occurrences total) only occur in the Italian version, for example *ALMENO* (at least), *CON* (with), *INFATTI* (indeed), *PER* (for).
- (b) 8 connectives (67 occurrences total) only occur in the LIS version, for example *CIRCA* (about), *as in* “Here I am”, *PURE* (also, additionally).
- (c) 25 connectives (925 occurrences total) occur in both versions.

For the third category, we have computed the ratio of the number of occurrences in Italian over the number of occurrences in LIS; the ratios are plotted in logarithmic scale in Figure 3. 0 on the scale corresponds to an ITA/LIS ratio equal to 1; positive numbers indicate that there are more occurrences in ITA, negative numbers that there are more occurrences in LIS. We can recognize three clusters by ratio:

- (c1) 9 connectives occurring in both languages, but mainly in Italian, for example *POCO* (a little), *PIÙ* (more), *SE* (if), *QUINDI* (hence).
- (c2) 13 connectives occurring in both languages with similar frequency, for example *SOLO* (only), *POI* (then), *O* (or), *MA* (but).
- (c3) 3 connectives occurring in both languages, but mainly in LIS: *MENO* (less), *ADESSO* (now), *INVECE* (instead).

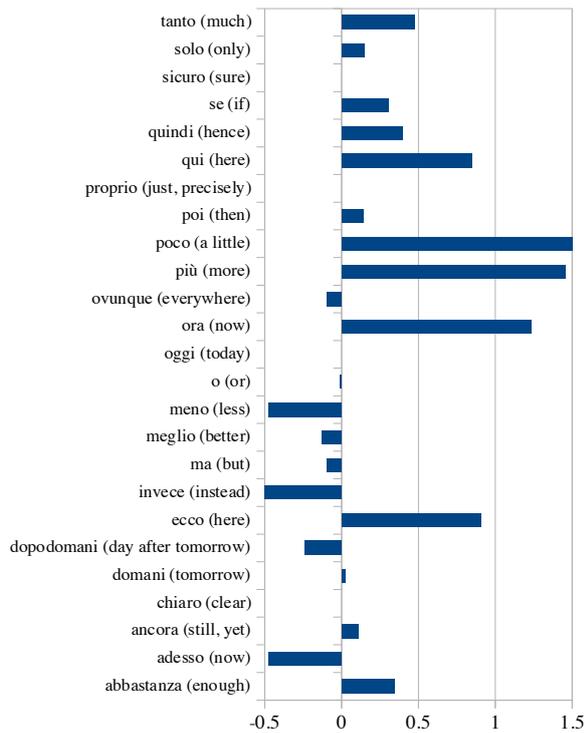

Figure 3: Ratio of ITA/LIS occurrences in logarithmic scale.

### 3 The effect of the Italian connectives on the LIS translation

From this basic frequency analysis we can already notice that a large number of connectives only appear in Italian, or have far more occurrences in Italian than in LIS. This is unsurprising, considering that LIS sentences tend to be shorter than Italian sentences in terms of number of signs/words (a fact which probably correlates with the increased energy and time requirements intrinsic into articulating a message using one's arms rather than one's tongue). However, our goal is to predict when a connective should be dropped and when it should be preserved. Furthermore, even if the connective does not appear in the LIS sentence as a directly corresponding sign, that does not mean that its presence in the Italian sentence has no effect on the translation. We hypothesize four different possible realizations for a connective in the Italian sentence:

- the connective word or phrase may map to a corresponding connective sign;
- the connective is not present as a sign, but may affect the morphology of the signs which translate words syntactically adjacent to the

connective;

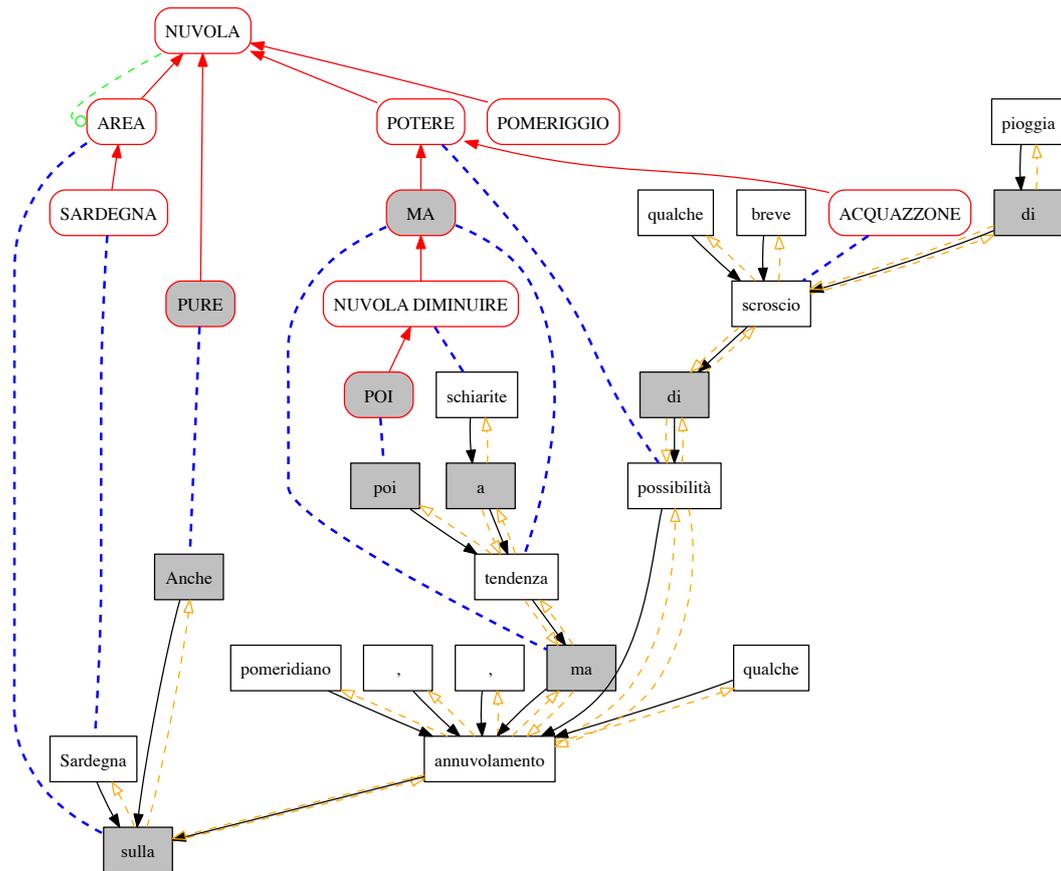

- the connective is not present as a sign, but its presence may be reflected by the fact that words connected by it map to signs which are close to each other in the LIS syntax tree;
- the connective is dropped altogether.

The second hypothesis deserves some explanation. The earliest treatments of LIS assumed that each sign (lemma) could be treated as invariant. Attempts to represent LIS in writing simply replaced each sign with a chosen Italian word (or phrase, if necessary) with the same meaning. Although this is still a useful way of representing the basic lemma, more recent studies have noted that LIS signs can undergo significant morphological variations which are lost under such a scheme. The AEWLIS format, in fact, was designed to preserve them.

Of course, morphological variations in LIS are not phonetic, like in a spoken language, but gestural (Volterra, 1987; Romeo, 1991). For example, the location in which a gesture is performed may be varied, or its speed, or the facial expressions that accompany it (Geraci et al., 2008). One particularly interesting axis of morphology is the positioning of the gesture in the signing space in front of the signer. This space is implicitly divided into a grid with a few different positions from left to right and from top to bottom (see HR – High Right, and LH – High Left, in Figure 2). Two or more signs can then be placed in different positions in this virtual space, and by performing other signs in the same positions the signer can express a backreference to the previously established entity at that location. One can even have a movement verb where the starting and ending positions of the gesture are positioned independently to indicate the source and destination of the movement. In other words, these morphological variations can perform a similar function to gender and number agreement in Italian backreferences, but they can also assume roles that in Italian would be performed by prepositions, which are connectives. In fact, as we will see later on, Italian prepositions are never translated as signs, but are often associated with morphological variations on related signs.

#### 3.1 Tree Alignment

Two of our four translation hypotheses involve a notion of distance on the syntax tree, and a no-

19\_f08\_2011-06-08\_10\_04\_10.xml  
 Anche sulla Sardegna qualche annuvolamento pomeridiano, possibilità di qualche breve scroscio di pioggia, ma tendenza poi a schiarite pomeriggio Sardegna area nuvola pure acquazzone potere ma poi nuvola diminuire

Figure 4: Example of integrated syntax trees.

tion of signs corresponding to words. Therefore, it is not sufficient to consider the LIS sentence and the Italian sentence separately. Instead, their syntax trees must be reconstructed and aligned. Tree alignment in a variety of forms has been extensively used in machine translation systems (Gildea, 2003; Eisner, 2003; May and Knight, 2007). As far as we know, we are the first to attempt the usage of tree alignment to aid in the translation between a spoken and a sign language, partly because corpora that include syntactic trees for sign language sentences hardly exist. (López-Ludeña et al., 2011) does use alignment techniques for translation from Spanish to Spanish Sign Language (SSL), but it is limited to alignment between words or phrases in Spanish, and glosses or sequences of glosses in SSL.

We have developed a pipeline that takes in input the corpus files, parses the Italian sentence with

an existing parser, and retrieves / builds a parse tree for the LIS sentence. The two trees are then aligned by exploiting the word/sign alignment. A sample output is shown in Figure 4.

**Italian sentence parsing.** Since the corpus contains the Italian sentences in plain, unstructured text form, they need to be parsed. We used the DeSR parser, a dependency parser pre-trained on a very large Italian corpus (Attardi et al., 2007; Ciarrita and Attardi, 2011). This parser produced the syntax trees and POS tagging that we used for the Italian part of the corpus.

**LIS syntax tree.** One of the attributes allowed by AEWLIS is “parent”, which points a sign to its parent in the syntax tree, or marks it as a root (see Figure 2). These hand-built syntax trees are available in roughly 1/4 of the AEWLIS files. Because the size of our corpus is already limited, and be-

cause no tools are available to generate LIS syntax trees, for the remaining 3/4 of the corpus we fell back on a simple linear tree where each sign is connected to its predecessor. This solution at least maintains locality in most cases.

**Word Alignment.** Having obtained syntax trees for the two sentences, we then needed to align them. For this purpose we used the Berkeley Word Aligner (BWA) <sup>1</sup> (Denero, 2007), a general tool for aligning sentences in bilingual corpora. BWA takes as input a series of matching sentences in two different languages, trains multiple unsupervised alignment models, and selects the optimal result using a testing set of manual alignments. The output is a list of aligned word indices for each input sentence pair. On our data set, BWA performance is as follows: Precision = 0.736364, Recall = 0.704348, AER = 0.280000.

**Integration.** The result is an integrated syntax tree representation of the Italian and LIS versions of the sentence, with arcs bridging aligned word/sign pairs. Since some connectives consist of multi-word phrases, the word nodes which are part of one are merged into a super-node that inherits all connections to other nodes. Figure 4 shows the end result for the Italian and LIS sentences in Figure 1 (the two sentences are repeated for convenience at the bottom of Figure 4). The rectangular boxes are words in the Italian sentence, while the rounded boxes are signs in the LIS sentence. The Italian tree has its root(s) at the bottom, while the LIS tree has its root(s) at the top. Solid arrows point from children to parent nodes in the syntax tree. Gray-shaded boxes represent connectives (words or signs, as indicated by the border of the box). Bold dashed lines show word alignment. Edges with round heads show relationships where a sign has a location attribute referencing another sign. Arrows with an empty triangular head trace the paths described in the next section.

### 3.2 Subtree alignment and path processing

At this point individual words are aligned, but that is not sufficient. Our hypotheses on the effect of connectives on translation requires us to align a tree fragment surrounding the Italian connective with the corresponding tree fragment on the LIS

side - where the connective may be missing. In effect, since we have hypothesized that the presence of a connective can affect the translation of the two subtrees that it connects, we would like to be able to align each of those subtrees to its translation. However, given the differences between the two languages, it is not easy to give a clear definition of this mapping - let alone to compute it.

Instead, we can take a step back to word-level alignment. We make the observation that, if two words belong to two different subtrees linked by a connective, so that the path between the two words goes through the connective, then the frontier between the LIS counterparts of those two subtrees should also lie along the path between the signs aligned with those two words. If the connective is preserved in translation as a sign, we should expect to find it along that path; if it is not, its effect should still be seen along that path, either in the form of morphological variations to the signs along the path, or in the shortness of the path itself.

The first step, then, is to split the Italian syntax tree by removing the connective. This yields one subtree containing the connective's parent node, if any, and one subtree for each of the connective's children, if any. The parent subtree typically contains most of the rest of the sentence, so only the direct ancestors of the connective are considered. Then, each pair of words belonging to different subtrees is linked by a path that goes through the connective in the original tree. Of these words, we select the ones that have aligned signs, and then we compute the path between each pair of signs aligned to words belonging to different subtrees. This gives us a set of paths to consider in the LIS syntax tree.

For example, let us consider the connective “di” between “possibilità” and “scroscio” in Figure 4.

- This node connects two subtrees: a child subtree containing “qualche, breve, scroscio, di, pioggia”, and a parent subtree containing the rest of the sentence.
- From each subtree, a set of paths is generated: all paths extending from the connective to the leaves of the child subtree (for example “scroscio, qualche” or “scroscio, di, pioggia”), and the path of direct ancestors in the parent tree (“sulla, annuolamento, possibilità”).
- Iterate through the cartesian product of each

pair of sets (in this case we have only one pair), and consider the full path formed by the two paths connected by the connective node (for instance, “sulla, annuolamento, possibilità, di, scroscio, breve”).

- For each of these paths, take the signs aligned to words on different sides of the target connective, and find the shortest path between those signs in the LIS syntax tree; we call this the aligned path. For example, from “possibilità” and “scroscio” we find “POTERE, ACQUAZZONE”. If this process generates multiple paths, only the maximal ones are kept.

By looking at words within a certain distance of the connective, at their aligned signs, and at the distance between those signs in the aligned path, the program then produces one or more “translation candidates” for each occurrence of a connective:

- Sign: if the connective word is aligned to a connective sign in LIS, that is its direct translation;

- Location: if morphology variations (currently limited to the “location” attribute, see Figure 2) are present on a sign aligned to an It. word belonging to one of the examined paths, and the word is less than 2 steps away from the connective, that morphological variation in LIS may capture the function of the connective;

- Close: if two It. words are connected by a connective, and they map to signs which have a very short path between them (up to 3 nodes, including the two signs), the connective may be reflected simply in this close connection between the translated subtrees in the LIS syntax tree;

- Missing: if none of the above hypotheses are possible, we hypothesize that the connective has been simply dropped.

Table 1 shows the results of this analysis. It includes only connectives with more than 10 occurrences. For each connective and translation hypothesis, the shading of the cell is proportional to

the fraction of occurrences where that hypothesis is possible; this fraction is also given as a percent. Note that Sign, Location and Close candidates are not mutually exclusive: for instance, an occurrence of a connective might be directly aligned with a sign, but at the same time it might fit the criteria for a Location candidate. For this reason, the sum of the percents in the four columns is not necessarily 100.

k-means clustering (MacQueen, 1967; Lloyd, 1982) has been applied to the connectives, with the aforementioned fractions as the features. The resulting five clusters are represented by the row groupings in the table.

The first cluster contains words which clearly have a corresponding sign in LIS, such as “domani” (tomorrow). “Domani” and “dopodomani” are not actually connectives, while “mentre”, “o” and “però” are. It is interesting to note that, while a logician might expect “e” (and) and “o” (or) to be treated similarly, they actually work quite differently in LIS: there is a specific sign for “o”, but there is no sign for “e”. Instead, signs are simply juxtaposed in LIS where “e” would be used in Italian.

The words in the second cluster also have a direct sign translation, but they are missing in the LIS translation around half of the time. Several words represent connections with previous statements or situations, such as “ancora” (again), “invece” (instead), “ma” (but). These appear to be often dropped in LIS when they reference a previous sentence, e.g. a sentence-initial “ma”; or when they are redundant in Italian, e.g. “ma” in “ma anche” (“but also”). Therefore, we think can see two phenomena at play here: a stronger principle of economy in LIS, and a reduced number of explicit connections across sentences.

The third cluster is similar to the second cluster, but with a higher percent of dropped connectives. This is probably related to the semantics of these five words. “Abbastanza” means “quite, enough”, and in general indicates a medium quantity, not particularly large nor particularly small. It is no surprise that this word is more likely to succumb to principles of economy in language. “Anche” means “also”, and is either translated as “PURE” (also) or dropped. This does not seem to depend on the specific circumstances of its usage; rather, it seems to be largely a stylistic choice by the translator. “Proprio” (“precisely”, “just”) has a corre-

sponding sign “PROPRIO”, but since it does not convey essential information it is a good candidate for dropping. “Quindi”, meaning “therefore”, has its own sign “QUINDI”, but once again the causal relationship it conveys is usually not essential to understanding what the weather will be, and thus it is frequently dropped.

The fourth cluster consists of connectives which are largely simply dropped. Some of these are elements that just contribute to the discourse flow in Italian, such as “per quanto riguarda” (“concerning”); in fact, this connective mainly occurs in sentence-initial position in the Italian sentences in our corpus and denotes a change of topic from the previous sentence, corroborating our hypothesis of a reduced use of explicit inter-sentence connections in LIS. It may seem strange for comparative and intensity markers such as “più” (more) or “poco” (a little) to be so consistently dropped, but it turns out that intensity variations for weather phenomena are often embedded into a specific sign, for example “NUVOLOSITÀ AUMENTARE” (increasing cloud cover).

The fifth cluster contains all Italian prepositions (with 10 or more occurrences in the corpus), none of which is translated as a sign (the 6 occurrences for “in”, the 4 for “su” and the 2 for “di” are due to alignment errors). We can conclude that prepositions do not exist in LIS as parts of speech; however, the prepositions in this cluster are often associated with morphological variations in the spatial positioning of related signs, which suggests that the role associated with these prepositions in Italian is performed by these variations in LIS. The conjunction “e” (and) also ends up in this cluster, although it has 8 legitimate sign alignments with “pure” (“too”); the rest are alignment errors. Unsurprisingly, all connectives in this class also have high ratings for the “close” hypothesis.

#### 4 Rule extraction

We trained a classifier to help a LIS generator determine how an Italian connective should be translated. Because the translation pipeline we plan to integrate with is rule-based, we chose a Decision Tree as our classifier: this allows rules to be easily extracted from the classification model.

In order to identify a single class for each example, we ranked the four possible translation candidates as follows: Sign is the strongest, then Location, then Close, and finally Missing is the

$\text{child1\_align} = \text{None} \cap \text{word} = \text{Per\_quanto\_riguarda} \cap \text{parent\_align} = \text{None} \Rightarrow \text{Missing}$   
 $\text{child1\_align} = \text{None} \cap \text{word} = \text{Per\_quanto\_riguarda} \cap \text{parent\_align} = \text{PREVEDERE} \Rightarrow \text{Close}$   
 $\text{child1\_align} = \text{None} \cap \text{word} = \text{o} \Rightarrow \text{Align(O)}$   
 $\text{child1\_align} = \text{None} \cap \text{word} = \text{su} \cap \text{child2\_align\_mykind} = \text{location} \cap \text{child2\_align} = \text{SICILIA} \Rightarrow \text{Location}$

Figure 5: Some rules extracted from the decision tree

weakest. Then, each example is labeled with the strongest translation candidate available for it: thus, for example, if the connective word appears to be translated with a connective sign, and the words it connects are also aligned to signs which are close to each other syntactically, then the class is Sign, not Close.

Our training data suffers from large imbalance between the “missing” class and the others. A classifier that simply labels all examples as “missing” would have an accuracy above 60%, and in fact, that is the classifier that we obtain if we attempt to automatically optimize the parameters of a Decision Tree (DT). We also note that, for connectives where both options are possible, choosing to translate them can make the sentence more verbose, but choosing to drop them risks losing part of the sentence’s meaning: the worse risk is the latter. Following accepted practice with unbalanced datasets (Chawla et al., 2004), we rebalanced the classes by duplicating all examples of the Align, Location and Close classes, but not those of the Missing class.

On our data set of connectives with at least 10 occurrences, we trained a DT using AdaBoost (Freund and Schapire, 1997). The features include the word neighboring the connective in the Italian syntax tree, their aligned signs if any, part of speech tags, and semantic categories such as time or location. The resulting tree is very large, but we provide a few examples of the rules that can be extracted from it in Figure 5.

Bootstrap evaluation shows our DT to have an accuracy of  $83.58\% \pm 1.03\%$ . In contrast, a baseline approach of taking the most common class for each connective results in an accuracy of  $68.70\% \pm 0.88\%$ . Furthermore, the baseline classifier has abysmal recall for the Close and Location classes (0.00% and 0.85%, respectively), which our DT greatly improves upon ( $86.73\%$  and  $75.32\%$ ).

In order to estimate the impact of the lack of a LIS syntax tree in most of the corpus, we also learned and evaluated a DT using only the 1/4 of the corpus for which LIS syntax trees are available. The accuracy is  $81.44\% \pm 2.03\%$ , versus a

baseline of  $71.55\% \pm 1.74\%$ . The recall for Close and Location is  $89.22\%$  and  $73.58\%$ , vs.  $0.00\%$  and  $3.51\%$  for the baseline. These results are comparable with the those obtained on the whole corpus, confirming that linear trees are a reasonable fallback.

Both clustering and classification were performed using RapidMiner 5.3.<sup>2</sup>

## 5 Conclusions and Future Work

The small size of our corpus, with around 375 bilingual sentences, posed a large challenge to the use of statistical methods; on the other hand, having no access to a LIS speaker prevented us from simply relying on a rule-based approach. By combining syntax tree processing with several machine learning techniques, we were able to analyze the corpus and detect patterns that show linguistic substance. We have produced initial results in terms of rule extraction, and we will be integrating these rules into the full Italian-LIS translation system to produce improved translation of connectives.

# Stop-probability estimates computed on a large corpus improve Unsupervised Dependency Parsing

David Mareček and Milan Straka

Charles University in Prague, Faculty of Mathematics and Physics

## Abstract

Even though the quality of unsupervised dependency parsers grows, they often fail in recognition of very basic dependencies. In this paper, we exploit a prior knowledge of STOP-probabilities (whether a given word has any children in a given direction), which is obtained from a large raw corpus using the reducibility principle. By incorporating this knowledge into Dependency Model with Valence, we managed to considerably outperform the state-of-the-art results in terms of average attachment score over 20 treebanks from CoNLL 2006 and 2007 shared tasks.

## 1 Introduction

The task of unsupervised dependency parsing (which strongly relates to the grammar induction task) has become popular in the last decade, and its quality has been greatly increasing during this period.

The first implementation of Dependency Model with Valence (DMV) (Klein and Manning, 2004) with a simple inside-outside inference algorithm (Baker, 1979) achieved 36% attachment score on English and was the first system outperforming the adjacent-word baseline.<sup>1</sup>

Current attachment scores of state-of-the-art unsupervised parsers are higher than 50% for many languages (Spitkovsky et al., 2012; Blunsom and Cohn, 2010). This is still far below the supervised approaches, but their indisputable advantage is the fact that no annotated treebanks are needed and the induced structures are not burdened by any linguistic conventions. Moreover,

<sup>1</sup>The adjacent-word baseline is a dependency tree in which each word is attached to the previous (or the following) word. The attachment score of 35.9% on all the WSJ test sentences was taken from (Blunsom and Cohn, 2010).

supervised parsers always only simulate the treebanks they were trained on, whereas unsupervised parsers have an ability to be fitted to different particular applications.

Some of the current approaches are based on the DMV, a generative model where the grammar is expressed by two probability distributions:  $P_{choose}(c_d|c_h, dir)$ , which generates a new child  $c_d$  attached to the head  $c_h$  in the direction  $dir$  (left or right), and  $P_{stop}(STOP|c_h, dir, \dots)$ , which makes a decision whether to generate another child of  $c_h$  in the direction  $dir$  or not.<sup>2</sup> Such a grammar is then inferred using sampling or variational methods.

Unfortunately, there are still cases where the inferred grammar is very different from the grammar we would expect, e.g. verbs become leaves instead of governing the sentences. Rasooli and Faili (2012) and Bisk and Hockenmaier (2012) made some efforts to boost the verbcentricity of the inferred structures; however, both of the approaches require manual identification of the POS tags marking the verbs, which renders them useless when unsupervised POS tags are employed.

The main contribution of this paper is a considerable improvement of unsupervised parsing quality by estimating the  $P_{stop}$  probabilities externally using a very large corpus, and employing this prior knowledge in the standard inference of DMV. The estimation is done using the reducibility principle introduced in (Mareček and Žabokrtský, 2012). The reducibility principle postulates that if a word (or a sequence of words) can be removed from a sentence without violating its grammatical correctness, it is a leaf (or a subtree) in its dependency structure. For the purposes of this paper, we assume the following hypothesis:

*If a sequence of words can be removed from*

<sup>2</sup>The  $P_{stop}$  probability may be conditioned by additional parameters, such as adjacency  $adj$  or fringe word  $c_f$ , which will be described in Section 4.

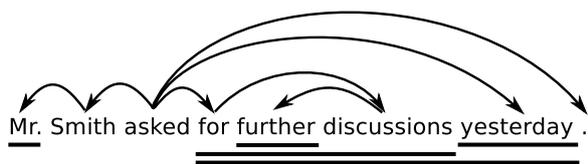

Figure 1: Example of a dependency tree. Sequences of words that can be reduced are underlined.

*a sentence without violating its grammatical correctness, no word outside the sequence depends on any word in the sequence.*

Our hypothesis is a generalization of the original hypothesis since it allows a reducible sequence to form several adjacent subtrees.

Let’s outline the connection between the  $P_{stop}$  probabilities and the property of reducibility. Figure 1 shows an example of a dependency tree. Sequences of reducible words are marked by thick lines below the sentence. Consider for example the word “*further*”. It can be removed and thus, according to our hypothesis, no other word depends on it. Therefore, we can deduce that the  $P_{stop}$  probability for such word is high both for the left and for the right direction. The phrase “*for further discussions*” is reducible as well and we can deduce that the  $P_{stop}$  of its first word (“*for*”) in the left direction is high since it cannot have any left children. We do not know anything about its right children, because they can be located within the sequence (and there is really one in Figure 1). Similarly, the word “*discussions*”, which is the last word in this sequence, cannot have any right children and we can estimate that its right  $P_{stop}$  probability is high. On the other hand, non-reducible words such, as the verb “*asked*” in our example, can have children, and therefore their  $P_{stop}$  can be estimated as low for both directions.

The most difficult task in this approach is to automatically recognize reducible sequences. This problem, together with the estimation of the stop-probabilities, is described in Section 3. Our model, not much different from the classic DMV, is introduced in Section 4. Section 5 describes the inference algorithm based on Gibbs sampling. Experiments and results are discussed in Section 6. Section 7 concludes the paper.

## 2 Related Work

**Reducibility:** The notion of reducibility belongs to the traditional linguistic criteria for recogniz-

ing dependency relations. As mentioned e.g. by Kübler et al. (2009), the head  $h$  of a construction  $c$  determines the syntactic category of  $c$  and can often replace  $c$ . In other words, the descendants of  $h$  can be often removed without making the sentence incorrect. Similarly, in the Dependency Analysis by Reduction (Lopatková et al., 2005), the authors assume that stepwise deletions of dependent elements within a sentence preserve its syntactic correctness. A similar idea of dependency analysis by splitting a sentence into all possible acceptable fragments is used by Gerdes and Kahane (2011).

We have directly utilized the aforementioned criteria for dependency relations in unsupervised dependency parsing in our previous paper (Mareček and Žabokrtský, 2012). Our dependency model contained a submodel which directly prioritized subtrees that form reducible sequences of POS tags. Reducibility scores of given POS tag sequences were estimated using a large corpus of Wikipedia articles. The weakness of this approach was the fact that longer sequences of POS tags are very sparse and no reducibility scores could be estimated for them. In this paper, we avoid this shortcoming by estimating the STOP probabilities for individual POS tags only.

Another task related to reducibility is *sentence compression* (Knight and Marcu, 2002; Cohn and Lapata, 2008), which was used for text summarization. The task is to shorten the sentences while retaining the most important pieces of information, using the knowledge of the grammar. Conversely, our task is to induce the grammar using the sentences and their shortened versions.

**Dependency Model with Valence (DMV)** has been the most popular approach to unsupervised dependency parsing in the recent years. It was introduced by Klein and Manning (2004) and further improved by Smith (2007) and Cohen et al. (2008). Headden III et al. (2009) introduce the Extended Valence Grammar and add lexicalization and smoothing. Blunsom and Cohn (2010) use tree substitution grammars, which allow learning of larger dependency fragments by employing the Pitman-Yor process. Spitkovsky et al. (2010) improve the inference using iterated learning of increasingly longer sentences. Further improvements were achieved by better dealing with punctuation (Spitkovsky et al., 2011b) and new “boundary” models (Spitkovsky et al., 2012).

**Other approaches** to unsupervised dependency parsing were described e.g. in (Søgaard, 2011), (Cohen et al., 2011), and (Bisk and Hockenmaier, 2012). There also exist “less unsupervised” approaches that utilize an external knowledge of the POS tagset. For example, Rasooli and Faili (2012) identify the last verb in the sentence, minimize its probability of reduction and thus push it to the root position. Naseem et al. (2010) make use of manually-specified universal dependency rules such as *Verb*→*Noun*, *Noun*→*Adjective*. McDonald et al. (2011) identify the POS tags by a cross-lingual transfer. Such approaches achieve better results; however, they are useless for grammar induction from plain text.

### 3 STOP-probability estimation

#### 3.1 Recognition of reducible sequences

We introduced a simple procedure for recognition of reducible sequences in (Mareček and Žabokrtský, 2012): The particular sequence of words is removed from the sentence and if the remainder of the sentence exists elsewhere in the corpus, the sequence is considered reducible. We provide an example in Figure 2. The bigram “*this weekend*” in the sentence “*The next competition is this weekend at Lillehammer in Norway.*” is reducible since the same sentence without this bigram, i.e., “*The next competition is at Lillehammer in Norway.*”, is in the corpus as well. Similarly, the prepositional phrase “*of Switzerland*” is also reducible.

It is apparent that only very few reducible sequences can be found by this procedure. If we use a corpus containing about 10,000 sentences, it is possible that we found no reducible sequences at all. However, we managed to find a sufficient amount of reducible sequences in corpora containing millions of sentences, see Section 6.1 and Table 1.

#### 3.2 Computing the STOP-probability estimations

Recall our hypothesis from Section 1: If a sequence of words is reducible, no word outside the sequence can depend on any word in the sequence. Or, in terms of dependency structure: A reducible sequence consists of one or more adjacent subtrees. This means that the first word of a reducible sequence does not have any left children and, similarly, the last word in a reducible sequence does

Martin Fourcade was sixth , maintaining his lead at the top of the overall World Cup standings , although Svendsen is now only 59 points away from the Frenchman in second . The next competition is this weekend at Lillehammer in Norway .

Larinto saw off allcomers at Kuopio with jumps of 129.5 and 124m for a total 240.9 points , just 0.1 points ahead of compatriot Matti Hautamaeki , who landed efforts of 127 and 129.5m . Third place went to Simon Ammann . Andreas Kofler , who won at the weekend at Kuusamo , was fourth but stays top of the season standings with 150 points .

Third place went to Simon Ammann of Switzerland . Ammann is currently just fifth , overall with 120 points . The next competition is at Lillehammer in Norway .

Figure 2: Example of reducible sequences of words found in a large corpus.

not have any right children. We make use of this property directly for estimating  $P_{stop}$  probabilities.

Hereinafter,  $P_{stop}^{est}(c_h, dir)$  denotes the STOP-probability we want to estimate from a large corpus;  $c_h$  is the head’s POS tag and  $dir$  is the direction in which the STOP probability is estimated. If  $c_h$  is very often in the first position of reducible sequences,  $P_{stop}^{est}(c_h, left)$  will be high. Similarly, if  $c_h$  is often in the last position of reducible sequences,  $P_{stop}^{est}(c_h, right)$  will be high.

For each POS tag  $c_h$  in the given corpus, we first compute its left and right “raw” score  $S_{stop}(c_h, left)$  and  $S_{stop}(c_h, right)$  as the relative number of times a word with POS tag  $c_h$  was in the first (or last) position in a reducible sequence found in the corpus. We do not deal with sequences longer than a trigram since they are highly biased.

$$S_{stop}(c_h, left) = \frac{\# \text{ red.seq. } [c_h, \dots] + \lambda}{\# c_h \text{ in the corpus}}$$

$$S_{stop}(c_h, right) = \frac{\# \text{ red.seq. } [\dots, c_h] + \lambda}{\# c_h \text{ in the corpus}}$$

Note that the  $S_{stop}$  scores are not probabilities. Their main purpose is to sort the POS tags according to their “reducibility”.

It may happen that for many POS tags there are no reducible sequences found. To avoid zero scores, we use a simple smoothing by adding  $\lambda$  to each count:

$$\lambda = \frac{\# \text{ all reducible sequences}}{W},$$

where  $W$  denotes the number of words in the given corpus. Such smoothing ensures that more frequent irreducible POS tags get a lower  $S_{stop}$  score than the less frequent ones.

Since reducible sequences found are very sparse, the values of  $S_{stop}(c_h, dir)$  scores are very small. To convert them to estimated probabilities  $P_{stop}^{est}(c_h, dir)$ , we need a smoothing that fulfills the following properties:

- (1)  $P_{stop}^{est}$  is a probability and therefore its value must be between 0 and 1.
- (2) The number of *no-stop* decisions (no matter in which direction) equals to  $W$  (number of words) since such decision is made before each word is generated. The number of *stop* decisions is  $2W$  since they come after generating the last children in both the directions. Therefore, the average  $P_{stop}^{est}(h, dir)$  over all words in the treebank should be  $2/3$ .

After some experimenting, we chose the following normalization formula

$$P_{stop}^{est}(c_h, dir) = \frac{S_{stop}(c_h, dir)}{S_{stop}(c_h, dir) + \nu}$$

with a normalization constant  $\nu$ . The condition (1) is fulfilled for any positive value of  $\nu$ . Its exact value is set in accordance with the requirement (2) so that the average value of  $P_{stop}^{est}$  is  $2/3$ .

$$\sum_{dir \in \{l, r\}} \sum_{c \in C} count(c) P_{stop}^{est}(c, dir) = \frac{2}{3} \cdot 2W,$$

where  $count(c)$  is the number of words with POS tag  $c$  in the corpus. We find the unique value of  $\nu$  that fulfills the previous equation numerically using a binary search algorithm.

## 4 Model

We use the standard generative Dependency Model with Valence (Klein and Manning, 2004). The generative story is the following: First, the head of the sentence is generated. Then, for each head, all its left children are generated, then the left STOP, then all its right children, and then the right STOP. When a child is generated, the algorithm immediately recurses to generate its subtree. When deciding whether to generate another child in the direction  $dir$  or the STOP symbol, we use the  $P_{stop}^{dmv}(STOP|c_h, dir, adj, c_f)$  model.

The new child  $c_d$  in the direction  $dir$  is generated according to the  $P_{choose}(c_d|c_h, dir)$  model. The probability of the whole dependency tree  $T$  is the following:

$$P_{tree}(T) = P_{choose}(head(T)|ROOT, right) \cdot P_{tree}(D(head(T)))$$

$$P_{tree}(D(c_h)) = \prod_{dir \in \{l, r\}} \prod_{\substack{c_d \in \\ deps(dir, h)}} P_{stop}^{dmv}(\neg STOP|c_h, dir, adj, c_f) P_{choose}(c_d|c_h, dir) P_{tree}(D(c_d)) P_{stop}^{dmv}(STOP|c_h, dir, adj, c_f),$$

where  $P_{tree}(D(c_h))$  is probability of the subtree governed by  $h$  in the tree  $T$ .

The set of features on which the  $P_{stop}^{dmv}$  and  $P_{choose}$  probabilities are conditioned varies among the previous works. Our  $P_{stop}^{dmv}$  depends on the head POS tag  $c_h$ , direction  $dir$ , adjacency  $adj$ , and fringe POS tag  $c_f$  (described below). The use of adjacency is standard in DMV and enables us to have different  $P_{stop}^{dmv}$  for situations when no child was generated so far ( $adj = 1$ ). That is,  $P_{stop}^{dmv}(c_h, dir, adj = 1, c_f)$  decides whether the word  $c_h$  has any children in the direction  $dir$  at all, whereas  $P_{stop}^{dmv}(h, dir, adj = 0, c_f)$  decides whether another child will be generated next to the already generated one. This distinction is of crucial importance for us: although we know how to estimate the STOP probabilities for  $adj = 1$  from large data, we do not know anything about the STOP probabilities for  $adj = 0$ .

The last factor  $c_f$ , called fringe, is the POS tag of the previously generated sibling in the current direction  $dir$ . If there is no such sibling (in case  $adj = 1$ ), the head  $c_h$  is used as the fringe  $c_f$ . This is a relatively novel idea in DMV, introduced by Spitzkovsky et al. (2012). We decided to use the fringe word in our model since it gives slightly better results.

We assume that the distributions of  $P_{choose}$  and  $P_{stop}^{dmv}$  are good if the majority of the probability mass is concentrated on few factors; therefore, we apply a Chinese Restaurant process (CRP) on them.

The probability of generating a new child node  $c_d$  attached to  $c_h$  in the direction  $dir$  given the history (all the nodes we have generated so far) is

computed using the following formula:

$$P_{choose}(c_d|c_h, dir) = \frac{\alpha_c \frac{1}{|C|} + count^-(c_d, c_h, dir)}{\alpha_c + count^-(c_h, dir)},$$

where  $count^-(c_d, c_h, dir)$  denotes the number of times a child node  $c_d$  has been attached to  $c_h$  in the direction  $dir$  in the history. Similarly,  $count^-(c_h, dir)$  is the number of times something has been attached to  $c_h$  in the direction  $dir$ . The  $\alpha_c$  is a hyperparameter and  $|C|$  is the number of distinct POS tags in the corpus.<sup>3</sup>

The STOP probability is computed in a similar way:

$$P_{stop}^{dmv}(STOP|c_h, dir, adj, c_f) = \frac{\alpha_s \frac{2}{3} + count^-(STOP, c_h, dir, adj, c_f)}{\alpha_s + count^-(c_h, dir, adj, c_f)}$$

where  $count^-(STOP, c_h, dir, adj, c_f)$  is the number of times a head  $c_h$  had the last child  $c_f$  in the direction  $dir$  in the history.

The contribution of this paper is the inclusion of the stop-probability estimates into the DMV. Therefore, we introduce a new model  $P_{stop}^{dmv+est}$ , in which the probability based on the previously generated data is linearly combined with the probability estimates based on large corpora (Section 3).

$$P_{stop}^{dmv+est}(STOP|c_h, dir, 1, c_f) = (1 - \beta) \cdot \frac{\alpha_s \frac{2}{3} + count^-(STOP, c_h, dir, 1, c_f)}{\alpha_s + count^-(c_h, dir, 1, c_f)} + \beta \cdot P_{stop}^{est}(c_h, dir)$$

$$P_{stop}^{dmv+est}(STOP|c_h, dir, 0, c_f) = P_{stop}^{dmv}(STOP|c_h, dir, 0, c_f)$$

The hyperparameter  $\beta$  defines the ratio between the CRP-based and estimation-based probability. The definition of the  $P_{stop}^{dmv+est}$  for  $adj = 0$  equals the basic  $P_{stop}^{dmv}$  since we are able to estimate only the probability whether a particular head POS tag  $c_h$  can or cannot have children in a particular direction, i.e if  $adj = 1$ .

<sup>3</sup>The number of classes  $|C|$  is often used in the denominator. We decided to put its reverse value into the numerator since we observed such model to perform better for a constant value of  $\alpha_c$  over different languages and tagsets.

Finally, we obtain the probability of the whole generated treebank as a product over the trees:

$$P_{treebank} = \prod_{T \in treebank} P_{tree}(T).$$

An important property of the CRP is the fact that the factors are exchangeable – i.e. no matter how the trees are ordered in the treebank, the  $P_{treebank}$  is always the same.

## 5 Inference

We employ the Gibbs sampling algorithm (Gilks et al., 1996). Unlike in (Mareček and Žabokrtský, 2012), where edges were sampled individually, we sample whole trees from all possibilities on a given sentence using dynamic programming. The algorithm works as follows:

1. A random projective dependency tree is assigned to each sentence in the corpus.
2. *Sampling*: We go through the sentences in a random order. For each sentence, we sample a new dependency tree based on all other trees that are currently in the corpus.
3. Step 2 is repeated in many iterations. In this work, the number of iterations was set to 1000.
4. After the burn-in period (which was set to the first 500 iterations), we start collecting counts of edges between particular words that appeared during the sampling.
5. *Parsing*: Based on the collected counts, we compute the final dependency trees using the Chu-Liu/Edmonds’ algorithm (1965) for finding maximum directed spanning trees.

### 5.1 Sampling

Our goal is to sample a new projective dependency tree  $T$  with probability proportional to  $P_{tree}(T)$ . Since the factors are exchangeable, we can deal with any tree as if it was the last one in the corpus.

We use dynamic programming to sample a tree with  $N$  nodes in  $\mathcal{O}(N^4)$  time. Nevertheless, we sample trees using a modified probability  $P'_{tree}(T)$ . In  $P_{tree}(T)$ , the probability of an edge depends on counts of all other edges, including the edges in the same tree. We instead use  $P'_{tree}(T)$ , where the counts are computed using only the other trees in the corpus, i.e., probabilities

of edges of  $T$  are independent. There is a standard way to sample using the real  $P_{tree}(T)$  – we can use  $P'_{tree}(T)$  as a proposal distribution in the Metropolis-Hastings algorithm (Hastings, 1970), which then produces trees with probabilities proportional to  $P_{tree}(T)$  using acceptance-rejection scheme. We do not take this approach and we sample proportionally to  $P'_{tree}(T)$  only, because we believe that for large enough corpora, the two distributions are nearly identical.

To sample a tree containing words  $w_1, \dots, w_N$  with probability proportional to  $P'_{tree}(T)$ , we first compute three tables:

- $t_i(g, i, j)$  for  $g < i$  or  $g > j$  is the sum of probabilities of any tree on words  $w_i, \dots, w_j$  whose root is a child of  $w_g$ , but not an outermost child in its direction;
- $t_o(g, i, j)$  is the same, but the tree is the outermost child of  $w_g$ ;
- $f_o(g, i, j)$  for  $g < i$  or  $g > j$  is the sum of probabilities of any forest on words  $w_i, \dots, w_j$ , such that all the trees are children of  $w_g$  and are the outermost children of  $w_g$  in their direction.

All the probabilities are computed using the  $P'_{tree}$ . If we compute the tables inductively from the smallest trees to the largest trees, we can precompute all the  $\mathcal{O}(N^3)$  values in  $\mathcal{O}(N^4)$  time.

Using these tables, we sample the tree recursively, starting from the root. At first, we sample the root  $r$  proportionally to the probability of a tree with the root  $r$ , which is a product of the probability of left children of  $r$  and right children of  $r$ . The probability of left children of  $r$  is either  $P'_{stop}(STOP|r, left)$  if  $r$  has no children, or  $P'_{stop}(\neg STOP|r, left)f_o(r, 1, r-1)$  otherwise; the probability of right children is analogous.

After sampling the root, we sample the ranges of its left children, if any. We sample the first left child range  $l_1$  proportionally either to  $t_o(r, 1, r-1)$  if  $l_1 = 1$ , or to  $t_i(r, l_1, r-1)f_o(r, 1, l_1-1)$  if  $l_1 > 1$ . Then we sample the second left child range  $l_2$  proportionally either to  $t_o(r, 1, l_1-1)$  if  $l_2 = 1$ , or to  $t_i(r, l_2, l_1-1)f_o(r, 1, l_2-1)$  if  $l_2 > 1$ , and so on, while there are any left children. The right children ranges are sampled similarly. Finally, we recursively sample the children, i.e., their roots, their children and so on. It is simple to verify using the definition of  $P_{tree}$  that the described method indeed samples trees proportionally to  $P'_{tree}$ .

## 5.2 Parsing

Beginning the 500th iteration, we start collecting counts of individual dependency edges during the remaining iterations. After each iteration is finished (all the trees in the corpus are re-sampled), we increment the counter of all directed pairs of nodes which are connected by a dependency edge in the current trees.

After the last iteration, we use these collected counts as weights and compute maximum directed spanning trees using the Chu-Liu/Edmonds' algorithm (Chu and Liu, 1965). Therefore, the resulting trees consist of edges maximizing the sum of individual counts:

$$T_{MST} = \arg \max_T \sum_{e \in T} count(e)$$

It is important to note that the MST algorithm may produce non-projective trees. Even if we average the strictly projective dependency trees, some non-projective edges may appear in the result. This might be an advantage since correct non-projective edges can be predicted; however, this relaxation may introduce mistakes as well.

## 6 Experiments

### 6.1 Data

We use two types of resources in our experiments. The first type are CoNLL treebanks from the year 2006 (Buchholz and Marsi, 2006) and 2007 (Nivre et al., 2007), which we use for inference and for evaluation. As is the standard practice in unsupervised parsing evaluation, we removed all punctuation marks from the trees. In case a punctuation node was not a leaf, its children are attached to the parent of the removed node.

For estimating the STOP probabilities (Section 3), we use the Wikipedia articles from W2C corpus (Majliš and Žabokrtský, 2012), which provide sufficient amount of data for our purposes. Statistics across languages are shown in Table 1.

The Wikipedia texts were automatically tokenized and segmented to sentences so that their tokenization was similar to the one in the CoNLL evaluation treebanks. Unfortunately, we were not able to find any segmenter for Chinese that would produce a desired segmentation; therefore, we removed Chinese from evaluation.

The next step was to provide the Wikipedia texts with POS tags. We employed the TnT tagger (Brants, 2000) which was trained on the re-

language	tokens (mil.)	red. seq.	language	tokens (mil.)	red. seq.

spective CoNLL training data. The quality of such tagging is not very high since we do not use any lexicons or pretrained models. However, it is sufficient for obtaining usable stop probability estimates.

## 6.2 Estimated STOP probabilities

We applied the algorithm described in Section 3 on the prepared Wikipedia corpora and obtained the stop-probabilities  $P_{stop}^{est}$  in both directions for all the languages and their POS tags. To evaluate the quality of our estimations, we compare them with  $P_{stop}^{tb}$ , the stop probabilities computed directly on the evaluation treebanks. The comparisons on five selected languages are shown in Figure 3. The individual points represent the individual POS tags, their size (area) shows their frequency in the particular treebank. The y-axis shows the stop probabilities estimated on Wikipedia by our algorithm, while the x-axis shows the stop probabilities computed on the evaluation CoNLL data. Ideally, the computed and estimated stop probabilities should be the same, i.e. all the points should be on the diagonal.

Let’s focus on the graphs for English. Our method correctly recognizes that adverbs RB and adjectives JJ are often leaves (their stop probabilities in both directions are very high). Moreover, the estimates for RB are even higher than JJ, which will contribute to attaching adverbs to adjectives and not reversely. Nouns (NN, NNS) are somewhere in the middle, the stop probabilities for proper nouns (NNP) are estimated higher, which is correct since they have much less modifiers than the common nouns NN. The determiners are more problematic. Their estimated stop probability is not very high (about 0.65), while in the real treebank they are almost always leaves.

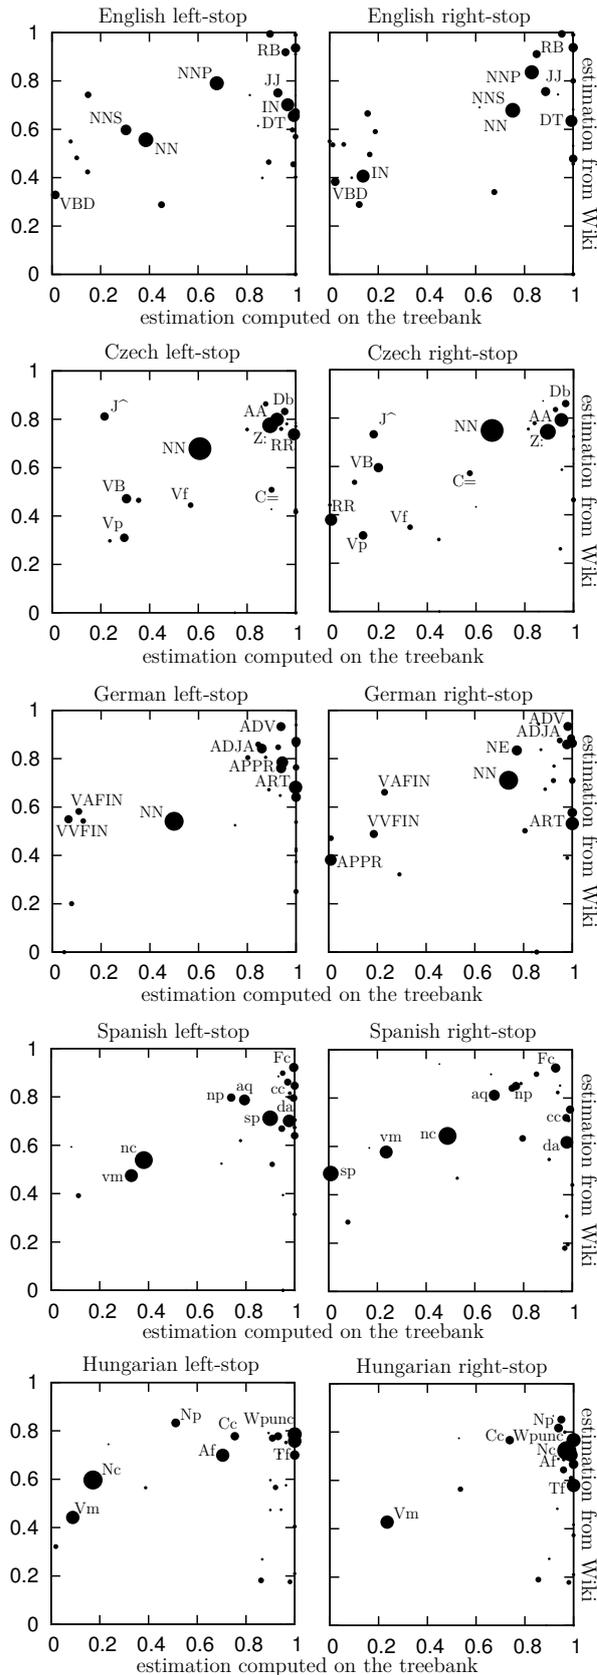

Figure 3: Comparison of  $P_{stop}^{est}$  probabilities estimated from raw Wikipedia corpora (y-axis) and of  $P_{stop}^{tb}$  probabilities computed from CoNLL treebanks (x-axis). The area of each point shows the relative frequency of an individual tag.

This is caused by the fact that determiners are often obligatory in English and cannot be simply removed as, e.g., adjectives. The stop probabilities of prepositions (IN) are also very well recognized. While their left-stop is very probable (prepositions always start prepositional phrases), their right-stop probability is very low. The verbs (the most frequent verbal tag is VBD) have very low both right and left-stop probabilities. Our estimation assigns them the stop probability about 0.3 in both directions. This is quite high, but still, it is one of the lowest among other more frequent tags, and thus verbs tend to be the roots of the dependency trees. We could make similar analyses for other languages, but due to space reasons we only provide graphs for Czech, German, Spanish, and Hungarian in Figure 3.

### 6.3 Settings

After a manual tuning, we have set our hyperparameters to the following values:

$$\alpha_c = 50, \quad \alpha_s = 1, \quad \beta = 1/3$$

We have also found that the Gibbs sampler does not always converge to a similar grammar. For a couple of languages, the individual runs end up with very different trees. To prevent such differences, we run each inference 50 times and take the run with the highest final  $P_{treebank}$  (see Section 4) for the evaluation.

### 6.4 Results

Table 2 shows the results of our unsupervised parser and compares them with results previously reported in other works. In order to see the impact of using the estimated stop probabilities (using model  $P_{stop}^{dmv+est}$ ), we provide results for classical DMV (using model  $P_{stop}^{dmv}$ ) as well. We do not provide results for Chinese since we do not have any appropriate tokenizer at our disposal (see Section 3), and also for Turkish from CoNLL 2006 since the data is not available to us.

We now focus on the third and fourth column of Table 2. The addition of estimated stop probabilities based on large corpora improves the parsing accuracy on 15 out of 20 treebanks. In many cases, the improvement is substantial, which means that the estimated stop probabilities forced the model to completely rebuild the structures. For example, in Bulgarian, if the  $P_{stop}^{dmv}$  model is used, all the prepositions are leaves and the verbs seldom govern sentences. If the  $P_{stop}^{dmv+est}$  model is used, prepositions correctly govern nouns and

verbs move to roots. We observe similar changes on Swedish as well. Unfortunately, there are also negative examples, such as Hungarian, where the addition of the estimated stop probabilities decreases the attachment score from 60.1% to 34%. This is probably caused by not very good estimates of the right-stop probability (see the last graph in Figure 3). Nevertheless, the estimated stop probabilities increase the average score over all the treebanks by more than 12% and therefore prove its usefulness.

In the last two columns of Table 2, we provide results of two other works reported in the last year. The first one (*spi12*) is the DMV-based grammar inducer by Spitzkovsky et al. (2012),<sup>4</sup> the second one (*mar12*) is our previous work (Mareček and Žabokrtský, 2012). Comparing with (Spitzkovsky et al., 2012), our parser reached better accuracy on 12 out of 20 treebanks. Although this might not seem as a big improvement, if we compare the average scores over the treebanks, our system significantly wins by more than 6%. The second system (*mar12*) outperforms our parser only on one treebank (on Italian by less than 3%) and its average score over all the treebanks is only 40%, i.e., more than 8% lower than the average score of our parser.

To see the theoretical upper bound of our model performance, we replaced the  $P_{stop}^{est}$  estimates by the  $P_{stop}^{tb}$  estimates computed from the evaluation treebanks and run the same inference algorithm with the same setting. The average attachment score of such reference DMV is almost 65%. This shows a huge space in which the estimation of STOP probabilities could be further improved.

## 7 Conclusions and Future Work

In this work, we studied the possibility of estimating the DMV stop-probabilities from a large raw corpus. We proved that such prior knowledge about stop-probabilities incorporated into the standard DMV model significantly improves the unsupervised dependency parsing and, since we are not aware of any other fully unsupervised dependency parser with higher average attachment score over CoNLL data, we state that we reached a new state-of-the-art result.<sup>5</sup>

<sup>4</sup>Possibly the current state-of-the-art results. They were compared with many previous works.

<sup>5</sup>A possible competitive work may be the work by Blunsom and Cohn (2010), who reached 55% accuracy on English as well. However, they do not provide scores measured on other CoNLL treebanks.

Table 2: Attachment scores on CoNLL 2006 and 2007 data. Standard deviations are provided in brackets. DMV model using standard  $P_{stop}^{dmv}$  probability is compared with DMV with  $P_{stop}^{dmv+est}$ , which incorporates STOP estimations based on reducibility principle. The reference DMV uses  $P_{stop}^{tb}$ , which are computed directly on the treebanks. The results reported in previous works by Spitkovsky et al. (2012), and Mareček and Žabokrtský (2012) follows.

In future work, we would like to focus on unsupervised parsing without gold POS tags (see e.g. Spitkovsky et al. (2011a) and Christodoulopoulos et al. (2012)). We suppose that many of the current works on unsupervised dependency parsers use gold POS tags only as a simplification of this task, and that the ultimate purpose of this effort is to develop a fully unsupervised induction of linguistic structure from raw texts that would be useful across many languages, domains, and applications.

The software which implements the algorithms described in this paper, together with  $P_{stop}^{est}$  estimations computed on Wikipedia texts, can be downloaded at

<http://ufal.mff.cuni.cz/~marecek/udp/>.

## Acknowledgments

This work has been supported by the AMALACH grant (DF12P01OVV02) of the Ministry of Culture of the Czech Republic.

Data and some tools used as a prerequisite for the research described herein have been provided by the LINDAT/CLARIN Large Infrastructural project, No. LM2010013 of the Ministry of Education, Youth and Sports of the Czech Republic.

We would like to thank Martin Popel, Zdeněk Žabokrtský, Rudolf Rosa, and three anonymous reviewers for many useful comments on the manuscript of this paper.

## Abstract

In this paper, we consider the problem of cross-formalism transfer in parsing. We are interested in parsing constituency-based grammars such as HPSG and CCG using a small amount of data specific for the target formalism, and a large quantity of coarse CFG annotations from the Penn Treebank. While all of the target formalisms share a similar basic syntactic structure with Penn Treebank CFG, they also encode additional constraints and semantic features. To handle this apparent discrepancy, we design a probabilistic model that jointly generates CFG and target formalism parses. The model includes features of both parses, allowing transfer between the formalisms, while preserving parsing efficiency. We evaluate our approach on three constituency-based grammars — CCG, HPSG, and LFG, augmented with the Penn Treebank-1. Our experiments show that across all three formalisms, the target parsers significantly benefit from the coarse annotations.<sup>1</sup>

## 1 Introduction

Over the last several decades, linguists have introduced many different grammars for describing the syntax of natural languages. Moreover, the ongoing process of developing new formalisms is intrinsic to linguistic research. However, before these grammars can be used for statistical parsing, they require annotated sentences for training. The difficulty of obtaining such annotations is a key limiting factor that inhibits the effective use of these grammars.

<sup>1</sup>The source code for the work is available at <http://groups.csail.mit.edu/rbg/code/grammar/acl2013>.

The standard solution to this bottleneck has relied on manually crafted transformation rules that map readily available syntactic annotations (e.g. the Penn Treebank) to the desired formalism. Designing these transformation rules is a major undertaking which requires multiple correction cycles and a deep understanding of the underlying grammar formalisms. In addition, designing these rules frequently requires external resources such as Wordnet, and even involves correction of the existing treebank. This effort has to be repeated for each new grammar formalism, each new annotation scheme and each new language.

In this paper, we propose an alternative approach for parsing constituency-based grammars. Instead of using manually-crafted transformation rules, this approach relies on a small amount of annotations in the target formalism. Frequently, such annotations are available in linguistic texts that introduce the formalism. For instance, a textbook on HPSG (Pollard and Sag, 1994) illustrates grammatical constructions using about 600 examples. While these examples are informative, they are not sufficient for training. To compensate for the annotation sparsity, our approach utilizes coarsely annotated data readily available in large quantities. A natural candidate for such coarse annotations is context-free grammar (CFG) from the Penn Treebank, while the target formalism can be any constituency-based grammars, such as Combinatory Categorical Grammar (CCG) (Steedman, 2001), Lexical Functional Grammar (LFG) (Bresnan, 1982) or Head-Driven Phrase Structure Grammar (HPSG) (Pollard and Sag, 1994). All of these formalisms share a similar basic syntactic structure with Penn Treebank CFG. However, the target formalisms also encode additional constraints and semantic features. For instance, Penn Treebank annotations do not make an explicit distinction between complement and adjunct, while all the above grammars mark these

roles explicitly. Moreover, even the identical syntactic information is encoded differently in these formalisms. An example of this phenomenon is the marking of subject. In LFG, this information is captured in the mapping equation, namely  $\uparrow \text{SBJ} = \downarrow$ , while Penn Treebank represents it as a functional tag, such as NP-SBJ. Figure 1 shows derivations in the three target formalisms we consider, as well as a CFG derivation. We can see that the derivations of these formalisms share the same basic structure, while the formalism-specific information is mainly encoded in the lexical entries and node labels.

To enable effective transfer the model has to identify shared structural components between the formalisms despite the apparent differences. Moreover, we do not assume parallel annotations. To this end, our model jointly parses the two corpora according to the corresponding annotations, enabling transfer via parameter sharing. In particular, we augment each target tree node with hidden variables that capture the connection to the coarse annotations. Specifically, each node in the target tree has two labels: an entry which is specific to the target formalism, and a latent label containing a value from the Penn Treebank tagset, such as NP (see Figure 2). This design enables us to represent three types of features: the target formalism-specific features, the coarse formalism features, and features that connect the two. This modeling approach makes it possible to perform transfer to a range of target formalisms, without manually drafting formalism-specific rules.

We evaluate our approach on three constituency-based grammars — CCG, HPSG, and LFG. As a source of coarse annotations, we use the Penn Treebank.<sup>2</sup> Our results clearly demonstrate that for all three formalisms, parsing accuracy can be improved by training with additional coarse annotations. For instance, the model trained on 500 HPSG sentences achieves labeled dependency F-score of 72.3%. Adding 15,000 Penn Treebank sentences during training leads to 78.5% labeled dependency F-score, an absolute improvement of 6.2%. To achieve similar performance in the absence of coarse annotations, the parser has to be trained on about 1,500 sentences, namely three times what is needed when using coarse annotations. Similar results are

<sup>2</sup>While the Penn Treebank-2 contains richer annotations, we decided to use the Penn Treebank-1 to demonstrate the feasibility of transfer from coarse annotations.

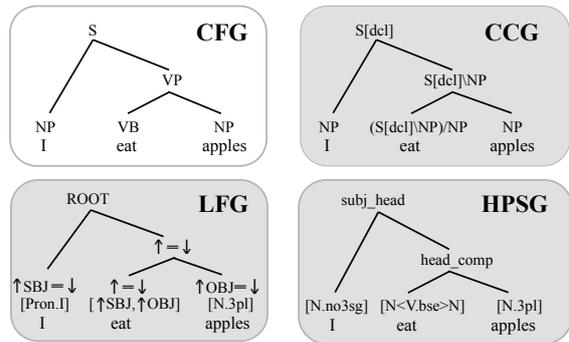

Figure 1: Derivation trees for CFG as well as CCG, HPSG and LFG formalisms.

also observed on CCG and LFG formalisms.

## 2 Related Work

Our work belongs to a broader class of research on transfer learning in parsing. This area has garnered significant attention due to the expense associated with obtaining syntactic annotations. Transfer learning in parsing has been applied in different contexts, such as multilingual learning (Snyder et al., 2009; Hwa et al., 2005; McDonald et al., 2006; McDonald et al., 2011; Jiang and Liu, 2009), domain adaptation (McClosky et al., 2010; Dredze et al., 2007; Blitzer et al., 2006), and cross-formalism transfer (Hockenmaier and Steedman, 2002; Miyao et al., 2005; Cahill et al., 2002; Riezler et al., 2002; Chen and Shanker, 2005; Candito et al., 2010).

There have been several attempts to map annotations in coarse grammars like CFG to annotations in richer grammar, like HPSG, LFG, or CCG. Traditional approaches in this area typically rely on manually specified rules that encode the relation between the two formalisms. For instance, mappings may specify how to convert traces and functional tags in Penn Treebank to the f-structure in LFG (Cahill, 2004). These conversion rules are typically utilized in two ways: (1) to create a new treebank which is consequently used to train a parser for the target formalism (Hockenmaier and Steedman, 2002; Clark and Curran, 2003; Miyao et al., 2005; Miyao and Tsujii, 2008), (2) to translate the output of a CFG parser into the target formalism (Cahill et al., 2002).

The design of these rules is a major linguistic and computational undertaking, which requires multiple iterations over the data to increase coverage (Miyao et al., 2005; Oepen et al., 2004). By nature, the mapping rules are formalism spe-

cific and therefore not transferable. Moreover, frequently designing such mappings involves modification to the original annotations. For instance, Hockenmaier and Steedman (2002) made thousands of POS and constituent modifications to the Penn Treebank to facilitate transfer to CCG. More importantly, in some transfer scenarios, deterministic rules are not sufficient, due to the high ambiguity inherent in the mapping. Therefore, our work considers an alternative set-up for cross-formalism transfer where a small amount of annotations in the target formalism is used as an alternative to using deterministic rules.

The limitation of deterministic transfer rules has been recognized in prior work (Riezler et al., 2002). Their method uses a hand-crafted LFG parser to create a set of multiple parsing candidates for a given sentence. Using the partial mapping from CFG to LFG as the guidance, the resulting trees are ranked based on their consistency with the labeled LFG bracketing imported from CFG. In contrast to this method, we neither require a parser for the target formalism, nor manual rules for partial mapping. Consequently, our method can be applied to many different target grammar formalisms without significant engineering effort for each one. The utility of coarse-grained treebanks is determined by the degree of structural overlap with the target formalism.

### 3 The Learning Problem

Recall that our goal is to learn how to parse the target formalisms while using two annotated sources: a small set of sentences annotated in the target formalism (e.g., CCG), and a large set of sentences with coarse annotations. For the latter, we use the CFG parses from the Penn Treebank. For simplicity we focus on the CCG formalism in what follows. We also generalize our model to other formalisms, as explained in Section 5.4.

Our notations are as follows: an input sentence is denoted by  $S$ . A CFG parse is denoted by  $y_{CFG}$  and a CCG parse is denoted by  $y_{CCG}$ . Clearly the set of possible values for  $y_{CFG}$  and  $y_{CCG}$  is determined by  $S$  and the grammar. The training set is a set of  $N$  sentences  $S_1, \dots, S_N$  with CFG parses  $y_{CFG}^1, \dots, y_{CFG}^N$ , and  $M$  sentences  $\bar{S}_1, \dots, \bar{S}_M$  with CCG parses  $y_{CCG}^1, \dots, y_{CCG}^M$ . It is important to note that we do not assume we have parallel data for CCG and CFG.

Our goal is to use such a corpus for learning

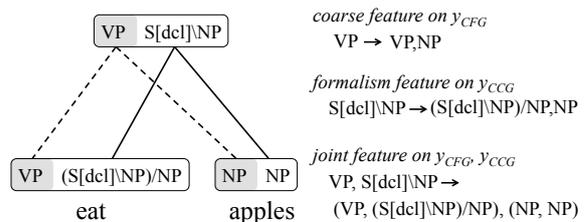

Figure 2: Illustration of the joint CCG-CFG representation. The shadowed labels correspond to the CFG derivation  $y_{CFG}$ , whereas the other labels correspond to the CCG derivation  $y_{CCG}$ . Note that the two derivations share the same (binarized) tree structure. Also shown are features that are turned on for this joint derivation (see Section 6).

how to generate CCG parses to unseen sentences.

## 4 A Joint Model for Two Formalisms

The key idea behind our work is to learn a joint distribution over CCG and CFG parses. Such a distribution can be marginalized to obtain a distribution over CCG or CFG and is thus appropriate when the training data is not parallel, as it is in our setting.

It is not immediately clear how to jointly model the CCG and CFG parses, which are structurally quite different. Furthermore, a joint distribution over these will become difficult to handle computationally if not constructed carefully. To address this difficulty, we make several simplifying assumptions. First, we assume that both parses are given in normal form, i.e., they correspond to binary derivation trees. CCG parses are already provided in this form in CCGBank. CFG parses in the Penn Treebank are not binary, and we therefore binarize them, as explained in Section 5.3.

Second, we assume that any  $y_{CFG}$  and  $y_{CCG}$  jointly generated must share the same derivation tree structure. This makes sense. Since both formalisms are constituency-based, their trees are expected to describe the same constituents. We denote the set of valid CFG and CCG joint parses for sentence  $S$  by  $\mathcal{Y}(S)$ .

The above two simplifying assumptions make it easy to define joint features on the two parses, as explained in Section 6. The representation and features are illustrated in Figure 2.

We shall work within the discriminative framework, where given a sentence we model a distribution over parses. As is standard in such settings, the distribution will be log-linear in a set of features of these parses. Denoting  $y = (y_{CFG}, y_{CCG})$ , we seek to model the distribution

$p(y|S)$  corresponding to the probability of generating a pair of parses (CFG and CCG) given a sentence. The distribution thus has the following form:

$$p_{joint}(y|S; \theta) = \frac{1}{Z(S; \theta)} e^{f(y,S) \cdot \theta}. \quad (1)$$

where  $\theta$  is a vector of parameters to be learned from data, and  $f(y, S)$  is a feature vector.  $Z(S; \theta)$  is a normalization (partition) function normalized over  $y \in \mathcal{Y}(S)$  the set of valid joint parses.

The feature vector contains three types of features: CFG specific, CCG specific and joint CFG-CCG. We denote these by  $f_{CFG}, f_{CCG}, f_{joint}$ . These depend on  $y_{CCG}, y_{CFG}$  and  $y$  respectively. Accordingly, the parameter vector  $\theta$  is a concatenation of  $\theta_{CCG}, \theta_{CFG}$  and  $\theta_{joint}$ .

As mentioned above, we can use Equation 1 to obtain distributions over  $y_{CCG}$  and  $y_{CFG}$  via marginalization. For the distribution over  $y_{CCG}$  we do precisely this, namely use:

$$p_{CCG}(y_{CCG}|S; \theta) = \sum_{y_{CFG}} p_{joint}(y|S; \theta) \quad (2)$$

For the distribution over  $y_{CFG}$  we could have marginalized  $p_{joint}$  over  $y_{CCG}$ . However, this computation is costly for each sentence, and has to be repeated for all the sentences. Instead, we assume that the distribution over  $y_{CFG}$  is a log-linear model with parameters  $\theta_{CFG}$  (i.e., a sub-vector of  $\theta$ ), namely:

$$p_{CFG}(y_{CFG}|S; \theta_{CFG}) = \frac{e^{f_{CFG}(y_{CFG}, S) \cdot \theta_{CFG}}}{Z(S; \theta_{CFG})}. \quad (3)$$

Thus, we assume that both  $p_{joint}$  and  $p_{CFG}$  have the same dependence on the  $f_{CFG}$  features.

**The Likelihood Objective:** Given the models above, it is natural to use maximum likelihood to find the optimal parameters. To do this, we define the following regularized likelihood function:

$$L(\theta) = \sum_{i=1}^N \log(p_{CFG}(y_{CFG}^i | S_i, \theta_{CFG})) + \sum_{i=1}^M \log(p_{CCG}(y_{CCG}^i | \bar{S}_i, \theta)) - \frac{\lambda}{2} \|\theta\|_2^2$$

where  $p_{CCG}$  and  $p_{CFG}$  are defined in Equations 2 and 3 respectively. The last term is the  $l_2$ -norm regularization. Our goal is then to find a  $\theta$  that maximizes  $L(\theta)$ .

**Training Algorithm:** For maximizing  $L(\theta)$  w.r.t.  $\theta$  we use the limited-memory BFGS algorithm (Nocedal and Wright, 1999). Calculating the gradient of  $L(\theta)$  requires evaluating the expected values of  $f(y, S)$  and  $f_{CFG}$  under the distributions  $p_{joint}$  and  $p_{CFG}$  respectively. This can be done via the inside-outside algorithm.<sup>3</sup>

**Parsing Using the Model:** To parse a sentence  $S$ , we calculate the maximum probability assignment for  $p_{joint}(y|S; \theta)$ .<sup>4</sup> The result is both a CFG and a CCG parse. Here we will mostly be interested in the CCG parse. The joint parse with maximum probability is found using a standard CYK chart parsing algorithm. The chart construction will be explained in Section 5.

## 5 Implementation

This section introduces important implementation details, including supertagging, feature forest pruning and binarization methods. Finally, we explain how to generalize our model to other constituency-based formalisms.

### 5.1 Supertagging

When parsing a target formalism tree, one needs to associate each word with a lexical entry. However, since the number of candidates is typically more than one thousand, the size of the chart explodes. One effective way of reducing the number of candidates is via supertagging (Clark and Curran, 2007). A supertagger is used for selecting a small set of lexical entry candidates for each word in the sentence. We use the tagger in (Clark and Curran, 2007) as a general supertagger for all the grammars considered. The only difference is that we use different lexical entries in different grammars.

### 5.2 Feature Forest Pruning

In the BFGS algorithm (see Section 4), feature expectation is computed using the inside-outside algorithm. To perform this dynamic programming efficiently, we first need to build the packed chart, namely the feature forest (Miyao, 2006) to represent the exponential number of all possible tree

<sup>3</sup>To speed up the implementation, gradient computation is parallelized, using the Message Passing Interface package (Gropp et al., 1999).

<sup>4</sup>An alternative approach would be to marginalize over  $y_{CFG}$  and maximize over  $y_{CCG}$ . However, this is a harder computational problem.

structures. However, a common problem for lexicalized grammars is that the forest size is too large. In CFG, the forest is pruned according to the inside probability of a simple generative PCFG model and a prior (Collins, 2003). The basic idea is to prune the trees with lower probability. For the target formalism, a common practice is to prune the forest using the supertagger (Clark and Curran, 2007; Miyao, 2006). In our implementation, we applied all pruning techniques, because the forest is a combination of CFG and target grammar formalisms (e.g., CCG or HPSG).

### 5.3 Binarization

We assume that the derivation tree in the target formalism is in a normal form, which is indeed the case for the treebanks we consider. As mentioned in Section 4, we would also like to work with binarized CFG derivations, such that all trees are in normal form and it is easy to construct features that link the two (see Section 6).

Since Penn Treebank trees are not binarized, we construct a simple procedure for binarizing them. The procedure is based on the available target formalism parses in the training corpus, which are binarized. We illustrate it with an example. In what follows, we describe derivations using the POS of the head words of the corresponding node in the tree. This makes it possible to transfer binarization rules between formalisms.

Suppose we want to learn the binarization rule of the following derivation in CFG:

$$NN \rightarrow (DT \ JJ \ NN) \quad (4)$$

We now look for binary derivations with these POS in the target formalism corpus, and take the most common binarization form. For example, we may find that the most common binarization to binarize the CFG derivation in Equation 4 is:

$$NN \rightarrow (DT \ (JJ \ NN))$$

If no (DT JJ NN) structure is observed in the CCG corpus, we first apply the binary branching on the children to the left of the head, and then on the children to the right of the head.

We also experiment with using fixed binarization rules such as left/right branching, instead of learning them. This results in a drop on the dependency F-score by about 5%.

### 5.4 Implementation in Other Formalisms

We introduce our model in the context of CCG, but the model can easily be generalized to other constituency-based grammars, such as HPSG and LFG. In a derivation tree, the formalism-specific information is mainly encoded in the lexical entries and the applied grammar rules, rather than the tree structures. Therefore we only need to change the node labels and lexical entries to the language-specific ones, while the framework of the model remains the same.

## 6 Features

Feature functions in log-linear models are designed to capture the characteristics of each derivation in the tree. In our model, as mentioned in Section 1, the features are also defined to enable information transfer between coarse and rich formalisms. In this section, we first introduce how different types of feature templates are designed, and then show an example of how the features help transfer the syntactic structure information. Note that the same feature templates are used for all the target grammar formalisms.

Recall that our  $y$  contains both the CFG and CCG parses, and that these use the same derivation tree structure. Each feature will consider either the CFG derivation, the CCG derivation or these two derivations jointly.

The feature construction is similar to constructions used in previous work (Miyao, 2006). The features are based on the atomic features listed in Table 1. These will be used to construct  $f(y, S)$  as explained next.

$hl$	lexical entries/CCG categories of the head word
$r$	grammar rules, i.e. HPSG schema, resulting CCG categories, LFG mapping equations
$sy$	CFG syntactic label of the node (e.g. NP, VP)
$d$	distance between the head words of the children
$c$	whether a comma exists between the head words of the children
$sp$	the span of the subtree rooted at the node
$hw$	surface form of the head word of the node
$hp$	part-of-speech of the head word
$p_i$	part-of-speech of the $i$ -th word in the sentence

Table 1: Templates of atomic features.

We define the following feature templates:  $f_{binary}$  for binary derivations,  $f_{unary}$  for unary derivations, and  $f_{root}$  for the root nodes. These use the atomic features in Table 1, resulting in the

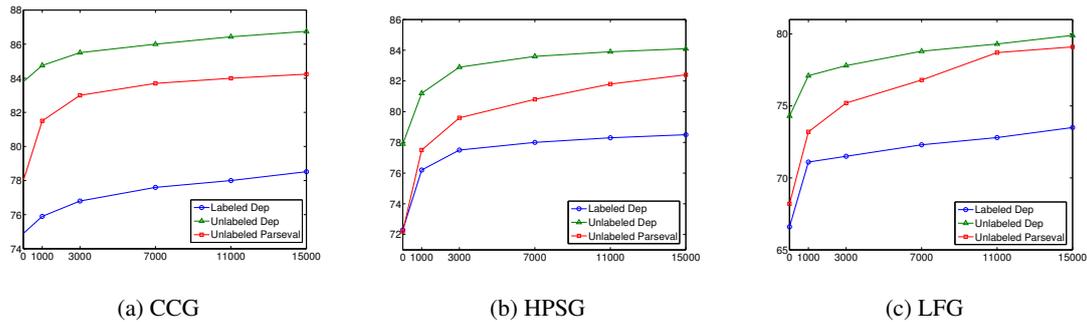

Figure 4: Model performance with 500 target formalism trees and different numbers of CFG trees, evaluated using labeled/unlabeled dependency F-score and unlabeled PARSEVAL.

crafted rules (Hockenmaier and Steedman, 2002; Miyao et al., 2005). Table 3 shows which sections of the treebanks were used in training, testing and development for both formalisms. Our LFG training dataset was constructed in a similar fashion (Cahill et al., 2002). However, we choose to use PARC700 as our LFG testing and development datasets, following the previous work by (Kaplan et al., 2004). It contains 700 manually annotated sentences that are randomly selected from Penn Treebank Section 23. The split of PARC700 follows the setting in (Kaplan et al., 2004). Since our model does not assume parallel data, we use distinct sentences in the source and target treebanks. Following previous work (Hockenmaier, 2003; Miyao and Tsujii, 2008), we only consider sentences not exceeding 40 words, except on PARC700 where all sentences are used.

**Evaluation Metrics:** We use two evaluation metrics. First, following previous work, we evaluate our method using the labeled and unlabeled predicate-argument dependency F-score. This metric is commonly used to measure parsing quality for the formalisms considered in this paper. The detailed definition of this measure as applied for each formalism is provided in (Clark and Curran, 2003; Miyao and Tsujii, 2008; Cahill et al., 2004). For CCG, we use the evaluation script from the C&C tools.<sup>5</sup> For HPSG, we evaluate all types of dependencies, including punctuations. For LFG, we consider the *preds-only* dependencies, which are the dependencies between pairs of words. Secondly, we also evaluate using unlabeled PARSEVAL, a standard measure for PCFG parsing (Petrov and Klein, 2007; Charniak and Johnson, 2005; Charniak, 2000; Collins, 1997). The dependency F-score captures both the target-

grammar labels and tree-structural relations. The unlabeled PARSEVAL is used as an auxiliary measure that enables us to separate these two aspects by focusing on the structural relations exclusively.

**Training without CFG Data:** To assess the impact of coarse data in the experiments below, we also consider the model trained only on formalism-specific annotations. When no CFG sentences are available, we assign all the CFG labels to a special value shared by all the nodes. In this set-up, the model reduces to a normal log-linear model for the target formalism.

**Parameter Settings:** During training, all the feature parameters  $\theta$  are initialized to zero. The hyperparameters used in the model are tuned on the development sets. We noticed, however, that the resulting values are consistent across different formalisms. In particular, we set the  $l_2$ -norm weight to  $\lambda = 1.0$ , the supertagger threshold to  $\beta = 0.01$ , and the PCFG pruning threshold to  $\alpha = 0.002$ .

## 8 Experiment and Analysis

**Impact of Coarse Annotations on Target Formalism:** To analyze the effectiveness of annotation transfer, we fix the number of annotated trees in the target formalism and vary the amount of coarse annotations available to the algorithm during training. In particular, we use 500 sentences with formalism-specific annotations, and vary the number of CFG trees from zero to 15,000.

As Figure 4 shows, CFG data boosts parsing accuracy for all the target formalisms. For instance, there is a gain of 6.2% in labeled dependency F-score for HPSG formalism when 15,000 CFG trees are used. Moreover, increasing the number of coarse annotations used in training leads to further improvement on different evaluation metrics.

<sup>5</sup> Available at <http://svn.ask.it.usyd.edu.au/trac/candc/wiki>

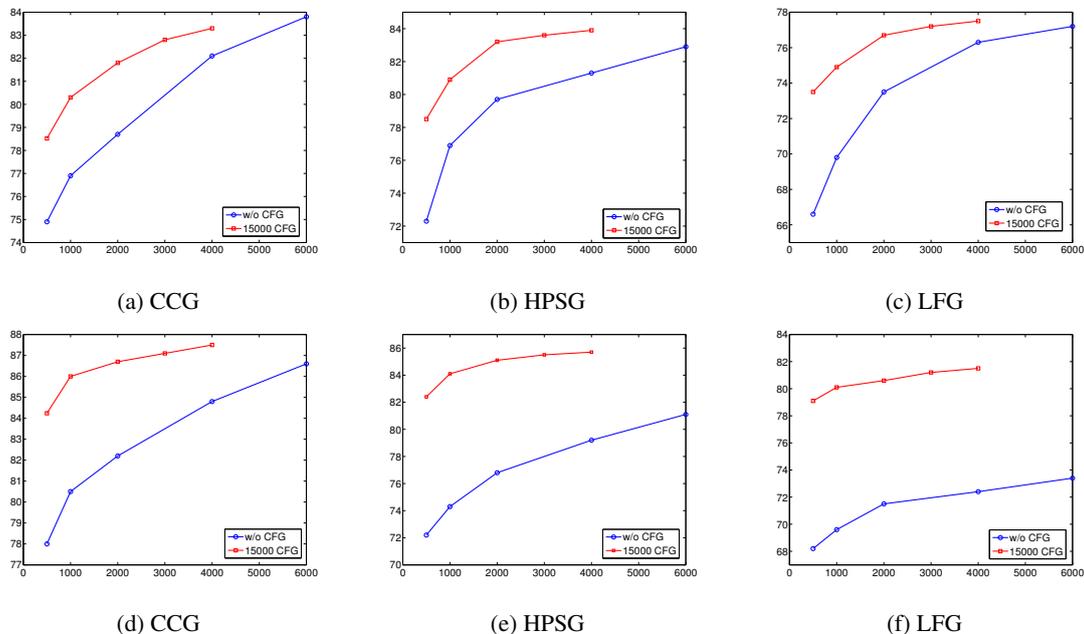

Figure 5: Model performance with different target formalism trees and zero or 15,000 CFG trees. The first row shows the results of labeled dependency F-score and the second row shows the results of unlabeled PARSEVAL.

### Tradeoff between Target and Coarse Annotations:

We also assess the relative contribution of coarse annotations when the size of annotated training corpus in the target formalism varies. In this set of experiments, we fix the number of CFG trees to 15,000 and vary the number of target annotations from 500 to 4,000. Figure 5 shows the relative contribution of formalism-specific annotations compared to that of the coarse annotations. For instance, Figure 5a shows that the parsing performance achieved using 2,000 CCG sentences can be achieved using approximately 500 CCG sentences when coarse annotations are available for training. More generally, the result convincingly demonstrates that coarse annotations are helpful for all the sizes of formalism-specific training data. As expected, the improvement margin decreases when more formalism-specific data is used.

Figure 5 also illustrates a slightly different characteristics of transfer performance between two evaluation metrics. Across all three grammars, we can observe that adding CFG data has a more pronounced effect on the PARSEVAL measure than the dependency F-score. This phenomenon can be explained as follows. The unlabeled PARSEVAL score (Figure 5d-f) mainly relies on the coarse structural information. On the other hand, predicate-argument dependency F-score (Figure 5a-c) also relies on the target grammar information. Because that our model only transfers structural information from the source

treebank, the gains of PARSEVAL are expected to be larger than that of dependency F-score.

Grammar	Parser	# Grammar trees	
		1,000	15,000
CCG	C&C	74.1 / 83.4	82.6 / 90.1
	Model	76.8 / 85.5	84.7 / 90.9
HPSG	Enju	75.8 / 80.6	84.2 / 87.3
	Model	76.9 / 82.0	84.9 / 88.3
LFG	Pipeline Annotator	68.5 / 74.0	82.6 / 85.9
	Model	69.8 / 76.6	81.1 / 84.7

Table 4: The labeled/unlabeled dependency F-score comparisons between our model and state-of-the-art parsers.

**Comparison to State-of-the-art Parsers:** We would also like to demonstrate that the above gains of our transfer model are achieved using an adequate formalism-specific parser. Since our model can be trained exclusively on formalism-specific data, we can compare it to state-of-the-art formalism-specific parsers. For this experiment, we choose the C&C parser (Clark and Curran, 2003) for CCG, Enju parser (Miyao and Tsujii, 2008) for HPSG and pipeline automatic annotator (Cahill et al., 2004) with Charniak parser for LFG. For all three parsers, we use the implementation provided by the authors with the default parameter values. All the models are trained on either 1,000 or 15,000 sentences annotated with formalism-specific trees, thus evaluating their performances on small scale or large scale of data. As Table 4 shows, our model is competitive with

all the baselines described above. It’s not surprising that Cahill’s model outperforms our log-linear model because it relies heavily on hand-crafted rules optimized for the dataset.

**Correspondence between CFG and Target Formalisms:** Finally, we analyze highly weighted features. Table 5 shows such features for HPSG; similar patterns are also found for the other grammar formalisms. The first two features are formalism-specific ones, the first for HPSG and the second for CFG. They show that we correctly learn a frequent derivation in the target formalism and CFG. The third one shows an example of a connection between CFG and the target formalism. Our model correctly learns that a syntactic derivation with children VP and NP is very likely to be mapped to the derivation  $(\text{head\_comp}) \rightarrow ([N\langle V \rangle N], [N.3\text{sg}])$  in HPSG.

Feature type	Features with high weight
Target formalism	<i>Template</i> $(r) \rightarrow (hl_l, hp_l)(hl_r, pr)$ <i>Examples</i> $(\text{head\_comp}) \rightarrow ([N\langle V \rangle N], \text{VB})([N.3\text{sg}], \text{NN})$
Coarse formalism	<i>Template</i> $(sy_p) \rightarrow (sy_l, hp_l)(sy_r, hp_r)$ <i>Examples</i> $(\text{VP}) \rightarrow (\text{VP}, \text{VB})(\text{NP}, \text{NN})$
Joint features	<i>Template</i> $(r) \rightarrow (hl_l, sy_l)(le_r, sy_r)$ <i>Examples</i> $(\text{head\_comp}) \rightarrow ([N\langle V \rangle N], \text{VP})([N.3\text{sg}], \text{NP})$

Table 5: Example features with high weight.

## 9 Conclusions

We present a method for cross-formalism transfer in parsing. Our model utilizes coarse syntactic annotations to supplement a small number of formalism-specific trees for training on constituency-based grammars. Our experimental results show that across a range of such formalisms, the model significantly benefits from the coarse annotations.

## Abstract

We propose a new variant of Tree-Adjoining Grammar that allows adjunction of full wrapping trees but still bears only context-free expressivity. We provide a transformation to context-free form, and a further reduction in probabilistic model size through factorization and pooling of parameters. This collapsed context-free form is used to implement efficient grammar estimation and parsing algorithms. We perform parsing experiments the Penn Treebank and draw comparisons to Tree-Substitution Grammars and between different variations in probabilistic model design. Examination of the most probable derivations reveals examples of the linguistically relevant structure that our variant makes possible.

## 1 Introduction

While it is widely accepted that natural language is not context-free, practical limitations of existing algorithms motivate Context-Free Grammars (CFGs) as a good balance between modeling power and asymptotic performance (Charniak, 1996). In constituent-based parsing work, the prevailing technique to combat this divide between efficient models and real world data has been to selectively strengthen the dependencies in a CFG by increasing the grammar size through methods such as symbol refinement (Petrov et al., 2006).

Another approach is to employ a more powerful grammatical formalism and devise constraints and transformations that allow use of essential efficient algorithms such as the Inside-Outside algorithm (Lari and Young, 1990) and CYK parsing. Tree-Adjoining Grammar (TAG) is a natural

starting point for such methods as it is the canonical member of the mildly context-sensitive family, falling just above CFGs in the hierarchy of formal grammars. TAG has a crucial advantage over CFGs in its ability to represent long distance interactions in the face of the interposing variations that commonly manifest in natural language (Joshi and Schabes, 1997). Consider, for example, the sentences

These pretzels are making me thirsty.  
These pretzels are not making me thirsty.  
These pretzels that I ate are making me thirsty.

Using a context-free language model with proper phrase bracketing, the connection between the words *pretzels* and *thirsty* must be recorded with three separate patterns, which can lead to poor generalizability and unreliable sparse frequency estimates in probabilistic models. While these problems can be overcome to some extent with large amounts of data, redundant representation of patterns is particularly undesirable for systems that seek to extract coherent and concise information from text.

TAG allows a linguistically motivated treatment of the example sentences above by generating the last two sentences through modification of the first, applying operations corresponding to negation and the use of a subordinate clause. Unfortunately, the added expressive power of TAG comes with  $O(n^6)$  time complexity for essential algorithms on sentences of length  $n$ , as opposed to  $O(n^3)$  for the CFG (Schabes, 1990). This makes TAG infeasible to analyze real world data in a reasonable time frame.

In this paper, we define oSTAG, a new way to constrain TAG in a conceptually simple way so

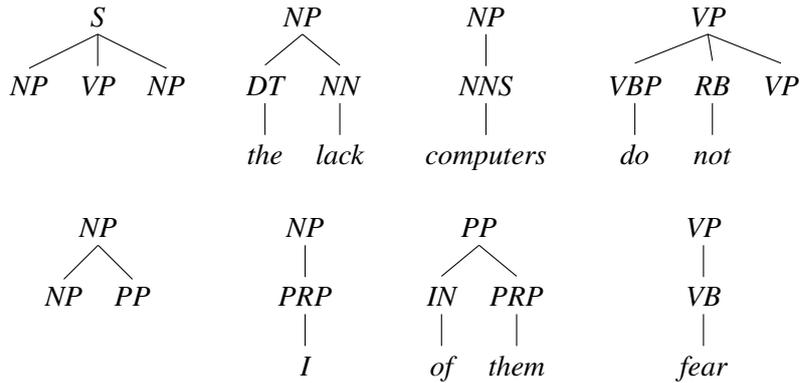

Figure 1: A simple Tree-Substitution Grammar using  $S$  as its start symbol. This grammar derives the sentences from a quote of Isaac Asimov’s - “I do not fear computers. I fear the lack of them.”

that it can be reduced to a CFG, allowing the use of traditional cubic-time algorithms. The reduction is reversible, so that the original TAG derivation can be recovered exactly from the CFG parse. We provide this reduction in detail below and highlight the compression afforded by this TAG variant on synthetic formal languages.

We evaluate OSTAG on the familiar task of parsing the Penn Treebank. Using an automatically induced Tree-Substitution Grammar (TSG), we heuristically extract an OSTAG and estimate its parameters from data using models with various reduced probabilistic models of adjunction. We contrast these models and investigate the use of adjunction in the most probable derivations of the test corpus, demonstrating the superior modeling performance of OSTAG over TSG.

## 2 TAG and Variants

Here we provide a short history of the relevant work in related grammar formalisms, leading up to a definition of OSTAG. We start with context-free grammars, the components of which are  $\langle N, T, R, S \rangle$ , where  $N$  and  $T$  are the sets of non-terminal and terminal symbols respectively, and  $S$  is a distinguished nonterminal, the start symbol. The rules  $R$  can be thought of as elementary trees of depth 1, which are combined by substituting a derived tree rooted at a nonterminal  $X$  at some leaf node in an elementary tree with a frontier node labeled with that same nonterminal. The derived trees rooted at the start symbol  $S$  are taken to be the trees generated by the grammar.

### 2.1 Tree-Substitution Grammar

By generalizing CFG to allow elementary trees in  $R$  to be of depth greater than or equal to 1, we

get the Tree-Substitution Grammar. TSG remains in the family of context-free grammars, as can be easily seen by the removal of the internal nodes in all elementary trees; what is left is a CFG that generates the same language. As a reversible alternative that preserves the internal structure, annotation of each internal node with a unique index creates a large number of deterministic CFG rules that record the structure of the original elementary trees. A more compact CFG representation can be obtained by marking each node in each elementary tree with a signature of its subtree. This transform, presented by Goodman (2003), can rein in the grammar constant  $G$ , as the crucial CFG algorithms for a sentence of length  $n$  have complexity  $O(Gn^3)$ .

A simple probabilistic model for a TSG is a set of multinomials, one for each nonterminal in  $N$  corresponding to its possible substitutions in  $R$ . A more flexible model allows a potentially infinite number of substitution rules using a Dirichlet Process (Cohn et al., 2009; Cohn and Blunsom, 2010). This model has proven effective for grammar induction via Markov Chain Monte Carlo (MCMC), in which TSG derivations of the training set are repeatedly sampled to find frequently occurring elementary trees. A straightforward technique for induction of a finite TSG is to perform this non-parametric induction and select the set of rules that appear in at least one sampled derivation at one or several of the final iterations.

### 2.2 Tree-Adjoining Grammar

Tree-adjoining grammar (TAG) (Joshi, 1985; Joshi, 1987; Joshi and Schabes, 1997) is an extension of TSG defined by a tuple  $\langle N, T, R, A, S \rangle$ , and differs from TSG only in the addition of a

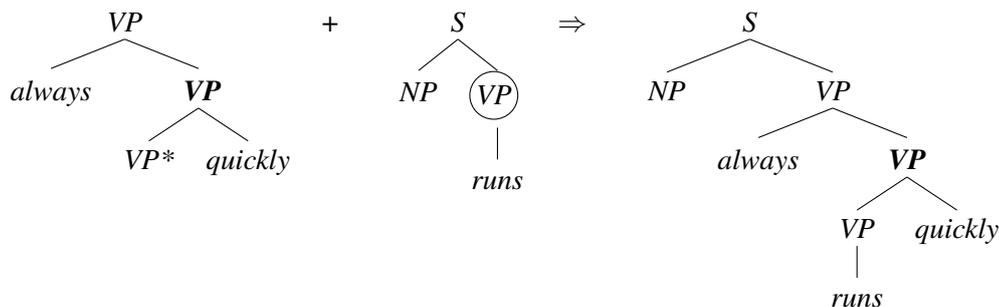

Figure 2: The adjunction operation combines the auxiliary tree (left) with the elementary tree (middle) to form a new derivation (right). The adjunction site is circled, and the foot node of the auxiliary tree is denoted with an asterisk. The OSTAG constraint would disallow further adjunction at the bold **VP** node only, as it is along the spine of the auxiliary tree.

set of auxiliary trees  $A$  and the adjunction operation that governs their use. An auxiliary tree  $\alpha$  is an elementary tree containing a single distinguished nonterminal leaf, the foot node, with the same symbol as the root of  $\alpha$ . An auxiliary tree with root and foot node  $X$  can be adjoined into an internal node of an elementary tree labeled with  $X$  by splicing the auxiliary tree in at that internal node, as pictured in Figure 2. We refer to the path between the root and foot nodes in an auxiliary tree as the *spine* of the tree.

As mentioned above, the added power afforded by adjunction comes at a serious price in time complexity. As such, probabilistic modeling for TAG in its original form is uncommon. However, a large effort in non-probabilistic grammar induction has been performed through manual annotation with the XTAG project (Doran et al., 1994).

### 2.3 Tree Insertion Grammar

Tree Insertion Grammars (TIGs) are a longstanding compromise between the intuitive expressivity of TAG and the algorithmic simplicity of CFGs. Schabes and Waters (1995) showed that by restricting the form of the auxiliary trees in  $A$  and the set of auxiliary trees that may adjoin at particular nodes, a TAG generates only context-free languages. The TIG restriction on auxiliary trees states that the foot node must occur as either the leftmost or rightmost leaf node. This introduces an important distinction between left, right, and wrapping auxiliary trees, of which only the first two are allowed in TIG. Furthermore, TIG disallows adjunction of left auxiliary trees on the spines of right auxiliary trees, and vice versa. This is to prevent the construction of wrapping auxiliary trees, whose removal is essential for the simplified

complexity of TIG.

Several probabilistic models have been proposed for TIG. While earlier approaches such as Hwa (1998) and Chiang (2000) relied on heuristic induction methods, they were nevertheless successful at parsing. Later approaches (Shindo et al., 2011; Yamangil and Shieber, 2012) were able to extend the non-parametric modeling of TSGs to TIG, providing methods for both modeling and grammar induction.

### 2.4 OSTAG

Our new TAG variant is extremely simple. We allow arbitrary initial and auxiliary trees, and place only one restriction on adjunction: we disallow adjunction at any node on the spine of an auxiliary tree below the root (though we discuss relaxing that constraint in Section 4.2). We refer to this variant as Off Spine TAG (OSTAG) and note that it allows the use of full wrapping rules, which are forbidden in TIG. This targeted blocking of recursion has similar motivations and benefits to the approximation of CFGs with regular languages (Mohri and Jan Nederhof, 2000).

The following sections discuss in detail the context-free nature of OSTAG and alternative probabilistic models for its equivalent CFG form. We propose a simple but empirically effective heuristic for grammar induction for our experiments on Penn Treebank data.

## 3 Transformation to CFG

To demonstrate that OSTAG has only context-free power, we provide a reduction to context-free grammar. Given an OSTAG  $\langle N, T, R, A, S \rangle$ , we define the set  $\mathcal{N}$  of nodes of the corresponding CFG to be pairs of a tree in  $R$  or  $A$  together with an

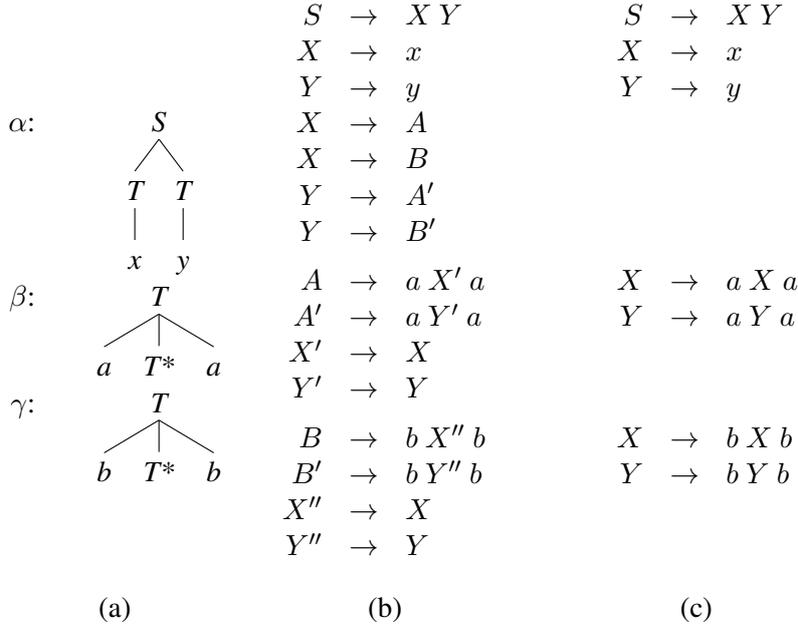

Figure 3: (a) OSTAG for the language  $xxw^Ryyv^R$  where  $w, v \in \{a|b\}^+$  and  $R$  reverses a string. (b) A CFG for the same language, which of necessity must distinguish between nonterminals  $X$  and  $Y$  playing the role of  $T$  in the OSTAG. (c) Simplified CFG, conflating nonterminals, but which must still distinguish between  $X$  and  $Y$ .

address (Gorn number (Gorn, 1965)) in that tree. We take the nonterminals of the target CFG grammar to be nodes or pairs of nodes, elements of the set  $\mathcal{N} + \mathcal{N} \times \mathcal{N}$ . We notate the pairs of nodes with a kind of “applicative” notation. Given two nodes  $\eta$  and  $\eta'$ , we notate a target nonterminal as  $\eta(\eta')$ .

Now for each tree  $\tau$  and each interior node  $\eta$  in  $\tau$  that is not on the spine of  $\tau$ , with children  $\eta_1, \dots, \eta_k$ , we add a context-free rule to the grammar

$$\eta \rightarrow \eta_1 \cdots \eta_k \quad (1)$$

and if interior node  $\eta$  is on the spine of  $\tau$  with  $\eta_s$  the child node also on the spine of  $\tau$  (that is, dominating the foot node of  $\tau$ ) and  $\eta'$  is a node (in any tree) where  $\tau$  is adjoinable, we add a rule

$$\eta(\eta') \rightarrow \eta_1 \cdots \eta_s(\eta') \cdots \eta_k \quad . \quad (2)$$

Rules of type (1) handle the expansion of a node not on the spine of an auxiliary tree and rules of type (2) a spinal node.

In addition, to initiate adjunction at any node  $\eta'$  where a tree  $\tau$  with root  $\eta$  is adjoinable, we use a rule

$$\eta' \rightarrow \eta(\eta') \quad (3)$$

and for the foot node  $\eta_f$  of  $\tau$ , we use a rule

$$\eta_f(\eta) \rightarrow \eta \quad (4)$$

The OSTAG constraint follows immediately from the structure of the rules of type (2). Any child spine node  $\eta_s$  manifests as a CFG nonterminal  $\eta_s(\eta')$ . If child spine nodes themselves allowed adjunction, we would need a type (3) rule of the form  $\eta_s(\eta') \rightarrow \eta_s(\eta')(\eta'')$ . This rule itself would feed adjunction, requiring further stacking of nodes, and an infinite set of CFG nonterminals and rules. This echoes exactly the stacking found in the LIG reduction of TAG.

To handle substitution, any frontier node  $\eta$  that allows substitution of a tree rooted with node  $\eta'$  engenders a rule

$$\eta \rightarrow \eta' \quad (5)$$

This transformation is reversible, which is to say that each parse tree derived with this CFG implies exactly one OSTAG derivation, with substitutions and adjunctions coded by rules of type (5) and (3) respectively. Depending on the definition of a TAG derivation, however, the converse is not necessarily true. This arises from the spurious ambiguity between adjunction at a substitution site (before applying a type (5) rule) versus the same adjunction at the root of the substituted initial tree (after applying a type (5) rule). These choices lead to different derivations in CFG form, but their TAG derivations can be considered conceptually

identical. To avoid double-counting derivations, which can adversely effect probabilistic modeling, type (3) and type (4) rules in which the side with the unapplied symbol is a nonterminal leaf can be omitted.

### 3.1 Example

The grammar of Figure 3(a) can be converted to a CFG by this method. We indicate for each CFG rule its type as defined above the production arrow. All types are used save type (5), as substitution is not employed in this example. For the initial tree  $\alpha$ , we have the following generated rules (with nodes notated by the tree name and a Gorn number subscript):

$$\begin{array}{ll} \alpha_\epsilon \xrightarrow{1} \alpha_1 \alpha_2 & \alpha_1 \xrightarrow{3} \beta_\epsilon(\alpha_1) \\ \alpha_1 \xrightarrow{1} x & \alpha_1 \xrightarrow{3} \gamma_\epsilon(\alpha_1) \\ \alpha_2 \xrightarrow{1} y & \alpha_2 \xrightarrow{3} \beta_\epsilon(\alpha_2) \\ & \alpha_2 \xrightarrow{3} \gamma_\epsilon(\alpha_2) \end{array}$$

For the auxiliary trees  $\beta$  and  $\gamma$  we have:

$$\begin{array}{ll} \beta_\epsilon(\alpha_1) \xrightarrow{2} a \beta_1(\alpha_1) a & \\ \beta_\epsilon(\alpha_2) \xrightarrow{2} a \beta_1(\alpha_2) a & \\ \beta_1(\alpha_1) \xrightarrow{4} \alpha_1 & \\ \beta_1(\alpha_2) \xrightarrow{4} \alpha_2 & \\ \gamma_\epsilon(\alpha_1) \xrightarrow{2} b \gamma_1(\alpha_1) b & \\ \gamma_\epsilon(\alpha_2) \xrightarrow{2} b \gamma_1(\alpha_2) b & \\ \gamma_1(\alpha_1) \xrightarrow{4} \alpha_1 & \\ \gamma_1(\alpha_2) \xrightarrow{4} \alpha_2 & \end{array}$$

The grammar of Figure 3(b) is simply a renaming of this grammar.

## 4 Applications

### 4.1 Compact grammars

The OSTAG framework provides some leverage in expressing particular context-free languages more compactly than a CFG or even a TSG can. As an example, consider the language of bracketed palindromes

$$Pal = a_i w a_i w^R a_i \mid \begin{array}{l} 1 \leq i \leq k \\ w \in \{b_j \mid 1 \leq j \leq m\}^* \end{array}$$

containing strings like  $a_2 b_1 b_3 a_2 b_3 b_1 a_2$ . Any TSG for this language must include as substrings some subpalindrome constituents for long enough strings. Whatever nonterminal covers such a

string, it must be specific to the  $a$  index within it, and must introduce at least one pair of  $b$ s as well. Thus, there are at least  $m$  such nonterminals, each introducing at least  $k$  rules, requiring at least  $km$  rules overall. The simplest such grammar, expressed as a CFG, is in Figure 4(a). The ability to use adjunction allows expression of the same language as an OSTAG with  $k + m$  elementary trees (Figure 4(b)). This example shows that an OSTAG can be quadratically smaller than the corresponding TSG or CFG.

### 4.2 Extensions

The technique in OSTAG can be extended to expand its expressiveness without increasing generative capacity.

First, OSTAG allows zero adjunctions on each node on the spine below the root of an auxiliary tree, but any non-zero finite bound on the number of adjunctions allowed on-spine would similarly limit generative capacity. The tradeoff is in the grammar constant of the effective probabilistic CFG; an extension that allows  $k$  levels of on spine adjunction has a grammar constant that is  $O(|\mathcal{N}|^{(k+2)})$ .

Second, the OSTAG form of adjunction is consistent with the TIG form. That is, we can extend OSTAG by allowing on-spine adjunction of left- or right-auxiliary trees in keeping with the TIG constraints without increasing generative capacity.

### 4.3 Probabilistic OSTAG

One major motivation for adherence to a context-free grammar formalism is the ability to employ algorithms designed for probabilistic CFGs such as the CYK algorithm for parsing or the Inside-Outside algorithm for grammar estimation. In this section we present a probabilistic model for an OSTAG grammar in PCFG form that can be used in such algorithms, and show that many parameters of this PCFG can be pooled or set equal to one and ignored. References to rules of types (1-5) below refer to the CFG transformation rules defined in Section 3. While in the preceding discussion we used Gorn numbers for clarity, our discussion applies equally well for the Goodman transform discussed above, in which each node is labeled with a signature of its subtree. This simply redefines  $\eta$  in the CFG reduction described in Section 3 to be a subtree indicator, and dramatically reduces redundancy in the generated grammar.

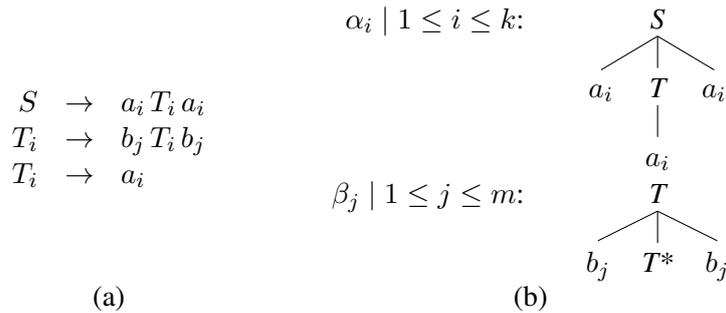

Figure 4: A CFG (a) and more compact OSTAG (b) for the language *Pal*

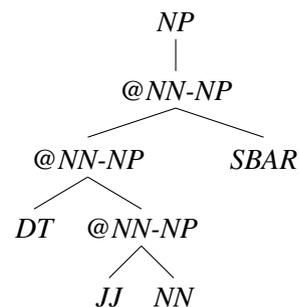

The first practical consideration is that CFG rules of type (2) are deterministic, and as such we need only record the rule itself and no associated parameter. Furthermore, these rules employ a template in which the stored symbol appears in the left-hand side and in exactly one symbol on the right-hand side where the spine of the auxiliary tree proceeds. One deterministic rule exists for this template applied to each  $\eta$ , and so we may record only the template. In order to perform CYK or IO, it is not even necessary to record the index in the right-hand side where the spine continues; these algorithms fill a chart bottom up and we can simply propagate the stored nonterminal up in the chart.

CFG rules of type (4) are also deterministic and do not require parameters. In these cases it is not necessary to record the rules, as they all have exactly the same form. All that is required is a check that a given symbol is adjoinable, which is true for all symbols except nonterminal leaves and applied symbols. Rules of type (5) are necessary to capture the probability of substitution and so we will require a parameter for each.

At first glance, it would seem that due to the identical domain of the left-hand sides of rules of types (1) and (3) a parameter is required for each such rule. To avoid this we propose the following factorization for the probabilistic expansion of an off spine node. First, a decision is made as to whether a type (1) or (3) rule will be used; this corresponds to deciding if adjunction will or will not take place at the node. If adjunction is rejected, then there is only one type (1) rule available, and so parameterization of type (1) rules is unnecessary. If we decide on adjunction, one of the available type (3) rules is chosen from a multinomial. By conditioning the probability of adjunction on varying amounts of information about the node, alternative models can easily be defined.

## 5 Experiments

As a proof of concept, we investigate OSTAG in the context of the classic Penn Treebank statistical parsing setup; training on section 2-21 and testing on section 23. For preprocessing, words that occur only once in the training data are mapped to the unknown categories employed in the parser of Petrov et al. (2006). We also applied the annotation from Klein and Manning (2003) that appends “-U” to each nonterminal node with a single child, drastically reducing the presence of looping unary chains. This allows the use of a coarse to fine parsing strategy (Charniak et al., 2006) in which a sentence is first parsed with the Maximum Likelihood PCFG and only constituents whose probability exceeds a cutoff of  $10^{-4}$  are allowed in the OSTAG chart. Designed to facilitate sister adjunction, we define our binarization scheme by example in which the added nodes, indicated by @, record both the parent and head child of the rule.

A compact TSG can be obtained automatically using the MCMC grammar induction technique of Cohn and Blunsom (2010), retaining all TSG rules that appear in at least one derivation in after 1000 iterations of sampling. We use EM to estimate the parameters of this grammar on sections 2-21, and use this as our baseline.

To generate a set of TAG rules, we consider each rule in our baseline TSG and find all possi-

	All	40	#Adj	#Wrap
TSG	85.00	86.08	–	–
TSG'	85.12	86.21	–	–
OSTAG <sup>1</sup>	85.42	86.43	1336	52
OSTAG <sup>2</sup>	85.54	86.56	1952	44
OSTAG <sup>3</sup>	85.86	86.84	3585	41

Figure 5: Parsing F-Score for the models under comparison for both the full test set and sentences of length 40 or less. For the OSTAG models, we list the number of adjunctions in the MPD of the full test set, as well as the number of wrapping adjunctions.

ble auxiliary root and foot node pairs it contains. For each such root/foot pair, we include the TAG rule implied by removal of the structure above the root and below the foot. We also include the TSG rule left behind when the adjunction of this auxiliary tree is removed. To be sure that experimental gains are not due to this increased number of TSG initial trees, we calculate parameters using EM for this expanded TSG and use it as a second baseline (TSG'). With our full set of initial and auxiliary trees, we use EM and the PCFG reduction described above to estimate the parameters of an OSTAG.

We investigate three models for the probability of adjunction at a node. The first uses a conservative number of parameters, with a Bernoulli variable for each symbol (OSTAG<sup>1</sup>). The second employs more parameters, conditioning on both the node's symbol and the symbol of its leftmost child (OSTAG<sup>2</sup>). The third is highly parameterized but most prone to data sparsity, with a separate Bernoulli distribution for each Goodman index  $\eta$  (OSTAG<sup>3</sup>). We report results for Most Probable Derivation (MPD) parses of section 23 in Figure 5.

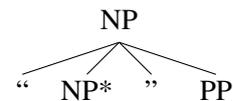

Our results show that OSTAG outperforms both baselines. Furthermore, the various parameterizations of adjunction with OSTAG indicate that, at least in the case of the Penn Treebank, the finer grained modeling of a full table of adjunction probabilities for each Goodman index OSTAG<sup>3</sup> overcomes the danger of sparse data estimates. Not only does such a model lead to better parsing performance, but it uses adjunction more extensively than its more lightly parameterized alternatives. While different representations make direct

comparison inappropriate, the OSTAG results lie in the same range as previous work with statistical TIG on this task, such as Chiang (2000) (86.00) and Shindo et al. (2011) (85.03).

The OSTAG constraint can be relaxed as described in Section 4.2 to allow any finite number of on-spine adjunctions without sacrificing context-free form. However, the increase to the grammar constant quickly makes parsing with such models an arduous task. To determine the effect of such a relaxation, we allow a single level of on-spine adjunction using the adjunction model of OSTAG<sup>1</sup>, and estimate this model with EM on the training data. We parse sentences of length 40 or less in section 23 and observe that on-spine adjunction is never used in the MPD parses. This suggests that the OSTAG constraint is reasonable, at least for the domain of English news text.

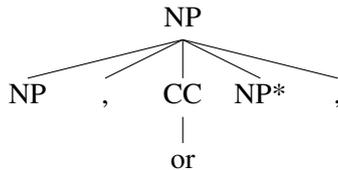

We performed further examination of the MPD using OSTAG for each of the sentences in the test corpus. As an artifact of the English language, the majority have their foot node on the left spine and would also be usable by TIG, and so we discuss the instances of wrapping auxiliary trees in these derivations that are uniquely available to OSTAG. We remove binarization for clarity and denote the foot node with an asterisk.

A frequent use of wrapping adjunction is to coordinate symbols such as quotes, parentheses, and dashes on both sides of a noun phrase. One common wrapping auxiliary tree in our experiments is

This is used frequently in the news text of the Wall Street Journal for reported speech when avoiding a full quotation. This sentence is an example of the way the rule is employed, using what Joshi and Schabes (1997) referred to as ‘‘factoring recursion from linguistic constraints’’ with TAG. Note that replacing the quoted noun phrase and its following prepositional phrase with the noun phrase itself yields a valid sentence, in line with the linguistic theory underlying TAG.

Another frequent wrapping rule, shown below, allows direct coordination between the contents of an appositive with the rest of the sentence.

This is a valuable ability, as it is common to use an appositive to provide context or explanation for a proper noun. As our information on proper nouns will most likely be very sparse, the appositive may be more reliably connected to the rest of the sentence. An example of this from one of the sentences in which this rule appears in the MPD is the phrase “since the market fell 156.83, or 8 %, a week after Black Monday”. The wrapping rule allows us to coordinate the verb “fell” with the pattern “X %” instead of 156.83, which is mapped to an unknown word category.

These rules highlight the linguistic intuitions that back TAG; if their adjunction were undone, the remaining derivation would be a valid sentence that simply lacks the modifying structure of the auxiliary tree. However, the MPD parses reveal that not all useful adjunctions conform to this paradigm, and that left-auxiliary trees that are not used for sister adjunction are susceptible to this behavior. The most common such tree is used to create noun phrases such as

P&G’s share of [the Japanese market]  
 the House’s repeal of [a law]  
 Apple’s family of [Macintosh Computers]  
 Canada’s output of [crude oil]

by adjoining the shared unbracketed syntax onto the NP dominating the bracketed text. If adjunction is taken to model modification, this rule drastically changes the semantics of the unmodified sentence. Furthermore, in some cases removing the adjunction can leave a grammatically incorrect sentence, as in the third example where the noun phrase changes plurality.

While our grammar induction method is a crude (but effective) heuristic, we can still highlight the qualities of the more important auxiliary trees by examining aggregate statistics over the MPD parses, shown in Figure 6. The use of left-auxiliary trees for sister adjunction is a clear trend, as is the predominant use of right-auxiliary trees for the complementary set of “regular” adjunctions, which is to be expected in a right branching language such as English. The statistics also

	All	Wrap	Right	Left
Total	3585 (1374)	41 (26)	1698 (518)	1846 (830)
Sister	2851 (1180)	17 (11)	1109 (400)	1725 (769)
Lex	2244 (990)	28 (19)	894 (299)	1322 (672)
FLex	1028 (558)	7 (2)	835 (472)	186 (84)

Figure 6: Statistics for MPD auxiliary trees using OSTAG<sup>3</sup>. The columns indicate type of auxiliary tree and the rows correspond respectively to the full set found in the MPD, those that perform sister adjunction, those that are lexicalized, and those that are fully lexicalized. Each cell shows the number of tokens followed by the number of types of auxiliary tree that fit its conditions.

reflect the importance of substitution in right-auxiliary trees, as they must capture the wide variety of right branching modifiers of the English language.

## 6 Conclusion

The OSTAG variant of Tree-Adjoining Grammar is a simple weakly context-free formalism that still provides for all types of adjunction and is a bit more concise than TSG (quadratically so). OSTAG can be reversibly transformed into CFG form, allowing the use of a wide range of well studied techniques in statistical parsing.

OSTAG provides an alternative to TIG as a context-free TAG variant that offers wrapping adjunction in exchange for recursive left/right spine adjunction. It would be interesting to apply both OSTAG and TIG to different languages to determine where the constraints of one or the other are more or less appropriate. Another possibility is the combination of OSTAG with TIG, which would strictly expand the abilities of both approaches.

The most important direction of future work for OSTAG is the development of a principled grammar induction model, perhaps using the same techniques that have been successfully applied to TSG and TIG. In order to motivate this and other related research, we release our implementation of EM and CYK parsing for OSTAG<sup>1</sup>. Our system performs the CFG transform described above and optionally employs coarse to fine pruning and relaxed (finite) limits on the number of spine adjunctions. As a TSG is simply a TAG without adjunction rules, our parser can easily be used as a TSG estimator and parser as well.

# Fast and Adaptive Online Training of Feature-Rich Translation Models

Spence Green, Sida Wang, Daniel Cer, and Christopher D. Manning

Computer Science Department, Stanford University

{spenceg, sidaw, danielcer, manning}@stanford.edu

## Abstract

We present a fast and scalable online method for tuning statistical machine translation models with large feature sets. The standard tuning algorithm—MERT—only scales to tens of features. Recent discriminative algorithms that accommodate sparse features have produced smaller than expected translation quality gains in large systems. Our method, which is based on stochastic gradient descent with an adaptive learning rate, scales to millions of features and tuning sets with tens of thousands of sentences, while still converging after only a few epochs. Large-scale experiments on Arabic-English and Chinese-English show that our method produces significant translation quality gains by exploiting sparse features. Equally important is our analysis, which suggests techniques for mitigating overfitting and domain mismatch, and applies to other recent discriminative methods for machine translation.

## 1 Introduction

Sparse, overlapping features such as words and  $n$ -gram contexts improve many NLP systems such as parsers and taggers. Adaptation of discriminative learning methods for these types of features to statistical machine translation (MT) systems, which have historically used idiosyncratic learning techniques for a few dense features, has been an active research area for the past half-decade. However, despite some research successes, feature-rich models are rarely used in annual MT evaluations. For example, among all submissions to the WMT and IWSLT 2012 shared tasks, just one participant tuned more than 30 features (Hasler et al., 2012a). Slow uptake of these methods may be due to implementation complexities, or to practical difficulties of configuring them for specific translation tasks (Gimpel and Smith, 2012; Simianer et al., 2012, *inter alia*).

We introduce a new method for training feature-rich MT systems that is effective yet comparatively easy to implement. The algorithm scales to millions of features and large tuning sets. It optimizes a logistic objective identical to that of PRO (Hopkins and May, 2011) with stochastic gradient descent, although other objectives are possible. The learning rate is set adaptively using AdaGrad (Duchi et al., 2011), which is particularly effective for the mixture of dense and sparse features present in MT models. Finally, feature selection is implemented as efficient  $L_1$  regularization in the forward-backward splitting (FOBOS) framework (Duchi and Singer, 2009). Experiments show that our algorithm converges faster than batch alternatives.

To learn good weights for the sparse features, most algorithms—including ours—benefit from more tuning data, and the natural source is the training bitext. However, the bitext presents two problems. First, it has a single reference, sometimes of lower quality than the multiple references in tuning sets from MT competitions. Second, large bitexts often comprise many text genres (Haddow and Koehn, 2012), a virtue for classical dense MT models but a curse for high dimensional models: bitext tuning can lead to a significant domain adaptation problem when evaluating on standard test sets. Our analysis separates and quantifies these two issues.

We conduct large-scale translation quality experiments on Arabic-English and Chinese-English. As baselines we use MERT (Och, 2003), PRO, and the Moses (Koehn et al., 2007) implementation of  $k$ -best MIRA, which Cherry and Foster (2012) recently showed to work as well as online MIRA (Chiang, 2012) for feature-rich models. The first experiment uses standard tuning and test sets from the NIST OpenMT competitions. The second experiment uses tuning and test sets sampled from the large bitexts. The new method yields significant improvements in both experiments. Our code is included in the Phrasal (Cer et al., 2010) toolkit, which is freely available.

## 2 Adaptive Online Algorithms

Machine translation is an unusual machine learning setting because multiple correct translations exist and decoding is comparatively expensive. When we have a large feature set and therefore want to tune on a large data set, batch methods are infeasible. Online methods can converge faster, and in practice they often find *better* solutions (Liang and Klein, 2009; Bottou and Bousquet, 2011, *inter alia*).

Recall that stochastic gradient descent (SGD), a fundamental online method, updates weights  $w$  according to

$$w_t = w_{t-1} - \eta \nabla \ell_t(w_{t-1}) \quad (1)$$

with loss function<sup>1</sup>  $\ell_t(w)$  of the  $t^{\text{th}}$  example, (sub)gradient of the loss with respect to the parameters  $\nabla \ell_t(w_{t-1})$ , and learning rate  $\eta$ .

SGD is sensitive to the learning rate  $\eta$ , which is difficult to set in an MT system that mixes frequent “dense” features (like the language model) with sparse features (e.g., for translation rules). Furthermore,  $\eta$  applies to each coordinate in the gradient, an undesirable property in MT where good sparse features may fire very infrequently. We would instead like to take larger steps for sparse features and smaller steps for dense features.

### 2.1 AdaGrad

AdaGrad is a method for setting an *adaptive learning rate* that comes with good theoretical guarantees. The theoretical improvement over SGD is most significant for high-dimensional, sparse features. AdaGrad makes the following update:

$$w_t = w_{t-1} - \eta \Sigma_t^{1/2} \nabla \ell_t(w_{t-1}) \quad (2)$$

$$\begin{aligned} \Sigma_t^{-1} &= \Sigma_{t-1}^{-1} + \nabla \ell_t(w_{t-1}) \nabla \ell_t(w_{t-1})^\top \\ &= \sum_{i=1}^t \nabla \ell_i(w_{i-1}) \nabla \ell_i(w_{i-1})^\top \end{aligned} \quad (3)$$

A diagonal approximation to  $\Sigma$  can be used for a high-dimensional vector  $w_t$ . In this case, AdaGrad is simple to implement and computationally cheap. Consider a single dimension  $j$ , and let scalars  $v_t = w_{t,j}$ ,  $g_t = \nabla_j \ell_t(w_{t-1})$ ,  $G_t = \sum_{i=1}^t g_i^2$ , then the update rule is

$$v_t = v_{t-1} - \eta G_t^{-1/2} g_t \quad (4)$$

$$G_t = G_{t-1} + g_t^2 \quad (5)$$

Compared to SGD, we just need to store  $G_t = \Sigma_{t,j,j}^{-1}$  for each dimension  $j$ .

<sup>1</sup>We specify the loss function for MT in section 3.1.

### 2.2 Prior Online Algorithms in MT

AdaGrad is related to two previous online learning methods for MT.

**MIRA** Chiang et al. (2008) described an adaption of MIRA (Crammer et al., 2006) to MT. MIRA makes the following update:

$$w_t = \arg \min_w \frac{1}{2\eta} \|w - w_{t-1}\|_2^2 + \ell_t(w) \quad (6)$$

The first term expresses *conservativity*: the weight should change as little as possible based on a single example, ensuring that it is never beneficial to overshoot the minimum.

The relationship to SGD can be seen by linearizing the loss function  $\ell_t(w) \approx \ell_t(w_{t-1}) + (w - w_{t-1})^\top \nabla \ell_t(w_{t-1})$  and taking the derivative of (6). The result is exactly (1).

**AROW** Chiang (2012) adapted AROW (Crammer et al., 2009) to MT. AROW models the current weight as a Gaussian centered at  $w_{t-1}$  with covariance  $\Sigma_{t-1}$ , and does the following update upon seeing training example  $x_t$ :

$$\begin{aligned} w_t, \Sigma_t = \\ \arg \min_{w, \Sigma} \frac{1}{\eta} D_{\text{KL}}(\mathcal{N}(w, \Sigma) || \mathcal{N}(w_{t-1}, \Sigma_{t-1})) \\ + \ell_t(w) + \frac{1}{2\eta} x_t^\top \Sigma x_t \end{aligned} \quad (7)$$

The KL-divergence term expresses a more general, directionally sensitive conservativity. Ignoring the third term, the  $\Sigma$  that minimizes the KL is actually  $\Sigma_{t-1}$ . As a result, the first two terms of (7) generalize MIRA so that we may be more conservative in some directions specified by  $\Sigma$ . To see this, we can write out the KL-divergence between two Gaussians in closed form, and observe that the terms involving  $w$  do not interact with the terms involving  $\Sigma$ :

$$\begin{aligned} w_t = \arg \min_w \frac{1}{2\eta} (w - w_{t-1})^\top \Sigma_{t-1}^{-1} (w - w_{t-1}) \\ + \ell_t(w) \end{aligned} \quad (8)$$

$$\begin{aligned} \Sigma_t = \arg \min_{\Sigma} \frac{1}{2\eta} \log \left( \frac{|\Sigma_{t-1}|}{|\Sigma|} \right) + \frac{1}{2\eta} \text{Tr}(\Sigma_{t-1}^{-1} \Sigma) \\ + \frac{1}{2\eta} x_t^\top \Sigma x_t \end{aligned} \quad (9)$$

The third term in (7), called the confidence term, gives us *adaptivity*, the notion that we should have smaller variance in the direction  $v$  as more data  $x_t$

is seen in direction  $v$ . For example, if  $\Sigma$  is diagonal and  $x_t$  are indicator features, the confidence term then says that the weight for a rarer feature should have more variance and vice-versa. Recall that for generalized linear models  $\nabla \ell_t(w) \propto x_t$ ; if we substitute  $x_t = \alpha_t \nabla \ell_t(w)$  into (9), differentiate and solve, we get:

$$\begin{aligned} \Sigma_t^{-1} &= \Sigma_{t-1}^{-1} + x_t x_t^\top \\ &= \Sigma_0^{-1} + \sum_{i=1}^t \alpha_i^2 \nabla \ell_i(w_{i-1}) \nabla \ell_i(w_{i-1})^\top \end{aligned} \quad (10)$$

The precision  $\Sigma_t^{-1}$  generally grows as more data is seen. Frequently updated features receive an especially high precision, whereas the model maintains large variance for rarely seen features.

If we substitute (10) into (8), linearize the loss  $\ell_t(w)$  as before, and solve, then we have the linearized AROW update

$$w_t = w_{t-1} - \eta \Sigma_t \nabla \ell_t(w_{t-1}) \quad (11)$$

which is also an adaptive update with per-coordinate learning rates specified by  $\Sigma_t$  (as opposed to  $\Sigma_t^{1/2}$  in AdaGrad).

### 2.3 Comparing AdaGrad, MIRA, AROW

Compare (3) to (10) and observe that if we set  $\Sigma_0^{-1} = 0$  and  $\alpha_t = 1$ , then the only difference between the AROW update (11) and the AdaGrad update (2) is a square root. Under a constant gradient, AROW decays the step size more aggressively ( $1/t$ ) compared to AdaGrad ( $1/\sqrt{t}$ ), and it is sensitive to the specification of  $\Sigma_0^{-1}$ .

Informally, SGD can be improved in the conservativity direction using MIRA so the updates do not overshoot. Second, SGD can be improved in the adaptivity direction using AdaGrad where the decaying stepsize is more robust and the adaptive stepsize allows better weight updates to features differing in sparsity and scale. Finally, AROW combines both adaptivity and conservativity. For MT, adaptivity allows us to deal with mixed dense/sparse features effectively without specific normalization.

Why do we choose AdaGrad over AROW? MIRA/AROW requires selecting the loss function  $\ell(w)$  so that  $w_t$  can be solved in closed-form, by a quadratic program (QP), or in some other way that is better than linearizing. This usually means choosing a hinge loss. On the other hand, AdaGrad/linearized AROW only requires that the gradient of the loss function can be computed efficiently.

---

### Algorithm 1 Adaptive online tuning for MT.

---

**Require:** Tuning set  $\{f_i, e_i^{1:k}\}_{i=1:M}$

- 1: Set  $w_0 = 0$
- 2: Set  $t = 1$
- 3: **repeat**
- 4:   **for**  $i$  in  $1 \dots M$  in random order **do**
- 5:     Decode  $n$ -best list  $N_i$  for  $f_i$
- 6:     Sample pairs  $\{d_{j,+}, d_{j,-}\}_{j=1:s}$  from  $N_i$
- 7:     Compute  $\mathcal{D}_i = \{\phi(d_{j,+}) - \phi(d_{j,-})\}_{j=1:s}$
- 8:     Set  $g_t = \nabla \ell(\mathcal{D}_i; w_{t-1})$
- 9:     Set  $\Sigma_t^{-1} = \Sigma_{t-1}^{-1} + g_t g_t^\top$  ▷ Eq. (3)
- 10:     Update  $w_t = w_{t-1} - \eta \Sigma_t^{1/2} g_t$  ▷ Eq. (2)
- 11:     Regularize  $w_t$  ▷ Eq. (15)
- 12:     Set  $t = t + 1$
- 13:   **end for**
- 14: **until** convergence

---

Linearized AROW, however, is less robust than AdaGrad empirically<sup>2</sup> and lacks known theoretical guarantees. Finally, by using AdaGrad, we separate adaptivity from conservativity. Our experiments suggest that adaptivity is actually more important.

## 3 Adaptive Online MT

Algorithm 1 shows the full algorithm introduced in this paper. AdaGrad (lines 9–10) is a crucial piece, but the loss function, regularization technique, and parallelization strategy described in this section are equally important in the MT setting.

### 3.1 Pairwise Logistic Loss Function

Algorithm 1 lines 5–8 describe the gradient computation. We cast MT tuning as *pairwise ranking* (Herbrich et al., 1999, *inter alia*), which Hopkins and May (2011) applied to MT. The pairwise approach results in simple, convex loss functions suitable for online learning. The idea is that for any two derivations, the ranking predicted by the model should be consistent with the ranking predicted by a gold sentence-level metric  $G$  like BLEU+1 (Lin and Och, 2004).

Consider a single source sentence  $f$  with associated references  $e^{1:k}$ . Let  $d$  be a derivation in an  $n$ -best list of  $f$  that has the target  $e = e(d)$  and the feature map  $\phi(d)$ . Let  $M(d) = w \cdot \phi(d)$  be the model score. For any derivation  $d_+$  that is better than  $d_-$  under  $G$ , we desire pairwise agreement such that

$$\begin{aligned} G(e(d_+), e^{1:k}) &> G(e(d_-), e^{1:k}) \\ &\iff M(d_+) > M(d_-) \end{aligned}$$

---

<sup>2</sup>According to experiments not reported in this paper.

Ensuring pairwise agreement is the same as ensuring  $w \cdot [\phi(d_+) - \phi(d_-)] > 0$ .

For learning, we need to select derivation pairs  $(d_+, d_-)$  to compute difference vectors  $x_+ = \phi(d_+) - \phi(d_-)$ . Then we have a 1-class separation problem trying to ensure  $w \cdot x_+ > 0$ . The derivation pairs are sampled with the algorithm of Hopkins and May (2011).

We compute difference vectors  $\mathcal{D}_t = \{x_+^{1:s}\}$  (Algorithm 1 line 7) from  $s$  pairs  $(d_+, d_-)$  for source sentence  $f_t$ . We use the familiar logistic loss:

$$\ell_t(w) = \ell(\mathcal{D}_t, w) = - \sum_{x_+ \in \mathcal{D}_t} \log \frac{1}{1 + e^{-w \cdot x_+}} \quad (12)$$

Choosing the hinge loss instead of the logistic loss results in the 1-class SVM problem. The 1-class separation problem is equivalent to the binary classification problem with  $x_+ = \phi(d_+) - \phi(d_-)$  as positive data and  $x_- = -x_+$  as negative data, which may be plugged into an existing logistic regression solver.

We find that Algorithm 1 works best with mini-batches instead of single examples. In line 4 we simply partition the tuning set so that  $i$  becomes a mini-batch of examples.

### 3.2 Updating and Regularization

Algorithm 1 lines 9–11 compute the adaptive learning rate, update the weights, and apply regularization. Section 2.1 explained the AdaGrad learning rate computation. To update and regularize the weights we apply the Forward-Backward Splitting (FOBOS) (Duchi and Singer, 2009) framework, which separates the two operations. The two-step FOBOS update is

$$w_{t-\frac{1}{2}} = w_{t-1} - \eta_{t-1} \nabla \ell_{t-1}(w_{t-1}) \quad (13)$$

$$w_t = \arg \min_w \frac{1}{2} \|w - w_{t-\frac{1}{2}}\|_2^2 + \eta_{t-1} r(w) \quad (14)$$

where (13) is just an unregularized gradient descent step and (14) balances the regularization term  $r(w)$  with staying close to the gradient step.

Equation (14) permits efficient  $L_1$  regularization, which is well-suited for selecting good features from exponentially many irrelevant features (Ng, 2004). It is well-known that feature selection is very important for feature-rich MT. For example, simple indicator features like lexicalized re-ordering classes are potentially useful yet bloat the feature set and, in the worst case, can negatively impact

---

### Algorithm 2 “Stale gradient” parallelization method for Algorithm 1.

---

**Require:** Tuning set  $\{f_i, e_i^{1:k}\}_{i=1:M}$

- 1: Initialize threadpool  $p_1, \dots, p_j$
- 2: Set  $t = 1$
- 3: **repeat**
- 4:   **for**  $i$  in  $1 \dots M$  in random order **do**
- 5:     Wait until any thread  $p$  is idle
- 6:     Send  $(f_i, e_i^{1:k}, t)$  to  $p$   $\triangleright$  Alg. 1 lines 5–8
- 7:     **while**  $\exists p'$  done with gradient  $g_{t'}$  **do**  $\triangleright t' \leq t$
- 8:       Update  $w_t = w_{t-1} - \eta g_{t'}$   $\triangleright$  Alg. 1 lines 9–11
- 9:       Set  $t = t + 1$
- 10:     **end while**
- 11:   **end for**
- 12: **until** convergence

---

search. Some of the features generalize, but many do not. This was well understood in previous work, so heuristic filtering was usually applied (Chiang et al., 2009, *inter alia*). In contrast, we need only select an appropriate regularization strength  $\lambda$ .

Specifically, when  $r(w) = \lambda \|w\|_1$ , the closed-form solution to (14) is

$$w_t = \text{sign}(w_{t-\frac{1}{2}}) \left[ |w_{t-\frac{1}{2}}| - \eta_{t-1} \lambda \right]_+ \quad (15)$$

where  $[x]_+ = \max(x, 0)$  is the clipping function that in this case sets a weight to 0 when it falls below the threshold  $\eta_{t-1} \lambda$ . It is straightforward to adapt this to AdaGrad with diagonal  $\Sigma$  by setting each dimension of  $\eta_{t-1,j} = \eta \Sigma_{t,jj}^{\frac{1}{2}}$  and by taking element-wise products.

We find that  $\nabla \ell_{t-1}(w_{t-1})$  only involves several hundred active features for the current example (or mini-batch). However, naively following the FOBOS framework requires updating millions of weights. But a practical benefit of FOBOS is that we can do lazy updates on just the active dimensions without any approximations.

### 3.3 Parallelization

Algorithm 1 is inherently sequential like standard online learning. This is undesirable in MT where decoding is costly. We therefore parallelize the algorithm with the “stale gradient” method of Langford et al. (2009) (Algorithm 2). A fixed threadpool of workers computes gradients in parallel and sends them to a master thread, which updates a central weight vector. Crucially, the weight updates need not be applied in order, so synchronization is unnecessary; the workers only idle at the end of an epoch. The consequence is that the update in line 8 of Algorithm 2 is with respect to gradient  $g_{t'}$  with  $t' \leq t$ . Langford et al. (2009) gave convergence results for

stale updating, but the bounds do not apply to our setting since we use  $L_1$  regularization. Nevertheless, Gimpel et al. (2010) applied this framework to other non-convex objectives and obtained good empirical results.

Our asynchronous, stochastic method has practical appeal for MT. During a tuning run, the online method decodes the tuning set under many more weight vectors than a MERT-style batch method. This characteristic may result in broader exploration of the search space, and make the learner more robust to local optima (Liang and Klein, 2009; Bottou and Bousquet, 2011, *inter alia*). The adaptive algorithm identifies appropriate learning rates for the mixture of dense and sparse features. Finally, large data structures such as the language model (LM) and phrase table exist in shared memory, obviating the need for remote queries.

## 4 Experiments

We built Arabic-English and Chinese-English MT systems with Phrasal (Cer et al., 2010), a phrase-based system based on alignment templates (Och and Ney, 2004). The corpora<sup>3</sup> in our experiments (Table 1) derive from several LDC sources from 2012 and earlier. We de-duplicated each bitext according to exact string match, and ensured that no overlap existed with the test sets. We produced alignments with the Berkeley aligner (Liang et al., 2006b) with standard settings and symmetrized via the grow-diag heuristic.

For each language we used SRILM (Stolcke, 2002) to estimate 5-gram LMs with modified Kneser-Ney smoothing. We included the monolingual English data and the respective target bitexts.

### 4.1 Feature Templates

The baseline “dense” model contains 19 features: the nine Moses baseline features, the hierarchical lexicalized re-ordering model of Galley and Manning (2008), the (log) count of each rule, and an indicator for unique rules.

To the dense features we add three high dimensional “sparse” feature sets. **Discrimina-**

<sup>3</sup>We tokenized the English with packages from the Stanford Parser (Klein and Manning, 2003) according to the Penn Treebank standard (Marcus et al., 1993), the Arabic with the Stanford Arabic segmenter (Green and DeNero, 2012) according to the Penn Arabic Treebank standard (Maamouri et al., 2008), and the Chinese with the Stanford Chinese segmenter (Chang et al., 2008) according to the Penn Chinese Treebank standard (Xue et al., 2005).

	Bilingual		Monolingual
	Sentences	Tokens	Tokens
Ar-En	6.6M	375M	990M
Zh-En	9.3M	538M	

Table 1: Bilingual and monolingual corpora used in these experiments. The monolingual English data comes from the AFP and Xinhua sections of English Gigaword 4 (LDC2009T13).

**tive phrase table (PT)**: indicators for each rule in the phrase table. **Alignments (AL)**: indicators for phrase-internal alignments and deleted (unaligned) source words. **Discriminative re-ordering (LO)**: indicators for eight lexicalized re-ordering classes, including the six standard monotone/swap/discontinuous classes plus the two simpler Moses monotone/non-monotone classes.

### 4.2 Tuning Algorithms

The primary baseline is the dense feature set tuned with MERT (Och, 2003). The Phrasal implementation uses the line search algorithm of Cer et al. (2008), uniform initialization, and 20 random starting points.<sup>4</sup> We tuned according to BLEU-4 (Papineni et al., 2002).

We built high dimensional baselines with two different algorithms. First, we tuned with batch PRO using the default settings in Phrasal ( $L_2$  regularization with  $\sigma=0.1$ ). Second, we ran the  $k$ -best batch MIRA (kb-MIRA) (Cherry and Foster, 2012) implementation in Moses. We did implement an online version of MIRA, and in small-scale experiments found that the batch variant worked just as well. Cherry and Foster (2012) reported the same result, and their implementation is available in Moses. We ran their code with standard settings.

Moses<sup>5</sup> also contains the discriminative phrase table implementation of (Hasler et al., 2012b), which is identical to our implementation using Phrasal. Moses and Phrasal accept the same phrase table and LM formats, so we kept those data structures in common. The two decoders also use the same multi-stack beam search (Och and Ney, 2004).

For our method, we used uniform initialization, 16 threads, and a mini-batch size of 20. We found that  $\eta=0.02$  and  $\lambda=0.1$  worked well on development sets for both languages. To compute the gradients

<sup>4</sup>Other system settings for all experiments: distortion limit of 5, a maximum phrase length of 7, and an  $n$ -best size of 200.

we sampled 15 derivation pairs for each tuning example and scored them with BLEU+1.

### 4.3 NIST OpenMT Experiment

The first experiment evaluates our algorithm when tuning and testing on standard test sets, each with four references. When we add features, our algorithm tends to overfit to a standard-sized tuning set like MT06. We thus concatenated MT05, MT06, and MT08 to create a larger tuning set.

Table 2 shows the Ar-En results. Our algorithm is competitive with MERT in the low dimensional “dense” setting, and compares favorably to PRO

with the PT feature set. PRO does not benefit from additional features, whereas our algorithm improves with both additional features and data. The underperformance of kb-MIRA may result from a difference between Moses and Phrasal: Moses MERT achieves only 45.62 on MT09. Moses PRO with the PT feature set is slightly worse, e.g., 44.52 on MT09. Nevertheless, kb-MIRA does not improve significantly over MERT, and also selects an unnecessarily large model.

The full feature set PT+AL+LO does help. With the PT feature set alone, our algorithm tuned on MT05/6/8 scores well below the best model, e.g.

Model	#features	Algorithm	Tuning Set	#refs	bitext5k-test	MT04	
Dense	19	MERT	MT06	45.08	4	39.28	51.42

Table 5: Zh-En results [BLEU-4 % uncased] for the bitext tuning experiment.

48.56 BLEU on MT09. For Ar-En, our algorithm thus has the desirable property of benefiting from more and better features, and more data.

Table 3 shows Zh-En results. Somewhat surprisingly our algorithm improves over MERT in the dense setting. When we add the discriminative phrase table, our algorithm improves over kb-MIRA, and over batch PRO on two evaluation sets. With all features and the MT05/6/8 tuning set, we improve significantly over all other models. PRO learns a smaller model with the PT+AL+LO feature set which is surprising given that it applies  $L_2$  regularization (AdaGrad uses  $L_1$ ). We speculate that this may be a consequence of stochastic learning. Our algorithm decodes each example with a new weight vector, thus exploring more of the search space for the same tuning set.

#### 4.4 Bitext Tuning Experiment

Tables 2 and 3 show that adding tuning examples improves translation quality. Nevertheless, even the larger tuning set is small relative to the bitext from which rules were extracted. He and Deng (2012) and Simianer et al. (2012) showed significant translation quality gains by tuning on the bitext. However, their bitexts matched the genre of their test sets. Our bitexts, like those of most large-scale systems, do not. Domain mismatch matters for the dense feature set (Haddow and Koehn, 2012). We show that it also matters for feature-rich MT.

Before aligning each bitext, we randomly sampled and sequestered 5k and 15k sentence tuning sets, and a 5k test set. We prevented overlap be-

$\mathcal{D}_A$	$\mathcal{D}_B$	$ A $	$ B $	$ A \cap B $
MT04	MT06	70k	72k	5.9k
MT04	MT568	70k	96k	7.6k
MT04	bitext5k	70k	67k	4.4k
MT04	bitext15k	70k	310k	10.5k

5ktest	bitext15k	82k	310k	14k

Table 6: Number of overlapping phrase table (+PT) features on various Zh-En dataset pairs.

tween the tuning sets and the test set. We then tuned a dense model with MERT on MT06, and feature-rich models on both MT05/6/8 and the bitext tuning set. Table 4 shows the Ar-En results. When tuned on bitext5k the translation quality gains are significant for bitext5k-test relative to tuning on MT05/6/8, which has multiple references. However, the bitext5k models do not generalize as well to the NIST evaluation sets as represented by the MT04 result. Table 5 shows similar trends for Zh-En.

## 5 Analysis

### 5.1 Feature Overlap Analysis

How many sparse features appear in both the tuning and test sets? In Table 6,  $A$  is the set of phrase table features that received a non-zero weight when tuned on dataset  $\mathcal{D}_A$  (same for  $B$ ). Column  $\mathcal{D}_A$  lists several Zh-En test sets used and column  $\mathcal{D}_B$  lists tuning sets. Our experiments showed that tuning on MT06 generalizes better to MT04 than tuning

on bitext5k, whereas tuning on bitext5k generalizes better to bitext5k-test than tuning on MT06. These trends are consistent with the level of feature overlap. Phrase table features in  $A \cap B$  are overwhelmingly short, simple, and correct phrases, suggesting  $L_1$  regularization is effective for feature selection. It is also important to balance the number of features with how well weights can be learned for those features, as tuning on bitext15k produced higher coverage for MT04 but worse generalization than tuning on MT06.

## 5.2 Domain Adaptation Analysis

To understand the domain adaptation issue we compared the non-zero weights in the discriminative phrase table (PT) for Ar-En models tuned on bitext5k and MT05/6/8. Table 7 illustrates a statistical idiosyncrasy in the data for the American and British spellings of program/programme. The mass is concentrated along the diagonal, probably because MT05/6/8 was prepared by NIST, an American agency, while the bitext was collected from many sources including Agence France Presse.

Of course, this discrepancy is consequential for both dense and feature-rich models. However, we observe that the feature-rich models fit the tuning data more closely. For example, the MT05/6/8 model learns rules like يتضمن برنامج  $\rightarrow$  *program includes*, برنامج  $\rightarrow$  *program of*, and نافذة البرنامج  $\rightarrow$  *program window*. Crucially, it does not learn the basic rule برنامج  $\rightarrow$  *program*.

In contrast, the bitext5k model contains basic rules such برنامج  $\rightarrow$  *programme*, هذا البرنامج  $\rightarrow$  *this programme*, and ذلك البرنامج  $\rightarrow$  *that programme*. It also contains more elaborate rules such as كانت نفقات البرنامج  $\rightarrow$  *programme expenses were* and برامج الرحلات الفضائية المأهولة  $\rightarrow$  *manned space flight programmes*. We observed similar trends for ‘defense/defence’, ‘analyze/analyse’, etc. This particular genre problem could be addressed with language-specific pre-processing, but our system solves it in a data-driven manner.

## 5.3 Re-ordering Analysis

We also analyzed re-ordering differences. Arabic matrix clauses tend to be verb-initial, meaning that the subject and verb must be swapped when translating to English. To assess re-ordering differences—if any—between the dense and feature-rich models, we selected all MT09 segments that began with one

	# bitext5k	# MT05/6/8
<i>programme</i>	185	0
<i>program</i>	19	449
PT rules w/ <i>programme</i>	353	79
PT rules w/ <i>program</i>	9	31

Table 7: Top: comparison of token counts in two Ar-En tuning sets for *programme* and *program*. Bottom: rule counts in the discriminative phrase table (PT) for models tuned on the two tuning sets. Both spellings correspond to the Arabic برنامج.

of seven common verbs: قال *qaal* ‘said’, صرح *SrH* ‘declared’, أشار *ashaar* ‘indicated’, كان *kaan* ‘was’, أعلِن *a<sup>c</sup>ln* ‘announced’, أضاف *aDaaf* ‘added’, ذكر *dhkr* ‘commented’. We compared the output of the MERT Dense model to our method with the full feature set, both tuned on MT06. Of the 208 source segments, 32 of the translation pairs contained different word order in the matrix clause. Our feature-rich model was correct 18 times (56.3%), Dense was correct 4 times (12.5%), and neither method was correct 10 times (31.3%).

- (1) ref: lebanese prime minister , fuad siniora , announced
  - a. and lebanese prime minister fuad siniora that
  - b. the lebanese prime minister fouad siniora announced
- (2) ref: the newspaper and television reported
  - a. she said the newspaper and television
  - b. television and newspaper said

In (1) the dense model (1a) drops the verb while the feature-rich model correctly re-orders and inserts it after the subject (1b). The coordinated subject in (2) becomes an embedded subject in the dense output (2a). The feature-rich model (2b) performs the correct re-ordering.

## 5.4 Runtime Comparison

Table 8 compares our method to standard implementations of the other algorithms. MERT parallelizes easily but runtime increases quadratically with  $n$ -best list size. PRO runs (single-threaded) L-BFGS to convergence on every epoch, a potentially slow procedure for the larger feature set. Moreover, both

		epochs	min.
MERT	Dense	22	180
PRO	+PT	25	35
kb-MIRA*	+PT	26	25
This paper	+PT	10	10
PRO	+PT+AL+LO	13	150
This paper	+PT+AL+LO	5	15

Table 8: Epochs to convergence (“epochs”) and approximate runtime per epoch in minutes (“min.”) for selected Zh-En experiments tuned on MT06. All runs executed on the same dedicated system with the same number of threads. (\*) Moses and kb-MIRA are written in C++, while all other rows refer to Java implementations in Phrasal.

the Phrasal and Moses PRO implementations use  $L_2$  regularization, which regularizes every weight on every update. kb-MIRA makes multiple passes through the  $n$ -best lists during each epoch. The Moses implementation parallelizes decoding but weight updating is sequential.

The core of our method is an inner product between the adaptive learning rate vector and the gradient. This is easy to implement and is very fast even for large feature sets. Since we applied lazy regularization, this inner product usually involves hundred-dimensional vectors. Finally, our method does not need to accumulate  $n$ -best lists, a practice that slows down the other algorithms.

## 6 Related Work

Our work relates most closely to that of Hasler et al. (2012b), who tuned models containing both sparse and dense features with Moses. A discriminative phrase table helped them improve slightly over a dense, online MIRA baseline, but their best results required initialization with MERT-tuned weights and re-tuning a single, shared weight for the discriminative phrase table with MERT. In contrast, our algorithm learned good high dimensional models from a uniform starting point.

Chiang (2012) adapted AROW to MT and extended previous work on online MIRA (Chiang et al., 2008; Watanabe et al., 2007). It was not clear if his improvements came from the novel Hope/Fear search, the conservativity gain from MIRA/AROW by solving the QP exactly, adaptivity, or sophisticated parallelization. In contrast, we show that

AdaGrad, which ignores conservativity and only capturing adaptivity, is sufficient.

Simianer et al. (2012) investigated SGD with a pairwise perceptron objective. Their best algorithm used *iterative parameter mixing* (McDonald et al., 2010), which we found to be slower than the stale gradient method in section 3.3. They regularized once at the end of each epoch, whereas we regularized each weight update. An empirical comparison of these two strategies would be an interesting future contribution.

Watanabe (2012) investigated SGD and even randomly selected pairwise samples as we did. He considered both softmax and hinge losses, observing better results with the latter, which solves a QP. Their parallelization strategy required a line search at the end of each epoch.

Many other discriminative techniques have been proposed based on: ramp loss (Gimpel, 2012); hinge loss (Cherry and Foster, 2012; Haddow et al., 2011; Arun and Koehn, 2007); maximum entropy (Xiang and Ittycheriah, 2011; Ittycheriah and Roukos, 2007; Och and Ney, 2002); perceptron (Liang et al., 2006a); and structured SVM (Tillmann and Zhang, 2006). These works use radically different experimental setups, and to our knowledge only (Cherry and Foster, 2012) and this work compare to at least two high dimensional baselines. Broader comparisons, though time-intensive, could help differentiate these methods.

## 7 Conclusion and Outlook

We introduced a new online method for tuning feature-rich translation models. The method is faster per epoch than MERT, scales to millions of features, and converges quickly. We used efficient  $L_1$  regularization for feature selection, obviating the need for the feature scaling and heuristic filtering common in prior work. Those comfortable with implementing vanilla SGD should find our method easy to implement. Even basic discriminative features were effective, so we believe that our work enables fresh approaches to more sophisticated MT feature engineering.

## Abstract

In this paper, we propose a novel reordering model based on sequence labeling techniques. Our model converts the reordering problem into a sequence labeling problem, i.e. a tagging task. Results on five Chinese-English NIST tasks show that our model improves the baseline system by 1.32 BLEU and 1.53 TER on average. Results of comparative study with other seven widely used reordering models will also be reported.

## 1 Introduction

The systematic word order difference between two languages poses a challenge for current statistical machine translation (SMT) systems. The system has to decide in which order to translate the given source words. This problem is known as the reordering problem. As shown in (Knight, 1999), if arbitrary reordering is allowed, the search problem is NP-hard.

Many ideas have been proposed to address the reordering problem. Within the phrase-based SMT framework there are mainly three stages where improved reordering could be integrated:

**In the preprocessing:** the source sentence is reordered by heuristics, so that the word order of source and target sentences is similar. (Wang et al., 2007) use manually designed rules to reorder parse trees of the source sentences. Based on shallow syntax, (Zhang et al., 2007) use rules to reorder the source sentences on the chunk level and provide a source-reordering lattice instead of a single reordered source sentence as input to the SMT system. Designing rules to reorder the source sentence is conceptually clear and usually easy to implement. In this way, syntax information can be incorporated into phrase-based SMT systems. However, one disadvantage is that the reliability of the rules is often language pair dependent.

**In the decoder:** we can add *constraints* or *models* into the decoder to reward good reordering options or penalize bad ones. For reordering constraints, early work includes ITG constraints (Wu, 1995) and IBM constraints (Berger et al., 1996). (Zens and Ney, 2003) did comparative study over different reordering constraints. This paper focuses on reordering models. For reordering models, we can further roughly divide the existing methods into three genres:

- *The reordering is a classification problem.* The classifier will make decision on next phrase's relative position with current phrase. The classifier can be trained with maximum likelihood like Moses lexicalized reordering (Koehn et al., 2007) and hierarchical lexicalized reordering model (Galley and Manning, 2008) or be trained under maximum entropy framework (Zens and Ney, 2006).
- *The reordering is a decoding order problem.* (Mariño et al., 2006) present a translation model that constitutes a language model of a sort of bilanguage composed of bilingual units. From the reordering point of view, the idea is that the correct reordering is a suitable order of translation units. (Feng et al., 2010) present a simpler version of (Mariño et al., 2006)'s model which utilize only source words to model the decoding order.
- *The reordering can be solved by outside heuristics.* We can put human knowledge into the decoder. For example, the simple jump model using linear distance tells the decoder that usually the long range reordering should be avoided. (Cherry, 2008) uses information from dependency trees to make the decoding process keep syntactic cohesion. (Feng et al., 2012) present a method that utilizes predicate-argument structures from semantic role labeling results as soft constraints.

**In the reranking framework:** in principle, all

the models in previous category can be used in the reranking framework, because in the reranking we have all the information (source and target words/phrases, alignment) about the translation process. (Och et al., 2004) describe the use of syntactic features in the rescoring step. However, they report the syntactic features contribute very small gains. One disadvantage of carrying out reordering in reranking is the representativeness of the N-best list is often a question mark.

In this paper, we propose a novel tagging style reordering model which is under the category “*The reordering is a decoding order problem*”. Our model converts the decoding order problem into a sequence labeling problem, i.e. a tagging task. The remainder of this paper is organized as follows: Section 2 introduces the basement of this research: the principle of statistical machine translation. Section 3 describes the proposed model. Section 4 briefly describes several reordering models with which we compare our method. Section 5 provides the experimental configuration and results. Conclusion will be given in Section 6.

## 2 Translation System Overview

In statistical machine translation, we are given a source language sentence  $f_1^J = f_1 \dots f_j \dots f_J$ . The objective is to translate the source into a target language sentence  $e_1^I = e_1 \dots e_i \dots e_I$ . The strategy is to choose the target sentence with the highest probability among all others:

$$\hat{e}_i^I = \arg \max_{I, e_1^I} \{Pr(e_1^I | f_1^J)\} \quad (1)$$

We model  $Pr(e_1^I | f_1^J)$  directly using a log-linear combination of several models (Och and Ney, 2002):

$$Pr(e_1^I | f_1^J) = \frac{\exp\left(\sum_{m=1}^M \lambda_m h_m(e_1^I, f_1^J)\right)}{\sum_{I', e_1^{I'}} \exp\left(\sum_{m=1}^M \lambda_m h_m(e_1^{I'}, f_1^J)\right)} \quad (2)$$

The denominator is to make the  $Pr(e_1^I | f_1^J)$  to be a probability distribution and it depends only on the source sentence  $f_1^J$ . For search, the decision rule is simply:

$$\hat{e}_i^I = \arg \max_{I, e_1^I} \left\{ \sum_{m=1}^M \lambda_m h_m(e_1^I, f_1^J) \right\} \quad (3)$$

The model scaling factors  $\lambda_1^M$  are trained with Minimum Error Rate Training (MERT). In this paper, the phrase-based machine translation system

is utilized (Och et al., 1999; Zens et al., 2002; Koehn et al., 2003).

## 3 Tagging-style Reordering Model

In this section, we describe the proposed novel model. First we will describe the training process. Then we explain how to use the model in the decoder.

### 3.1 Modeling

Figure 1 shows the modeling steps. The first step is word alignment training. Figure 1(a) is an example after GIZA++ training. If we regard this alignment as a translation result, i.e. given the source sentence  $f_1^7$ , the system translates it into the target sentence  $e_1^7$ , then the alignment link set  $\{a_1 = 3, a_3 = 2, a_4 = 4, a_4 = 5, a_5 = 7, a_6 = 6, a_7 = 6\}$  reveals the decoding process, i.e. the alignment implies the order in which the source words should be translated, e.g. the first generated target word  $e_1$  has no alignment, we can regard it as a translation from a NULL source word; then the second generated target word  $e_2$  is translated from  $f_3$ . We reorder the source side of the alignment to get Figure 1(b). Figure 1(b) implies the source sentence decoding sequence information, which is depicted in Figure 1(c). Using this example we describe the strategies we used for special cases in the transformation from Figure 1(b) to Figure 1(c):

- ignore the unaligned target word, e.g.  $e_1$
- the unaligned source word should follow its preceding word, the unaligned feature is kept with a \* symbol, e.g.  $f_2^*$  is after  $f_1$
- when one source word is aligned to multiple target words, only keep the alignment that links the source word to the first target word, e.g.  $f_4$  is linked to  $e_5$  and  $e_6$ , only  $f_4 - e_5$  is kept. In other words, we use this strategy to guarantee that every source word appears only once in the source decoding sequence.
- when multiple source words are aligned to one target word, put together the source words according to their original relative positions, e.g.  $e_6$  is linked to  $f_6$  and  $f_7$ . So in the decoding sequence,  $f_6$  is before  $f_7$ .

Now Figure 1(c) shows the original source sentence and its decoding sequence. By using the strategies above, it is guaranteed that the source sentence and its decoding sequence have the ex-

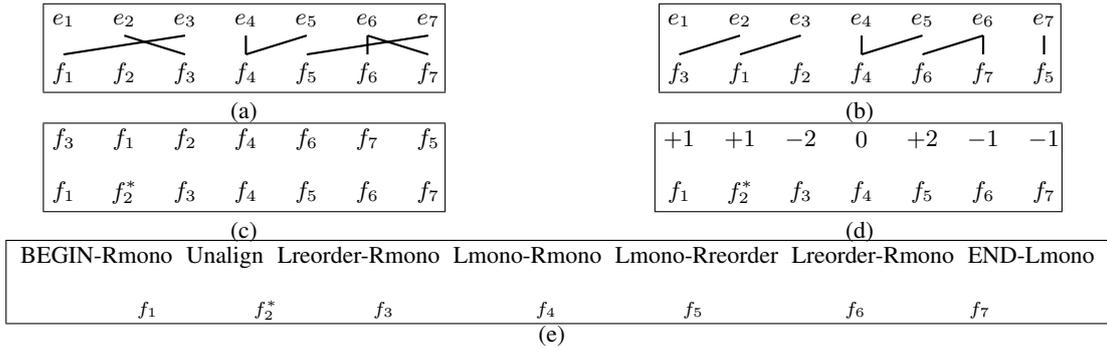

Figure 1: modeling process illustration.

actly same length. Hence the relation can be modeled by a function  $F(f)$  which assigns a value for each source word  $f$ . Figure 1(d) manifests this function. The positive function values mean that compared to the original position in the source sentence, its position in the decoding sequence should move rightwards. If the function value is 0, the word’s position in original source sentence and its decoding sequence is same. For example,  $f_1$  is the first word in the source sentence but it is the second word in the decoding sequence. So its function value is +1 (move rightwards one position).

Now Figure 1(d) converts the reordering problem into a sequence labeling or tagging problem. To make the computational cost to a reasonable level, we do a final step simplification in Figure 1(e). Suppose the longest sentence length is 100, then according to Figure 1(d), there are 200 tags (from -99 to +99 plus the unalign tag). As we will see later, this number is too large for our task. We instead design nine tags. For a source word  $f_j$  in one source sentence  $f_1^J$ , the tag of  $f_j$  will be one of the following:

- Unalign**  $f_j$  is an unaligned source word
- BEGIN-Rmono**  $j = 1$  and  $f_{j+1}$  is translated *after*  $f_j$  (Rmono for right monotonic)
- BEGIN-Rreorder**  $j = 1$  and  $f_{j+1}$  is translated *before*  $f_j$  (Rreorder for right reordered)
- END-Lmono**  $j = J$  and  $f_{j-1}$  translated *before*  $f_j$  (Lmono for left monotonic)
- END-Lreorder**  $j = J$  and  $f_{j-1}$  translated *after*  $f_j$  (Lreorder for left reordered)
- Lmono-Rmono**  $1 < j < J$  and  $f_{j-1}$  translated *before*  $f_j$  and  $f_j$  translated *before*  $f_{j+1}$
- Lreorder-Rmono**  $1 < j < J$  and  $f_{j-1}$  translated *after*  $f_j$  and  $f_j$  translated *before*  $f_{j+1}$
- Lmono-Rreorder**  $1 < j < J$  and  $f_{j-1}$  translated *before*  $f_j$  and  $f_j$  translated *after*  $f_{j+1}$
- Lreorder-Rreorder**  $1 < j < J$  and  $f_{j-1}$  trans-

lated *after*  $f_j$  and  $f_j$  translated *after*  $f_{j+1}$

Up to this point, we have converted the reordering problem into a tagging problem with nine tags. The transformation in Figure 1 is conducted for all the sentence pairs in the bilingual training corpus. After that, we have built an “annotated” corpus for the training. For this supervised learning task, we choose the approach conditional random fields (CRFs) (Lafferty et al., 2001; Sutton and McCallum, 2006; Lavergne et al., 2010) and recurrent neural network (RNN) (Elman, 1990; Jordan, 1990; Lang et al., 1990).

For the first method, we adopt the linear-chain CRFs. However, even for the simple linear-chain CRFs, the complexity of learning and inference grows quadratically with respect to the number of output labels and the amount of structural features which are with regard to adjacent pairs of labels. Hence, to make the computational cost as low as possible, two measures have been taken. Firstly, as described above we reduce the number of tags to nine. Secondly, we add source sentence part-of-speech (POS) tags to the input. For features with window size one to three, both source words and its POS tags are used. For features with window size four and five, only POS tags are used.

As the second method, we use recurrent neural network (RNN). RNN is closely related with Multilayer Perceptrons (MLP) (Rumelhart et al., 1986), but the output of one or more hidden layers is reused as additional inputs for the network in the next time step. This structure allows the RNN to learn whole sequences without restricting itself to a fixed input window. A plain RNN has only access to the previous events in the input sequence. Hence we adopt the bidirectional RNN (BRNN) (Schuster and Paliwal, 1997) which reads the input sequence from both directions before making the prediction. The long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) is applied to

counter the effects that long distance dependencies are hard to learn with gradient descent. This is often referred to as vanishing gradient problem (Bengio et al., 1994).

### 3.2 Decoding

Once the model training is finished, we make inference on develop and test corpora which means that we get the labels of the source sentences that need to be translated. In the decoder, we add a new model which checks the labeling consistency when scoring an extended state. During the search, a sentence pair  $(f_1^J, e_1^I)$  will be formally splitted into a segmentation  $S_1^K$  which consists of  $K$  phrase pairs. Each  $s_k = (i_k; b_k, j_k)$  is a triple consisting of the last position  $i_k$  of the  $k$ th target phrase  $\tilde{e}_k$ . The start and end position of the  $k$ th source phrase  $\tilde{f}_k$  are  $b_k$  and  $j_k$ . Suppose the search state is now extended with a new phrase pair  $(\tilde{f}_k, \tilde{e}_k)$ :  $\tilde{f}_k := f_{b_k} \dots f_{j_k}$  and  $\tilde{e}_k := e_{i_{k-1}+1} \dots e_{i_k}$ . We have access to the old coverage vector, from which we know if the new phrase's left neighboring source word  $f_{b_k-1}$  and right neighboring source word  $f_{j_k+1}$  have been translated. We also have the word alignment within the new phrase pair, which is stored during the phrase extraction process. Based on the old coverage vector and alignment, we can repeat the transformation in Figure 1 to calculate the labels for the new phrase. The added model will then check the consistence between the calculated labels and the labels predicted by the reordering model. The number of source words that have inconsistent labels is the penalty and is then added into the log-linear framework as a new feature.

## 4 Comparative Study

The second part of this paper is comparative study on reordering models. Here we briefly describe those models which will be compared to later.

### 4.1 Moses lexicalized reordering model

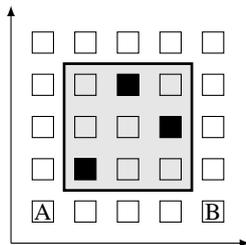

Figure 2: lexicalized reordering model illustration.

Moses (Koehn et al., 2007) contains a word-based orientation model, which has three types of reordering: (m) monotone order, (s) switch with previous phrase and (d) discontinuous. Figure 2 is an example. The definitions of reordering types are as follows:

**monotone** for current phrase, if a word alignment to the bottom left (point A) exists and there is no word alignment point at the bottom right position (point B).

**swap** for current phrase, if a word alignment to the bottom right (point B) exists and there is no word alignment point at the bottom left position (point A).

**discontinuous** all other cases

Our implementation is same with the default behavior of Moses lexicalized reordering model. We count how often each extracted phrase pair is found with each of the three reordering types. The add-0.5 smoothing is then applied. Finally, the probability is estimated with maximum likelihood principle.

### 4.2 Maximum entropy reordering model

Figure 3 is an illustration of (Zens and Ney, 2006).  $j$  is the source word position which is aligned to the last target word of the current phrase.  $j'$  is the last source word position of the current phrase.  $j''$  is the source word position which is aligned to the first target word position of the next phrase. (Zens and Ney, 2006) proposed a maximum entropy classifier to predict the orientation of the next phrase given the current phrase. The orientation class  $c_{j,j',j''}$  is defined as:

$$c_{j,j',j''} = \begin{cases} \text{left,} & \text{if } j'' < j \\ \text{right,} & \text{if } j'' > j \text{ and } j'' - j' > 1 \\ \text{monotone,} & \text{if } j'' > j \text{ and } j'' - j' = 1 \end{cases} \quad (4)$$

The orientation probability is modeled in a log-linear framework using a set of  $N$  feature functions  $h_n(f_1^J, e_1^I, i, j, c_{j,j',j''})$ ,  $n = 1, \dots, N$ . The whole model is:

$$p_{\lambda_1^N}(c_{j,j',j''} | f_1^J, e_1^I, i, j) = \frac{\exp(\sum_{n=1}^N \lambda_n h_n(f_1^J, e_1^I, i, j, c_{j,j',j''}))}{\sum_{c'} \exp(\sum_{n=1}^N \lambda_n h_n(f_1^J, e_1^I, i, j, c'))} \quad (5)$$

Different features can be used, we use the source and target word features to train the model.

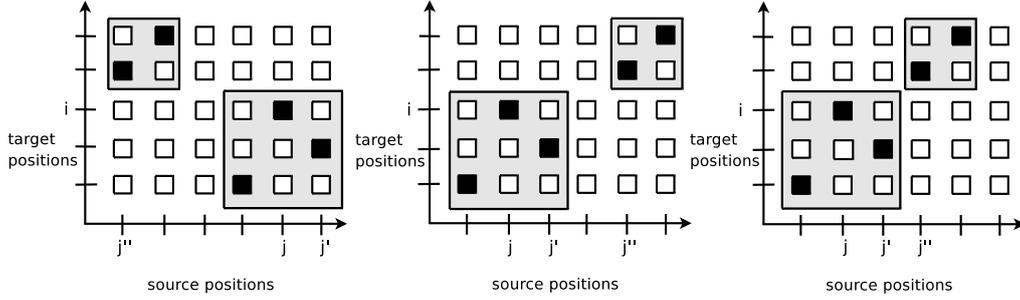

Figure 3: phrase orientation: left, right and monotone.  $j$  is the source word position aligned to the last target word of current phrase.  $j'$  is the last source word position of current phrase.  $j''$  is the source word position aligned to the first target word position of the next phrase.

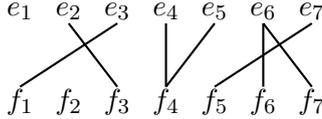

Figure 4: bilingual LM illustration. The bilingual sequence is  $e_1-$ ,  $e_2-f_3$ ,  $e_3-f_1$ ,  $e_4-f_4$ ,  $e_5-f_4$ ,  $e_6-f_6-f_7$ ,  $e_7-f_5$ .

### 4.3 Bilingual LM

The previous two models belong to “*The reordering is a classification problem*”. Now we turn to “*The reordering is a decoding order problem*”. (Mariño et al., 2006) implement a translation model using  $n$ -grams. In this way, the translation system can take full advantage of the smoothing and consistency provided by standard back-off  $n$ -gram models. Figure 4 is an example. The interpretation is that given the sentence pair  $(f_1^7, e_1^7)$  and its alignment, the correct translation order is  $e_1-$ ,  $e_2-f_3$ ,  $e_3-f_1$ ,  $e_4-f_4$ ,  $e_5-f_4$ ,  $e_6-f_6-f_7$ ,  $e_7-f_5$ . Notice the bilingual units have been ordered according to the target side, as the decoder writes the translation in a left-to-right way. Using the example we describe the strategies used for special cases:

- keep the unaligned target word, e.g.  $e_1-$
- remove the unaligned source word, e.g.  $f_2$
- when one source word aligned to multiple target words, duplicate the source word for each target word, e.g.  $e_4-f_4$ ,  $e_5-f_4$
- when multiple source words aligned to one target word, put together the source words for that target word, e.g.  $e_6-f_6-f_7$

After the operation in Figure 4 was done for all bilingual sentence pairs, we get a decoding sequence corpus. We build a 9-gram LM using SRILM toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing.

The model is added as an additional feature in Equation (2). To use the bilingual LM, the search state must be augmented to keep the bilingual unit

decoding sequence. In search, the bilingual LM is applied similar to the standard target side LM. The bilingual sequence of phrase pairs will be extracted using the same strategy in Figure 4. Suppose the search state is now extended with a new phrase pair  $(\tilde{f}, \tilde{e})$ .  $\tilde{F}$  is the bilingual sequence for the new phrase pair  $(\tilde{f}, \tilde{e})$  and  $\tilde{F}^i$  is the  $i^{\text{th}}$  unit within  $\tilde{F}$ .  $\tilde{F}'$  is the bilingual sequence history for current state. We compute the feature score  $h_{bilm}(\tilde{F}, \tilde{F}')$  of the extended state as follows:

$$h_{bilm}(\tilde{F}, \tilde{F}') = \lambda \cdot \sum_{i=1}^{|\tilde{F}|} \log p(\tilde{F}^i | \tilde{F}', \tilde{F}^1, \dots, \tilde{F}^{i-1}) \quad (6)$$

$\lambda$  is the scaling factor for this model.  $|\tilde{F}|$  is the length of the bilingual decoding sequence.

### 4.4 Source decoding sequence LM

(Feng et al., 2010) present a simpler version of the above bilingual LM where they use only the source side to model the decoding order. The source word decoding sequence in Figure 4 is then  $f_3, f_1, f_2, f_4, f_6, f_7, f_5$ . We also build a 9-gram LM based on the source word decoding sequences. The usage of the model is same as bilingual LM.

### 4.5 Syntactic cohesion model

The previous two models belong to “*The reordering is a decoding order problem*”. Now we turn to “*The reordering can be solved by outside heuristics*”. (Cherry, 2008) proposed a syntactic cohesion model. The core idea is that the syntactic structure of the source sentence should be preserved during translation. This structure is represented by a source sentence dependency tree. The algorithm is as follows: given the source sentence and its dependency tree, during the translation process, once a hypothesis is extended, check if the source dependency tree contains a subtree  $T$  such that:

- Its translation is already started (at least one node is covered)
- It is interrupted by the new added phrase (at least one word in the new source phrase is not in  $T$ )
- It is not finished (after the new phrase is added, there is still at least one free node in  $T$ )

If so, we say this hypothesis violates the subtree  $T$ , and the model returns the number of subtrees that this hypothesis violates.

#### 4.6 Semantic cohesion model

(Feng et al., 2012) propose two structure features from semantic role labeling (SRL) results. Similar to the previous model, the SRL information is used as soft constraints. During decoding process, the first feature will report how many event layers that one search state violates and the second feature will report the amount of semantic roles that one search state violates. In this paper, the two features have been used together. So when the semantic cohesion model is used, both features will be triggered.

#### 4.7 Tree-based jump model

(Wang et al., 2007) present a pre-reordering method for Chinese-English translation task. In Section 3.6 of (Zhang, 2013), instead of doing hard reordering decision, the author uses the rules as soft constraints in the decoder. In this paper, we use the similar method as described in (Zhang, 2013). Our strategy is: firstly, we parse the source sentences to get constituency trees. Then we manipulate the trees using heuristics described by (Wang et al., 2007). The leaf nodes in the revised tree constitute the reordered source sentence. Finally, in the log-linear framework (Equation 2) a new jump model is added which uses the reordered source sentence to calculate the cost. For example, the original sentence  $f_1 f_2 f_3 f_4 f_5$  is now converted by rules into the new sentence  $f_1 f_5 f_3 f_2 f_4$ . For decoding, we still use the original sentence. Suppose previously translated source phrase is  $f_1$  and the current phrase is  $f_5$ . Then the standard jump model gives cost  $q_{Dist} = 4$  and the new tree-based jump model will return a cost  $q_{Dist.new} = 1$ .

## 5 Experiments

In this section, we describe the baseline setup, the CRFs training results, the RNN training results

and translation experimental results.

### 5.1 Experimental Setup

Our baseline is a phrase-based decoder, which includes the following models: an  $n$ -gram target-side language model (LM), a phrase translation model and a word-based lexicon model. The latter two models are used for both directions:  $p(f|e)$  and  $p(e|f)$ . Additionally we use phrase count features, word and phrase penalty. The reordering model for the baseline system is the distance-based jump model which uses linear distance. This model does not have hard limit. We list the important information regarding the experimental setup below. All those conditions have been kept same in this work.

- lowercased training data from the GALE task (Table 1, UN corpus not included) alignment trained with GIZA++
- tuning corpus: NIST06  
test corpora: NIST02 03 04 05 and 08
- 5-gram LM (1 694 412 027 running words) trained by SRILM toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing training data: target side of bilingual data.
- BLEU (Papineni et al., 2001) and TER (Snover et al., 2005) reported all scores calculated in lowercase way.
- Wapiti toolkit (Lavergne et al., 2010) used for CRFs; RNN is built by the RNNLIB toolkit.

<b>Vocabulary</b>	1 125 437	739 251

Table 1: translation model and LM training data statistics

Table 1 contains the data statistics used for translation model and LM. For the reordering model, we take two further filtering steps. Firstly, we delete the sentence pairs if the source sentence length is one. When the source sentence has only one word, the translation will be always monotonic and the reordering model does not need to learn this. Secondly, we delete the sentence pairs if the source sentence contains more than three contiguous unaligned words. When this happens, the sentence pair is usually low quality hence not suitable for learning. The main purpose of the two filtering steps is to further lay down the computational burden. The label distribution is depicted in Figure 5. We can see that most words are monotonic. We then divide the corpus to three parts:

## 5.2 CRFs Training Results

The toolkit Wapiti (Lavergne et al., 2010) is used in this paper. We choose the classical optimization algorithm limited memory BFGS (L-BFGS) (Liu and Nocedal, 1989). For regularization, Wapiti uses both the  $\ell^1$  and  $\ell^2$  penalty terms, yielding the elastic-net penalty of the form

$$\rho_1 \cdot \|\theta\|_1 + \frac{\rho_2}{2} \cdot \|\theta\|_2^2 \quad (7)$$

In this work, we use as many features as possible because  $\ell^1$  penalty  $\rho_1 \|\theta\|_1$  is able to yield sparse parameter vectors, i.e. using a  $\ell^1$  penalty term implicitly performs the feature selection. The computational costs are given here: on a cluster with two AMD Opteron(tm) Processor 6176 (total 24 cores), the training time is about 16 hours, peak memory is around 120G. Several experiments have been done to find the suitable hyperparameter  $\rho_1$  and  $\rho_2$ , we choose the model with lowest error rate on validation corpus for translation experiments. The error rate of the chosen model on test corpus (the test corpus in Table 2) is 25.75% for token error rate and 69.39% for sequence error rate. Table 3 is the feature template we set initially which generates 722 999 637 features. Some examples are given in Table 4. After training 36 902 363 features are kept.

## 5.3 RNN Training Results

We also applied RNN to the task as an alternative approach to CRFs. The here used RNN implementation is RNNLIB which has support for long short term memory (LSTM) (Graves, 2008). We used a one of k encoding for the input word and also for the labels. After testing several configurations over the validation corpus we used a network with

So for the current label in this table,  $x[-1, 2]/x[0, 2]$  is Lmono-Rmono/UNALIGN and  $x[-1, 1]/x[0, 1]/x[1, 1]$  is PN/VC/VV.

LSTM 200 nodes in the hidden layer. The RNN has a token error rate of 27.31% and a sentence error rate of 77.00% over the test corpus in Table 2. The RNN is trained on a similar computer as above. RNNLIB utilizes only one thread. The training time is about three and a half days and peak memory consumption is 1G .

## 5.4 Comparison of CRFs and RNN errors

CRFs performs better than RNN (token error rate 25.75% vs 27.31%). Both error rate values are much higher than what we usually see in part-of-speech tagging task. The main reason is that the “annotated” corpus is converted from word alignment which contains lots of error. However, as we

Table 6: RNN Confusion Matrix. Abbreviations: Lmono(Lm) Lreorder(Lr) Rmono(Rm) Rreorder(Rr)

will show later, the model trained with both CRFs and RNN help to improve the translation quality.

Table 5 and Table 6 demonstrate the confusion matrix of the CRFs and RNN errors over the test corpus. The rows represent the correct tag that the classifier should have predicted and the columns are the actually predicted tags. E.g. the number 687724 in first row and first column of Table 5 tells that there are 687724 correctly labeled **Unalign** tags. The number 15084 in first row and second column of Table 5 represents that there are 15084 **Unalign** tags labeled incorrectly to **Begin-Rmono**. Therefore, numbers on the diagonal from the upper left to the lower right corner represent the amount of correctly classified tags and all other numbers show the amount of false labels. The many zeros show that both classifier rarely make mistake for the label “**BEGIN-\***” which only occur at the beginning of a sentence. The same is true for the “**END-\***” labels.

## 5.5 Translation Results

Results are summarized in Table 7. Please read the caption for the meaning of abbreviations. An **Index** column is added for score reference convenience (B for BLEU; T for TER). For the proposed model, significance testing results on both BLEU and TER are reported (B2 and B3 compared to B1, T2 and T3 compared to T1). We perform bootstrap resampling with bounds estimation as described in (Koehn, 2004). The 95% confidence threshold

(denoted by † in the table) is used to draw significance conclusions. We add a column **avg.** to show the average improvements.

From Table 7 we see that the proposed reordering model using CRFs improves the baseline by 0.98 BLEU and 1.21 TER on average, while the proposed reordering model using RNN improves the baseline by 1.32 BLEU and 1.53 TER on average. For line B2 B3 and T2 T3, most scores are better than their corresponding baseline values with more than 95% confidence. The results show that our proposed idea improves the baseline system and RNN trained model performs better than CRFs trained model, in terms of both automatic measure and significance test. To investigate why RNN has lower performance for the tagging task but achieves better BLEU, we build a 3-gram LM on the source side of the training corpus in Table 2 and perplexity values are listed in Table 8. The perplexity of the test corpus for reordering model comparison is much lower than those NIST corpora for translation experiments. In other words, there exists mismatch of the data for reordering model training and actual MT data. This could explain why CRFs is superior to RNN for labeling problem while RNN is better for MT tasks.

For the comparative study, the best method is the tree-based jump model (JUMPTREE). Our proposed model ranks the second position. The difference is tiny: on average only 0.08 BLEU (B3 and B10) and 0.15 TER (T3 and T10). Even with

a strong system (B11 and T11), our model is still able to provide improvements (B12 and T12).

## 6 Conclusion

In this paper, a novel tagging style reordering model has been proposed. By our method, the reordering problem is converted into a sequence labeling problem so that the whole source sentence is taken into consideration for reordering decision. By adding an unaligned word tag, the unaligned word phenomenon is automatically implanted in the proposed model. The model is utilized as soft constraints in the decoder. In practice, we do not experience decoding memory increase nor speed slow down.

We choose CRFs and RNN to accomplish the sequence labeling task. The CRFs achieves lower error rate on the tagging task but RNN trained model is better for the translation task. Experimental results show that our model is stable and improves the baseline system by 0.98 BLEU and 1.21 TER (trained by CRFs) and 1.32 BLEU and 1.53 TER (trained by RNN). Most of the scores

are better than their corresponding baseline values with more than 95% confidence. We also compare our method with several other popular reordering models. Our model ranks the second position which is slightly worse than the tree-based jump model. However, the tree-based jump model relies on manually designed reordering rules which does not exist for many language pairs while our model can be easily adapted to other translation tasks. We also show that the proposed model is able to improve a very strong baseline system.

The main contributions of the paper are: propose the tagging-style reordering model and improve the translation quality; compare two sequence labeling techniques CRFs and RNN; compare our method with seven other reordering models. To our best knowledge, it is the first time that the above two comparisons have been reported .

# A Markov Model of Machine Translation using Non-parametric Bayesian Inference

Yang Feng and Trevor Cohn

Department of Computer Science

## Abstract

Most modern machine translation systems use phrase pairs as translation units, allowing for accurate modelling of phrase-internal translation and reordering. However phrase-based approaches are much less able to model sentence level effects between different phrase-pairs. We propose a new model to address this imbalance, based on a word-based Markov model of translation which generates target translations left-to-right. Our model encodes word and phrase level phenomena by conditioning translation decisions on previous decisions and uses a hierarchical Pitman-Yor Process prior to provide dynamic adaptive smoothing. This mechanism implicitly supports not only traditional phrase pairs, but also gapping phrases which are non-consecutive in the source. Our experiments on Chinese to English and Arabic to English translation show consistent improvements over competitive baselines, of up to +3.4 BLEU.

## 1 Introduction

Recent years have witnessed burgeoning development of statistical machine translation research, notably phrase-based (Koehn et al., 2003) and syntax-based approaches (Chiang, 2005; Galley et al., 2006; Liu et al., 2006). These approaches model sentence translation as a sequence of simple translation decisions, such as the application of a phrase translation in phrase-based methods or a grammar rule in syntax-based approaches. In order to simplify modelling, most MT models make an independence assumption, stating that the translation decisions in a derivation are independent of one another. This conflicts with the intuition behind phrase-based MT, namely that translation decisions should be dependent on con-

text. On one hand, the use of phrases can memorize local context and hence helps to generate better translation compared to word-based models (Brown et al., 1993; Och and Ney, 2003). On the other hand, this mechanism requires each phrase to be matched strictly and to be used as a whole, which precludes the use of discontinuous phrases and leads to poor generalisation to unseen data (where large phrases tend not to match).

In this paper we propose a new model to drop the independence assumption, by instead modelling correlations between translation decisions, which we use to induce translation derivations from aligned sentences (akin to word alignment). We develop a Markov model over translation decisions, in which each decision is conditioned on previous  $n$  most recent decisions. Our approach employs a sophisticated Bayesian non-parametric prior, namely the hierarchical Pitman-Yor Process (Teh, 2006; Teh et al., 2006) to represent back-off from larger to smaller contexts. As a result, we need only use very simple translation units – primarily single words, but can still describe complex multi-word units through correlations between their component translation decisions. We further decompose the process of generating each target word into component factors: finishing the translating, jumping elsewhere in the source, emitting a target word and deciding the fertility of the source words.

Overall our model has the following features:

1. enabling model parameters to be shared between similar translation decisions, thereby obtaining more reliable statistics and generalizing better from small training sets.
2. learning a much richer set of translation fragments, such as *gapping* phrases, e.g., the translation for the German *werde ... ankommen* in English is *will arrive ...*
3. providing a unifying framework spanning word-based and phrase-based model of translation, while incorporating explicit transla-

tion, insertion, deletion and reordering components.

We demonstrate our model on Chinese-English and Arabic-English translation datasets. The model produces uniformly better translations than those of a competitive phrase-based baseline, amounting to an improvement of up to 3.4 BLEU points absolute.

## 2 Related Work

Word based models have a long history in machine translation, starting with the venerable IBM translation models (Brown et al., 1993) and the hidden Markov model (Vogel et al., 1996). These models are still in wide-spread use today, albeit only as a preprocessing step for inferring word level alignments from sentence-aligned parallel corpora. They combine a number of factors, including distortion and fertility, which have been shown to improve word-alignment and translation performance over simpler models. Our approach is similar to these works, as we also develop a word-based model, and explicitly consider similar translation decisions, alignment jumps and fertility. We extend these works in two important respects: 1) while they assume a simple parameterisation by making *iid* assumptions about each translation factor, we instead allow for rich correlations by modelling sequences of translation decisions; and 2) we develop our model in the Bayesian framework, using a hierarchical Pitman-Yor Process prior with rich backoff semantics between high and lower order sequences of translation decisions. Together this results in a model with rich expressiveness but can still generalize well to unseen data.

More recently, a number of authors have proposed Markov models for machine translation. Vaswani et al. (2011) propose a rule Markov model for a tree-to-string model which models correlations between pairs of minimal rules, and use Kneser-Ney smoothing to alleviate the problems of data sparsity. Similarly, Crego et al. (2011) develop a bilingual language model which incorporates words in the source and target languages to predict the next unit, which they use as a feature in a translation system. This line of work was extended by Le et al. (2012) who develop a novel estimation algorithm based around discriminative projection into continuous spaces. Also relevant is Durrani et al. (2011), who present a sequence model of translation including reordering.

Our work also uses bilingual information, using the source words as part of the conditioning context. In contrast to these approaches which primarily address the decoding problem, we focus on the learning problem of inferring alignments from parallel sentences. Additionally, we develop a full generative model using a Bayesian prior, and incorporate additional factors besides lexical items, namely jumps in the source and word fertility.

Another aspect of this paper is the implicit support for phrase-pairs that are discontinuous in the source language. This idea has been developed explicitly in a number of previous approaches, in grammar based (Chiang, 2005) and phrase-based systems (Galley and Manning, 2010). The latter is most similar to this paper, and shows that discontinuous phrases compliment standard contiguous phrases, improving expressiveness and translation performance. Unlike their work, here we develop a complimentary approach by constructing a generative model which can induce these rich rules directly from sentence-aligned corpora.

## 3 Model

Given a source sentence, our model infers a latent derivation which produces a target translation and meanwhile gives a word alignment between the source and the target. We consider a process in which the target string is generated using a left-to-right order, similar to the decoding strategy used by phrase-based machine translation systems (Koehn et al., 2003). During this process we maintain a position in the source sentence, which can jump around to allow for different sentence ordering in the target vs. source languages. In contrast to phrase-based models, we use words as our basic translation unit, rather than multi-word phrases. Furthermore, we decompose the decisions involved in generating each target word to a number of separate factors, where each factor is modelled separately and conditioned on a rich history of recent translation decisions.

### 3.1 Markov Translation

Our model generates target translation left-to-right word by word. The generative process employs the following recursive procedure to construct the target sentence conditioned on the source:

```
 $i \leftarrow 1$   
while Not finished do  
    Decide whether to finish the translation,  $\xi_i$ 
```

Step	Source sentence	Translation	<i>finish</i>	<i>jump</i>	<i>emission</i>
0	— Je le prends				
1	— <u>Je</u> le prends	I	<i>no</i>	<i>monotone</i>	Je → I
2	— <u>Je</u> le prends	I 'll	<i>no</i>	<i>insert</i>	null → 'll
3	— <u>Je</u> le prends	I 'll take	<i>no</i>	<i>forward</i>	prends → take
4	— Je <u>le</u> prends	I 'll take that	<i>no</i>	<i>backward</i>	le → that
5	— Je <u>le</u> prends	I 'll take that one	<i>no</i>	<i>stay</i>	le → one
6	— Je <u>le</u> prends	I 'll take that one	<i>yes</i>		

Figure 1: Translation agenda of Je le prends → I 'll take that one.

**if**  $\xi_i = \text{false}$  **then**  
 Select a source word to jump to  
 Emit a target word for the source word  
**end if**  
 $i \leftarrow i + 1$   
**end while**

In the generation of each target word, our model includes three separate factors: the binary *finish* decision, a *jump* decision to move to a different source word, and *emission* which translates or otherwise inserts a word in the target string. This generative process resembles the sequence of translation decisions considered by a standard MT decoder (Koehn et al., 2003), but note that our approach differs in that there is no constraint that all words are translated exactly once. Instead source words can be skipped or repeatedly translated. This makes the approach more suitable for learning alignments, e.g., to account for word fertilities (see §3.3), while also permitting inference using Gibbs sampling (§4).

More formally, we can express our probabilistic model as

$$\begin{aligned}
 p_{bs}(e_1^I, a_1^I | f_1^J) &= \prod_{i=1}^{I+1} p(\xi_i | f_{a_i-n}^{i-1}, e_{i-n}^{i-1}) \\
 &\times \prod_{i=1}^I p(\tau_i | f_{a_i-n}^{i-1}, e_{i-n}^{i-1}) \\
 &\times \prod_{i=1}^I p(e_i | \tau_i, f_{a_i-n}^i, e_{i-n}^{i-1}) \quad (1)
 \end{aligned}$$

where  $\xi_i$  is the finish decision for target position  $i$ ,  $\tau_i$  is the jump decision to source word  $f_{a_i}$  and  $f_{a_i-n}^i$  is the source words for target positions  $i-n, i-n+1, \dots, i$ . Each of the three distributions (finish, jump and emission) is drawn respectively from hierarchical Pitman-Yor Process priors, as described in Section 3.2.

The jump decision  $\tau_i$  in Equation 1 demands further explanation. Instead of modelling jump distances explicitly, which poses problems for

generalizing between different lengths of sentences and general parameter explosion, we consider a small handful of types of jump based on the distance between the current source word  $a_i$  and the previous source word  $a_{i-1}$ , i.e.,  $d_i = a_i - a_{i-1}$ .<sup>1</sup> We bin jumps into five types:

- insert*;
- backward*, if  $d_i < 0$ ;
- stay*, if  $d_i = 0$ ;
- monotone*, if  $d_i = 1$ ;
- forward*, if  $d_i > 1$ .

The special jump type *insert* handles null alignments, denoted  $a_i = 0$  which licence spurious insertions in the target string.

To illustrate this translation process, Figure 1 shows the example translation  $\langle Je\ le\ prends,\ I\ 'll\ take\ that\ one \rangle$ . Initially we set the source position before the first source word *Je*. Then in step 1, we decide not to finish (finish=*no*), jump to source word *Je* and translate it as *I*. Next, we again decide not to finish, jump to the *null* source word and insert *'ll*. The process continues until in step 6 we elect to finish (finish=*yes*), at which point the translation is complete, with target string *I 'll take that one*.

### 3.2 Hierarchical Pitman-Yor Process

The Markov assumption limits the context of each distribution to the  $n$  most recent translation decisions, which limits the number of model parameters. However for any non-trivial value  $n > 0$ , overfitting is a serious concern. We counter the problem of a large parameter space using a Bayesian non-parametric prior, namely the hierarchical Pitman-Yor Process (PYP). The PYP describes distributions over possibly infinite event spaces that follow a power law, with few events taking the majority of the probability mass and a long tail of less frequent events. We consider a hierarchical PYP, where a sequence of chained PYP

<sup>1</sup>For a target position aligned to null, we denote its source word as *null* and set its aligned source position as that of the previous target word that is aligned to non-null.

priors allow backoff from larger to smaller contexts such that our model can learn rich contextual models for known (large) contexts while also still being able to generalize well to unseen contexts (using smaller histories).

### 3.2.1 Pitman-Yor Process

A PYP (Pitman and Yor, 1997) is defined by its discount parameter  $0 \leq a < 1$ , strength parameter  $b > -a$  and base distribution  $G_0$ . For a distribution drawn from a PYP,  $G \sim \mathcal{PYP}(a, b, G_0)$ , marginalising out  $G$  leads to a simple distribution which can be described using a variant of the Chinese Restaurant Process (CRP). In this analogy we imagine a restaurant has an infinite number of tables and each table can accommodate an infinite number of customers. Each customer (a sample from  $G$ ) walks in one at a time and seats themselves at a table. Finally each table is served a communal dish (a draw from  $G_0$ ), which is served to each customer seated at the table. The assignment of customers to tables is such that popular tables are more likely to be chosen, and this rich-get-richer dynamic produces power-law distributions with few events (the dishes at popular tables) dominating the distribution.

More formally, at time  $n$  a customer enters and selects a table  $k$  which is either a table having been seated ( $1 \leq k \leq K^-$ ) or an empty table ( $k = K^- + 1$ ) by

$$p(t_n = k | \mathbf{t}_{-n}) = \begin{cases} \frac{c_{\mathbf{t}_k}^- - a}{n-1+b} & 1 \leq k \leq K^- \\ \frac{aK^- + b}{n-1+b} & k = K^- + 1 \end{cases}$$

where  $t_n$  is the table selected by the customer  $n$ ,  $\mathbf{t}_{-n}$  is the seating arrangement of previous  $n-1$  customers,  $c_{\mathbf{t}_k}^-$  is the number of customers seated at table  $k$  in  $\mathbf{t}_{-n}$  and  $K^- = K(\mathbf{t}_{-n})$  is the number of tables in  $\mathbf{t}_{-n}$ .

If the customer sits at an empty table, a dish  $h$  is served to his table by the probability of  $G_0(h)$ , otherwise, he can only share with others the dish having been served to his table.<sup>2</sup> Overall, the probability of the customer being served a dish  $h$  is

$$p(o_n = h | \mathbf{t}_{-n}, \mathbf{o}_{-n}) = \frac{c_{\mathbf{o}_h}^- - aK_h^-}{n-1+b} + \frac{(aK^- + b)}{n-1+b} G_0(h)$$

where  $o_n$  is the dish served to the customer  $n$ ,  $\mathbf{o}_{-n}$  is the dish accommodation of previous  $n-1$  customers,  $c_{\mathbf{o}_h}^-$  is the number of customers who are

<sup>2</sup>We also say the customer is served with this dish.

served with the dish  $h$  in  $\mathbf{o}_{-n}$  and  $K_h^-$  is the number of tables served with the dish  $h$  in  $\mathbf{t}_{-n}$ .

The hierarchical PYP (hPYP; Teh (2006)) is an extension of the PYP in which the base distribution  $G_0$  is itself a PYP distribution. This parent (base) distribution can itself have a PYP as a base distribution, giving rise to hierarchies of arbitrary depth. Like the PYP, inference under the hPYP can be also described in terms of CRP whereby each table in one restaurant corresponds to a dish in the next deeper level, and is said to share the same dish. Whenever an empty table is seated in one level, a customer must enter the restaurant in the next deeper level and find a table to sit. This process continues until the customer is assigned a shared table or the deepest level of the hierarchy is reached. A similar process occurs when a customer leaves, where newly emptied tables must be propagated up the hierarchy in the form of departing customers. There is not space for a complete treatment of the hPYP and the particulars of inference; we refer the interested reader to Teh (2006).

### 3.2.2 A Hierarchical PYP Translation Model

We draw the distributions for the various translation factors from respective hierarchical PYP priors, as shown in Figure 2 for the finish, jump and emission factors. For the emission factor (Figure 2c), we draw the target word  $e_i$  from a distribution conditioned on the last two source and target words, as well as the current source word,  $f_{a_i}$  and the current jump type  $\tau_i$ . Here the draw of a target word corresponds to a customer entering and which target word to emit corresponds to which dish to be served to the customer in the CRP. The hierarchical prior encodes a backoff path in which the jump type is dropped first, followed by pairs of source and target words from least recent to most recent. The final backoff stages drop the current source word, terminating with the uniform base distribution over the target vocabulary  $V$ .

The distributions over the other two factors in Figure 2 follow a similar pattern. Note however that these distributions don't condition on the current source word, and consequently have fewer levels of backoff. The terminating base distribution for the finish factor is a uniform distribution with equal probability for finishing versus continuing. The jump factor has an additional conditioning variable  $t$  which encodes whether the previous alignment is near the start or end of the source sentence. This information affects which of the jump values are legal from the current position, such

$$\begin{array}{lll}
\xi_i | f_{a^{i-2}}^{i-1}, e_{i-2}^{i-1} \sim G_{f_{a^{i-2}, e_{i-2}^{i-1}}}^\xi & \tau_i | f_{a^{i-2}}^{i-1}, e_{i-2}^{i-1}, t \sim G_{f_{a^{i-2}, e_{i-2}^{i-1}}, t}^\tau & e_i | \tau_i, f_{a^{i-2}}^{i-1}, e_{i-2}^{i-1} \sim G_{\tau_i, f_{a^{i-2}, e_{i-2}^{i-1}}}^e \\
G_{f_{a^{i-2}, e_{i-2}^{i-1}}}^\xi \sim \mathcal{PYP}(a_3^\xi, b_3^\xi, G_{f_{a^{i-1}, e_{i-1}^{i-1}}}^\xi) & G_{f_{a^{i-2}, e_{i-2}^{i-1}}, t}^\tau \sim \mathcal{PYP}(a_3^\tau, b_3^\tau, G_{f_{a^{i-1}, e_{i-1}^{i-1}}, t}^\tau) & G_{\tau_i, f_{a^{i-2}, e_{i-2}^{i-1}}}^e \sim \mathcal{PYP}(a_5^e, b_5^e, G_{f_{a^{i-2}, e_{i-2}^{i-1}}}^e) \\
G_{f_{a^{i-1}, e_{i-1}^{i-1}}}^\xi \sim \mathcal{PYP}(a_2^\xi, b_2^\xi, G^\xi) & G_{f_{a^{i-1}, e_{i-1}^{i-1}}, t}^\tau \sim \mathcal{PYP}(a_2^\tau, b_2^\tau, G_t^\tau) & G_{f_{a^{i-2}, e_{i-2}^{i-1}}}^e \sim \mathcal{PYP}(a_4^e, b_4^e, G_{f_{a^{i-1}, e_{i-1}^{i-1}}}^e) \\
G^\xi \sim \mathcal{PYP}(a_1^\xi, b_1^\xi, G_0^\xi) & G_t^\tau \sim \mathcal{PYP}(a_1^\tau, b_1^\tau, G_{0,t}^\tau) & G_{f_{a^{i-1}, e_{i-1}^{i-1}}}^e \sim \mathcal{PYP}(a_3^e, b_3^e, G_{f_{a^i}^e}) \\
G_0^\xi \sim \mathcal{U}(\frac{1}{2}) & G_{0,t}^\tau \sim \mathcal{U} & G_{f_{a^i}^e} \sim \mathcal{PYP}(a_2^e, b_2^e, G^e) \\
& & G^e \sim \mathcal{PYP}(a_1^e, b_1^e, G_0^e) \\
& & G_0^e \sim \mathcal{U}(\frac{1}{|V|})
\end{array}$$

(b) Jump factor
(c) Emission factor

Figure 2: Distributions over the translation factors and their hierarchical priors.

that a jump could not go outside the bounds of the source sentence. Accordingly we maintain separate distributions for each setting, and each has a different uniform base distribution parameterized according to the number of possible jump types.

### 3.3 Fertility

For each target position, our Markov model may select a source word which has been covered, which means a source word may be linked to several target positions. Therefore, we introduce *fertility* to denote the number of target positions a source word is linked to in a sentence pair. Brown et al. (1993) have demonstrated the usefulness of fertility in probability estimation: IBM models 3–5 exhibit large improvements over models 1–2. On these grounds, we include fertility to produce our *advanced* model,

$$p_{ad}(e_1^I, a_1^I | f_1^J) = p_{bs}(e_1^I, a_1^I | f_1^J) \prod_{j=1}^J p(\phi_j | f_{j-n}^j) \quad (2)$$

where  $\phi_j$  is the fertility of source word  $f_j$  in the sentence pair  $\langle f_1^J, e_1^I \rangle$  and  $p_{bs}$  is the basic model defined in Eq. 1. In order to avoid problems of data sparsity, we bin fertility into three types, a) *zero*, if  $\phi = 0$ ; b) *single*, if  $\phi = 1$ ; and c) *multiple*, if  $\phi > 1$ .

We draw the fertility variables from a hierarchical PYP distribution, using three levels of backoff,

$$\begin{aligned}
\phi_j | f_{j-1}^j &\sim G_{f_{j-1}^j}^\phi \\
G_{f_{j-1}^j}^\phi &\sim \mathcal{PYP}(a_3^\phi, b_3^\phi, G_{f_j}^\phi) \\
G_{f_j}^\phi &\sim \mathcal{PYP}(a_2^\phi, b_2^\phi, G^\phi) \\
G^\phi &\sim \mathcal{PYP}(a_1^\phi, b_1^\phi, G_0^\phi) \\
G_0^\phi &\sim \mathcal{U}(\frac{1}{3})
\end{aligned}$$

where we condition the fertility of each word token on the token to its left, which we drop during the first stage of backoff to simple word-based fertility. The last level of backoff further generalises to a shared fertility across all words. In this way we gain the benefits of local context on fertility, while including more general levels to allow wider applicability.

## 4 Gibbs Sampling

To train the model, we use Gibbs sampling, a Markov Chain Monte Carlo (MCMC) technique for posterior inference. Specifically we seek to infer the latent sequence of translation decisions given a corpus of sentence pairs. Given the structure of our model, a word alignment uniquely specifies the translation decisions and the sequence follows the order of the target sentence left to right. Our Gibbs sampler operates by sampling an update to the alignment of each target word in the corpus. It visits each sentence pair in the corpus in a random order and resamples the alignments for each target position as follows. First we discard the alignment to the current target word and decrement the counts of all factors affected by this alignment in their top level distributions (which will percolate down to the lower restaurants). Next we calculate posterior probabilities for all possible alignment to this target word based on the table occupancies in the hPYP. Finally we draw an alignment and increment the table counts for the translation decisions affected by the new alignment.

More specifically, we consider sampling from Equation 2 with  $n = 2$ . When changing the alignment to a target word  $e_i$  from  $j'$  to  $j$ , the *finish*, *jump* and *emission* for three target positions  $i, i + 1, i + 2$  and *fertility* for two source positions  $j, j'$  may be affected. This leads to the following

decrement	increment
$\xi(\text{no} \mid \text{null}, \text{'ll}, \text{Je}, \text{I})$	$\xi(\text{no} \mid \text{null}, \text{'ll}, \text{Je}, \text{I})$
$\xi(\text{no} \mid \text{p..s}, \text{take}, \text{null}, \text{'ll})$	$\xi(\text{no} \mid \text{Je}, \text{take}, \text{null}, \text{'ll})$
$\xi(\text{no} \mid \text{le}, \text{that}, \text{p..s}, \text{take})$	$\xi(\text{no} \mid \text{le}, \text{that}, \text{Je}, \text{take})$
$\tau(f \mid \text{null}, \text{'ll}, \text{Je}, \text{I})$	$\tau(s \mid \text{null}, \text{'ll}, \text{Je}, \text{I})$
$\tau(b \mid \text{p..s}, \text{take}, \text{null}, \text{'ll})$	$\tau(m \mid \text{Je}, \text{take}, \text{null}, \text{'ll})$
$\tau(s \mid \text{le}, \text{that}, \text{p..s}, \text{take})$	$\tau(s \mid \text{le}, \text{that}, \text{Je}, \text{take})$
$e(\text{take} \mid f, \text{p..s}, \text{null}, \text{'ll}, \text{Je}, \text{I})$	$e(\text{take} \mid s, \text{Je}, \text{null}, \text{'ll}, \text{Je}, \text{I})$
$e(\text{that} \mid b, \text{le}, \text{p..s}, \text{take}, \text{null}, \text{'ll})$	$e(\text{that} \mid m, \text{le}, \text{Je}, \text{take}, \text{null}, \text{'ll})$
$e(\text{one} \mid s, \text{le}, \text{le}, \text{that}, \text{p..s}, \text{take})$	$e(\text{one} \mid s, \text{le}, \text{le}, \text{that}, \text{Je}, \text{take})$
$\phi(\text{single} \mid \text{p..s}, \text{le})$	$\phi(\text{multiple} \mid \text{Je}, \langle s \rangle)$

Table 1: The count update when changing the aligned source word of take from prends to Je in Figure 1. Key: f–forward s–stay b–backward m–monotone p..s–prends.

posterior probability

$$p(a_i = j \mid \mathbf{t}_{-i}, \mathbf{o}_{-i}) \propto \prod_{l=i}^{i+2} p(\xi_l) p(\tau_l) p(e_l) \times \frac{p(\phi_j + 1) p(\phi_{j'} - 1)}{p(\phi_j) p(\phi_{j'})} \quad (3)$$

where  $\phi_j, \phi_{j'}$  are the fertilities before changing the link and for brevity we omit the conditioning contexts. For example, in Figure 1, we sample for target word *take* and change the aligned source word from *prends* to *Je*, then the items for which we need to decrement and increment the counts by one are shown in Table 1 and the posterior probability corresponding to the new alignment is the product of the hierarchical PYP probabilities of all increment items divided by the probability of the fertility of *prends* being *single*.

Maintaining the current state of the hPYP as events are incremented and decremented is non-trivial and the naive approach requires significant book-keeping and has poor runtime behaviour. For this we adopt the approach of Blunsom et al. (2009b), who present a method for maintaining table counts without needing to record the table assignments for each translation decision. Briefly, this algorithm samples the table assignment during the increment and decrement operations, which is then used to maintain aggregate table statistics. This can be done efficiently and without the need for explicit table assignment tracking.

#### 4.1 Hyperparameter Inference

In our model, we treat all hyper-parameters  $\{(a^x, b^x), x \in (\xi, \tau, e, \phi)\}$  as latent random variables rather than fixed parameters. This means our model is parameter free, and requires no user intervention when adapting to different data sets. For

the discount parameter, we employ a uniform Beta distribution  $a^x \sim \text{Beta}(1, 1)$  while for the strength parameter, we employ a vague Gamma distribution  $b^x \sim \text{Gamma}(10, 0.1)$ . All restaurants in the same level share the same hyper-prior and the hyper-parameters for all levels are resampled using slice sampling (Johnson and Goldwater, 2009) every 10 iterations.

#### 4.2 Parallel Implementation

As mentioned above, the hierarchical PYP takes into consideration a rich history to evaluate the probabilities of translation decisions. But this leads to difficulties when applying the model to large data sets, particularly in terms of tracking the table and customer counts. We apply the technique from Blunsom et al. (2009a) of using multiple processors to perform approximate Gibbs sampling which they showed achieved equivalent performance to the exact Gibbs sampler. Each process performs sampling on a subset of the corpus using local counts, and communicates changes to these counts after each full iteration. All the count deltas are then aggregated by each process to refresh the counts at the end of each iteration. In this way each process uses slightly “out-of-date” counts, but can process the data independently of the other processes. We found that this approximation improved the runtime significantly with no noticeable effect on accuracy.

### 5 Experiments

In principle our model could be directly used as a MT decoder or as a feature in a decoder. However in this paper we limit our focus to inducing word alignments, i.e., by using the model to infer alignments which are then used in a standard phrase-based translation pipeline. We leave full decoding for later work, which we anticipate would further improve performance by exploiting gapping phrases and other phenomena that implicitly form part of our model but are not represented in the phrase-based decoder. Decoding under our model would be straight-forward in principle, as the generative process was designed to closely parallel the search procedure in the phrase-based model.<sup>3</sup>

Three data sets were used in the experiments: two Chinese to English data sets on small (IWSLT) and larger corpora (FBIS), and Arabic

<sup>3</sup>However the reverse translation probability would be intractable, as this does not decompose following a left-to-right generation order in the target language.

to English translation. Our experiments seek to test how the model compares to a GIZA++ baseline, quantifies the effect of each factor in the probabilistic model (i.e., jump, fertility), and the effect of different initialisations of the sampler. We present results on translation quality and word alignment.

## 5.1 Data Setup

The Markov order of our model in all experiments was set to  $n = 2$ , as shown in Equation 2. For each data set, Gibbs sampling was performed on the training set in each direction (source-to-target and target-to-source), initialized using GIZA++.<sup>4</sup> We used the *grow* heuristic to combine the GIZA++ alignments in both directions (Koehn et al., 2003), which we then intersect with the predictions of GIZA++ in the relevant translation direction. This initialisation setup gave the best results (we compare other initialisations in §5.2). The two Gibbs samplers were “burned in” for the first 1000 iterations, after which we ran a further 500 iterations selecting every 50th sample. A phrase table was constructed using these 10 sets of multiple alignments after combining each pair of directional alignments using the *grow-diag-final* heuristic. Using multiple samples in this way constitutes Monte Carlo averaging, which provides a better estimate of uncertainty cf. using a single sample.<sup>5</sup>

The alignment used for the baseline results was produced by combining bidirectional GIZA++ alignments using the *grow-diag-final* heuristic. We used the Moses machine translation decoder (Koehn et al., 2007), using the default features and decoding settings. We compared the performance of Moses using the alignment produced by our model and the baseline alignment, evaluating translation quality using BLEU (Papineni et al., 2002) with case-insensitive  $n$ -gram matching with  $n = 4$ . We used minimum error rate training (Och, 2003) to tune the feature weights to maximise the BLEU score on the development set.

## 5.2 IWSLT Corpus

The first experiments are on the IWSLT data set for Chinese-English translation. The training data consists of 44k sentences from the tourism and travel domain. For the development set we use both ASR devset 1 and 2 from IWSLT 2005, and

<sup>4</sup>All GIZA++ alignments used in our experiments were produced by IBM model4.

<sup>5</sup>The effect on translation scores is modest, roughly amounting to +0.2 BLEU versus using a single sample.

System	Dev	IWSLT05
baseline	45.78	49.98
Markov+ $f_s+e$	49.13	51.54
Markov+ $f_s+e+j$	49.68	52.55
Markov+ $f_s+e+j+f_t$	51.32	53.41

Table 2: Impact of adding factors to our Markov model, showing BLEU scores on IWSLT. Key:  $f_s$ –finish  $e$ –emission  $j$ –jump  $f_t$ –fertility.

for the test set we use the IWSLT 2005 test set. The language model is a 3-gram language model trained using the SRILM toolkit (Stolcke, 2002) on the English side of the training data. Because the data set is small, we performed Gibbs sampling on a single processor.

First we check the effect of the model factors *jump* and *fertility*. Both *emission* and *finish* factors are indispensable to the generative translation process, and consequently these two factors are included in all runs. Table 2 shows translation result for various models, including a baseline and our Markov model with different combinations of factors. Note that even the simplest Markov model far outperforms the GIZA++ baseline (+1.5 BLEU) despite the baseline (IBM model 4) including a number of advanced features (e.g., *jump*, *fertility*) that are not present in the basic Markov model. This improvement is a result of the Markov model making use of rich bilingual contextual information coupled with sophisticated backoff, as opposed to GIZA++ which considers much more local events, with nothing larger than word-class bigrams. Our model shows large improvements as the extra factors are included. *Jump* yields an improvement of +1 BLEU by capturing consistent reordering patterns. Adding *fertility* results in a further +1 BLEU point improvement. Like the IBM models, our approach allows each source word to produce any number of target words. This capacity allows for many non-sensical alignments such as dropping many source words, or aligning single source words to several target words. Explicitly modelling fertility allows for more consistent alignments, especially for special words such as punctuation which usually have a fertility of one.

Next we check the stability of our model with different initialisations. We compare different combination techniques for merging the GIZA++ alignments: *grow-diag-final* (denoted as *gdf*), *intersection* and *grow*. Table 3 shows that the different initialisations have only a small effect on

system	gdf	intersection	grow
baseline	49.98	48.44	50.11
our model	52.96	52.79	53.41

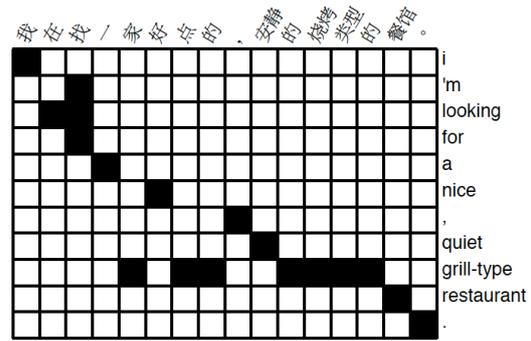

Table 3: Machine translation performance in BLEU % on the IWSLT 2005 Chinese-English test set. The Gibbs samplers were initialized with three different alignments, shown as columns.

the results of our model. While the baseline results vary by up to 1.7 BLEU points for the different alignments, our Markov model provided more stable results with the biggest difference of 0.6. Among the three initialisations, we get the best result with the initialisation of *grow*. *Gdf* often introduces alignment links involving function words which should instead be aligned to null. *Intersection* includes many fewer alignments, typically only between content words, and the sparsity means that words can only have a fertility of either 0 or 1. This leads to the initialisation being a strong mode which is difficult to escape from during sampling. Despite this problem, it has only a mild negative effect on the performance of our model, which is probably due to improvements in the alignments for words that truly should be dropped or aligned only to one word. *Grow* provides a good compromise between *gdf* and *intersection*, and we use this initialisation in all our subsequent experiments.

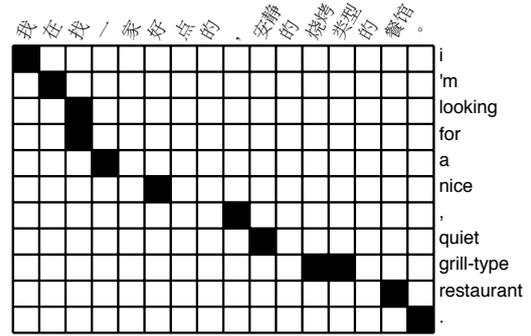

Figure 3 shows an example comparing alignments produced by our model and the GIZA++ baseline, in both cases after combining the two directional models. Note that GIZA++ has linked many function words which should be left unaligned, by using rare English terms as garbage collectors. Consequently this only allows for the extraction of few large phrase-pairs (e.g. <在找, 'm looking for>) and prevents the extraction of some good phrases (e.g. <烧烤类型的, grill-type>, for “家” and “点的” are wrongly aligned to “grill-type”). In contrast, our model better aligns the function words, such that many more useful phrase pairs can be extracted, i.e., <在, 'm>, <找, looking for>, <烧烤类型, grill-type> and their combinations with neighbouring phrase pairs.

### 5.3 FBIS Corpus

Theoretically, Bayesian models should outperform maximum likelihood approaches on small data sets, due to their improved modelling of un-

(a) GIZA++ baseline

(b) our model

Figure 3: Comparison of an alignment inferred by the baseline vs. our approach.

certainty. For larger datasets, however, the difference between the two techniques should narrow. Hence one might expect that upon moving to larger translation datasets our gains might evaporate. This chain of reasoning ignores the fact that our model is considerably richer than the baseline IBM models, in that we model rich contextual correlations between translation decisions, and consequently our approach has a lower inductive bias. For this reason our model should continue to improve with more data, by inferring better estimates of translation decision  $n$ -grams. A caveat though is that inference by sampling becomes less efficient on larger data sets due to stronger modes, requiring more iterations for convergence.

To test whether our improvements carry over to larger datasets, we assess the performance of our model on the FBIS Chinese-English data set. Here the training data consists of the non-UN portions and non-HK Hansards portions of the NIST training corpora distributed by the LDC, totalling 303k sentence pairs with 8m and 9.4m words of Chinese and English, respectively. For the development set we use the NIST 2002 test set, and evaluate performance on the test sets from NIST 2003

	NIST02	NIST03	NIST05
baseline	33.31	30.09	29.01
our model	33.83	31.02	30.23

Table 4: Translation performance on Chinese to English translation, showing BLEU% for models trained on the FBIS data set.

and 2005. The language model is a 3-gram LM trained on Xinhua portion of the Gigaword corpus using the SRILM toolkit with modified Kneser-Ney smoothing. As the FBIS data set is large, we employed 3-processor MPI for each Gibbs sampler, which ran in half the time compared to using a single processor.

Table 4 shows the results on the FBIS data set. Our model outperforms the baseline on both test sets by about 1 BLEU. This provides evidence that our model performs well in the large data setting, with our rich modelling of context still proving useful. The non-parametric nature of the model allows for rich dynamic backoff behaviour such that it can learn accurate models in both high and low data scenarios.

#### 5.4 Arabic English translation

Translation between Chinese and English is very difficult, particularly due to word order differences which are not handled well by phrase-based approaches. In contrast Arabic to English translation needs less reordering, and phrase-based models produce better translations. This translation task is a good test for the generality of our approach. Our Ar-En training data comprises several LDC corpora,<sup>6</sup> using the same experimental setup as in Blunsom et al. (2009a). Overall there are 276k sentence pairs and 8.21m and 8.97m words in Arabic and English, respectively. We evaluate on the NIST test sets from 2003 and 2005, and the 2002 test set was used for MERT training.

Table 5 shows the results. On all test sets our approach outperforms the baseline, and for the NIST03 test set the improvement is substantial, with a +0.74 BLEU improvement. In general the improvements are more modest than for the Chinese-English results above. We suggest that this is due to the structure of Arabic-English translation better suiting the modelling assumptions behind IBM model 4, particularly its bias towards monotone translations. Consequently the addi-

<sup>6</sup>LDC2004E72, LDC2004T17, LDC2004T18, LDC2006T02

	F1%	NIST02	NIST03	NIST05
baseline	64.9	57.00	48.75	48.93
our model	65.7	57.14	49.49	48.96

Table 5: Translation performance on Arabic to English translation, showing BLEU%. Also shown is word-alignment accuracy.

tional context provided by our model is less important. Table 5 also reports alignment results on manually aligned Ar-En sentence pairs,<sup>7</sup> measuring the F1 score for the GIZA++ baseline alignments and the alignment from the final sample with our model.<sup>8</sup> Our model outperforms the baseline, although the improvement is modest.

## 6 Conclusions and Future Work

This paper proposes a word-based Markov model of translation which correlates translation decisions by conditioning on recent decisions, and incorporates a hierarchical Pitman-Yor process prior permitting elaborate backoff behaviour. The model can learn sequences of translation decisions, akin to phrases in standard phrase-based models, while simultaneously learning word level phenomena. This mechanism generalises the concept of phrases in phrase-based MT, while also capturing richer phenomena such as gapping phrases in the source. Experiments show that our model performs well both on the small and large datasets for two different translation tasks, consistently outperforming a competitive baseline. In this paper the model was only used to infer word alignments; in future work we intend to develop a decoding algorithm for directly translating with the model.

# Scaling Semi-supervised Naive Bayes with Feature Marginals

Michael R. Lucas and Doug Downey

Northwestern University

2133 Sheridan Road

Evanston, IL 60208

mlucas@u.northwestern.edu

ddowney@eecs.northwestern.edu

## Abstract

Semi-supervised learning (SSL) methods augment standard machine learning (ML) techniques to leverage unlabeled data. SSL techniques are often effective in text classification, where labeled data is scarce but large unlabeled corpora are readily available. However, existing SSL techniques typically require multiple passes over the entirety of the unlabeled data, meaning the techniques are not applicable to large corpora being produced today.

In this paper, we show that improving marginal word frequency estimates using unlabeled data can enable semi-supervised text classification that scales to massive unlabeled data sets. We present a novel learning algorithm, which optimizes a Naive Bayes model to accord with statistics calculated from the unlabeled corpus. In experiments with text topic classification and sentiment analysis, we show that our method is both more scalable and more accurate than SSL techniques from previous work.

## 1 Introduction

Semi-supervised Learning (SSL) is a Machine Learning (ML) approach that utilizes large amounts of unlabeled data, combined with a smaller amount of labeled data, to learn a target function (Zhu, 2006; Chapelle et al., 2006). SSL is motivated by a simple reality: the amount of available machine-readable data is exploding, while human capacity for hand-labeling data for any given ML task remains relatively constant. Experiments in text classification and other domains have demonstrated that by leveraging unlabeled data, SSL techniques improve machine learning performance when human input is limited

(e.g., (Nigam et al., 2000; Mann and McCallum, 2010)).

However, current SSL techniques have scalability limitations. Typically, for each target concept to be learned, a semi-supervised classifier is trained using iterative techniques that execute multiple passes over the unlabeled data (e.g., Expectation-Maximization (Nigam et al., 2000) or Label Propagation (Zhu and Ghahramani, 2002)). This is problematic for text classification over large unlabeled corpora like the Web: new target concepts (new tasks and new topics of interest) arise frequently, and performing even a single pass over a large corpus for each new target concept is intractable.

In this paper, we present a new SSL text classification approach that scales to large corpora. Instead of utilizing unlabeled examples directly for each given target concept, our approach is to precompute a small set of *statistics* over the unlabeled data in advance. Then, for a given target class and labeled data set, we utilize the statistics to improve a classifier.

Specifically, we introduce a method that extends Multinomial Naive Bayes (MNB) to leverage marginal probability statistics  $P(w)$  of each word  $w$ , computed over the unlabeled data. The marginal statistics are used as a constraint to improve the class-conditional probability estimates  $P(w|+)$  and  $P(w|-)$  for the positive and negative classes, which are often noisy when estimated over sparse labeled data sets. We refer to the technique as MNB with Frequency Marginals (MNB-FM).

In experiments with large unlabeled data sets and sparse labeled data, we find that MNB-FM is both faster and more accurate on average than standard SSL methods from previous work, including Label Propagation, MNB with Expectation-Maximization, and the recent Semi-supervised Frequency Estimate (SFE) algorithm (Su et al., 2011). We also analyze how MNB-

FM improves accuracy, and find that surprisingly MNB-FM is especially useful for improving class-conditional probability estimates for words that never occur in the training set.

The paper proceeds as follows. We formally define the task in Section 2. Our algorithm is defined in Section 3. We present experimental results in Section 4, and analysis in Section 5. We discuss related work in Section 6 and conclude in Section 7 with a discussion of future work.

## 2 Problem Definition

We consider a semi-supervised classification task, in which the goal is to produce a mapping from an instance space  $\mathcal{X}$  consisting of  $T$ -tuples of non-negative integer-valued features  $\mathbf{w} = (w_1, \dots, w_T)$ , to a binary output space  $\mathcal{Y} = \{-, +\}$ . In particular, our experiments will focus on the case in which the  $w_i$ 's represent word counts in a given document, in a corpus of vocabulary size  $T$ .

We assume the following inputs:

- A set of zero or more *labeled* documents  $D_L = \{(\mathbf{w}^d, y^d) | d = 1, \dots, n\}$ , drawn i.i.d. from a distribution  $P(\mathbf{w}, y)$  for  $\mathbf{w} \in \mathcal{X}$  and  $y \in \mathcal{Y}$ .
- A large set of *unlabeled* documents  $D_U = \{(\mathbf{w}^d) | d = n+1, \dots, n+u\}$  drawn from the marginal distribution  $P(\mathbf{w}) = \sum_y P(\mathbf{w}, y)$ .

The goal of the task is to output a classifier  $f : \mathcal{X} \rightarrow \mathcal{Y}$  that performs well in predicting the classes of given unlabeled documents. The metrics of evaluation we focus on in our experiments are detailed in Section 4.

Our semi-supervised technique utilizes statistics computed over the labeled corpus, denoted as follows. We use  $N_w^+$  to denote the sum of the occurrences of word  $w$  over all documents in the positive class in the labeled data  $D_L$ . Also, let  $N^+ = \sum_{w \in D_L} N_w^+$  be the sum value of all word counts in the labeled positive documents. The count of the remaining words in the positive documents is represented as  $N_{\neg w}^+ = N^+ - N_w^+$ . The quantities  $N^-$ ,  $N_w^-$ , and  $N_{\neg w}^-$  are defined similarly for the negative class.

## 3 MNB with Feature Marginals

We now introduce our algorithm, which scalably utilizes large unlabeled data stores for classifica-

tion tasks. The technique builds upon the multinomial Naive Bayes model, and is denoted as MNB with Feature Marginals (MNB-FM).

### 3.1 MNB-FM Method

In the text classification setting, each feature value  $w^d$  represents count of observations of word  $w$  in document  $d$ . MNB makes the simplifying assumption that word occurrences are conditionally independent of each other given the class (+ or -) of the example. Formally, let the probability  $P(w|+)$  of the  $w$  in the positive class be denoted as  $\theta_w^+$ . Let  $P(+)$  denote the prior probability that a document is of the positive class, and  $P(-) = 1 - P(+)$  the prior for the negative class. Then MNB represents the class probability of an example as:

$$P(+|d) = \frac{\prod_{w \in d} (\theta_w^+)^{w^d} P(+)}{\prod_{w \in d} (\theta_w^-)^{w^d} P(-) + \prod_{w \in d} (\theta_w^+)^{w^d} P(+)} \quad (1)$$

MNB estimates the parameters  $\theta_w^+$  from the corresponding counts in the training set. The maximum-likelihood estimate of  $\theta_w^+$  is  $N_w^+/N^+$ , and to prevent zero-probability estimates we employ ‘‘add-1’’ smoothing (typical in MNB) to obtain the estimate:

$$\theta_w^+ = \frac{N_w^+ + 1}{N^+ + |T|}.$$

After MNB calculates  $\theta_w^+$  and  $\theta_w^-$  from the training set for each feature in the feature space, it can then classify test examples using Equation 1.

MNB-FM attempts to improve MNB’s estimates of  $\theta_w^+$  and  $\theta_w^-$ , using statistics computed over the unlabeled data. Formally, MNB-FM leverages the equality:

$$P(w) = \theta_w^+ P_t(+)+ \theta_w^- P_t(-) \quad (2)$$

The left-hand-side of Equation 2,  $P(w)$ , represents the probability that a given randomly drawn token from the unlabeled data happens to be the word  $w$ . We write  $P_t(+)$  to denote the probability that a randomly drawn *token* (i.e. a word occurrence) from the corpus comes from the positive class. Note that  $P_t(+)$  can differ from  $P(+)$ , the prior probability that a document is positive, due to variations in document length.  $P_t(-)$  is defined similarly for the negative class. MNB-FM is motivated by the insight that the left-hand-side of

Equation 2 can be estimated in advance, without knowledge of the target class, simply by counting the number of tokens of each word in the unlabeled data.

MNB-FM then uses this improved estimate of  $P(w)$  as a constraint to improve the MNB parameters on the right-hand-side of Equation 2. We note that  $P_t(+)$  and  $P_t(-)$ , even for a small training set, can typically be estimated reliably—every token in the training data serves as an observation of these quantities. However, for large and sparse feature spaces common in settings like text classification, many features occur in only a small fraction of examples—meaning  $\theta_w^+$  and  $\theta_w^-$  must be estimated from only a handful of observations. MNB-FM attempts to improve the noisy estimates  $\theta_w^+$  and  $\theta_w^-$  utilizing the robust estimate for  $P(w)$  computed over unlabeled data.

Specifically, MNB-FM proceeds by assuming the MLEs for  $P(w)$  (computed over unlabeled data),  $P_t(+)$ , and  $P_t(-)$  are correct, and re-estimates  $\theta_w^+$  and  $\theta_w^-$  under the constraint in Equation 2.

First, the maximum likelihood estimates of  $\theta_w^+$  and  $\theta_w^-$  given the training data  $D_L$  are:

$$\begin{aligned} & \arg \max_{\theta_w^+, \theta_w^-} P(D_L | \theta_w^+, \theta_w^-) \\ &= \arg \max_{\theta_w^+, \theta_w^-} \theta_w^{+(N_w^+)} (1 - \theta_w^+)^{(N_{-w}^+)} \\ & \quad \theta_w^{-(N_w^-)} (1 - \theta_w^-)^{(N_{-w}^-)} \\ &= \arg \max_{\theta_w^+, \theta_w^-} N_w^+ \ln(\theta_w^+) + N_{-w}^+ \ln(1 - \theta_w^+) + \\ & \quad N_w^- \ln(\theta_w^-) + N_{-w}^- \ln(1 - \theta_w^-) \end{aligned} \quad (3)$$

We can rewrite the constraint in Equation 2 as:

$$\theta_w^- = K - \theta_w^+ L$$

where for compactness we represent:

$$K = \frac{P(w)}{P_t(-)}; L = \frac{P_t(+)}{P_t(-)}.$$

Substituting the constraint into Equation 3 shows that we wish to choose  $\theta_w^+$  as:

$$\begin{aligned} & \arg \max_{\theta_w^+} N_w^+ \ln(\theta_w^+) + N_{-w}^+ \ln(1 - \theta_w^+) + \\ & \quad N_w^- \ln(K - L\theta_w^+) + N_{-w}^- \ln(1 - K + L\theta_w^+) \end{aligned}$$

The optimal values for  $\theta_w^+$  are thus located at the solutions of:

$$0 = \frac{N_w^+}{\theta_w^+} + \frac{N_{-w}^+}{\theta_w^+ - 1} + \frac{LN_w^-}{L\theta_w^+ - K} + \frac{LN_{-w}^-}{L\theta_w^+ - K + 1}$$

Both  $\theta_w^+$  and  $\theta_w^-$  are constrained to valid probabilities in  $[0,1]$  when  $\theta_w^+ \in [0, \frac{K}{L}]$ . If  $N_{-w}^+$  and  $N_w^-$  have non-zero counts, vertical asymptotes exist at 0 and  $\frac{K}{L}$  and guarantee a solution in this range. Otherwise, a valid solution may not exist. In that case, we default to the add-1 Smoothing estimates used by MNB. Finally, after optimizing the values  $\theta_w^+$  and  $\theta_w^-$  for each word  $w$  as described above, we normalize the estimates to obtain valid conditional probability distributions, i.e. with  $\sum_w \theta_w^+ = \sum_w \theta_w^- = 1$

### 3.2 MNB-FM Example

The following concrete example illustrates how MNB-FM can improve MNB parameters using the statistic  $P(w)$  computed over unlabeled data. The example comes from the Reuters Aptemod text classification task addressed in Section 4, using bag-of-words features for the Earnings class. In one experiment with 10 labeled training examples, we observed 5 positive and 5 negative examples, with the word “resources” occurring three times in the set (once in the positive class, twice in the negative class).

MNB uses add-1 smoothing to estimate the conditional probability of the word “resources” in each class as  $\theta_w^+ = \frac{1+1}{216+33504} = 5.93e-5$ , and  $\theta_w^- = \frac{2+1}{547+33504} = 8.81e-5$ . Thus,  $\frac{\theta_w^+}{\theta_w^-} = 0.673$  implying that “resources” is a negative indicator of the Earnings class. However, this estimate is inaccurate. In fact, over the *full* dataset, the parameter values we observe are  $\theta_w^+ = \frac{93}{168549} = 5.70e-4$  and  $\theta_w^- = \frac{263}{564717} = 4.65e-4$ , with a ratio of  $\frac{\theta_w^+}{\theta_w^-} = 1.223$ . Thus, in actuality, the word “resources” is a mild *positive* indicator of the Earnings class. Yet because MNB estimates its parameters from only the sparse training data, it can be inaccurate.

The optimization in MNB-FM seeks to accord its parameter estimates with the feature frequency, computed from unlabeled data, of  $P(w) = 4.89e-4$ . We see that compared with  $P(w)$ , the  $\theta_w^+$  and  $\theta_w^-$  that MNB estimates from the training data are both too low by almost an order of magnitude. Further, the maximum likelihood estimate for  $\theta_w^-$  (based on an occurrence count of 2 out of 547 observations) is somewhat more reliable than that for  $\theta_w^+$  (1 of 216 observations). As a result,  $\theta_w^+$  is adjusted upward relatively *more* than  $\theta_w^-$  via MNB-FM’s constrained ML estimation. MNB-FM returns  $\theta_w^+ = 6.52e-5$  and  $\theta_w^- = 6.04e-5$ . The ratio

$\frac{\theta_w^+}{\theta_w^-}$  is 1.079, meaning MNB-FM correctly identifies the word “resources” as an indicator of the positive class.

The above example illustrates how MNB-FM can leverage frequency marginal statistics computed over unlabeled data to improve MNB’s conditional probability estimates. We analyze how frequently MNB-FM succeeds in improving MNB’s estimates in practice, and the resulting impact on classification accuracy, below.

## 4 Experiments

In this section, we describe our experiments quantifying the accuracy and scalability of our proposed technique. Across multiple domains, we find that MNB-FM outperforms a variety of approaches from previous work.

### 4.1 Data Sets

We evaluate on two text classification tasks: topic classification, and sentiment detection. In topic classification, the task is to determine whether a test document belongs to a specified topic. We train a classifier separately (i.e., in a binary classification setting) for each topic and measure classification performance for each class individually.

The sentiment detection task is to determine whether a document is written with a positive or negative sentiment. In our case, the goal is to determine if the given text belongs to a positive review of a product.

#### 4.1.1 RCV1

The Reuters RCV1 corpus is a standard large corpus used for topic classification evaluations (Lewis et al., 2004). It includes 804,414 documents with several nested target classes. We consider the 5 largest base classes after punctuation and stopwords were removed. The vocabulary consisted of 288,062 unique words, and the total number of tokens in the data set was 99,702,278. Details of the classes can be found in Table 1.

#### 4.1.2 Reuters Aptemod

While MNB-FM is designed to improve the scalability of SSL to large corpora, some of the comparison methods from previous work were not tractable on the large topic classification data set RCV1. To evaluate these methods, we also experimented with the Reuters Aptemod dataset (Yang and Liu, 1999), consisting of 10,788 documents belonging to 90 classes. We consider the 10 most

Class	# Positive
CCAT	381327 (47.40%)
GCAT	239267 (29.74%)
MCAT	204820 (25.46%)
ECAT	119920 (14.91%)
GPOL	56878 (7.07%)

Table 1: RCV1 dataset details

Class	# Positive

Wheat	283 (2.6%)
Corn	237 (2.2%)

Table 2: Aptemod dataset details

frequent classes, with varying degrees of positive/negative skew. Punctuation and stopwords were removed during preprocessing. The Aptemod data set contained 33,504 unique words and a total of 733,266 word tokens. Details of the classes can be found in Table 2.

#### 4.1.3 Sentiment Classification Data

In the domain of Sentiment Classification, we tested on the Amazon dataset from (Blitzer et al., 2007). Stopwords listed in an included file were ignored for our experiments and we only considered unigram features. Unlike the two Reuters data sets, each category had a unique set of documents of varying size. For our experiments, we only used the 10 largest categories. Details of the categories can be found in Table 3.

In the Amazon Sentiment Classification data set, the task is to determine whether a review is positive or negative based solely on the reviewer’s submitted text. As such, the positive and negative

Class	# Instances	# Positive	Vocabulary

Table 3: Amazon dataset details

labels are equally relevant. For our metrics, we calculate the scores for both the positive and negative class and report the average of the two (in contrast to the Reuters data sets, in which we only report the scores for the positive class).

## 4.2 Comparison Methods

In addition to Multinomial Naive Bayes (discussed in Section 3), we evaluate against a variety of supervised and semi-supervised techniques from previous work, which provide a representation of the state of the art. Below, we detail the comparison methods that we re-implemented for our experiments.

### 4.2.1 NB + EM

We implemented a semi-supervised version of Naive Bayes with Expectation Maximization, based on (Nigam et al., 2000). We found that 15 iterations of EM was sufficient to ensure approximate convergence of the parameters.

We also experimented with different weighting factors to assign to the unlabeled data. While performing per-data-split cross-validation was computationally prohibitive for NB+EM, we performed experiments on one class from each data set that revealed weighting unlabeled examples at 1/5 the weight of a labeled example performed best. We found that our re-implementation of NB+EM slightly outperformed published results on a separate data set (Mann and McCallum, 2010), validating our design choices.

### 4.2.2 Logistic Regression

We implemented Logistic Regression using L2-Normalization, finding this to outperform L1-Normalized and non-normalized versions. The strength of the normalization was selected for each training data set of each size utilized in our experiments.

The strength of the normalization in the logistic regression required cross-validation, which we limited to 20 values logarithmically spaced between  $10^{-4}$  and  $10^4$ . The optimal value was selected based upon the best average F1 score over the 10 folds. We selected a normalization parameter separately for each subset of the training data during experimentation.

### 4.2.3 Label Propagation

For our large unlabeled data set sizes, we found that a standard Label Propagation (LP) approach,

which considers propagating information between all pairs of unlabeled examples, was not tractable. We instead implemented a constrained version of LP for comparison.

In our implementation, we limit the number of edges in the propagation graph. Each node propagates to only to its 10 nearest neighbors, where distance is calculated as the cosine distance between the tf-idf representation of two documents. We found the tf-idf weighting to improve performance over that of simple cosine distance. Propagation was run for 100 iterations or until the entropy dropped below a predetermined threshold, whichever occurred first. Even with these aggressive constraints, Label Propagation was intractable to execute on some of the larger data sets, so we do not report LP results for the RCV1 dataset or for the 5 largest Amazon categories.

### 4.2.4 SFE

We also re-implemented a version of the recent Semi-supervised Frequency Estimate approach (Su et al., 2011). SFE was found to outperform MNB and NB+EM in previous work. Consistent with our MNB implementation, we use Add-1 Smoothing in our SFE calculations although its use is not specifically mentioned in (Su et al., 2011).

SFE also augments multinomial Naive Bayes with the frequency information  $P(w)$ , although in a manner distinct from MNB-FM. In particular, SFE uses the equality  $P(+|w) = P(+, w)/P(w)$  and estimates the rhs using  $P(w)$  computed over all the unlabeled data, rather than using only labeled data as in standard MNB. The primary distinction between MNB-FM and SFE is that SFE adjusts sparse estimates  $P(+, w)$  in the same way as non-sparse estimates, whereas MNB-FM is designed to adjust sparse estimates more than non-sparse ones. Further, it can be shown that as  $P(w)$  of a word  $w$  in the unlabeled data becomes larger than that in the labeled data, SFE's estimate of the ratio  $P(w|+)/P(w|-)$  approaches one. Depending on the labeled data, such an estimate can be arbitrarily inaccurate. MNB-FM does not have this limitation.

## 4.3 Results

For each data set, we evaluate on 50 randomly drawn training splits, each comprised of 1,000 randomly selected documents. Each set included at least one positive and one negative document. We

respected the order of the training splits such that each sample was a strict subset of any larger training sample of the same split.

We evaluate on the standard metric of F1 with respect to the target class. For Amazon, in which both the “positive” and “negative” classes are potential target classes, we evaluate using macro-averaged scores.

The primary results of our experiments are shown in Table 4. The results show that MNB-FM improves upon the MNB classifier substantially, and also tends to outperform the other SSL and supervised learning methods we evaluated. MNB-FM is the best performing method over all data sets when the labeled data is limited to 10 and 100 documents, except for training sets of size 10 in Aptemod, where MNB has a slight edge.

Tables 5 and 6 present detailed results of the experiments on the RCV1 data set. These experiments are limited to the 5 largest base classes and show the F1 performance of MNB-FM and the various comparison methods, excluding Label Propagation which was intractable on this data set.

Table 7: Runtimes of SSL methods (sec.)

The runtimes of our methods can be seen in Table 7. The results show the runtimes of the SSL methods discussed in this paper as the size of the unlabeled dataset grows. As expected, we find that MNB-FM has runtime similar to MNB, and scales much better than methods that take multiple passes over the unlabeled data.

## 5 Analysis

From our experiments, it is clear that the performance of MNB-FM improves on MNB, and in many cases outperforms all existing SSL algorithms we evaluated. MNB-FM improves the conditional probability estimates in MNB and, surprisingly, we found that it can often improve these estimates for words that do not even occur in the training set.

Tables 8 and 9 show the details of the improvements MNB-FM makes on the feature marginal estimates. We ran MNB-FM and MNB on the RCV1 class MCAT and stored the computed feature marginals for direct comparison. For each word in the vocabulary, we compared each classifier’s conditional probability ratios, i.e.  $\theta^+/\theta^-$ , to the true value over the entire data set. We computed which classifier was closer to the correct ratio for each word. These results were averaged over 5 iterations. From the data, we can see that MNB-FM improves the estimates for many words *not* seen in the training set as well as the most common words, even with small training sets.

### 5.1 Ranking Performance

We also analyzed how well the different methods *rank*, rather than classify, the test documents. We evaluated ranking using the R-precision metric, equal to the precision (i.e. fraction of positive documents classified correctly) of the  $R$  highest-ranked test documents, where  $R$  is the total number of positive test documents.

Logistic Regression performed particularly well on the R-Precision Metric, as can be seen in Tables 10, 11, and 12. Logistic Regression performed less well in the F1 metric. We find that NB+EM

Word Freq.	Fraction Improved vs MNB			Avg Improvement vs MNB			Probability Mass		
	Known	Half Known	Unknown	Known	Half Known	Unknown	Known	Half Known	Unknown
$0-10^{-6}$	-	0.165	<b>0.847</b>	-	-0.805	<b>0.349</b>	-	0.02%	7.69%

$> 10^{-3}$	-	-	-	-	-	-	-	-	-

Table 9: Analysis of Feature Marginal Improvement of MNB-FM over MNB ( $|D_L| = 100$ ). Data is for the RCV1 MCAT category (see Table 8). MNB-FM improves estimates by a substantial amount for unknown words and also the most common known and half-known words.

performs particularly well on the R-precision metric on ApteMod, suggesting that its modelling assumptions are more accurate for that particular data set (NB+EM performs significantly worse on the other data sets, however). MNB-FM performs essentially equivalently well, on average, to the best competing method (Logistic Regression) on the large RCV1 data set. However, these experiments show that MNB-FM offers more advantages in document classification than in document ranking.

The ranking results show that LR may be preferred when ranking is important. However, LR underperforms in classification tasks (in terms of F1, Tables 4-6). The reason for this is that LR’s learned classification threshold becomes less accurate when datasets are small and classes are highly

Class	MNB-FM	SFE	MNB	NBEM	LProp	Logist.

skewed. In these cases, LR classifies too frequently in favor of the larger class which is detrimental to its performance. This effect is visible in Tables 5 and 6, where LR’s performance significantly drops for the ECAT and GPOL classes. ECAT and GPOL represent only 14.91% and 7.07% of the RCV1 dataset, respectively.

## 6 Related Work

To our knowledge, MNB-FM is the first approach that utilizes a small set of statistics computed over

a large unlabeled data set as constraints to improve a semi-supervised classifier. Our experiments demonstrate that MNB-FM outperforms previous approaches across multiple text classification techniques including topic classification and sentiment analysis. Further, the MNB-FM approach offers scalability advantages over most existing semi-supervised approaches.

Current popular Semi-Supervised Learning approaches include using Expectation-Maximization on probabilistic models (e.g. (Nigam et al., 2000)); Transductive Support Vector Machines (Joachims, 1999); and graph-based methods such as Label Propagation (LP) (Zhu and Ghahramani, 2002) and their more recent, more scalable variants (e.g. identifying a small number of representative unlabeled examples (Liu et al., 2010)). In general, these techniques require passes over the entirety of the unlabeled data for each new learning task, intractable for massive unlabeled data sets. Naive implementations of LP cannot scale to large unlabeled data sets, as they have time complexity that increases quadratically with the number of unlabeled examples. Recent LP techniques have achieved greater scalability through the use of parallel processing and heuristics such as Approximate-Nearest Neighbor (Subramanya and Bilmes, 2009), or by decomposing the similarity matrix (Lin and Cohen, 2011). Our approach, by contrast, is to pre-compute a small set of marginal statistics over the unlabeled data, which eliminates the need to scan unlabeled data for each new task. Instead, the complexity of MNB-FM is proportional only to the number of unique words in the labeled data set.

In recent work, Su et al. propose the Semi-supervised Frequency Estimate (SFE), which like MNB-FM utilizes the marginal probabilities of features computed from unlabeled data to improve the Multinomial Naive Bayes (MNB) classifier (Su et al., 2011). SFE has the same scalability advantages as MNB-FM. However, unlike our approach, SFE does not compute maximum-likelihood estimates using the marginal statistics as a constraint. Our experiments show that MNB-FM substantially outperforms SFE.

A distinct method for pre-processing unlabeled data in order to help scale semi-supervised learning techniques involves dimensionality reduction or manifold learning (Belkin and Niyogi, 2004), and for NLP tasks, identifying word representa-

tions from unlabeled data (Turian et al., 2010). In contrast to these approaches, MNB-FM preserves the original feature set and is more scalable (the marginal statistics can be computed in a single pass over the unlabeled data set).

## 7 Conclusion

We presented a novel algorithm for efficiently leveraging large unlabeled data sets for semi-supervised learning. Our MNB-FM technique optimizes a Multinomial Naive Bayes model to accord with statistics of the unlabeled corpus. In experiments across topic classification and sentiment analysis, MNB-FM was found to be more accurate and more scalable than several supervised and semi-supervised baselines from previous work.

In future work, we plan to explore utilizing richer statistics from the unlabeled data, beyond word marginals. Further, we plan to experiment with techniques for unlabeled data sets that also include continuous-valued features. Lastly, we also wish to explore ensemble approaches that combine the best supervised classifiers with the improved class-conditional estimates provided by MNB-FM.

## Abstract

We present two latent variable models for learning character types, or *personas*, in film, in which a persona is defined as a set of mixtures over latent lexical classes. These lexical classes capture the stereotypical actions of which a character is the agent and patient, as well as attributes by which they are described. As the first attempt to solve this problem explicitly, we also present a new dataset for the text-driven analysis of film, along with a benchmark testbed to help drive future work in this area.

## 1 Introduction

Philosophers and dramatists have long argued whether the most important element of narrative is *plot* or *character*. Under a classical Aristotelian perspective, plot is supreme;<sup>1</sup> modern theoretical dramatists and screenwriters disagree.<sup>2</sup>

Without addressing this debate directly, much computational work on narrative has focused on learning the sequence of events by which a story is defined; in this tradition we might situate seminal work on learning procedural scripts (Schank and Abelson, 1977; Regneri et al., 2010), narrative chains (Chambers and Jurafsky, 2008), and plot structure (Finlayson, 2011; Elsner, 2012; McIntyre and Lapata, 2010; Goyal et al., 2010).

We present a complementary perspective that addresses the importance of *character* in defining

<sup>1</sup>“Dramatic action . . . is not with a view to the representation of character: character comes in as subsidiary to the actions . . . The Plot, then, is the first principle, and, as it were, the soul of a tragedy: Character holds the second place.” *Poetics* I.VI (Aristotle, 335 BCE).

<sup>2</sup>“Aristotle was mistaken in his time, and our scholars are mistaken today when they accept his rulings concerning character. Character was a great factor in Aristotle’s time, and no fine play ever was or ever will be written without it” (Egri, 1946, p. 94); “What the reader wants is fascinating, complex characters” (McKee, 1997, 100).

a story. Our testbed is film. Under this perspective, a character’s latent internal nature drives the action we observe. Articulating narrative in this way leads to a natural generative story: we first decide that we’re going to make a particular kind of movie (e.g., a romantic comedy), then decide on a set of character types, or *personas*, we want to see involved (the PROTAGONIST, the LOVE INTEREST, the BEST FRIEND). After picking this set, we fill out each of these roles with specific attributes (*female, 28 years old, klutzy*); with this cast of characters, we then sketch out the set of events by which they interact with the world and with each other (*runs but just misses the train, spills coffee on her boss*) – through which they reveal to the viewer those inherent qualities about themselves. This work is inspired by past approaches that infer typed semantic arguments along with narrative schemas (Chambers and Jurafsky, 2009; Regneri et al., 2011), but seeks a more holistic view of character, one that learns from stereotypical attributes in addition to plot events. This work also naturally draws on earlier work on the unsupervised learning of verbal arguments and semantic roles (Pereira et al., 1993; Grenager and Manning, 2006; Titov and Klementiev, 2012) and unsupervised relation discovery (Yao et al., 2011).

This character-centric perspective leads to two natural questions. First, can we learn what those standard personas are by how individual characters (who instantiate those types) are portrayed? Second, can we learn the set of attributes and actions by which we recognize those common types? How do we, as viewers, recognize a VILLIAN?

At its most extreme, this perspective reduces to learning the grand archetypes of Joseph Campbell (1949) or Carl Jung (1981), such as the HERO or TRICKSTER. We seek, however, a more fine-grained set that includes not only archetypes, but stereotypes as well – characters defined by a fixed set of actions widely known to be representative of

a class. This work offers a data-driven method for answering these questions, presenting two probabilistic generative models for inferring latent character types.

This is the first work that attempts to learn explicit character personas in detail; as such, we present a new dataset for character type induction in film and a benchmark testbed for evaluating future work.<sup>3</sup>

## 2 Data

### 2.1 Text

Our primary source of data comes from 42,306 movie plot summaries extracted from the November 2, 2012 dump of English-language Wikipedia.<sup>4</sup> These summaries, which have a median length of approximately 176 words,<sup>5</sup> contain a concise synopsis of the movie’s events, along with implicit descriptions of the characters (e.g., “rebel leader Princess Leia,” “evil lord Darth Vader”). To extract structure from this data, we use the Stanford CoreNLP library<sup>6</sup> to tag and syntactically parse the text, extract entities, and resolve coreference within the document. With this structured representation, we extract linguistic features for each character, looking at immediate verb governors and attribute syntactic dependencies to all of the entity’s mention headwords, extracted from the typed dependency tuples produced by the parser; we refer to “CCprocessed” syntactic relations described in de Marneffe and Manning (2008):

- **Agent verbs.** Verbs for which the entity is an agent argument (*nsubj* or *agent*).
- **Patient verbs.** Verbs for which the entity is the patient, theme or other argument (*dobj*, *nsubjpass*, *iobj*, or any prepositional argument *prep\_\**).
- **Attributes.** Adjectives and common noun words that relate to the mention as adjectival modifiers, noun-noun compounds, appositives, or copulas (*nsubj* or *appos* governors, or *nsubj*, *appos*, *amod*, *nn* dependents of an entity mention).

<sup>3</sup>All datasets and software for replication can be found at <http://www.ark.cs.cmu.edu/personas>.

<sup>4</sup><http://dumps.wikimedia.org/enwiki/>

<sup>5</sup>More popular movies naturally attract more attention on Wikipedia and hence more detail: the top 1,000 movies by box office revenue have a median length of 715 words.

<sup>6</sup><http://nlp.stanford.edu/software/corenlp.shtml>

These three roles capture three different ways in which character personas are revealed: the actions they take on others, the actions done to them, and the attributes by which they are described. For every character we thus extract a bag of  $(r, w)$  tuples, where  $w$  is the word lemma and  $r$  is one of {agent verb, patient verb, attribute} as identified by the above rules.

### 2.2 Metadata

Our second source of information consists of character and movie metadata drawn from the November 4, 2012 dump of Freebase.<sup>7</sup> At the movie level, this includes data on the language, country, release date and detailed genre (365 non-mutually exclusive categories, including “Epic Western,” “Revenge,” and “Hip Hop Movies”). Many of the characters in movies are also associated with the actors who play them; since many actors also have detailed biographical information, we can ground the characters in what we know of those real people – including their gender and estimated age at the time of the movie’s release (the difference between the release date of the movie and the actor’s date of birth).

Across all 42,306 movies, entities average 3.4 agent events, 2.0 patient events, and 2.1 attributes. For all experiments described below, we restrict our dataset to only those events that are among the 1,000 most frequent overall, and only characters with at least 3 events. 120,345 characters meet this criterion; of these, 33,559 can be matched to Freebase actors with a specified gender, and 29,802 can be matched to actors with a given date of birth. Of all actors in the Freebase data whose age is given, the average age at the time of movie is 37.9 (standard deviation 14.1); of all actors whose gender is known, 66.7% are male.<sup>8</sup> The age distribution is strongly bimodal when conditioning on gender: the average age of a female actress at the time of a movie’s release is 33.0 (s.d. 13.4), while that of a male actor is 40.5 (s.d. 13.7).

## 3 Personas

One way we recognize a character’s latent type is by observing the stereotypical actions they

<sup>7</sup><http://download.freebase.com/datadumps/>

<sup>8</sup>Whether this extreme 2:1 male/female ratio reflects an inherent bias in film or a bias in attention on Freebase (or Wikipedia, on which it draws) is an interesting research question in itself.

perform (e.g., VILLAINS *strangle*), the actions done to them (e.g., VILLAINS are *foiled* and *arrested*) and the words by which they are described (VILLAINS are *evil*). To capture this intuition, we define a *persona* as a set of three typed distributions: one for the words for which the character is the agent, one for which it is the patient, and one for words by which the character is attributively modified. Each distribution ranges over a fixed set of latent word classes, or *topics*. Figure 1 illustrates this definition for a toy example: a ZOMBIE persona may be characterized as being the agent of primarily *eating* and *killing* actions, the patient of *killing* actions, and the object of *dead* attributes. The topic labeled *eat* may include words like *eat*, *drink*, and *devour*.

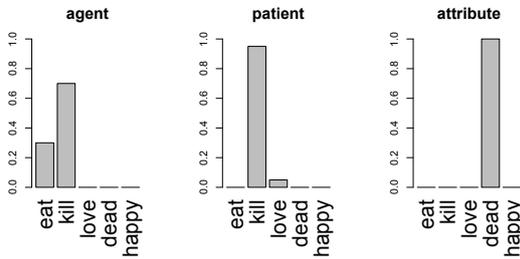

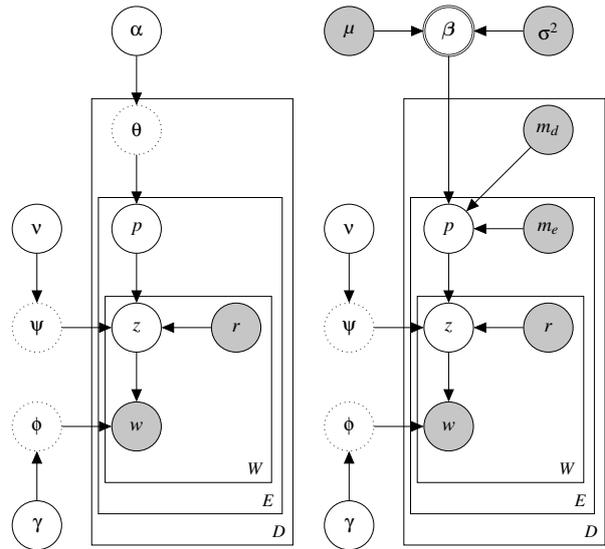

Figure 1: A *persona* is a set of three distributions over latent topics. In this toy example, the ZOMBIE persona is primarily characterized by being the agent of words from the *eat* and *kill* topics, the patient of *kill* words, and the object of words from the *dead* topic.

## 4 Models

Both models that we present here simultaneously learn three things: 1.) a soft clustering over words to topics (e.g., the verb “strangle” is mostly a type of *Assault* word); 2.) a soft clustering over topics to personas (e.g., VILLAINS perform a lot of *Assault* actions); and 3.) a hard clustering over characters to personas (e.g., Darth Vader is a VILLAIN.) They each use different evidence: since our data includes not only textual features (in the form of actions and attributes of the characters) but also non-textual information (such as movie genre, age and gender), we design a model that exploits this additional source of information in discriminating between character types; since this extralinguistic information may not always be available, we also design a model that learns only from the text itself. We present the text-only model first

$P$	Number of personas (hyperparameter)
$K$	Number of word topics (hyperparameter)
$D$	Number of movie plot summaries
$E$	Number of characters in movie $d$
$W$	Number of (role, word) tuples used by character $e$
$\phi_k$	Topic $k$ 's distribution over $V$ words.
$r$	Tuple role: agent verb, patient verb, attribute
$\psi_{p,r}$	Distribution over topics for persona $p$ in role $r$
$\theta_d$	Movie $d$ 's distribution over personas
$p_e$	Character $e$ 's persona (integer, $p \in \{1..P\}$ )
$j$	A specific $(r, w)$ tuple in the data
$z_j$	Word topic for tuple $j$
$w_j$	Word for tuple $j$
$\alpha$	Concentration parameter for Dirichlet model
$\beta$	Feature weights for regression model
$\mu, \sigma^2$	Gaussian mean and variance (for regularizing $\beta$ )
$m_d$	Movie features (from movie metadata)
$m_e$	Entity features (from movie actor metadata)
$\nu_r, \gamma$	Dirichlet concentration parameters

Figure 2: **Above:** Dirichlet persona model (left) and persona regression model (right). **Bottom:** Definition of variables.

for simplicity. Throughout,  $V$  is the word vocabulary size,  $P$  is the number of personas, and  $K$  is the number of topics.

### 4.1 Dirichlet Persona Model

In the most basic model, we only use information from the structured text, which comes as a bag of  $(r, w)$  tuples for each character in a movie, where  $w$  is the word lemma and  $r$  is the relation of the word with respect to the character (one of agent verb, patient verb or attribute, as outlined in §2.1 above). The generative story runs as follows. First, let there be  $K$  latent word topics; as in LDA (Blei et al., 2003), these are words that will be soft-clustered together by virtue of appearing in similar contexts. Each latent word cluster

$\phi_k \sim \text{Dir}(\gamma)$  is a multinomial over the  $V$  words in the vocabulary, drawn from a Dirichlet parameterized by  $\gamma$ . Next, let a persona  $p$  be defined as a set of three multinomials  $\psi_p$  over these  $K$  topics, one for each typed role  $r$ , each drawn from a Dirichlet with a role-specific hyperparameter ( $\nu_r$ ).

Every document (a movie plot summary) contains a set of characters, each of which is associated with a single latent persona  $p$ ; for every observed  $(r, w)$  tuple associated with the character, we sample a latent topic  $k$  from the role-specific  $\psi_{p,r}$ . Conditioned on this topic assignment, the observed word is drawn from  $\phi_k$ . The distribution of these personas for a given document is determined by a document-specific multinomial  $\theta$ , drawn from a Dirichlet parameterized by  $\alpha$ .

Figure 2 (above left) illustrates the form of the model. To simplify inference, we collapse out the persona-topic distributions  $\psi$ , the topic-word distributions  $\phi$  and the persona distribution  $\theta$  for each document. Inference on the remaining latent variables – the persona  $p$  for each character type and the topic  $z$  for each word associated with that character – is conducted via collapsed Gibbs sampling (Griffiths and Steyvers, 2004); at each iteration, for each character  $e$ , we sample their persona  $p_e$ :

$$P(p_e = k \mid p_{-e}, z, \alpha, \nu) \propto \left( c_{d,k}^{-e} + \alpha_k \right) \times \prod_j \frac{(c_{r_j,k,z_j}^{-e} + \nu_{r_j})}{(c_{r_j,k,\star}^{-e} + K\nu_{r_j})} \quad (1)$$

Here,  $c_{d,k}^{-e}$  is the count of all characters in document  $d$  whose current persona sample is also  $k$  (not counting the current character  $e$  under consideration),<sup>9</sup>  $j$  ranges over all  $(r_j, w_j)$  tuples associated with character  $e$ . Each  $c_{r_j,k,z_j}^{-e}$  is the count of all tuples with role  $r_j$  and current topic  $z_j$  used with persona  $k$ .  $c_{r_j,k,\star}^{-e}$  is the same count, summing over all topics  $z$ . In other words, the probability that character  $e$  embodies persona  $k$  is proportional to the number of other characters in the plot summary who also embody that persona (plus the Dirichlet hyperparameter  $\alpha_k$ ) times the contribution of each observed word  $w_j$  for that character, given its current topic assignment  $z_j$ .

Once all personas have been sampled, we sam-

<sup>9</sup>The  $-e$  superscript denotes counts taken without considering the current sample for character  $e$ .

ple the latent topics for each tuple as the following.

$$P(z_j = k \mid p, z_{-j}, w, r, \nu, \gamma) \propto \frac{(c_{r_j,p,k}^{-j} + \nu_{r_j})}{(c_{r_j,p,\star}^{-j} + K\nu_{r_j})} \times \frac{(c_{k,w_j}^{-j} + \gamma)}{(c_{k,\star}^{-j} + V\gamma)} \quad (2)$$

Here, conditioned on the current sample  $p$  for the character’s persona, the probability that tuple  $j$  originates in topic  $k$  is proportional to the number of other tuples with that same role  $r_j$  drawn from the same topic for that persona ( $c_{r_j,p,k}^{-j}$ ), normalized by the number of other  $r_j$  tuples associated with that persona overall ( $c_{r_j,p,\star}^{-j}$ ), multiplied by the number of times word  $w_j$  is associated with that topic ( $c_{k,w_j}^{-j}$ ) normalized by the total number of other words associated with that topic overall ( $c_{k,\star}^{-j}$ ).

We optimize the values of the Dirichlet hyperparameters  $\alpha, \nu$  and  $\gamma$  using slice sampling with a uniform prior every 20 iterations for the first 500 iterations, and every 100 iterations thereafter. After a burn-in phase of 10,000 iterations, we collect samples every 10 iterations (to lessen autocorrelation) until a total of 100 have been collected.

## 4.2 Persona Regression

To incorporate observed metadata in the form of movie genre, character age and character gender, we adopt an “upstream” modeling approach (Mimno and McCallum, 2008), letting those observed features influence the conditional probability with which a given character is expected to assume a particular persona, prior to observing any of their actions. This captures the increased likelihood, for example, that a 25-year-old male actor in an action movie will play an ACTION HERO than he will play a VALLEY GIRL.

To capture these effects, each character’s latent persona is no longer drawn from a document-specific Dirichlet; instead, the  $P$ -dimensional simplex is the output of a multiclass logistic regression, where the document genre metadata  $m_d$  and the character age and gender metadata  $m_e$  together form a feature vector that combines with persona-specific feature weights to form the following log-linear distribution over personas, with the probability for persona  $k$  being:

$$P(p = k \mid m_d, m_e, \beta) = \frac{\exp([m_d; m_e]^\top \beta_k)}{1 + \sum_{j=1}^{P-1} \exp([m_d; m_e]^\top \beta_j)} \quad (3)$$

The persona-specific  $\beta$  coefficients are learned through Monte Carlo Expectation Maximization

(Wei and Tanner, 1990), in which we alternate between the following:

1. Given current values for  $\beta$ , for all characters  $e$  in all plot summaries, sample values of  $p_e$  and  $z_j$  for all associated tuples.
2. Given input metadata features  $m$  and the associated sampled values of  $p$ , find the values of  $\beta$  that maximize the standard multiclass logistic regression log likelihood, subject to  $\ell_2$  regularization.

Figure 2 (above right) illustrates this model. As with the Dirichlet persona model, inference on  $p$  for step 1 is conducted with collapsed Gibbs sampling; the only difference in the sampling probability from equation 1 is the effect of the prior, which here is deterministically fixed as the output of the regression.

$$P(p_e = k \mid p_{-e}, z, \nu, m_d, m_e, \beta) \propto \exp([m_d; m_e]^\top \beta_k) \times \prod_j \frac{(c_{r_j, k, z_j}^- + \nu_{r_j})}{(c_{r_j, k, * }^- + K\nu_{r_j})} \quad (4)$$

The sampling equation for the topic assignments  $z$  is identical to that in equation 2. In practice we optimize  $\beta$  every 1,000 iterations, until a burn-in phase of 10,000 iterations has been reached; at this point we following the same sampling regime as for the Dirichlet persona model.

## 5 Evaluation

We evaluate our methods in two quantitative ways by measuring the degree to which we recover two different sets of gold-standard clusterings. This evaluation also helps offer guidance for model selection (in choosing the number of latent topics and personas) by measuring performance on an objective task.

### 5.1 Character Names

First, we consider all character names that occur in at least two separate movies, generally as a consequence of remakes or sequels; this includes proper names such as “Rocky Balboa,” “Oliver Twist,” and “Indiana Jones,” as well as generic type names such as “Gang Member” and “The Thief”; to minimize ambiguity, we only consider character names consisting of at least two tokens. Each of these names is used by at least two different characters; for example, a character named “Jason Bourne” is portrayed in *The Bourne Identity*, *The Bourne Supremacy*, and *The Bourne Ultimatum*. While

these characters are certainly free to assume different roles in different movies, we believe that, in the aggregate, they should tend to embody the same character type and thus prove to be a natural clustering to recover. 970 character names occur at least twice in our data, and 2,666 individual characters use one of those names. Let those 970 character names define 970 unique gold clusters whose members include the individual characters who use that name.

### 5.2 TV Tropes

As a second external measure of validation, we consider a manually created clustering presented at the website TV Tropes,<sup>10</sup> a wiki that collects user-submitted examples of common tropes (narrative, character and plot devices) found in television, film, and fiction, among other media. While TV Tropes contains a wide range of such conventions, we manually identified a set of 72 tropes that could reasonably be labeled character types, including THE CORRUPT CORPORATE EXECUTIVE, THE HARDBOILED DETECTIVE, THE JERK JOCK, THE KLUTZ and THE SURFER DUDE.

We manually aligned user-submitted examples of characters embodying these 72 character types with the canonical references in Freebase to create a test set of 501 individual characters. While the 72 character tropes represented here are a more subjective measure, we expect to be able to at least partially recover this clustering.

### 5.3 Variation of Information

To measure the similarity between the two clusterings of movie characters, gold clusters  $\mathcal{G}$  and induced latent persona clusters  $\mathcal{C}$ , we calculate the variation of information (Meilă, 2007):

$$VI(\mathcal{G}, \mathcal{C}) = H(\mathcal{G}) + H(\mathcal{C}) - 2I(\mathcal{G}, \mathcal{C}) \quad (5)$$

$$= H(\mathcal{G}|\mathcal{C}) + H(\mathcal{C}|\mathcal{G}) \quad (6)$$

VI measures the information-theoretic distance between the two clusterings: a lower value means greater similarity, and  $VI = 0$  if they are identical. Low VI indicates that (induced) clusters and (gold) clusters tend to overlap; i.e., knowing a character’s (induced) cluster usually tells us their (gold) cluster, and vice versa. Variation of information is a metric (symmetric and obeys triangle

<sup>10</sup><http://tvtropes.org>

		Character Names §5.1			TV Tropes §5.2		
$K$	Model	$P = 25$	$P = 50$	$P = 100$	$P = 25$	$P = 50$	$P = 100$
25	Persona regression	7.73	7.32	6.79	6.26	6.13	5.74

	Dirichlet persona	55.3 (↑30%)	49.5 (↑24%)	45.2 (↑18%)	39.7 (↑34%)	29.9 (↑24%)	23.6 (↑19%)

Table 2: Purity scores of recovering gold clusters. Higher values are better. Each absolute purity score is paired with its improvement over a controlled baseline of permuting the learned labels while keeping the cluster proportions the same.

inequality), and has a number of other desirable properties.

Table 1 presents the VI between the learned persona clusters and gold clusters, for varying numbers of personas ( $P = \{25, 50, 100\}$ ) and topics ( $K = \{25, 50, 100\}$ ). To determine significance with respect to a random baseline, we conduct a *permutation test* (Fisher, 1935; Pitman, 1937) in which we randomly shuffle the labels of the learned persona clusters and count the number of times in 1,000 such trials that the VI of the observed persona labels is lower than the VI of the permuted labels; this defines a nonparametric  $p$ -value. All results presented are significant at  $p < 0.001$  (i.e. observed VI is never lower than the simulation VI).

Over all tests in comparison to both gold clusterings, we see VI improve as both  $P$  and, to a lesser extent,  $K$  increase. While this may be expected as the number of personas increase to match the number of distinct types in the gold clusters (970 and 72, respectively), the fact that VI improves as the number of latent topics increases suggests that more fine-grained topics are helpful for capturing nuanced character types.<sup>11</sup>

The difference between the persona regression model and the Dirichlet persona model here is not

<sup>11</sup>This trend is robust to the choice of cluster metric: here VI and  $F$ -score have a correlation of  $-0.87$ ; as more latent topics and personas are added, clustering improves (causing the  $F$ -score to go up and the VI distance to go down).

significant; while VI allows us to compare models with different numbers of latent clusters, its requirement that clusterings be mutually informative places a high overhead on models that are fundamentally unidirectional (in Table 1, for example, the room for improvement between two models of the same  $P$  and  $K$  is naturally smaller than the bigger difference between different  $P$  or  $K$ ). While we would naturally prefer a text-only model to be as expressive as a model that requires potentially hard to acquire metadata, we tease apart whether a distinction actually does exist by evaluating the purity of the gold clusters with respect to the labels assigned them.

## 5.4 Purity

For gold clusters  $\mathcal{G} = \{g_1 \dots g_k\}$  and inferred clusters  $\mathcal{C} = \{c_1 \dots c_j\}$  we calculate purity as:

$$\text{Purity} = \frac{1}{N} \sum_k \max_j |g_k \cap c_j| \quad (7)$$

While purity cannot be used to compare models of different persona size  $P$ , it can help us distinguish between models of the same size. A model can attain perfect purity, however, by placing all characters into a single cluster; to control for this, we present a controlled baseline in which each character is assigned a latent character type label proportional to the size of the latent clusters we have learned (so that, for example, if one latent persona cluster contains 3.2% of the total characters,

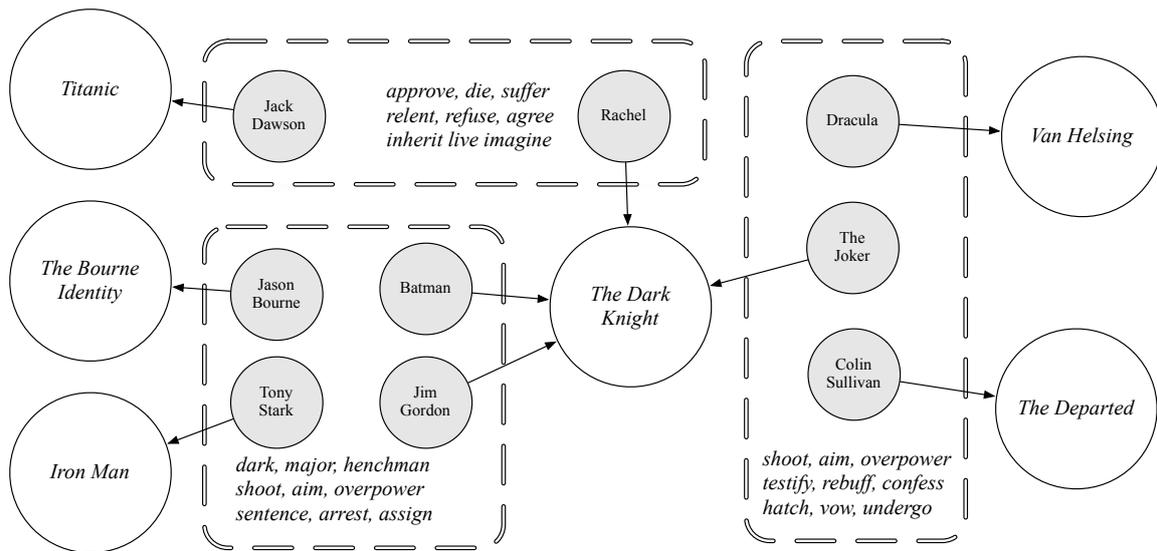

Figure 3: Dramatis personae of *The Dark Knight* (2008), illustrating 3 of the 100 character types learned by the persona regression model, along with links from other characters in those latent classes to other movies. Each character type is listed with the top three latent topics with which it is associated.

the probability of selecting that persona at random is 3.2%). Table 2 presents each model’s absolute purity score paired with its improvement over its controlled permutation (e.g.,  $\uparrow 41\%$ ).

Within each fixed-size partition, the use of metadata yields a substantial improvement over the Dirichlet model, both in terms of absolute purity and in its relative improvement over its sized-controlled baseline. In practice, we find that while the Dirichlet model distinguishes between character personas in different movies, the persona regression model helps distinguish between different personas within the same movie.

## 6 Exploratory Data Analysis

As with other generative approaches, latent persona models enable exploratory data analysis. To illustrate this, we present results from the persona regression model learned above, with 50 latent lexical classes and 100 latent personas. Figure 3 visualizes this data by focusing on a single movie, *The Dark Knight* (2008); the movie’s protagonist, Batman, belongs to the same latent persona as Detective Jim Gordon, as well as other action movie protagonists Jason Bourne and Tony Stark (*Iron Man*). The movie’s antagonist, The Joker, belongs to the same latent persona as Dracula from *Van Helsing* and Colin Sullivan from *The Departed*, illustrating the ability of personas to be informed by, but still cut across, different genres.

Table 3 presents an exhaustive list of all 50 top-

ics, along with an assigned label that consists of the single word with the highest PMI for that class. Of note are topics relating to romance (*unite, marry, woo, elope, court*), commercial transactions (*purchase, sign, sell, owe, buy*), and the classic criminal schema from Chambers (2011) (*sentence, arrest, assign, convict, promote*).

Table 4 presents the most frequent 14 personas in our dataset, illustrated with characters from the 500 highest grossing movies. The personas learned are each three separate mixtures of the 50 latent topics (one for agent relations, one for patient relations, and one for attributes), as illustrated in figure 1 above. Rather than presenting a  $3 \times 50$  histogram for each persona, we illustrate them by listing the most characteristic topics, movie characters, and metadata features associated with it. Characteristic actions and features are defined as those having the highest smoothed pointwise mutual information with that class; exemplary characters are those with the highest posterior probability of being drawn from that class. Among the personas learned are canonical male action heroes (exemplified by the protagonists of *The Bourne Supremacy*, *Speed*, and *Taken*), superheroes (*Hulk*, *Batman and Robin*, *Hector of Troy*) and several romantic comedy types, largely characterized by words drawn from the FLIRT topic, including *flirt, reconcile, date, dance* and *forgive*.

Label	Most characteristic words	Label	Most characteristic words
UNITE	unite marry woo elope court	SWITCH	switch confirm escort report instruct
PURCHASE	purchase sign sell owe buy	INFATUATE	infatuate obsess acquaint revolve concern
SHOOT	shoot aim overpower interrogate kill	ALIEN	alien child governor bandit priest
EXPLORE	explore investigate uncover deduce	CAPTURE	capture corner transport imprison trap

Table 4: Of 100 latent personas learned, we present the top 14 by frequency. Actions index the latent topic classes presented in table 3; subscripts denote whether the character is predominantly the agent ( $a$ ), patient ( $p$ ) or is modified by an attribute ( $m$ ).

## 7 Conclusion

We present a method for automatically inferring latent character personas from text (and metadata, when available). While our testbed has been textual synopses of film, this approach is easily extended to other genres (such as novelistic fiction) and to non-fictional domains as well, where the choice of portraying a real-life person as embodying a particular kind of persona may, for instance, give insight into questions of media framing and bias in newswire; self-presentation of individual personas likewise has a long history in communication theory (Goffman, 1959) and may be useful for inferring user types for personalization systems (El-Arini et al., 2012). While the goal of this work has been to induce a set of latent character classes and partition all characters among them, one interesting question that remains is how a specific character’s actions may informatively be at odds with their inferred persona, given the choice of that persona as the single best fit to explain the actions we observe. By examining how any individual character deviates from the behavior indicative of their type, we might be able to paint a more nuanced picture of how a character can embody a specific persona while resisting it at the same time.

## Acknowledgments

We thank Megan Morrison at the CMU School of Drama for early conversations guiding our work, as well as the anonymous reviewers for helpful comments. # Scalable Decipherment for Machine Translation via Hash Sampling

Sujith Ravi

Google

Mountain View, CA 94043

sravi@google.com

## Abstract

In this paper, we propose a new Bayesian inference method to train statistical machine translation systems using only non-parallel corpora. Following a probabilistic *decipherment* approach, we first introduce a new framework for decipherment training that is flexible enough to incorporate any number/type of features (besides simple bag-of-words) as side-information used for estimating translation models. In order to perform fast, efficient Bayesian inference in this framework, we then derive a *hash sampling* strategy that is inspired by the work of Ahmed et al. (2012). The new translation hash sampler enables us to scale elegantly to complex models (for the first time) and large vocabulary/corpora sizes. We show empirical results on the OPUS data—our method yields the best BLEU scores compared to existing approaches, while achieving significant computational speedups (several orders faster). We also report for the first time—BLEU score results for a large-scale MT task using only non-parallel data (EMEA corpus).

## 1 Introduction

Statistical machine translation (SMT) systems these days are built using large amounts of bilingual parallel corpora. The parallel corpora are used to estimate translation model parameters involving word-to-word translation tables, fertilities, distortion, phrase translations, syntactic transformations, etc. But obtaining parallel data is an expensive process and not available for all language

pairs or domains. On the other hand, monolingual data (in written form) exists and is easier to obtain for many languages. Learning translation models from monolingual corpora could help address the challenges faced by modern-day MT systems, especially for low resource language pairs. Recently, this topic has been receiving increasing attention from researchers and new methods have been proposed to train statistical machine translation models using only monolingual data in the source and target language. The underlying motivation behind most of these methods is that statistical properties for linguistic elements are shared across different languages and some of these similarities (mappings) could be automatically identified from large amounts of monolingual data.

The MT literature does cover some prior work on extracting or augmenting partial lexicons using non-parallel corpora (Rapp, 1995; Fung and McKeown, 1997; Koehn and Knight, 2000; Haghghi et al., 2008). However, none of these methods attempt to train end-to-end MT models, instead they focus on mining bilingual lexicons from monolingual corpora and often they require parallel seed lexicons as a starting point. Some of them (Haghghi et al., 2008) also rely on additional linguistic knowledge such as orthography, etc. to mine word translation pairs across related languages (e.g., Spanish/English). Unsupervised training methods have also been proposed in the past for related problems in decipherment (Knight and Yamada, 1999; Snyder et al., 2010; Ravi and Knight, 2011a) where the goal is to decode unknown scripts or ciphers.

The body of work that is more closely related to ours include that of Ravi and Knight (2011b) who introduced a *decipherment* approach for training translation models using only monolingual cor-

pora. Their best performing method uses an EM algorithm to train a word translation model and they show results on a Spanish/English task. Nuhn et al. (2012) extend the former approach and improve training efficiency by pruning translation candidates prior to EM training with the help of context similarities computed from monolingual corpora.

In this work we propose a new Bayesian inference method for estimating translation models from scratch using only monolingual corpora. Secondly, we introduce a new feature-based representation for sampling translation candidates that allows one to incorporate any amount of additional features (beyond simple bag-of-words) as side-information during decipherment training. Finally, we also derive a new accelerated sampling mechanism using locality sensitive hashing inspired by recent work on fast, probabilistic inference for unsupervised clustering (Ahmed et al., 2012). The new sampler allows us to perform fast, efficient inference with more complex translation models (than previously used) and scale better to large vocabulary and corpora sizes compared to existing methods as evidenced by our experimental results on two different corpora.

## 2 Decipherment Model for Machine Translation

We now describe the decipherment problem formulation for machine translation.

**Problem Formulation:** Given a source text  $f$  (i.e., source word sequences  $f_1 \dots f_m$ ) and a monolingual target language corpus, our goal is to decipher the source text and produce a target translation.

Contrary to standard machine translation training scenarios, here we have to estimate the translation model  $P_\theta(f|e)$  parameters using only monolingual data. During decipherment training, our objective is to estimate the model parameters in order to maximize the probability of the source text  $f$  as suggested by Ravi and Knight (2011b).

$$\arg \max_{\theta} \prod_f \sum_e P(e) \cdot P_\theta(f|e) \quad (1)$$

For  $P(e)$ , we use a word n-gram language model (LM) trained on monolingual target text. We then estimate the parameters of the translation model  $P_\theta(f|e)$  during training.

**Translation Model:** Machine translation is a much more complex task than solving other decipherment tasks such as word substitution ciphers (Ravi and Knight, 2011b; Dou and Knight, 2012). The mappings between languages involve non-determinism (i.e., words can have multiple translations), re-ordering of words can occur as grammar and syntax varies with language, and in addition word insertion and deletion operations are also involved.

Ideally, for the translation model  $P(f|e)$  we would like to use well-known statistical models such as IBM Model 3 and estimate its parameters  $\theta$  using the EM algorithm (Dempster et al., 1977). But training becomes intractable with complex translation models and scalability is also an issue when large corpora sizes are involved and the translation tables become huge to fit in memory. So, instead we use a simplified generative process for the translation model as proposed by Ravi and Knight (2011b) and used by others (Nuhn et al., 2012) for this task:

1. Generate a target (e.g., English) string  $e = e_1 \dots e_l$ , with probability  $P(e)$  according to an n-gram language model.
2. Insert a NULL word at any position in the English string, with uniform probability.
3. For each target word token  $e_i$  (including NULLs), choose a source word translation  $f_i$ , with probability  $P_\theta(f_i|e_i)$ . The source word may be NULL.
4. Swap any pair of adjacent source words  $f_{i-1}, f_i$ , with probability  $P(\text{swap})$ ; set to 0.1.
5. Output the foreign string  $f = f_1 \dots f_m$ , skipping over NULLs.

Previous approaches (Ravi and Knight, 2011b; Nuhn et al., 2012) use the EM algorithm to estimate all the parameters  $\theta$  in order to maximize likelihood of the foreign corpus. Instead, we propose a new Bayesian inference framework to estimate the translation model parameters. In spite of using Bayesian inference which is typically slow in practice (with standard Gibbs sampling), we show later that our method is scalable and permits decipherment training using more complex translation models (with several additional parameters).

## 2.1 Adding Phrases, Flexible Reordering and Fertility to Translation Model

We now extend the generative process (described earlier) to more complex translation models.

**Non-local Re-ordering:** The generative process described earlier limits re-ordering to local or adjacent word pairs in a source sentence. We extend this to allow re-ordering between any pair of words in the sentence.

**Fertility:** We also add a fertility model  $P_{\theta_{fert}}$  to the translation model using the formula:

$$P_{\theta_{fert}} = \prod_i n_{\theta}(\phi_i|e_i) \cdot p_1^{\phi_0} \quad (2)$$

$$n_{\theta}(\phi_i|e_i) = \frac{\alpha_{fert} \cdot P_0(\phi_i|e_i) + C^{-i}(e_i, \phi_i)}{\alpha_{fert} + C^{-i}(e_i)} \quad (3)$$

where,  $P_0$  represents the base distribution (which is set to uniform) in a Chinese Restaurant Process (CRP)<sup>1</sup> for the fertility model and  $C^{-i}$  represents the count of events occurring in the history excluding the observation at position  $i$ .  $\phi_i$  is the number of source words aligned to (i.e., generated by) the target word  $e_i$ . We use sparse Dirichlet priors for all the translation model components.<sup>2</sup>  $\phi_0$  represents the target NULL word fertility and  $p_1$  is the insertion probability which is fixed to 0.1. In addition, we set a maximum threshold for fertility values  $\phi_i \leq \gamma \cdot m$ , where  $m$  is the length of the source sentence. This discourages a particular target word (e.g., NULL word) from generating too many source words in the same sentence. In our experiments, we set  $\gamma = 0.3$ . We enforce this constraint in the training process during sampling.<sup>3</sup>

**Modeling Phrases:** Finally, we extend the translation candidate set in  $P_{\theta}(f_i|e_i)$  to model phrases in addition to words for the target side (i.e.,  $e_i$  can now be a word or a phrase<sup>4</sup> previously seen in the monolingual target corpus). This greatly increases the training time since in each sampling step, we now have many more  $e_i$  candidates to choose from. In Section 4, we describe how we deal

<sup>1</sup>Each component in the translation model (word/phrase translations  $P_{\theta}(f_i|e_i)$ , fertility  $P_{\theta_{fert}}$ , etc.) is modeled using a CRP formulation.

<sup>2</sup>i.e., All the concentration parameters are set to low values;  $\alpha_{f|e} = \alpha_{fert} = 0.01$ .

<sup>3</sup>We only apply this constraint when training on source text/corpora made of long sentences (>10 words) where the sampler might converge very slowly. For short sentences, a sparse prior on fertility  $\alpha_{fert}$  typically discourages a target word from being aligned to too many different source words.

<sup>4</sup>Phrase size is limited to two words in our experiments.

with this problem by using a fast, efficient sampler based on hashing that allows us to speed up the Bayesian inference significantly whereas standard Gibbs sampling would be extremely slow.

## 3 Feature-based representation for Source and Target

The model described in the previous section while being flexible in describing the translation process, poses several challenges for training. As the source and target vocabulary sizes increase the size of the translation table ( $|V_f| \cdot |V_e|$ ) increases significantly and often becomes too huge to fit in memory. Additionally, performing Bayesian inference with such a complex model using standard Gibbs sampling can be very slow in practice. Here, we describe a new method for doing Bayesian inference by first introducing a feature-based representation for the source and target words (or phrases) from which we then derive a novel proposal distribution for sampling translation candidates.

We represent both source and target words in a *vector space* similar to how documents are represented in typical information retrieval settings. But unlike documents, here each word  $\mathbf{w}$  is associated with a feature vector  $w^1 \dots w^d$  (where  $w^i$  represents the weight for the feature indexed by  $i$ ) which is constructed from monolingual corpora. For instance, *context features* for word  $\mathbf{w}$  may include other words (or phrases) that appear in the immediate context (n-gram window) surrounding  $\mathbf{w}$  in the monolingual corpus. Similarly, we can add other features based on *topic models*, *orthography* (Haghighi et al., 2008), *temporal* (Klementiev et al., 2012), etc. to our representation all of which can be extracted from monolingual corpora.

Next, given two high dimensional vectors  $\mathbf{u}$  and  $\mathbf{v}$  it is possible to calculate the similarity between the two words denoted by  $s(\mathbf{u}, \mathbf{v})$ . The feature construction process is described in more detail below:

**Target Language:** We represent each word (or phrase)  $e_i$  with the following contextual features along with their counts: (a)  $f_{-context}$ : every (word n-gram, position) pair immediately preceding  $e_i$  in the monolingual corpus (n=1, position=-1), (b) similar features  $f_{+context}$  to model the context following  $e_i$ , and (c) we also throw in generic context features  $f_{scontext}$  without position information—every word that co-occurs with  $e_i$  in the same sen-

tence. While the two position-features provide specific context information (may be sparse for large monolingual corpora), this feature is more generic and captures long-distance co-occurrence statistics.

**Source Language:** Words appearing in a source sentence  $f$  are represented using the corresponding target translation  $e = e_1 \dots e_m$  generated for  $f$  in the current sample during training. For each source word  $f_j \in f$ , we look at the corresponding word  $e_j$  in the target translation. We then extract all the context features of  $e_j$  in the target translation sample sentence  $e$  and add these features ( $f_{-context}, f_{+context}, f_{scontext}$ ) with weights to the feature representation for  $f_j$ .

Unlike the target word feature vectors (which can be pre-computed from the monolingual target corpus), the feature vector for every source word  $f_j$  is dynamically constructed from the target translation sampled in each training iteration. This is a key distinction of our framework compared to previous approaches that use contextual similarity (or any other) features constructed from static monolingual corpora (Rapp, 1995; Koehn and Knight, 2000; Nuhn et al., 2012).

Note that as we add more and more features for a particular word (by training on larger monolingual corpora or adding new types of features, etc.), it results in the feature representation becoming more sparse (especially for source feature vectors) which can cause problems in efficiency as well as robustness when computing similarity against other vectors. In the next section, we will describe how we mitigate this problem by projecting into a low-dimensional space by computing hash signatures.

In all our experiments, we only use the features described above for representing source and target words. We note that the new sampling framework is easily extensible to many additional feature types (for example, monolingual topic model features, etc.) which can be efficiently handled by our inference algorithm and could further improve translation performance but we leave this for future work.

#### 4 Bayesian MT Decipherment via Hash Sampling

The next step is to use the feature representations described earlier and iteratively sample a target word (or phrase) translation candidate  $e_i$  for every

word  $f_i$  in the source text  $f$ . This involves choosing from  $|V_e|$  possible target candidates in every step which can be highly inefficient (and infeasible for large vocabulary sizes). One possible strategy is to compute similarity scores  $s(\mathbf{w}_{f_i}, \mathbf{w}_{e'})$  between the current source word feature vector  $\mathbf{w}_{f_i}$  and feature vectors  $\mathbf{w}_{e' \in V_e}$  for all possible candidates in the target vocabulary. Following this, we can prune the translation candidate set by keeping only the top candidates  $e^*$  according to the similarity scores. Nuhn et al. (2012) use a similar strategy to obtain a more compact translation table that improves runtime efficiency for EM training. Their approach requires calculating and sorting all  $|V_e| \cdot |V_f|$  distances in time  $O(V^2 \cdot \log(V))$ , where  $V = \max(|V_e|, |V_f|)$ .

**Challenges:** Unfortunately, there are several additional challenges which makes inference very hard in our case. Firstly, we would like to include as many features as possible to represent the source/target words in our framework besides simple bag-of-words context similarity (for example, left-context, right-context, and other general-purpose features based on topic models, etc.). This makes the complexity far worse (in practice) since the dimensionality of the feature vectors  $d$  is a much higher value than  $|V_e|$ . Computing similarity scores alone (naïvely) would incur  $O(|V_e| \cdot d)$  time which is prohibitively huge since we have to do this for every token in the source language corpus. Secondly, for Bayesian inference we need to sample from a distribution that involves computing probabilities for all the components (language model, translation model, fertility, etc.) described in Equation 1. This distribution needs to be computed for every source word token  $f_i$  in the corpus, for all possible candidates  $e_i \in V_e$  and the process has to be repeated for multiple sampling iterations (typically more than 1000). Doing standard collapsed Gibbs sampling in this scenario would be very slow and intractable.

We now present an alternative fast, efficient inference strategy that overcomes many of the challenges described above and helps accelerate the sampling process significantly. First, we set our translation models within the context of a more generic and widely known family of distributions—mixtures of exponential families. Then we derive a novel proposal distribution for sampling translation candidates and introduce a new sampler for decipherment training that

is based on locality sensitive hashing (LSH).

Hashing methods such as LSH have been widely used in the past in several scenarios including NLP applications (Ravichandran et al., 2005). Most of these approaches employ LSH within heuristic methods for speeding up nearest-neighbor look up and similarity computation techniques. However, we use LSH hashing within a probabilistic framework which is very different from the typical use of LSH.

Our work is inspired by some recent work by Ahmed et al. (2012) on speeding up Bayesian inference for unsupervised clustering. We use a similar technique as theirs but a different approximate distribution for the proposal, one that is better-suited for machine translation models and without some of the additional overhead required for computing certain terms in the original formulation.

**Mixtures of Exponential Families:** The translation models described earlier (Section 2) can be represented as mixtures of exponential families, specifically mixtures of multinomials. In exponential families, distributions over random variables are given by:

$$p(x; \theta) = \exp(\langle \phi(x), \theta \rangle) - g(\theta) \quad (4)$$

where,  $\phi : \mathcal{X} \rightarrow \mathcal{F}$  is a map from  $x$  to the space of sufficient statistics and  $\theta \in \mathcal{F}$ . The term  $g(\theta)$  ensures that  $p(x; \theta)$  is properly normalized.  $\mathcal{X}$  is the domain of observations  $X = x_1, \dots, x_m$  drawn from some distribution  $p$ . Our goal is to estimate  $p$ . In our case, this refers to the translation model from Equation 1.

We also choose corresponding conjugate Dirichlet distributions for priors which have the property that the posterior distribution  $p(\theta|X)$  over  $\theta$  remains in the same family as  $p(\theta)$ .

Note that the (translation) model in our case consists of multiple exponential families components—a multinomial pertaining to the language model (which remains fixed<sup>5</sup>), and other components pertaining to translation probabilities  $P_\theta(f_i|e_i)$ , fertility  $P_{\theta_{fert}}$ , etc. To do collapsed Gibbs sampling under this model, we would perform the following steps during sampling:

1. For a given source word token  $f_i$  draw target

translation

$$\begin{aligned} e_i &\sim p(e_i|F, E^{-i}) \\ &\propto p(e) \cdot p(f_i|e_i, F^{-i}, E^{-i}) \\ &\quad \cdot p_{fert}(\cdot|e_i, F^{-i}, E^{-i}) \cdot \dots \end{aligned} \quad (5)$$

where,  $F$  is the full source text and  $E$  the full target translation generated during sampling.

2. Update the sufficient statistics for the changed target translation assignments.

For large target vocabularies, computing  $p(f_i|e_i, F^{-i}, E^{-i})$  dominates the inference procedure. We can accelerate this step significantly using a good proposal distribution via hashing.

**Locality Sensitive Hash Sampling:** For general exponential families, here is a Taylor approximation for the data likelihood term (Ahmed et al., 2012):

$$p(x|\cdot) \approx \exp(\langle \phi(x), \theta^* \rangle) - g(\theta^*) \quad (6)$$

where,  $\theta^*$  is the expected parameter (sufficient statistics).

For sampling the translation model, this involves computing an expensive inner product  $\langle \phi(f_i), \theta_{e'}^* \rangle$  for each source word  $f_i$  which has to be repeated for every translation candidate  $e'$ , including candidates that have very low probabilities and are unlikely to be chosen as the translation for  $f_j$ .

So, during decipherment training a standard collapsed Gibbs sampler will waste most of its time on expensive computations that will be discarded in the end anyways. Also, unlike some standard generative models used in other unsupervised learning scenarios (e.g., clustering) that model only observed features (namely words appearing in the document), here we would like to enrich the translation model with a lot more features (side-information).

Instead, we can accelerate the computation of the inner product  $\langle \phi(f_i), \theta_{e'}^* \rangle$  using a *hash sampling* strategy similar to (Ahmed et al., 2012). The underlying idea here is to use binary hashing (Charikar, 2002) to explore only those candidates  $e'$  that are sufficiently close to the best matching translation via a proposal distribution. Next, we briefly introduce some notations and existing theoretical results related to binary hashing before describing the hash sampling procedure.

For any two vectors  $u, v \in \mathbb{R}^n$ ,

$$\langle u, v \rangle = \|u\| \cdot \|v\| \cdot \cos \angle(u, v) \quad (7)$$

<sup>5</sup>A high value for the LM concentration parameter  $\alpha$  ensures that the LM probabilities do not deviate too far from the original fixed base distribution during sampling.

$$\angle(u, v) = \pi Pr\{sgn[\langle u, w \rangle] \neq sgn[\langle v, w \rangle]\} \quad (8)$$

where,  $w$  is a random vector drawn from a symmetric spherical distribution and the term inside  $Pr\{\cdot\}$  represents the relation between the signs of the two inner products.

Let  $h^l(v) \in \{0, 1\}^l$  be an  $l$ -bit binary hash of  $v$  where:  $[h^l(v)]_i := sgn[\langle v, w_i \rangle]$ ;  $w_i \sim U_m$ . Then the probability of matching signs is given by:

$$z^l(u, v) := \frac{1}{l} \|h(u) - h(v)\|_1 \quad (9)$$

So,  $z^l(u, v)$  measures how many bits differ between the hash vectors  $h(u)$  and  $h(v)$  associated with  $u, v$ . Combining this with Equations 6 and 7 we can estimate the unnormalized log-likelihood of a source word  $f_i$  being translated as target  $e'$  via:

$$s^l(f_i, e') \propto \|\theta_{e'}\| \cdot \|\phi(f_i)\| \cdot \cos \pi z^l(\phi(f_i), \theta_{e'}) \quad (10)$$

For each source word  $f_i$ , we now sample from this new distribution (after normalization) instead of the original one. The binary hash representation for the two vectors yield significant speedups during sampling since Hamming distance computation between  $h(u)$  and  $h(v)$  is highly optimized on modern CPUs. Hence, we can compute an estimate for the inner product quite efficiently.<sup>6</sup>

**Updating the hash signatures:** During training, we compute the target candidate projection  $h(\theta_{e'})$  and corresponding norm only once<sup>7</sup> which is different from the setup of Ahmed et al. (2012). The source word projection  $\phi(f_i)$  is dynamically updated in every sampling step. Note that doing this naïvely would scale slowly as  $O(Dl)$  where  $D$  is the total number of features but instead we can update the hash signatures in a more efficient manner that scales as  $O(D_{i>0}l)$  where  $D_{i>0}$  is the number of non-zero entries in the feature representation for the source word  $\phi(f_i)$ . Also, we do not need to store the random vectors  $w$  in practice since these can be computed on the fly using hash functions. The inner product approximation also yields some theoretical guarantees for the hash sampler.<sup>8</sup>

<sup>6</sup>We set  $l = 32$  bits in our experiments.

<sup>7</sup>In practice, we can ignore the *norm* terms to further speed up sampling since this is only an estimate for the proposal distribution and we follow this with the Metropolis Hastings step.

<sup>8</sup>For further details, please refer to (Ahmed et al., 2012).

## 4.1 Metropolis Hastings

In each sampling step, we use the distribution from Equation 10 as a proposal distribution in a Metropolis Hastings scheme to sample target translations for each source word.

Once a new target translation  $e'$  is sampled for source word  $f_i$  from the proposal distribution  $q(\cdot) \propto \exp^{s^l(f_i, e')}$ , we accept the proposal (and update the corresponding hash signatures) according to the probability  $r$

$$r = \frac{q(e_i^{old}) \cdot p_{new}(\cdot)}{q(e_i^{new}) \cdot p_{old}(\cdot)} \quad (11)$$

where,  $p_{old}(\cdot), p_{new}(\cdot)$  are the true conditional likelihood probabilities according to our model (including the language model component) for the old, new sample respectively.

## 5 Training Algorithm

Putting together all the pieces described in the previous section, we perform the following steps:

1. *Initialization:* We initialize the starting sample as follows: for each source word token, randomly sample a target word. If the source word also exists in the target vocabulary, then choose identity translation instead of the random one.<sup>9</sup>

2. *Hash Sampling Steps:* For each source word token  $f_i$ , run the hash sampler:

(a) Generate a proposal distribution by computing the hamming distance between the feature vectors for the source word and each target translation candidate. Sample a new target translation  $e_i$  for  $f_i$  from this distribution.

(b) Compute the acceptance probability for the chosen translation using a Metropolis Hastings scheme and accept (or reject) the sample. In practice, computation of the acceptance probability only needs to be done every  $r$  iterations (where  $r$  can be anywhere from 5 or 100).

Iterate through steps (2a) and (2b) for every word in the source text and then repeat this process for multiple iterations (usually 1000).

3. *Other Sampling Operators:* After every  $k$  iterations,<sup>10</sup> perform the following sampling operations:

(a) Re-ordering: For each source word token  $f_i$  at position  $i$ , randomly choose another position  $j$

<sup>9</sup>Initializing with identity translation rather than random choice helps in some cases, especially for *unknown* words that involve named entities, etc.

<sup>10</sup>We set  $k = 3$  in our experiments.

Corpus	Language	Sent.	Words	Vocab.
OPUS	Spanish	13,181	39,185	562
	English	19,770	61,835	411
EMEA	French	550,000	8,566,321	41,733
	Spanish	550,000	7,245,672	67,446

Table 1: Statistics of non-parallel corpora used here.

in the source sentence and swap the translations  $e_i$  with  $e_j$ . During the sampling process, we compute the probabilities for the two samples—the original and the swapped versions, and then sample an alignment from this distribution.

(b) Deletion: For each source word token, delete the current target translation (i.e., align it with the target NULL token). As with the re-ordering operation, we sample from a distribution consisting of the original and the deleted versions.

4. *Decoding the foreign sentence*: Finally, once the training is done (i.e., after all sampling iterations) we choose the final sample as our target translation output for the source text.

## 6 Experiments and Results

We test our method on two different corpora. To evaluate translation quality, we use BLEU score (Papineni et al., 2002), a standard evaluation measure used in machine translation.

First, we present MT results on non-parallel Spanish/English data from the OPUS corpus (Tiedemann, 2009) which was used by Ravi and Knight (2011b) and Nuhn et al. (2012). We show that our method achieves the best performance (BLEU scores) on this task while being significantly faster than both the previous approaches. We then apply our method to a much larger non-parallel French/Spanish corpus constructed from the EMEA corpus (Tiedemann, 2009). Here the vocabulary sizes are much larger and we show how our new Bayesian decipherment method scales well to this task in spite of using complex translation models. We also report the first BLEU results on such a large-scale MT task under truly non-parallel settings (without using any parallel data or seed lexicon).

For both the MT tasks, we also report BLEU scores for a baseline system using *identity* translations for common words (words appearing in both source/target vocabularies) and random translations for other words.

### 6.1 MT Task and Data

**OPUS movie subtitle corpus** (Tiedemann, 2009): This is a large open source collection of parallel corpora available for multiple language pairs. We use the same non-parallel Spanish/English corpus used in previous works (Ravi and Knight, 2011b; Nuhn et al., 2012). The details of the corpus are listed in Table 1. We use the entire Spanish source text for decipherment training and evaluate the final English output to report BLEU scores.

**EMEA corpus** (Tiedemann, 2009): This is a parallel corpus made out of PDF documents (articles from the medical domain) from the European Medicines Agency. We reserve the first 1k sentences in French as our source text (also used in decipherment training). To construct a non-parallel corpus, we split the remaining 1.1M lines as follows: first 550k sentences in French, last 550k sentences in Spanish. The latter is used to construct a target language model used for decipherment training. The corpus statistics are shown in Table 1.

### 6.2 Results

**OPUS**: We compare the MT results (BLEU scores) from different systems on the OPUS corpus in Table 2. The first row displays baseline performance. The next three rows 1a–1c display performance achieved by two methods from Ravi and Knight (2011b). Rows 2a, 2b show results from the of Nuhn et al. (2012). The last two rows display results for the new method using Bayesian hash sampling. Overall, using a 3-gram language model (instead of 2-gram) for decipherment training improves the performance for all methods. We observe that our method produces much better results than the others even with a 2-gram LM. With a 3-gram LM, the new method achieves the best performance; the highest BLEU score reported on this task. It is also interesting to note that the hash sampling method yields much better results than the Bayesian inference method presented in (Ravi and Knight, 2011b). This is due to the accelerated sampling scheme introduced earlier which helps it converge to better solutions faster.

Table 2 (last column) also compares the efficiency of different methods in terms of CPU time required for training. Both our 2-gram and 3-gram based methods are significantly faster than those previously reported for EM based training methods presented in (Ravi and Knight, 2011b; Nuhn

Method	BLEU	Time (hours)
Baseline system ( <i>identity translations</i> )	6.9	
1a. EM with 2-gram LM (Ravi and Knight, 2011b)	15.3	~850h
1b. EM with whole-segment LM (Ravi and Knight, 2011b)	19.3	
1c. Bayesian IBM Model 3 with 2-gram LM (Ravi and Knight, 2011b)	15.1	
2a. EM+Context with 2-gram LM (Nuhn et al., 2012)	15.2	50h
2b. EM+Context with 3-gram LM (Nuhn et al., 2012)	20.9	200h
3. Bayesian (standard) Gibbs sampling with 2-gram LM	-	222h
4a. Bayesian Hash Sampling* with 2-gram LM ( <i>this work</i> )	<b>20.3</b>	2.6h
4b. Bayesian Hash Sampling* with 3-gram LM ( <i>this work</i> ) (*sampler was run for 1000 iterations)	<b>21.2</b>	2.7h

Table 2: Comparison of MT performance (BLEU scores) and efficiency (running time in CPU hours) on the Spanish/English OPUS corpus using only non-parallel corpora for training. For the Bayesian methods 4a and 4b, the samplers were run for 1000 iterations each on a single machine (1.8GHz Intel processor). For 1a, 2a, 2b, we list the training times as reported by Nuhn et al. (2012) based on their EM implementation for different settings.

Method	BLEU
Baseline system ( <i>identity translations</i> )	3.0
Bayesian Hash Sampling with 2-gram LM vocab= <i>full</i> ( $V_e$ ), add_fertility= <i>no</i>	4.2
vocab= <i>pruned</i> *, add_fertility= <i>yes</i>	<b>5.3</b>

Table 3: MT results on the French/Spanish EMEA corpus using the new hash sampling method. \*The last row displays results when we sample target translations from a *pruned* candidate set (most frequent 1k Spanish words + identity translation candidates) which enables the sampler to run much faster when using more complex models.

et al., 2012). This is very encouraging since Nuhn et al. (2012) reported obtaining a speedup by pruning translation candidates (to  $\sim 1/8$ th the original size) prior to EM training. On the other hand, we sample from the full set of translation candidates including additional target phrase (of size 2) candidates which results in a much larger vocabulary consisting of 1600 candidates ( $\sim 4$  times the original size), yet our method runs much faster and yields better results. The table also demonstrates the significant speedup achieved by the hash sampler over a standard Gibbs sampler for the same model ( $\sim 85$  times faster when using a 2-gram LM).

We also compare the results against MT performance from *parallel training*—MOSES system (Koehn et al., 2007) trained on 20k sentence pairs. The comparable number for Table 2 is 63.6 BLEU.

Spanish ( $e$ )		French ( $f$ )
el	→	les
la	→	la
por	→	des
sección	→	rubrique
administración	→	administration

Table 4: Sample (1-best) Spanish/French translations produced by the new method on the EMEA corpus using word translation models trained with non-parallel corpora.

**EMEA Results** Table 3 shows the results achieved by our method on the larger task involving EMEA corpus. Here, the target vocabulary  $V_e$  is much higher (67k). In spite of this challenge and the model complexity, we can still perform decipherment training using Bayesian inference. We report the first BLEU score results on such a large-scale task using a 2-gram LM. This is achieved without using any seed lexicon or parallel corpora. The results are encouraging and demonstrates the ability of the method to scale to large-scale settings while performing efficient inference with complex models, which we believe will be especially useful for future MT application in scenarios where parallel data is hard to obtain. Table 4 displays some sample 1-best translations learned using this method.

For comparison purposes, we also evaluate MT performance on this task using *parallel training* (MOSES trained with hundred sentence pairs) and observe a BLEU score of 11.7.

## 7 Discussion and Future Work

There exists some work (Dou and Knight, 2012; Klementiev et al., 2012) that uses monolingual corpora to induce phrase tables, etc. These when combined with standard MT systems such as Moses (Koehn et al., 2007) trained on parallel corpora, have been shown to yield some BLEU score improvements. Nuhn et al. (2012) show some sample English/French lexicon entries learnt using EM algorithm with a pruned translation candidate set on a portion of the Gigaword corpus<sup>11</sup> but do not report any actual MT results. In addition, as we showed earlier our method can use Bayesian inference (which has a lot of nice properties compared to EM for unsupervised natural language tasks (Johnson, 2007; Goldwater and Griffiths, 2007)) and still scale easily to large vocabulary, data sizes while allowing the models to grow in complexity. Most importantly, our method produces better translation results (as demonstrated on the OPUS MT task). And to our knowledge, this is the first time that anyone has reported MT results under truly non-parallel settings on such a large-scale task (EMEA).

Our method is also easily extensible to out-of-domain translation scenarios similar to (Dou and Knight, 2012). While their work also uses Bayesian inference with a slice sampling scheme, our new approach uses a novel hash sampling scheme for decipherment that can easily scale to more complex models. The new decipherment framework also allows one to easily incorporate additional information (besides standard word translations) as features (e.g., context features, topic features, etc.) for unsupervised machine translation which can help further improve the performance in addition to accelerating the sampling process. We already demonstrated the utility of this system by going beyond words and incorporating phrase translations in a decipherment model for the first time.

In the future, we can obtain further speedups (especially for large-scale tasks) by parallelizing the sampling scheme seamlessly across multiple machines and CPU cores. The new framework can also be stacked with complementary techniques such as slice sampling, blocked (and type) sampling to further improve inference efficiency.

<sup>11</sup><http://www ldc.upenn.edu/Catalog/catalogEntry.jsp?catalogId=LDC2003T05>

## 8 Conclusion

To summarize, our method is significantly faster than previous methods based on EM or Bayesian with standard Gibbs sampling and obtains better results than any previously published methods for the same task. The new framework also allows performing Bayesian inference for decipherment applications with more complex models than previously shown. We believe this framework will be useful for further extending MT models in the future to improve translation performance and for many other unsupervised decipherment application scenarios.

## Abstract

The English 's possessive construction occurs frequently in text and can encode several different semantic relations; however, it has received limited attention from the computational linguistics community. This paper describes the creation of a semantic relation inventory covering the use of 's, an inter-annotator agreement study to calculate how well humans can agree on the relations, a large collection of possessives annotated according to the relations, and an accurate automatic annotation system for labeling new examples. Our 21,938 example dataset is by far the largest annotated possessives dataset we are aware of, and both our automatic classification system, which achieves 87.4% accuracy in our classification experiment, and our annotation data are publicly available.

## 1 Introduction

The English 's possessive construction occurs frequently in text—approximately 1.8 times for every 100 hundred words in the Penn Treebank<sup>1</sup> (Marcus et al., 1993)—and can encode a number of different semantic relations including ownership (*John's car*), part-of-whole (*John's arm*), extent (*6 hours' drive*), and location (*America's rivers*). Accurate automatic possessive interpretation could aid many natural language processing (NLP) applications, especially those that build semantic representations for text understanding, text generation, question answering, or information extraction. These interpretations could be valuable for machine translation to or from languages that allow different semantic relations to be encoded by

<sup>†</sup>The authors were affiliated with the USC Information Sciences Institute at the time this work was performed.

the possessive/genitive.

This paper presents an inventory of 17 semantic relations expressed by the English 's-construction, a large dataset annotated according to the this inventory, and an accurate automatic classification system. The final inter-annotator agreement study achieved a strong level of agreement, 0.78 Fleiss' Kappa (Fleiss, 1971) and the dataset is easily the largest manually annotated dataset of possessive constructions created to date. We show that our automatic classification system is highly accurate, achieving 87.4% accuracy on a held-out test set.

## 2 Background

Although the linguistics field has devoted significant effort to the English possessive (§6.1), the computational linguistics community has given it limited attention. By far the most notable exception to this is the line of work by Moldovan and Badulescu (Moldovan and Badulescu, 2005; Badulescu and Moldovan, 2009), who define a taxonomy of relations, annotate data, calculate inter-annotator agreement, and perform automatic classification experiments. Badulescu and Moldovan (2009) investigate both 's-constructions and *of* constructions in the same context using a list of 36 semantic relations (including OTHER). They take their examples from a collection of 20,000 randomly selected sentences from Los Angeles Times news articles used in TREC-9. For the 960 extracted 's-possessive examples, only 20 of their semantic relations are observed, including OTHER, with 8 of the observed relations occurring fewer than 10 times. They report a 0.82 Kappa agreement (Siegel and Castellan, 1988) for the two computational semantics graduates who annotate the data, stating that this strong result “can be explained by the instructions the annotators received

<sup>1</sup>Possessive pronouns such as *his* and *their* are treated as 's constructions in this work.

prior to annotation and by their expertise in Lexical Semantics.”

Moldovan and Badulescu experiment with several different classification techniques. They find that their *semantic scattering* technique significantly outperforms their comparison systems with its F-measure score of 78.75. Their SVM system performs the worst with only 23.25% accuracy—surprisingly low, especially considering that 220 of the 960 ‘s examples have the same label.

Unfortunately, Badulescu and Moldovan (2009) have not publicly released their data<sup>2</sup>. Also, it is sometimes difficult to understand the meaning of the semantic relations, partly because most relations are only described by a single example and, to a lesser extent, because the bulk of the given examples are *of*-constructions. For example, why *President of Bolivia* warrants a SOURCE/FROM relation but *University of Texas* is assigned to LOCATION/SPACE is unclear. Their relations and provided examples are presented below in Table 1.

Relation	Examples
POSSESSION	Mary’s book
KINSHIP	Mary’s brother
PROPERTY	John’s coldness
AGENT	investigation of the crew
TEMPORAL	last year’s exhibition
DEPICTION-DEPICTED	a picture of my niece
PART-WHOLE	the girl’s mouth
CAUSE	death of cancer
MAKE/PRODUCE	maker of computer
LOCATION/SPACE	Univerity of Texas
SOURCE/FROM	President of Bolivia
TOPIC	museum of art
ACCOMPANIMENT	solution of the problem
EXPERIENCER	victim of lung disease
RECIPIENT	Josephine’s reward
ASSOCIATED WITH	contractors of shipyard
MEASURE	hundred (sp?) of dollars
THEME	acquisition of the holding
RESULT	result of the review
OTHER	state of emergency

Table 1: The 20 (out of an original 36) semantic relations observed by Badulescu and Moldovan (2009) along with their examples.

### 3 Dataset Creation

We created the dataset used in this work from three different sources, each representing a distinct genre—newswire, non-fiction, and fiction. Of the

<sup>2</sup>Email requests asking for relation definitions and the data were not answered, and, thus, we are unable to provide an informative comparison with their work.

21,938 total examples, 15,330 come from sections 2–21 of the Penn Treebank (Marcus et al., 1993). Another 5,266 examples are from *The History of the Decline and Fall of the Roman Empire* (Gibbon, 1776), a non-fiction work, and 1,342 are from *The Jungle Book* (Kipling, 1894), a collection of fictional short stories. For the Penn Treebank, we extracted the examples using the provided gold standard parse trees, whereas, for the latter cases, we used the output of an open source parser (Tratz and Hovy, 2011).

## 4 Semantic Relation Inventory

The initial semantic relation inventory for possessives was created by first examining some of the relevant literature on possessives, including work by Badulescu and Moldovan (2009), Barker (1995), Quirk et al. (1985), Rosenbach (2002), and Taylor (1996), and then manually annotating the large dataset of examples. Similar examples were grouped together to form initial categories, and groups that were considered more difficult were later reexamined in greater detail. Once all the examples were assigned to initial categories, the process of refining the definitions and annotations began.

In total, 17 relations were created, not including OTHER. They are shown in Table 3 along with approximate (best guess) mappings to relations defined by others, specifically those of Quirk et al. (1985), whose relations are presented in Table 2, as well as Badulescu and Moldovan’s (2009) relations.

Relation	Examples
POSSESSIVE	my wife’s father
SUBJECTIVE	boy’s application
OBJECTIVE	the family’s support
ORIGIN	the general’s letter
DESCRIPTIVE	a women’s college
MEASURE	ten days’ absense
ATTRIBUTE	the victim’s courage
PARTITIVE	the baby’s eye
APPOSITION (marginal)	Dublin’s fair city

Table 2: The semantic relations proposed by Quirk et al. (1985) for ‘s along with some of their examples.

### 4.1 Refinement and Inter-annotator Agreement

The semantic relation inventory was refined using an iterative process, with each iteration involv-

Relation	Example	HDFRE	JB	PTB	Mappings
SUBJECTIVE	Dora’s travels	1083	89	3169	Q:SUBJECTIVE, B:AGENT
PRODUCER’S PRODUCT	Ford’s Taurus	47	44	1183	Q:ORIGIN, B:MAKE/PRODUCE B:RESULT
OBJECTIVE	Mowgli’s capture	380	7	624	Q:OBJECTIVE, B:THEME
CONTROLLER/OWNER/USER	my apartment	882	157	3940	QB:POSSESSIVE
MENTAL EXPERIENCER	Sam’s fury	277	22	232	Q:POSSESSIVE, B:EXPERIENCER
RECIPIENT	their bonuses	12	6	382	Q:POSSESSIVE, B:RECIPIENT
MEMBER’S COLLECTION	John’s family	144	31	230	QB:POSSESSIVE
PARTITIVE	John’s arm	253	582	451	Q:PARTITIVE, B:PART-WHOLE
LOCATION	Libya’s people	24	0	955	Q:POSSESSIVE, B:SOURCE/FROM B:LOCATION/SPACE
TEMPORAL	today’s rates	0	1	623	Q:POSSESSIVE, B:TEMPORAL
EXTENT	6 hours’ drive	8	10	5	QB:MEASURE
KINSHIP	Mary’s kid	324	156	264	Q:POSSESSIVE, B:KINSHIP
ATTRIBUTE	picture’s vividness	1013	34	1017	Q:ATTRIBUTE, B:PROPERTY
TIME IN STATE	his years in Ohio	145	32	237	QB:POSSESSIVE

OTHER RELATIONAL NOUN	his friend	629	112	1772	QB:POSSESSIVE
OTHER	your Lordship	33	59	146	B:OTHER

Table 3: Possessive semantic relations along with examples, counts, and approximate mappings to other inventories. Q and B represent Quirk et al. (1985) and Badulescu and Moldovan (2009), respectively. HDFRE, JB, PTB: *The History of the Decline and Fall of the Roman Empire*, *The Jungle Book*, and the Penn Treebank, respectively.

ing the annotation of a random set of 50 examples. Each set of examples was extracted such that no two examples had an identical *possessee* word. For a given example, annotators were instructed to select the most appropriate option but could also record a second-best choice to provide additional feedback. Figure 1 presents a screenshot of the HTML-based annotation interface. After the annotation was complete for a given round, agreement and entropy figures were calculated and changes were made to the relation definitions and dataset. The number of refinement rounds was arbitrarily limited to five. To measure agreement, in addition to calculating simple percentage agreement, we computed Fleiss’ Kappa (Fleiss, 1971), a measure of agreement that incorporates a correction for agreement due to chance, similar to Cohen’s Kappa (Cohen, 1960), but which can be used to measure agreement involving more than two annotations per item. The agreement and entropy figures for these five intermediate annotation rounds are given in Table 4. In all the possessive annotation tables, Annotator A refers to the primary author and the labels B and C refer to two additional annotators.

To calculate a final measure of inter-annotator agreement, we randomly drew 150 examples from the dataset not used in the previous refinement iterations, with 50 examples coming from each of

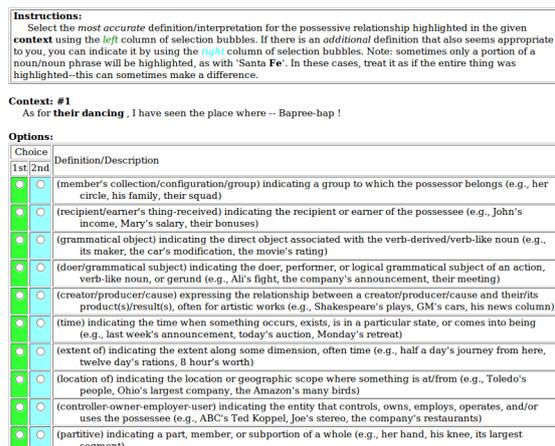

Figure 1: Screenshot of the HTML template page used for annotation.

the three original data sources. All three annotators initially agreed on 82 of the 150 examples, leaving 68 examples with at least some disagreement, including 17 for which all three annotators disagreed.

Annotators then engaged in a new task in which they re-annotated these 68 examples, in each case being able to select only from the definitions previously chosen for each example by at least one annotator. No indication of who or how many people had previously selected the definitions was

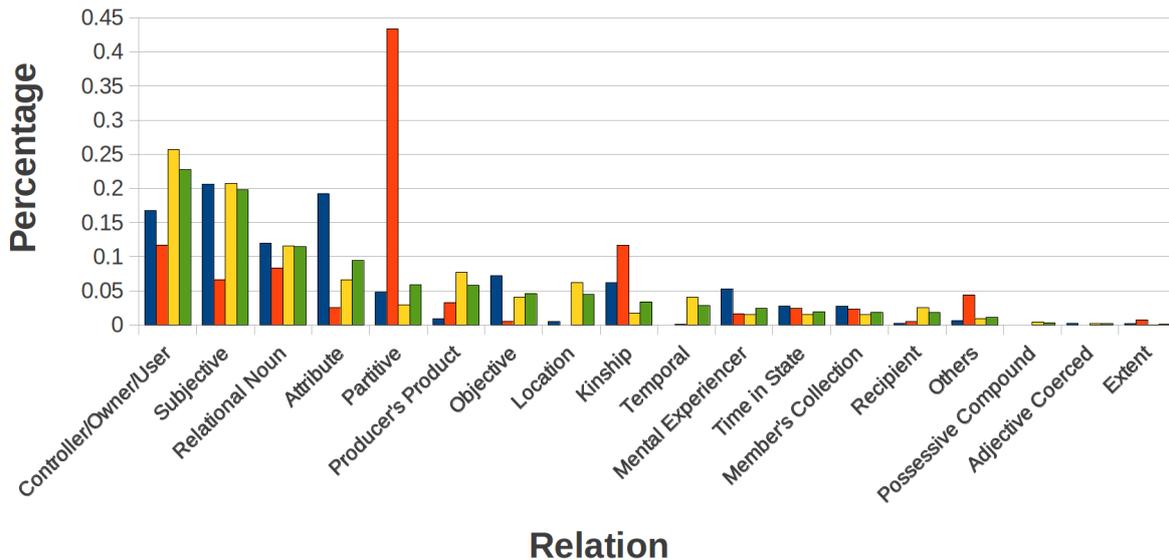

Figure 2: Semantic relation distribution for the dataset presented in this work. HDFRE: History of the Decline and Fall of the Roman Empire; JB: Jungle Book; PTB: Sections 2–21 of the Wall Street Journal portion of the Penn Treebank.

given<sup>3</sup>. Annotators were instructed not to choose a definition simply because they thought they had chosen it before or because they thought someone else had chosen it. After the revision process, all three annotators agreed in 109 cases and all three disagreed in only 6 cases. During the revision process, Annotator A made 8 changes, B made 20 changes, and C made 33 changes. Annotator A likely made the fewest changes because he, as the primary author, spent a significant amount of time thinking about, writing, and re-writing the definitions used for the various iterations. Annotator C’s annotation work tended to be less consistent in general than Annotator B’s throughout this work as well as in a different task not discussed within this paper, which probably why Annotator C made more changes than Annotator B. Prior to this revision process, the three-way Fleiss’ Kappa score was 0.60 but, afterwards, it was at 0.78. The inter-annotator agreement and entropy figures for before and after this revision process, including pairwise scores between individual annotators, are presented in Tables 5 and 6.

## 4.2 Distribution of Relations

The distribution of semantic relations varies somewhat by the data source. *The Jungle Book*’s distribution is significantly different from the oth-

<sup>3</sup>Of course, if three definitions were present, it could be inferred that all three annotators had initially disagreed.

ers, with a much larger percentage of PARTITIVE and KINSHIP relations. The Penn Treebank and *The History of the Decline and Fall of the Roman Empire* were substantially more similar, although there are notable differences. For instance, the LOCATION and TEMPORAL relations almost never occur in *The History of the Decline and Fall of the Roman Empire*. Whether these differences are due to variations in genre, time period, and/or other factors would be an interesting topic for future study. The distribution of relations for each data source is presented in Figure 2.

Though it is harder to compare across datasets using different annotation schemes, there are at least a couple notable differences between the distribution of relations for Badulescu and Moldovan’s (2009) dataset and the distribution of relations used in this work. One such difference is the much higher percentage of examples labeled as TEMPORAL—11.35% vs only 2.84% in our data. Another difference is a higher incidence of the KINSHIP relation (6.31% vs 3.39%), although it is far less frequent than it is in *The Jungle Book* (11.62%).

## 4.3 Encountered Ambiguities

One of the problems with creating a list of relations expressed by ’s-constructions is that some examples can potentially fit into multiple categories. For example, *Joe’s resentment* encodes

both SUBJECTIVE relation and MENTAL EXPERIENCER relations and *UK's cities* encodes both PARTITIVE and LOCATION relations. A representative list of these types of issues along with examples designed to illustrate them is presented in Table 7.

## 5 Experiments

For the automatic classification experiments, we set aside 10% of the data for test purposes, and used the the remaining 90% for training. We used 5-fold cross-validation performed using the training data to tweak the included feature templates and optimize training parameters.

### 5.1 Learning Approach

The LIBLINEAR (Fan et al., 2008) package was used to train linear Support Vector Machine (SVMs) for all the experiments in the one-against-the-rest style. All training parameters took their default values with the exception of the C parameter, which controls the tradeoff between margin width and training error and which was set to 0.02, the point of highest performance in the cross-validation tuning.

### 5.2 Feature Generation

For feature generation, we conflated the possessive pronouns ‘his’, ‘her’, ‘my’, and ‘your’ to ‘person.’ Similarly, every term matching the case-insensitive regular expression `(corp|col|plc|in|clag|ltd|llc)\.?` was replaced with the word ‘corporation.’

All the features used are functions of the following five words.

- The possessor word
- The possessee word
- The syntactic governor of the possessee word
- The set of words between the possessor and possessee word (e.g., *first* in *John's first kiss*)
- The word to the right of the possessee

The following feature templates are used to generate features from the above words. Many of these templates utilize information from WordNet (Fellbaum, 1998).

- WordNet link types (link type list) (e.g., attribute, hypernym, entailment)
- Lexicographer filenames (lexnames)—top level categories used in WordNet (e.g., noun.body, verb.cognition)

- Set of words from the WordNet definitions (gloss terms)
- The list of words connected via WordNet *part-of* links (part words)
- The word's text (the word itself)
- A collection of affix features (e.g., -ion, -er, -ity, -ness, -ism)
- The last {2,3} letters of the word
- List of all possible parts-of-speech in WordNet for the word
- The part-of-speech assigned by the part-of-speech tagger
- WordNet hypernyms
- WordNet synonyms
- Dependent words (all words linked as children in the parse tree)
- Dependency relation to the word's syntactic governor

### 5.3 Results

The system predicted correct labels for 1,962 of the 2,247 test examples, or 87.4%. The accuracy figures for the test instances from the Penn Treebank, *The Jungle Book*, and *The History of the Decline and Fall of the Roman Empire* were 88.8%, 84.7%, and 80.6%, respectively. The fact that the score for *The Jungle Book* was the lowest is somewhat surprising considering it contains a high percentage of body part and kinship terms, which tend to be straightforward, but this may be because the other sources comprise approximately 94% of the training examples.

Given that human agreement typically represents an upper bound on machine performance in classification tasks, the 87.4% accuracy figure may be somewhat surprising. One explanation is that the examples pulled out for the inter-annotator agreement study each had a unique *possessee* word. For example, “expectations”, as in “analyst's expectations”, occurs 26 times as the possessee in the dataset, but, for the inter-annotator agreement study, at most one of these examples could be included. More importantly, when the initial relations were being defined, the data were first sorted based upon the possessee and then the possessor in order to create blocks of similar examples. Doing this allowed multiple examples to be assigned to a category more quickly because one can decide upon a category for the whole lot at once and then just extract the few, if any, that belong to other categories. This is likely to be both faster and more consistent than examining each

Iteration	Agreement (%)			Fleiss' $\kappa$				Entropy

First Relation	Second Relation	Example
PARTITIVE	CONTROLLER/...	<i>BoA's Mr. Davis</i>
PARTITIVE	LOCATION	<i>UK's cities</i>
PARTITIVE	OBJECTIVE	<i>BoA's adviser</i>
PARTITIVE	OTHER RELATIONAL NOUN	<i>BoA's chairman</i>
PARTITIVE	PRODUCER'S PRODUCT	<i>the lamb's wool</i>
CONTROLLER/...	PRODUCER'S PRODUCT	<i>the bird's nest</i>
CONTROLLER/...	OBJECTIVE	<i>his assistant</i>
CONTROLLER/...	LOCATION	<i>Libya's oil company</i>
CONTROLLER/...	ATTRIBUTE	<i>Joe's strength</i>
CONTROLLER/...	MEMBER'S COLLECTION	<i>the colonel's unit</i>
CONTROLLER/...	RECIPIENT	<i>Joe's trophy</i>
RECIPIENT	OBJECTIVE	<i>Joe's reward</i>
SUBJECTIVE	PRODUCER'S PRODUCT	<i>Joe's announcement</i>
SUBJECTIVE	OBJECTIVE	<i>its change</i>
SUBJECTIVE	CONTROLLER/...	<i>Joe's employee</i>
SUBJECTIVE	LOCATION	<i>Libya's devolution</i>
SUBJECTIVE	MENTAL EXPERIENCER	<i>Joe's resentment</i>
OBJECTIVE	MENTAL EXPERIENCER	<i>Joe's concern</i>
OBJECTIVE	LOCATION	<i>the town's inhabitants</i>
KINSHIP	OTHER RELATIONAL NOUN	<i>his fiancée</i>

Table 7: Ambiguous/multiclass possessive examples.

example in isolation. This advantage did not exist in the inter-annotator agreement study.

#### 5.4 Feature Ablation Experiments

To evaluate the importance of the different types of features, the same experiment was re-run multiple times, each time including or excluding exactly one feature template. Before each variation, the C

parameter was retuned using 5-fold cross validation on the training data. The results for these runs are shown in Table 8.

Based upon the leave-one-out and only-one feature evaluation experiment results, it appears that the possessee word is more important to classification than the possessor word. The possessor word is still valuable though, with it likely being more

valuable for certain categories (e.g., TEMPORAL and LOCATION) than others (e.g., KINSHIP). Hypernym and gloss term features proved to be about equally valuable. Curiously, although hypernyms are commonly used as features in NLP classification tasks, gloss terms, which are rarely used for these tasks, are approximately as useful, at least in this particular context. This would be an interesting result to examine in greater detail.

## 6 Related Work

### 6.1 Linguistics

Semantic relation inventories for the English 's-construction have been around for some time; Taylor (1996) mentions a set of 6 relations enumerated by Poutsma (1914–1916). Curiously, there is not a single dominant semantic relation inventory for possessives. A representative example of semantic relation inventories for 's-constructions is the one given by Quirk et al. (1985) (presented earlier in Section 2).

Interestingly, the set of relations expressed by possessives varies by language. For example, Classical Greek permits a *standard of comparison* relation (e.g., “better than Plato”) (Nikiforidou, 1991), and, in Japanese, some relations are expressed in the opposite direction (e.g., “blue eye’s doll”) while others are not (e.g., “Tanaka’s face”) (Nishiguchi, 2009).

To explain how and why such seemingly different relations as *whole+part* and *cause+effect* are expressed by the same linguistic phenomenon, Nikiforidou (1991) pursues an approach of *metaphorical structuring* in line with the work of Lakoff and Johnson (1980) and Lakoff (1987). She thus proposes a variety of such metaphors as THINGS THAT HAPPEN (TO US) ARE (OUR) POSSESSIONS and CAUSES ARE ORIGINS to explain how the different relations expressed by possessives extend from one another.

Certainly, not all, or even most, of the linguistics literature on English possessives focuses on creating lists of semantic relations. Much of the work covering the semantics of the 's construction in English, such as Barker’s (1995) work, dwells on the split between cases of *relational* nouns, such as *sister*, that, by their very definition, hold a specific relation to other real or conceptual things, and *non-relational*, or *sortal* nouns (Löbner, 1985), such as *car*.

Vikner and Jensen’s (2002) approach for han-

dling these disparate cases is based upon Pustejovsky’s (1995) generative lexicon framework. They coerce sortal nouns (e.g., *car*) into being relational, purporting to create a uniform analysis. They split *lexical possession* into four types: *inherent*, *part-whole*, *agentive*, and *control*, with *agentive* and *control* encompassing many, if not most, of the cases involving sortal nouns.

A variety of other issues related to possessives considered by the linguistics literature include adjectival modifiers that significantly alter interpretation (e.g., *favorite* and *former*), double genitives (e.g., *book of John’s*), bare possessives (i.e., cases where the possessee is omitted, as in “Eat at Joe’s”), possessive compounds (e.g., *driver’s license*), the syntactic structure of possessives, definitiveness, changes over the course of history, and differences between languages in terms of which relations may be expressed by the genitive. Representative work includes that by Barker (1995), Taylor (1996), Heine (1997), Partee and Borschev (1998), Rosenbach (2002), and Vikner and Jensen (2002).

### 6.2 Computational Linguistics

Though the relation between nominals in the English possessive construction has received little attention from the NLP community, there is a large body of work that focuses on similar problems involving noun-noun relation interpretation/paraphrasing, including interpreting the relations between the components of noun compounds (Butnariu et al., 2010), disambiguating preposition senses (Litkowski and Hargraves, 2007), or annotating the relation between nominals in more arbitrary constructions within the same sentence (Hendrickx et al., 2009).

Whereas some of these lines of work use fixed inventories of semantic relations (Lauer, 1995; Nastase and Szpakowicz, 2003; Kim and Baldwin, 2005; Girju, 2009; Ó Séaghdha and Copestake, 2009; Tratz and Hovy, 2010), other work allows for a nearly infinite number of interpretations (Butnariu and Veale, 2008; Nakov, 2008). Recent SemEval tasks (Butnariu et al., 2009; Hendrickx et al., 2013) pursue this more open-ended strategy. In these tasks, participating systems recover the implicit predicate between the nouns in noun compounds by creating potentially unique paraphrases for each example. For instance, a system might generate the paraphrase *made of* for the noun com-

Table 8: Results for leave-one-out and only-one feature template ablation experiment results for all feature templates sorted by the only-one case. L, R, C, G, B, and N stand for *left word (possessor)*, *right word (possessee)*, *pairwise combination of outputs for possessor and possessee*, *syntactic governor of possessee*, *all tokens between possessor and possessee*, and *the word next to the possessee (on the right)*, respectively. The C parameter value used to train the SVMs is shown in parentheses.

pound *pepperoni pizza*. Computer-generated results are scored against a list of human-generated options in order to rank the participating systems. This approach could be applied to possessives interpretation as well.

Concurrent with the lack of NLP research on the subject is the absence of available annotated datasets for training, evaluation, and analysis. The NomBank project (Meyers et al., 2004) provides coarse annotations for some of the possessive constructions in the Penn Treebank, but only those that meet their criteria.

## 7 Conclusion

In this paper, we present a semantic relation inventory for 's possessives consisting of 17 relations expressed by the English 's construction, the

largest available manually-annotated collection of possessives, and an effective method for automatically assigning the relations to unseen examples. We explain our methodology for building this inventory and dataset and report a strong level of inter-annotator agreement, reaching 0.78 Kappa overall. The resulting dataset is quite large, at 21,938 instances, and crosses multiple domains, including news, fiction, and historical non-fiction. It is the only large fully-annotated publicly-available collection of possessive examples that we are aware of. The straightforward SVM-based automatic classification system achieves 87.4% accuracy—the highest automatic possessive interpretation accuracy figured reported to date. These high results suggest that SVMs are a good choice for automatic possessive interpre-

tation systems, in contrast to Moldovan and Badulescu (2005) findings. The data and software presented in this paper are available for download at <http://www.isi.edu/publications/licensed-sw/fanparser/index.html>.

## 8 Future Work

Going forward, we would like to examine the various ambiguities of possessives described in Section 4.3. Instead of trying to find the one-best interpretation for a given possessive example, we would like to produce a list of *all* appropriate interpretations.

Another avenue for future research is to study variation in possessive use across genres, including scientific and technical genres. Similarly, one could automatically process large volumes of text from various time periods to investigate changes in the use of the possessive over time.

## Acknowledgments

We would like to thank Charles Zheng and Sarah Benzel for all their annotation work and valuable feedback.

### Abstract

This paper presents novel methods for modeling *numerical common sense*: the ability to infer whether a given number (e.g., *three billion*) is large, small, or normal for a given context (e.g., *number of people facing a water shortage*). We first discuss the necessity of numerical common sense in solving textual entailment problems. We explore two approaches for acquiring numerical common sense. Both approaches start with extracting numerical expressions and their *context* from the Web. One approach estimates the distribution of numbers co-occurring within a context and examines whether a given value is large, small, or normal, based on the distribution. Another approach utilizes textual patterns with which speakers explicitly express their judgment about the value of a numerical expression. Experimental results demonstrate the effectiveness of both approaches.

### 1 Introduction

Textual entailment recognition (RTE) involves a wide range of semantic inferences to determine whether the meaning of a hypothesis sentence ( $h$ ) can be inferred from another text ( $t$ ) (Dagan et al., 2006). Although several evaluation campaigns (e.g., PASCAL/TAC RTE challenges) have made significant progress, the RTE community recognizes the necessity of a deeper understanding of the core phenomena involved in textual inference. Such recognition comes from the ideas that crucial progress may derive from decomposing the complex RTE task into basic phenomena and from solving each basic phenomenon separately (Bentivogli et al., 2010; Sammons et al., 2010; Cabrio and Magnini, 2011; Toledo et al., 2012).

Given this background, we focus on solving one of the basic phenomena in RTE: semantic inference related to numerical expressions. The specific problem we address is acquisition of *numerical common sense*. For example,

(1)  $t$  : *Before long, 3b people will face a water shortage in the world.*

$h$  : *Before long, a serious water shortage will occur in the world.*

Although recognizing the entailment relation between  $t$  and  $h$  is frustratingly difficult, we assume this inference is decomposable into three phases:

3b people face a water shortage.

$\Leftrightarrow$  3,000,000,000 people face a water shortage.

$\models$  many people face a water shortage.

$\models$  a serious water shortage.

In the first phase, it is necessary to recognize  $3b$  as a numerical expression and to resolve the expression  $3b$  into the exact amount *3,000,000,000*. The second phase is much more difficult because we need subjective but common-sense knowledge that *3,000,000,000 people* is a large number.

In this paper, we address the first and second phases of inference as an initial step towards semantic processing with numerical expressions. The contributions of this paper are four-fold.

1. We examine instances in existing RTE corpora, categorize them into groups in terms of the necessary semantic inferences, and discuss the impact of this study for solving RTE problems with numerical expressions.
2. We describe a method of normalizing numerical expressions referring to the same amount in text into a unified semantic representation.
3. We present approaches for aggregating numerical common sense from examples of numerical expressions and for judging whether a given amount is large, small, or normal.

4. We demonstrate the effectiveness of this approach, reporting experimental results and analyses in detail. Although it would be ideal to evaluate the impact of this study on the overall RTE task, we evaluate each phase separately. We do this because the existing RTE data sets tend to exhibit very diverse linguistic phenomena, and it is difficult to employ such data for evaluating the real impact of this study.

## 2 Related work

Surprisingly, NLP research has paid little attention to semantic processing of numerical expressions. This is evident when we compare with temporal expressions, for which corpora (e.g., ACE-2005<sup>1</sup>, TimeBank<sup>2</sup>) were developed with annotation schemes (e.g., TIMEX<sup>3</sup>, TimeML<sup>4</sup>).

Several studies deal with numerical expressions in the context of information extraction (Bakalov et al., 2011), information retrieval (Fontoura et al., 2006; Yoshida et al., 2010), and question answering (Moriceau, 2006). Numbers such as product prices and weights have been common targets of information extraction. Fontoura et al. (2006) and Yoshida et al. (2010) presented algorithms and data structures that allow number-range queries for searching documents. However, these studies do not interpret the quantity (e.g., *3,000,000,000*) of a numerical expression (e.g., *3b people*), but rather treat numerical expressions as strings.

Banerjee et al. (2009) focused on quantity consensus queries, in which there is uncertainty about the quantity (e.g., *weight airbus A380 pounds*). Given a query, their approach retrieves documents relevant to the query and identifies the quantities of numerical expressions in the retrieved documents. They also proposed methods for enumerating and ranking the candidates for the consensus quantity intervals. Even though our study shares a similar spirit (modeling of consensus for quantities) with Banerjee et al. (2009), their goal is different: to determine ground-truth values for queries.

In question answering, to help “sanity check” answers with numerical values that were

way out of common-sense ranges, IBM’s PI-QUANT (Prager et al., 2003; Chu-Carroll et al., 2003) used information in Cyc (Lenat, 1995). For example, their question-answering system rejects *200 miles* as a candidate answer for the *height of Mt. Everest*, since Cyc knows mountains are between 1,000 and 30,000 ft. high. They also consider the problem of variations in the precision of numbers (e.g., *5 million*, *5.1 million*, *5,200,390*) and unit conversions (e.g., *square kilometers* and *acres*).

Some recent studies delve deeper into the semantic interpretation of numerical expressions. Aramaki et al. (2007) focused on the physical size of an entity to predict the semantic relation between entities. For example, knowing that a *book* has a physical size of 20 cm × 25 cm and that a *library* has a size of 10 m × 10 m, we can estimate that a library contains a book (content-container relation). Their method acquires knowledge about entity size from the Web (by issuing queries like “*book (\*cm x \*cm)*”), and integrates the knowledge as features for the classification of relations.

Davidov and Rappoport (2010) presented a method for the extraction from the Web and approximation of numerical object attributes such as height and weight. Given an object-attribute pair, the study expands the object into a set of comparable objects and then approximates the numerical values even when no exact value can be found in a text. Aramaki et al. (2007) and Davidov and Rappoport (2010) rely on hand-crafted patterns (e.g., “*Object is \* [unit] tall*”), focusing on a specific set of numerical attributes (e.g., height, weight, size). In contrast, this study can handle any kind of target and situation that is quantified by numbers, e.g., number of people facing a water shortage.

Recently, the RTE community has started to pay some attention to the appropriate processing of numerical expressions. Iftene (2010) presented an approach for matching numerical ranges expressed by a set of phrases (e.g., *more than* and *at least*). Tsuboi et al. (2011) designed hand-crafted rules for matching intervals expressed by temporal expressions. However, these studies do not necessarily focus on semantic processing of numerical expressions; thus, these studies do not normalize units of numerical expressions nor make inferences with numerical common sense.

Sammons et al. (2010) reported that most systems submitted to RTE-5 failed on examples

<sup>1</sup><http://www.itl.nist.gov/iad/mig/tests/ace/ace05/>

<sup>2</sup><http://www.timeml.org/site/timebank/timebank.html>

<sup>3</sup><http://timex2.mitre.org/>

<sup>4</sup><http://timeml.org/site/index.html>

where numeric reasoning was necessary. They argued the importance of aligning numerical quantities and performing numerical reasoning in RTE. LoBue and Yates (2011) identified 20 categories of common-sense knowledge that are prevalent in RTE. One of the categories comprises arithmetic knowledge (including computations, comparisons, and rounding). They concluded that many kinds of the common-sense knowledge have received scarce attention from researchers even though the knowledge is essential to RTE. These studies provided a closer look at the phenomena involved in RTE, but they did not propose a solution for handling numerical expressions.

### 3 Investigation of textual-entailment pairs with numerical expressions

In this section, we investigate textual entailment (TE) pairs in existing corpora in order to study the core phenomena that establish an entailment relation. We used two Japanese TE corpora: RITE (Shima et al., 2011) and Odani et al. (2008). RITE is an evaluation workshop of textual entailment organized by NTCIR-9, and it targets the English, Japanese, and Chinese languages. We used the Japanese portions of the development and training data. Odani et al. (2008) is another Japanese corpus that was manually created. The total numbers of text-hypothesis ( $T$ - $H$ ) pairs are 1,880 (RITE) and 2,471 (Odani).

We manually selected sentence pairs in which one or both of the sentences contained a numerical expression. Here, we define the term *numerical expression* as an expression containing a number or quantity represented by a numeral and a unit. For example, *3 kilometers* is a numerical expression with the numeral *3* and the unit *kilometer*. Note that *intensity of 4* is not a numerical expression because *intensity* is not a unit.

We obtained 371 pairs from the 4,351  $T$ - $H$  pairs. We determined the inferences needed to prove ENTAILMENT or CONTRADICTION of the hypotheses, and classified the 371 pairs into 11 categories. Note that we ignored  $T$ - $H$  pairs in which numerical expressions were unnecessary to prove the entailment relation (e.g., *Socrates was sentenced to death by 500 jury members* and *Socrates was sentenced to death*). Out of 371 pairs, we identified 114 pairs in which numerical expressions played a central role in the entailment relation.

Table 1 summarizes the categories of TE phenomena we found in the data set. The largest category is *numerical matching* (32 pairs). We can infer an entailment relation in this category by aligning two numerical expressions, e.g., *2.2 million*  $\models$  *over 800 thousand*. This is the most fundamental task in numerical reasoning, interpreting the amount (number, unit, and range) in a numerical expression. We address this task in Section 4.1. The second largest category requires common sense about numerical amounts. In order to recognize textual entailment of pairs in this category, we need common-sense knowledge about humans' subjective judgment of numbers. We consider this problem in Section 5.

To summarize, this study covers 37.9% of the instances in Table 1, focusing on the first and second categories. Due to space limitations, we omit the explanations for the other phenomena, which require such things as lexical knowledge, arithmetic operations, and counting. The coverage of this study might seem small, but it is difficult to handle varied phenomena with a unified approach. We believe that this study forms the basis for investigating other phenomena of numerical expressions in the future.

### 4 Collecting numerical expressions from the Web

In this paper, we explore two approaches to acquiring numerical common sense. Both approaches start with extracting numerical expressions and their *context* from the Web. We define a *context* as the verb and its arguments that appear around a numerical expression.

For instance, the context of *3b people* in the sentence *3b people face a water shortage* is “face” and “water shortage.” In order to extract and aggregate numerical expressions in various documents, we converted the numerical expressions into semantic representations (to be described in Section 4.1), and extracted their context (to be described in Section 4.2).

The first approach for acquiring numerical common sense estimates the distribution of numbers that co-occur within a context, and examines whether a given value is large, small, or normal based on that distribution (to be described in Section 5.1). The second approach utilizes textual patterns with which speakers explicitly express their judgment about the value of a numerical ex-

Category	Definition	Example	#
Numerical matching	Aligning numerical expressions in T and H, considering differences in unit, range, etc.	<i>t</i> : It is said that there are about 2.2 million alcoholics in the whole country. <i>h</i> : It is estimated that there are over 800 thousand people who are alcoholics.	32
Numerical common sense	Inferring by interpreting the numerical amount (large or small).	<i>t</i> : In the middle of the 21st century, 7 billion people, corresponding to 70% of the global population, will face a water shortage. <i>h</i> : It is concerning that a serious water shortage will spread around the world in the near future.	12
Lexical knowledge	Inferring by using numerical aspects of word meanings.	<i>t</i> : Mr. and Ms. Sato celebrated their 25th wedding anniversary. <i>h</i> : Mr. and Ms. Sato celebrated their silver wedding anniversary.	12
Arithmetic	Arithmetic operations including addition and subtraction.	<i>t</i> : The number of 2,000-yen bills in circulation has increased to 450 million, in contrast with 440 million 5,000-yen bills. <i>h</i> : The number of 2,000-yen bills in circulation exceeds the number of 5,000-yen bills by 10 million bills.	11
Numeric-range expression of verbs	Numerical ranges expressed by verbs (e.g., <i>exceed</i> ).	<i>t</i> : It is recorded that the maximum wave height reached 13.8 meters during the Sea of Japan Earthquake Tsunami in May 1983. <i>h</i> : During the Sea of Japan Earthquake, the height of the tsunami exceeded 10 meters.	9
Simple Rewrite Rule	This includes various simple rules for rewriting.	<i>t</i> : The strength of Taro’s grip is No. 1 in his class. <i>h</i> : Taro’s grip is the strongest in his class.	7
State change	Expressing the change of a value by a multiplier or ratio.	<i>t</i> : Consumption of pickled plums is 1.5 times the rate of 20 years ago. <i>h</i> : Consumption of pickled plums has increased.	6
Ordinal numbers	Inference by interpreting ordinal numbers.	<i>t</i> : Many precious lives were sacrificed in the Third World War. <i>h</i> : So far, there have been at least three World Wars.	6
Temporal expression	Inference by interpreting temporal expressions such as anniversary, age, and ordinal numbers.	<i>t</i> : Mr. and Ms. Sato celebrate their 25th wedding anniversary. <i>h</i> : Mr. and Ms. Sato got married 25 years ago.	3
Count	Counting up the number of various entities.	<i>t</i> : In Japan, there are the Asian Triopsidae, the American Triopsidae, and the European Triopsidae. <i>h</i> : In Japan, there are 3 types of Triopsidae.	3

kilogram(s)	set-unit: ‘g’; multiply-value: 1,000
kg	set-unit: ‘g’; multiply-value: 1,000
ton(s)	set-unit: ‘g’; multiply-value: 1,000,000
nin ( <i>people</i> )	set-unit: ‘nin’ ( <i>person</i> )
about	set-modifier: ‘about’
as many as	set-modifier: ‘large’
as little as	set-modifier: ‘small’

Table 3: An example of unit/modifier dictionary

pression (to be explained in Section 5.2).

In this study, we acquired numerical common sense from a collection of 8 billion sentences in 100 million Japanese Web pages (Shinzato et al., 2012). For this reason, we originally designed text patterns specialized for Japanese dependency trees. For the sake of the readers’ understanding, this paper uses examples with English translations for explaining language-independent concepts, and both Japanese and English translations for explaining language-dependent concepts.

#### 4.1 Extracting and normalizing numerical expressions

The first step for collecting numerical expressions is to recognize when a numerical expression is mentioned and then to normalize it into a semantic representation. This is the most fundamental

step in numerical reasoning and has a number of applications. For example, this step handles cases of *numerical matching*, as in Table 1.

The semantic representation of a numerical expression consists of three fields: the value or range of the real number(s)<sup>5</sup>, the unit (a string), and the optional modifiers. Table 2 shows some examples of numerical expressions and their semantic representations. During normalization, we identified spelling variants (e.g., *kilometer* and *km*) and transformed auxiliary units into their corresponding canonical units (e.g., *2 tons* and *2,000 kg* to *2,000,000 grams*). When a numerical expression is accompanied by a modifier such as *over*, *about*, or *more than*, we updated the value and modifier fields appropriately.

<sup>5</sup>Internally, all values are represented by ranges (e.g., 75 is represented by the range [75, 75]).

We developed an extractor and a normalizer for Japanese numerical expressions<sup>6</sup>. We will outline the algorithm used in the normalizer with an example sentence: “Roughly three thousand kilograms of meats have been provided every day.”

1. Find numbers in the text by using regular expressions and convert the non-Arabic numbers into their corresponding Arabic numbers. For example, we find *three thousand*<sup>7</sup> and represent it as 3,000.
2. Check whether the words that precede or follow the number are units that are registered in the dictionary. Transform any auxiliary units. In the example, we find that *kilograms*<sup>8</sup> is a unit. We multiply the value 3,000 by 1,000, and obtain the value 3,000,000 with the unit *g*.
3. Check whether the words that precede or follow the number have a modifier that is registered in the dictionary. Update the value and modifier fields if necessary. In the example, we find *roughly* and set *about* in the modifier field.

We used a dictionary<sup>9</sup> to perform procedures 2 and 3 (Table 3). If the words that precede or follow an extracted number match an entry in the dictionary, we change the semantic representation as described in the operation.

The modifiers ‘large’ and ‘small’ require elaboration because the method in Section 5.2 relies heavily on these modifiers. We activated the modifier ‘large’ when a numerical expression occurred with the Japanese word *mo*, which roughly corresponds to *as many as*, *as large as*, or *as heavy as* in English<sup>10</sup>. Similarly, we activated the modifier ‘small’ when a numerical expression occurred with the word *shika*, which roughly corresponds to *as little as*, *as small as*, or *as light as*<sup>11</sup>. These modifiers are important for this study, reflecting the writer’s judgment about the amount.

<sup>6</sup>The software is available at <http://www.cl.ecei.tohoku.ac.jp/~katsuma/software/normalizeNumexp/>

<sup>7</sup>In Japanese 3,000 is denoted by the Chinese symbols “三千”.

<sup>8</sup>We write kilograms as “キログラム” in Japanese.

<sup>9</sup>The dictionary is bundled with the tool. See Footnote 6.

<sup>10</sup>In Japanese, we can use the word *mo* with a numerical expression to state that the amount is ‘large’ regardless of how large it is (e.g., large, big, many, heavy).

<sup>11</sup>Similarly, we can use the word *shika* with any adjective.

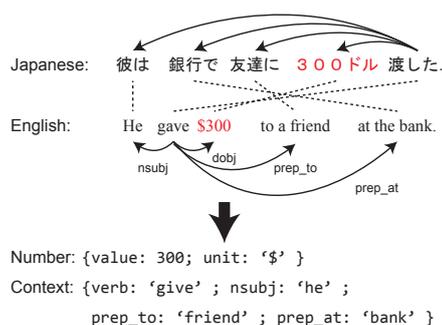

Figure 1: Example of context extraction

## 4.2 Extraction of context

The next step in acquiring numerical common sense is to capture the context of numerical expressions. Later, we will aggregate numbers that share the same context (see Section 5). The context of a numerical expression should provide sufficient information to determine what it measures. For example, given the sentence, “He gave \$300 to a friend at the bank,” it would be better if we could generalize the context to *someone gives money to a friend* for the numerical expression \$300. However, it is a nontrivial task to design an appropriate representation of varying contexts. For this reason, we employ a simple rule to capture the context of numerical expressions: we represent the context with the verb that governs the numerical expression and its typed arguments.

Figure 1 illustrates the procedure for extracting the context of a numerical expression<sup>12</sup>. The component in Section 4.1 recognizes \$300 as a numerical expression, then normalizes it into a semantic representation. Because the numerical expression is a dependent of the verb *gave*, we extract the verb and its arguments (except for the numerical expression itself) as the context. After removing inflections and function words from the arguments, we obtain the context representation of Figure 1.

## 5 Acquiring numerical common sense

In this section, we present two approaches for acquiring numerical common sense from a collection of numerical expressions and their contexts. Both approaches start with collecting the numbers (in semantic representation) and contexts of numerical expressions from a large number of sentences (Shinzato et al., 2012), and storing them

<sup>12</sup>The English dependency tree might look peculiar because it is translated from the Japanese dependency tree.

in a database. When a context and a value are given for a prediction (hereinafter called the query context and query value, respectively), these approaches judge whether the query value is large, small, or normal.

### 5.1 Distribution-based approach

Given a query context and query value, this approach retrieves numbers associated with the query context and draws a distribution of normalized numbers. This approach considers the distribution estimated for the query context and determines if the value is within the top 5 percent (large), within the bottom 5 percent (small), or is located in between these regions (normal).

The underlying assumption of this approach is that the real distribution of a query (e.g., *money given to a friend*) can be approximated by the distribution of numbers co-occurring with the context (e.g., *give* and *friend*) on the Web. However, the context space generated in Section 4.2 may be too sparse to find numbers in the database, especially when a query context is fine-grained. Therefore, when no item is retrieved for the query context, we employ a backoff strategy to drop some of the uninformative elements in the query context: elements are dropped from the context based on the type of argument, in this order: *he* (prep\_to), *kara* (prep\_from), *ha* (nsubj), *yoru* (prep\_from), *made* (prep\_to), *nite* (prep\_at), *de* (prep\_at, prep\_by), *ni* (prep\_at), *wo* (doobj), *ga* (nsubj), and verb.

### 5.2 Clue-based approach

This approach utilizes textual clues with which a speaker explicitly expresses his or her judgment about the amount of a numerical expression. We utilize large and small modifiers (described in Section 4.1), which correspond to textual clues *mo* (*as many as*, *as large as*) and *shika* (*only*, *as few as*), respectively, for detecting humans' judgments. For example, we can guess that \$300 is large if we find an evidential sentence<sup>13</sup>, *He gave as much as \$100 to a friend*.

Similarly to the distribution-based approach, this approach retrieves numbers associated with the query context. This approach computes the

<sup>13</sup>Although the sentence states a judgment about \$100, we can infer that \$300 is also large because \$300 > \$100.

largeness  $L(x)$  of a value  $x$ :

$$L(x) = \frac{p_l(x)}{p_s(x) + p_l(x)}, \quad (1)$$

$$p_l(x) = \frac{|\{r|r_v < x \wedge r_m \ni large\}|}{|\{r|r_m \ni large\}|}, \quad (2)$$

$$p_s(x) = \frac{|\{r|r_v > x \wedge r_m \ni small\}|}{|\{r|r_m \ni small\}|}. \quad (3)$$

In these equations,  $r$  denotes a retrieved item for the query context, and  $r_v$  and  $r_m$  represent the normalized value and modifier flags, respectively, of the item  $r$ . The numerator of Equation 2 counts the number of numerical expressions that support the judgment that  $x$  is large<sup>14</sup>, and its denominator counts the total number of numerical expressions with *large* as a modifier. Therefore,  $p_l(x)$  computes the ratio of times there is textual evidence that says that  $x$  is large, to the total number of times there is evidences with *large* as a modifier. In an analogous way,  $p_s(x)$  is defined to be the ratio for evidence that says  $x$  is small. Hence,  $L(x)$  approaches 1 if everyone on the Web claims that  $x$  is large, and approaches 0 if everyone claims that  $x$  is small. This approach predicts *large* if  $L(x) > 0.95$ , *small* if  $L(x) < 0.05$ , and *normal* otherwise.

## 6 Experiments

### 6.1 Normalizing numerical expressions

We evaluated the method that we described in Section 4.1 for extracting and normalizing numerical expressions. In order to prepare a gold-standard data set, we obtained 1,041 sentences by randomly sampling about 1% of the sentences containing numbers (Arabic digits and/or Chinese numerical characters) in a Japanese Web corpus (100 million pages) (Shinzato et al., 2012). For every numerical expression in these sentences, we manually determined a tuple of the normalized value, unit, and modifier. Here, non-numerical expressions such as temporal expressions, telephone numbers, and postal addresses, which were very common, were beyond the scope of the project<sup>15</sup>. We obtained 329 numerical expressions from the 1,041 sentences.

We evaluated the correctness of the extraction and normalization by measuring the precision and

<sup>14</sup>This corresponds to the events where we find an evidence expression "as many as  $r_v$ ", where  $r_v < x$ .

<sup>15</sup>If a tuple was extracted from a non-numerical expression, we regarded this as a false positive

recall using the gold-standard data set<sup>16</sup>. Our method performed with a precision of 0.78 and a recall of 0.92. Most of the false negatives were caused by the incompleteness of the unit dictionary. For example, the proposed method could not identify *1Ghz* as a numerical expression because the unit dictionary did not register *Ghz* but *GHz*. It is trivial to improve the recall of the method by enriching the unit dictionary.

The major cause of false positives was the semantic ambiguity of expressions. For example, the proposed method identified *Seven Hills* as a numerical expression although it denotes a location name. In order to reduce false positives, it may be necessary to utilize broader contexts when locating numerical expressions; this could be done by using, for example, a named entity recognizer. This is the next step to pursue in future work.

However, these errors do not have a large effect on the estimation of the distribution of the numerical values that occur with specific named entities and idiomatic phrases. Moreover, as explained in Section 5, we draw distributions for fine-grained contexts of numerical expressions. For these reasons, we think that the current performance is sufficient for acquiring numerical common sense.

## 6.2 Acquisition of numerical common sense

### 6.2.1 Preparing an evaluation set

We built a gold-standard data set for numerical common sense. We applied the method in Section 4.1 to sentences sampled at random from the Japanese Web corpus (Shinzato et al., 2012), and we extracted 2,000 numerical expressions. We asked three human judges to annotate every numerical expression with one of six labels, *small*, *relatively small*, *normal*, *relatively large*, *large*, and *unsure*. The label *relatively small* could be applied to a numerical expression when the judge felt that the amount was rather small (below the normal) but hesitated to label it *small*. The label *relatively large* was defined analogously. We gave the following criteria for labeling an item as *unsure*: when the judgment was highly dependent on the context; when the sentence was incomprehensible; and when it was a non-numerical expressions (false positives of the method are discussed in Section 4.1).

Table 4 reports the inter-annotator agreement.

<sup>16</sup>All fields (value, unit, modifier) of the extracted tuple must match the gold-standard data set.

Agreement	# expressions
3 annotators	735 (36.7%)
2 annotators	963 (48.2%)
no agreement	302 (15.1%)
Total	2000 (100.0%)

Table 4: Inter-annotator agreement

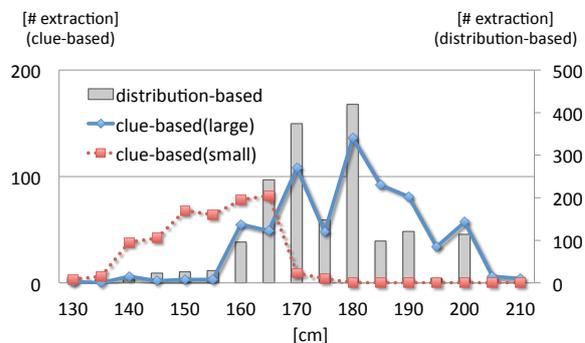

Figure 2: Distributions of numbers with large and small modifiers for the context *human's height*.

For the evaluation of numerical expressions in the data set, we used those for which at least two annotators assigned the same label. After removing the *unsure* instances, we obtained 640 numerical expressions (20 *small*, 35 *relatively small*, 152 *normal*, 263 *relatively large*, and 170 *large*) as the evaluation set.

### 6.2.2 Results

The proposed method extracted about 23 million pairs of numerical expressions and their context from the corpus (with 100 million Web pages). About 15% of the extracted pairs were accompanied by either a large or small modifier. Figure 2 depicts the distributions of the context *human's height* produced by the distribution-based and clue-based approaches. These distributions are quite reasonable as common-sense knowledge: we can interpret that numbers under 150 cm are perceived as small and those above 180 cm as large.

We measured the correctness of the proposed methods on the gold-standard data. For this evaluation, we employed two criteria for correctness: strict and lenient. With the strict criterion, the method must predict a label identical to that in the gold-standard. With the lenient criterion, the method was also allowed to predict either *large/small* or *normal* when the gold-standard label was *relatively large/small*.

Table 5 reports the precision (P), recall (R), F1 (F1), and accuracy (Acc) of the proposed methods.

No.	System	Gold	Sentence	Remark
1	small	small	I think that <u>three men</u> can create such a great thing in the world.	Correct
2	normal	normal	I have <u>two cats</u> .	Correct
3	large	large	It's <u>above 32 centigrade</u> .	Correct
4	large	large	I earned <u>10 million yen</u> from horse racing.	Correct
5	small	normal	There are <u>2 reasons</u> .	<i>Difficulty in judging small.</i> Since a few people say, "There are only 2 reasons," our approach predicted a <i>small</i> label.
6	small	large	Ten or more people came, and my eight-mat room was packed.	<i>Difficulty in modeling the context</i> because this sentence omits the locational argument for the verb <i>came</i> . We should extract the context as <i>the number of people who came to my eight-mat room</i> instead of <i>the number of people who came</i> .
7	small	normal	I have <u>two friends</u> who have broken up with their boyfriends recently.	<i>Difficulty in modeling the context.</i> We should extract context as <i>the number of friends who have broken up with their boyfriends recently</i> instead of <i>the number of friends</i> .
8	small	large		<i>Lack of knowledge.</i> We extract the context as <i>the number of heads of a turtle</i> , but no corresponding information was found on the Web.

Table 6: Output example and error analysis. We present translations of the sentences, which were originally in Japanese.

Approach	Label	P	R	F1	Acc
Distribution	large+	0.892	0.498	0.695	0.760
	normal+	0.753	0.935	0.844	
	small+	0.273	0.250	0.262	
Distribution	large	0.861	0.365	0.613	0.590
	normal	0.529	0.908	0.719	
	small	0.222	0.100	0.161	
Clue	large+	0.923	0.778	0.851	0.770
	normal+	0.814	0.765	0.790	
	small+	0.228	0.700	0.464	
Clue	large	0.896	0.659	0.778	0.620
	normal	0.593	0.586	0.590	
	small	0.164	0.550	0.357	

Table 5: Precision (P), recall (R), F1 score (F1), and accuracy (Acc) of the acquisition of numerical common sense.

Labels with the suffix ‘+’ correspond to the lenient criterion. The clue-based approach achieved 0.851 F1 (for large), 0.790 F1 (for normal), and 0.464 (for small) with the lenient criterion. The performance is surprisingly good, considering the subjective nature of this task.

The clue-based approach was slightly better than the distribution-based approach. In particular, the clue-based approach is good at predicting large and small labels, whereas the distribution-based approach is good at predicting normal labels. We found some targets for which the distribution on the Web is skewed from the ‘real’ distribution. For example, let us consider the distribution of the context “*the amount of money that a person wins in a lottery*”. We can find a number of sentences like *if you won the 10-million-dollar lottery, ...*. In other words, people talk about a large amount of money even if they did not win any money at all. In order to remedy this problem,

we may need to enrich the context representation by introducing, for example, the factuality of an event.

### 6.2.3 Discussion

Table 6 shows some examples of predictions from the clue-based approach. Because of space limitations, we mention only the false instances of this approach.

The clue-based approach tends to predict *small* even if the gold-standard label is *normal*. About half of the errors of the clue-based approach were of this type; this is why the precision for *small* and the recall for *normal* are low. The cause of this error is exemplified by the sentence, “there are two reasons.” Human judges label *normal* to the numerical expression *two reasons*, but the method predicts *small*. This is because a few people say *there are only two reasons*, but no one says *there are as many as two reasons*. In order to handle these cases, we may need to incorporate the distribution information with the clue-based approach.

We found a number of examples for which modeling the context is difficult. Our approach represents the context of a numerical expression with the verb that governs the numerical expression and its typed arguments. However, this approach sometimes misses important information, especially when an argument of the verb is omitted (Example 6). The approach also suffers from the relative clause in Example 7, which conveys an essential context of the number. These are similar to the scope-ambiguity problem such as encoun-

tered with negation and quantification; it is difficult to model the scope when a numerical expression refers to a situation.

Furthermore, we encountered some false examples even when we were able to precisely model the context. In Example 8, the proposed method was unable to predict the label correctly because no corresponding information was found on the Web. The proposed method might more easily predict a label if we could generalize the word *turtle* as *animal*. It may be worth considering using language resources (e.g., WordNet) to generalize the context.

## 7 Conclusions

We proposed novel approaches for acquiring numerical common sense from a collection of texts. The approaches collect numerical expressions and their contexts from the Web, and acquire numerical common sense by considering the distributions of normalized numbers and textual clues such as *mo (as many as) and shika (only, as few as)*. The experimental results showed that our approaches can successfully judge whether a given amount is large, small, or normal. The implementations and data sets used in this study are available on the Web<sup>17</sup>. We believe that acquisition of numerical common sense is an important step towards a deeper understanding of inferences with numbers.

There are three important future directions for this research. One is to explore a more sophisticated approach for precisely modeling the contexts of numbers. Because we confirmed in this paper that these two approaches have different characteristics, it would be interesting to incorporate textual clues into the distribution-based approach by using, for example, machine learning techniques. Finally, we are planning to address the ‘third phase’ of the example explained in Section 1: associating *many people face a water shortage with a serious water shortage*.

## Abstract

Generative probabilistic models have been used for content modelling and template induction, and are typically trained on small corpora in the target domain. In contrast, vector space models of distributional semantics are trained on large corpora, but are typically applied to domain-general lexical disambiguation tasks. We introduce Distributional Semantic Hidden Markov Models, a novel variant of a hidden Markov model that integrates these two approaches by incorporating contextualized distributional semantic vectors into a generative model as observed emissions. Experiments in slot induction show that our approach yields improvements in learning coherent entity clusters in a domain. In a subsequent extrinsic evaluation, we show that these improvements are also reflected in multi-document summarization.

## 1 Introduction

Detailed domain knowledge is crucial to many NLP tasks, either as an input for language understanding, or as the goal itself, to acquire such knowledge. For example, in information extraction, a list of slots in the target domain is given to the system, and in natural language generation, content models are trained to learn the content structure of texts in the target domain for information structuring and automatic summarization.

Generative probabilistic models have been one popular approach to content modelling. An important advantage of this approach is that the structure of the model can be adapted to fit the assumptions about the structure of the domain and the nature of the end task. As this field has progressed, the formal structures that are assumed to represent a

domain have increased in complexity and become more hierarchical. Earlier work assumes a flat set of topics (Barzilay and Lee, 2004), which are expressed as states of a latent random variable in the model. Later work organizes topics into a hierarchy from general to specific (Haghighi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tur, 2010). Recently, Cheung et al. (2013) formalized a domain as a set of *frames* consisting of prototypical sequences of *events*, *slots*, and *slot fillers* or *entities*, inspired by classical AI work such as Schank and Abelson's (1977) scripts. We adopt much of this terminology in this work. For example, in the CRIMINAL INVESTIGATIONS domain, there may be events such as a murder, an investigation of the crime, an arrest, and a trial. These would be indicated by *event heads* such as *kill*, *arrest*, *charge*, *plead*. Relevant slots would include VICTIM, SUSPECT, AUTHORITIES, PLEA, etc.

One problem faced by this line of work is that, by their nature, these models are typically trained on a small corpus from the target domain, on the order of hundreds of documents. The small size of the training corpus makes it difficult to estimate reliable statistics, especially for more powerful features such as higher-order N-gram features or syntactic features.

By contrast, distributional semantic models are trained on large, domain-general corpora. These methods model word meaning using the contexts in the training corpus in which the word appears. The most popular approach today is a vector space representation, in which each dimension corresponds to some context word, and the value at that dimension corresponds to the strength of the association between the context word and the target word being modelled. A notion of word similarity arises naturally from these models by comparing the similarity of the word vectors, for example by using a cosine measure. Recently, these models have been extended by considering how distribu-

tional representations can be modified depending on the specific context in which the word appears (Mitchell and Lapata, 2008, for example). Contextualization has been found to improve performance in tasks like lexical substitution and word sense disambiguation (Thater et al., 2011).

In this paper, we propose to inject contextualized distributional semantic vectors into generative probabilistic models, in order to combine their complementary strengths for domain modelling. There are a number of potential advantages that distributional semantic models offer. First, they provide domain-general representations of word meaning that cannot be reliably estimated from the small target-domain corpora on which probabilistic models are trained. Second, the contextualization process allows the semantic vectors to implicitly encode disambiguated word sense and syntactic information, without further adding to the complexity of the generative model.

Our model, the Distributional Semantic Hidden Markov Model (DSHMM), incorporates contextualized distributional semantic vectors into a generative probabilistic model as observed emissions. We demonstrate the effectiveness of our model in two domain modelling tasks. First, we apply it to slot induction on guided summarization data over five different domains. We show that our model outperforms a baseline version of our method that does not use distributional semantic vectors, as well as a recent state-of-the-art template induction method. Then, we perform an extrinsic evaluation using multi-document summarization, wherein we show that our model is able to learn event and slot topics that are appropriate to include in a summary. From a modelling perspective, these results show that probabilistic models for content modelling and template induction benefit from distributional semantics trained on a much larger corpus. From the perspective of distributional semantics, this work broadens the variety of problems to which distributional semantics can be applied, and proposes methods to perform inference in a probabilistic setting beyond geometric measures such as cosine similarity.

## 2 Related Work

Probabilistic content models were proposed by Barzilay and Lee (2004), and related models have since become popular for summarization (Fung and Ngai, 2006; Haghghi and Vanderwende,

2009), and information ordering (Elsner et al., 2007; Louis and Nenkova, 2012). Other related generative models include topic models and structured versions thereof (Blei et al., 2003; Gruber et al., 2007; Wallach, 2008). In terms of domain learning in the form of template induction, heuristic methods involving multiple clustering steps have been proposed (Filatova et al., 2006; Chambers and Jurafsky, 2011). Most recently, Cheung et al. (2013) propose PROFINDER, a probabilistic model for frame induction inspired by content models. Our work is similar in that we assume much of the same structure within a domain and consequently in the model as well (Section 3), but whereas PROFINDER focuses on finding the “correct” number of frames, events, and slots with a nonparametric method, this work focuses on integrating global knowledge in the form of distributional semantics into a probabilistic model. We adopt one of their evaluation procedures and use it to compare with PROFINDER in Section 5.

Vector space models form the basis of modern information retrieval (Salton et al., 1975), but only recently have distributional models been proposed that are compositional (Mitchell and Lapata, 2008; Clark et al., 2008; Grefenstette and Sadrzadeh, 2011, *inter alia*), or that contextualize the meaning of a word using other words in the same phrase (*co-compositionality*) (Erk and Padó, 2008; Dinu and Lapata, 2010; Thater et al., 2011). We recently showed how such models can be evaluated for their ability to support semantic inference for use in complex NLP tasks like question answering or automatic summarization (Cheung and Penn, 2012).

Combining distributional information and probabilistic models has actually been explored in previous work. Usually, an ad-hoc clustering step precedes training and is used to bias the initialization of the probabilistic model (Barzilay and Lee, 2004; Louis and Nenkova, 2012), or the clustering is interleaved with iterations of training (Fung et al., 2003). By contrast, our method better modularizes the two, and provides a principled way to train the model. More importantly, previous ad-hoc clustering methods only use distributional information derived from the target domain itself; initializing based on domain-general distributional information can be problematic because it can bias training towards a local optimum that is inappropriate for the target domain, leading to poor per-

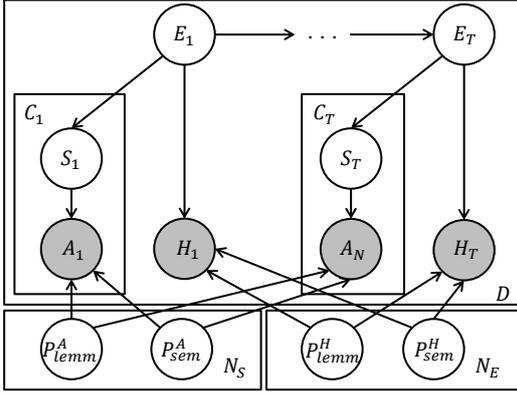

Figure 1: Graphical representation of our model. Distributions that generate the latent variables and hyperparameters are omitted for clarity.

formance.

### 3 Distributional Semantic Hidden Markov Models

We now describe the DSHMM model. This model can be thought of as an HMM with two layers of latent variables, representing events and slots in the domain. Given a document consisting of a sequence of  $T$  clauses headed by propositional heads  $\vec{H}$  (verbs or event nouns), and argument noun phrases  $\vec{A}$ , a DSHMM models the joint probability of observations  $\vec{H}$ ,  $\vec{A}$ , and latent random variables  $\vec{E}$  and  $\vec{S}$  representing domain events and slots respectively; i.e.,  $P(\vec{H}, \vec{A}, \vec{E}, \vec{S})$ .

The basic structure of our model is similar to PROFINDER. Each timestep in the model generates one clause in the document. More specifically, it generates the event heads and arguments which are crucial in identifying events and slots. We assume that event heads are verbs or event nouns, while arguments are the head words of their syntactically dependent noun phrases. We also assume that the sequence of clauses and the clause-internal syntactic structure are fixed, for example by applying a dependency parser. Within each clause, a hierarchy of latent and observed variables maps to corresponding elements in the clause (Table 1), as follows:

**Event Variables** At the top-level, a categorical latent variable  $E_t$  with  $N_E$  possible states represents the event that is described by clause  $t$ . Its value is conditioned on the previous time step’s event variable, following the standard, first-order Markov assumption ( $P^E(E_t|E_{t-1})$ , or  $P_{init}^E(E_1)$

Node	Component	Textual unit
$E_t$	Event	Clause
$S_{ta}$	Slot	Noun phrase
$H_t$	Event head	Verb/event noun
$A_{ta}$	Event argument	Noun phrase

Table 1: The correspondence between nodes in our graphical model, the domain components that they model, and the related elements in the clause.

for the first clause). The internal structure of the clause is generated by conditioning on the state of  $E_t$ , including the head of the clause, and the slots for each argument in the clause.

**Slot Variables** Categorical latent variables with  $N_S$  possible states represent the slot that an argument fills, and are conditioned on the event variable in the clause,  $E_t$  (i.e.,  $P^S(S_{ta}|E_t)$ , for the  $a$ th slot variable). The state of  $S_{ta}$  is then used to generate an argument  $A_{ta}$ .

**Head and Argument Emissions** The head of the clause  $H_t$  is conditionally dependent on  $E_t$ , and each argument  $A_{ta}$  is likewise conditioned on its slot variable  $S_{ta}$ . Unlike in most applications of HMMs in text processing, in which the representation of a token is simply its word or lemma identity, tokens in DSHMM are also associated with a vector representation of their meaning *in context* according to a distributional semantic model (Section 3.1). Thus, the emissions can be decomposed into pairs  $H_t = (\text{lemma}(H_t), \text{sem}(H_t))$  and  $A_{ta} = (\text{lemma}(A_{ta}), \text{sem}(A_{ta}))$ , where *lemma* and *sem* are functions that return the lemma identity and the semantic vector respectively. The probability of the head of a clause is thus:

$$P^H(H_t|E_t) = P_{lemm}^H(\text{lemma}(H_t)|E_t) \quad (1) \\ \times P_{sem}^H(\text{sem}(H_t)|E_t),$$

and the probability of a clausal argument is likewise:

$$P^A(A_{ta}|S_{ta}) = P_{lemm}^A(\text{lemma}(A_{ta})|S_{ta}) \quad (2) \\ \times P_{sem}^A(\text{sem}(A_{ta})|S_{ta}).$$

All categorical distributions are smoothed using add- $\delta$  smoothing (i.e., uniform Dirichlet priors). Based on the independence assumptions described above, the joint probability distribution can be fac-

tored into:

$$\begin{aligned}
P(\vec{H}, \vec{A}, \vec{E}, \vec{S}) &= P_{init}^E(E_1) \\
&\times \prod_{t=2}^T P^E(E_t|E_{t-1}) \prod_{t=1}^T P^H(H_t|E_t) \\
&\times \prod_{t=1}^T \prod_{a=1}^{C_t} P^S(S_{ta}|E_t) P^A(A_{ta}|S_{ta}).
\end{aligned} \quad (3)$$

### 3.1 Vector Space Models of Semantics

In this section, we describe several methods for producing the semantic vectors associated with each event head or argument; i.e., the function *sem*. We chose several simple, but widely studied models, to investigate whether they can be effectively integrated into DSHMM. We start with a description of the training of a basic model without any contextualization, then describe several contextualized models based on recent work.

**Simple Vector Space Model** In the basic version of the model (SIMPLE), we train a term-context matrix, where rows correspond to target words, and columns correspond to context words. Training begins by counting context words that appear within five words of the target word, ignoring stopwords. We then convert the raw counts to positive pointwise mutual information scores, which has been shown to improve word similarity correlation results (Turney and Pantel, 2010). We set thresholds on the frequencies of words for inclusion as target and context words (given in Section 4). Target words which fall below the threshold are modelled as *UNK*. All the methods below start from this basic vector representation.

**Component-wise Operators** Mitchell and Lapata (2008) investigate using component-wise operators to combine the vectors of verbs and their intransitive subjects. We use component-wise operators to contextualize our vectors, but by combining with all of the arguments, and regardless of the event head’s category. Let event head  $h$  be the syntactic head of a number of arguments  $a_1, a_2, \dots, a_m$ , and  $\vec{v}_h, \vec{v}_{a_1}, \vec{v}_{a_2}, \dots, \vec{v}_{a_m}$  be their respective vector representations according to the SIMPLE method. Then, their contextualized vectors  $\vec{c}_h^{M\&L}, \vec{c}_{a_1}^{M\&L}, \dots, \vec{c}_{a_m}^{M\&L}$  would be:

$$\vec{c}_h^{M\&L} = \vec{v}_h \odot \left( \bigodot_{i=1}^m \vec{v}_{a_i} \right) \quad (4)$$

$$\vec{c}_{a_i}^{M\&L} = \vec{v}_{a_i} \odot \vec{v}_h, \forall i = 1 \dots m, \quad (5)$$

where  $\odot$  represents a component-wise operator, addition or multiplication, and  $\bigodot$  represents its repeated application. We tested component-wise addition (M&L+) and multiplication (M&L $\times$ ).

**Selectional Preferences** Erk and Padó (2008) (E&P) incorporate *inverse selectional preferences* into their contextualization function. The intuition is that a word should be contextualized such that its vector representation becomes more similar to the vectors of other words that its dependency neighbours often take in the same syntactic position. For example, suppose *catch* is the head of the noun *ball*, in the relation of a direct object. Then, the vector for *ball* would be contextualized to become similar to the vectors for other frequent direct objects of *catch*, such as *baseball*, or *cold*. Likewise, the vector for *catch* would be contextualized to become similar to the vectors for *throw*, *hit*, etc. Formally, let  $h$  take  $a$  as its argument in relation  $r$ . Then:

$$\vec{c}_h^{E\&P} = \vec{v}_h \times \prod_{i=1}^m \sum_{w \in \mathcal{L}} freq(w, r, a_i) \cdot \vec{v}_w, \quad (6)$$

$$\vec{c}_a^{E\&P} = \vec{v}_a \times \sum_{w \in \mathcal{L}} freq(h, r, w) \cdot \vec{v}_w, \quad (7)$$

where  $freq(h, r, a)$  is the frequency of  $h$  occurring as the head of  $a$  in relation  $r$  in the training corpus,  $\mathcal{L}$  is the lexicon, and  $\times$  represents component-wise multiplication.

### Dimensionality Reduction and Vector Emission

After contextualization, we apply singular value decomposition (SVD) for dimensionality reduction to reduce the number of model parameters, keeping the  $k$  most significant singular values and vectors. In particular, we apply SVD to the  $m$ -by- $n$  term-context matrix  $M$  produced by the SIMPLE method, resulting in the truncated matrices  $M \approx U_k \Sigma_k V_k^T$ , where  $U_k$  is a  $m$ -by- $k$  matrix,  $\Sigma_k$  is  $k$ -by- $k$ , and  $V_k$  is  $n$ -by- $k$ . This takes place after contextualization, so the component-wise operators apply in the original semantic space. Afterwards, the contextualized vector in the original space,  $\vec{c}$ , can be transformed into a vector in the reduced space,  $\vec{c}^R$ , by  $\vec{c}^R = \Sigma_k^{-1} V_k^T \vec{c}$ .

Distributional semantic vectors are traditionally compared by measures which ignore vector magnitudes, such as cosine similarity, but a multivariate Gaussian is sensitive to magnitudes. Thus, the final step is to normalize  $\vec{c}^R$  into a unit vector by dividing it by its L2 norm,  $\|\vec{c}^R\|$ .

We model the emission of these contextualized vectors in DSHMM as multivariate Gaussian distributions, so the semantic vector emissions can be written as  $P_{sem}^H, P_{sem}^A \sim \mathcal{N}(\mu, \Sigma)$ , where  $\mu \in \mathbb{R}^k$  is the mean and  $\Sigma \in \mathbb{R}^{k \times k}$  is the covariance matrix. To avoid overfitting, we regularize the covariance using its conjugate prior, the Inverse-Wishart distribution. We follow the “neutral” setting of hyperparameters given by Ornoneit and Tresp (1995), so that the MAP estimate for the covariance matrix for (event or slot) state  $i$  becomes:

$$\Sigma_i = \frac{\sum_j r_{ij}(x_j - \mu_i)(x_j - \mu_i)^T + \beta I}{\sum_j r_{ij} + 1}, \quad (8)$$

where  $j$  indexes all the relevant semantic vectors  $x_j$  in the training set,  $r_{ij}$  is the posterior responsibility of state  $i$  for vector  $x_j$ , and  $\beta$  is the remaining hyperparameter that we tune to adjust the amount of regularization. To further reduce model complexity, we set the off-diagonal entries of the resulting covariance matrix to zero.

### 3.2 Training and Inference

Inference in DSHMM is accomplished by the standard Inside-Outside and tree-Viterbi algorithms, except that the tree structure is fixed, so there is no need to sum over all possible subtrees. Model parameters are learned by the Expectation-Maximization (EM) algorithm. We tune the hyperparameters  $(N_E, N_S, \delta, \beta, k)$  and the number of EM iterations by two-fold cross-validation<sup>1</sup>.

### 3.3 Summary and Generative Process

In summary, the following steps are applied to train a DSHMM:

1. Train a distributional semantic model on a large, domain-general corpus.
2. Preprocess and generate contextualized vectors of event heads and arguments in the small corpus in the target domain.
3. Train the DSHMM using the EM algorithm.

The formal generative process is as follows:

1. Draw categorical distributions  $P_{init}^E$ ;  $P^E, P^S, P_{lemm}^H$  (one per event state);  $P_{lemm}^A$  (one per slot state) from Dirichlet priors.
2. Draw multivariate Gaussians  $P_{sem}^H, P_{sem}^A$  for each event and slot state, respectively.

<sup>1</sup>The topic cluster splits and the hyperparameter settings are available at <http://www.cs.toronto.edu/~jcheung/dshmm/dshmm.html>.

3. Generate the documents, clause by clause.

Generating a clause at position  $t$  consists of these steps:

1. Generate the event state  $E_t \sim P^E$  (or  $P_{init}^E$ ).
2. Generate the event head components  $lemm(H_t) \sim P_{lemm}^H, sem(H_t) \sim P_{sem}^H$ .
3. Generate a number of slot states  $S_{ta} \sim P^S$ .
4. For each slot, generate the argument components  $lemm(A_{ta}) \sim P_{lemm}^A, sem(A_{ta}) \sim P_{sem}^A$ .

## 4 Experiments

We trained the distributional semantic models using the Annotated Gigaword corpus (Napoles et al., 2012), which has been automatically preprocessed and is based on Gigaword 5th edition. This corpus contains almost ten million news articles and more than 4 billion tokens. We used those articles marked as “stories” — the vast majority of them. We modelled the 50,000 most common lemmata as target words, and the 3,000 most common lemmata as context words.

We then trained DSHMM and conducted our evaluations on the TAC 2010 guided summarization data set (Owczarzak and Dang, 2010). Lemmatization and extraction of event heads and arguments are done by preprocessing with the Stanford CoreNLP tool suite (Toutanova et al., 2003; de Marneffe et al., 2006). This data set contains 46 topic clusters of 20 articles each, grouped into five topic categories or domains. For example, one topic cluster in the ATTACK category is about the *Columbine Massacre*. Each topic cluster contains eight human-written “model” summaries (“model” here meaning a gold standard). Half of the articles and model summaries in a topic cluster are used in the guided summarization task, and the rest are used in the update summarization task.

We chose this data set because it allows us to conduct various domain-modelling evaluations. First, templates for the domains are provided, and the model summaries are annotated with slots from the template, allowing for an intrinsic evaluation of slot induction (Section 5). Second, it contains multiple domain instances for each of the domains, and each domain instance comes annotated with eight model summaries, allowing for an extrinsic evaluation of our system (Section 6).

## 5 Guided Summarization Slot Induction

We first evaluated our models on their ability to produce coherent clusters of entities belonging to the same slot, adopting the experimental procedure of Cheung et al. (2013).

As part of the official TAC evaluation procedure, model summaries were manually segmented into *contributors*, and labelled with the slot in the TAC template that the contributor expresses. For example, a summary fragment such as *On 20 April 1999, a massacre occurred at Columbine High School* is segmented into the contributors: (*On 20 April 1999*, WHEN); (*a massacre occurred*, WHAT); and (*at Columbine High School*, WHERE).

In the slot induction evaluation, this annotation is used as follows. First, the maximal noun phrases are extracted from the contributors and clustered based on the TAC slot of the contributor. These clusters of noun phrases then become the gold standard clusters against which automatic systems are compared. Noun phrases are considered to be matched if the lemmata of their head words are the same and they are extracted from the same summary. This accounts for the fact that human annotators often only label the first occurrence of a word that belongs to a slot in a summary, and follows the standard evaluation procedure in previous information extraction tasks, such as MUC-4. Pronouns and demonstratives are ignored. This extraction process is noisy, because the meaning of some contributors depends on an entire verb phrase, but we keep this representation to allow a direct comparison to previous work.

Because we are evaluating unsupervised systems, the clusters produced by the systems are not labelled, and must be matched to the gold standard clusters. This matching is performed by mapping to each gold cluster the best system cluster according to F1. The same system cluster may be mapped multiple times, because several TAC slots can overlap. For example, in the NATURAL DISASTERS domain, an *earthquake* may fit both the WHAT slot as well as the CAUSE slot, because it generated a *tsunami*.

We trained a DSHMM separately for each of the five domains with different semantic models, tuning hyperparameters by two-fold cross-validation. We then extracted noun phrase clusters from the model summaries according to the slot labels produced by running the Viterbi algorithm on them.

Method	P	R	F1
HMM w/o semantics	13.8	64.1	22.6*
DSHMM w/ SIMPLE	20.9	27.5	23.7
DSHMM w/ E&P	20.7	27.9	23.8
PROFINDER	<b>23.7</b>	25.0	24.3
DSHMM w/ M&L+	19.7	<b>36.3</b>	25.6*
DSHMM w/ M&L×	22.1	33.2	<b>26.5*</b>

Table 2: Slot induction results on the TAC guided summarization data set. Asterisks (\*) indicate that the model is statistically significantly different from PROFINDER in terms of F1 at  $p < 0.05$ .

**Results** We compared DSHMM to two baselines. Our first baseline is PROFINDER, a state-of-the-art template inducer which Cheung et al. (2013) showed to outperform the previous heuristic clustering method of Chambers and Jurafsky (2011). Our second baseline is our DSHMM model, without the semantic vector component, (HMM w/o semantics). To calculate statistical significance, we use the paired bootstrap method, which can accommodate complex evaluation metrics like F1 (Berg-Kirkpatrick et al., 2012).

Table 2 shows that performance of the models. Overall, PROFINDER significantly outperforms the HMM baseline, but not any of the DSHMM models by F1. DSHMM with contextualized semantic vectors achieves the highest F1s, and are significantly better than PROFINDER. All of the differences in precision and recall between PROFINDER and the other models are significant. The baseline HMM model has highly imbalanced precision and recall. We think this is because the model is unable to successfully produce coherent clusters, so the best-case mapping procedure during evaluation picked large clusters that have high recall. PROFINDER has slightly higher precision, which may be due to its non-parametric split-merge heuristic. We plan to investigate whether this learning method could improve DSHMM’s performance further. Importantly, the contextualization of the vectors seems to be beneficial, at least with the M&L component-wise operators. In the next section, we show that the improvement from contextualization transfers to multi-document summarization results.

## 6 Multi-document Summarization: An Extrinsic Evaluation

We next evaluated our models extrinsically in the setting of extractive, multi-document summarization. To use the trained DSHMM for extractive summarization, we need a decoding procedure for selecting sentences in the source text to include in the summary. Inspired by the KLSUM and HIRSUM methods of Haghighi and Vanderwende (2009), we develop a criterion based on Kullback-Leibler (KL) divergence between distributions estimated from the source text, and those estimated from the summary. The assumption here is that these distributions should match in a good summary. We describe two methods to use this criterion: a basic unsupervised method (Section 6.1), and a supervised variant that makes use of in-domain summaries to learn the salient slots and events in the domain (Section 6.2).

### 6.1 A KL-based Criterion

There are four main component distributions from our model that should be considered during extraction: (1) the distribution of events, (2) the distribution of slots, (3) the distribution of event heads, and (4) the distribution of arguments. We estimate (1) as the context-independent probability of being in a certain event state, which can be calculated using the Inside-Outside algorithm. Given a collection of documents  $D$  which make up the source text, the distribution of event topics  $\hat{P}^E(E)$  is estimated as:

$$\hat{P}^E(E = e) = \frac{1}{Z} \sum_{d \in D} \sum_t \frac{In_t(e)Out_t(e)}{P(d)}, \quad (9)$$

where  $In_t(e)$  and  $Out_t(e)$  are the values of the inside and outside trellises at timestep  $t$  for some event state  $e$ , and  $Z$  is a normalization constant. The distribution for a set of sentences in a candidate summary,  $\hat{Q}^E(E)$ , is identical, except the summation is over the clauses in the candidate summary. Slot distributions  $\hat{P}^S(S)$  and  $\hat{Q}^S(S)$  (2) are defined analogously, where the summation occurs along all the slot variables.

For (3) and (4), we simply use the MLE estimates of the lemma emissions, where the estimates are made over the source text and the candidate summary instead of over the entire training set. All of the candidate summary distributions (i.e., the “ $\hat{Q}$  distributions”) are smoothed by

a small amount, so that the KL-divergence is always finite. Our KL criterion combines the above components linearly, weighting the lemma distributions by the probability of their respective event or slot state:

$$\begin{aligned} KLScore = & \quad (10) \\ & \mathcal{D}_{KL}(\hat{P}^E || \hat{Q}^E) + \mathcal{D}_{KL}(\hat{P}^S || \hat{Q}^S) \\ & + \sum_{e=1}^{N_E} \hat{P}^E(e) \mathcal{D}_{KL}(\hat{P}^H(H|e) || \hat{Q}^H(H|e)) \\ & + \sum_{s=1}^{N_S} \hat{P}^S(s) \mathcal{D}_{KL}(\hat{P}^A(A|s) || \hat{Q}^A(A|s)) \end{aligned}$$

To produce a summary, sentences from the source text are greedily added such that  $KLScore$  is minimized at each step, until the desired summary length is reached, discarding sentences with fewer than five words.

### 6.2 Supervised Learning

The above unsupervised method results in summaries that closely mirror the source text in terms of the event and slot distributions, but this ignores the fact that not all such topics should be included in a summary. It also ignores genre-specific, stylistic considerations about characteristics of good summary sentences. For example, Woodsend and Lapata (2012) find several factors that indicate sentences should *not* be included in an extractive summary, such as the presence of personal pronouns. Thus, we implemented a second method, in which we modify the KL criterion above by estimating  $\hat{P}^E$  and  $\hat{P}^S$  from other model summaries that are drawn from the same domain (i.e. topic category), except for those summaries that are written for the specific topic cluster to be used for evaluation.

### 6.3 Method and Results

We used the best performing models from the slot induction task and the above unsupervised and supervised methods based on KL-divergence to produce 100-word summaries of the guided summarization source text clusters. We did not compare against PROFINDER, as its structure is different and would have required a different procedure than the KL-criterion we developed above. As shown in the previous evaluation, however, the HMM baseline without semantics and DSHMM with SIMPLE perform similarly in terms of F1,

Method	ROUGE-1		ROUGE-2		ROUGE-SU4	
	<i>unsup.</i>	<i>sup.</i>	<i>unsup.</i>	<i>sup.</i>	<i>unsup.</i>	<i>sup.</i>
Leading baseline	28.0	–	5.39	–	8.6	–
HMM w/o semantics	32.3	32.7	<b>6.45</b>	6.49	10.1	10.2
DSHMM w/ SIMPLE	32.1	32.7	5.81	6.50	9.8	10.2
DSHMM w/ M&L+	32.1	33.4	6.27	6.82	10.0	10.6
DSHMM w/ M&L×	32.4	<b>34.3*</b>	6.35	7.11 <sup>^</sup>	10.2	<b>11.0*</b>
DSHMM w/ E&P	<b>32.8</b>	33.8*	6.38	<b>7.31*</b>	<b>10.3</b>	10.8*

Table 3: TAC 2010 summarization results by three settings of ROUGE. Asterisks (\*) indicate that the model is statistically significantly better than the HMM model without semantics at a 95% confidence interval, a caret ^ indicates that the value is marginally so.

so we consider these competitive baselines. We did not evaluate with the update summarization task, because our method has not been adapted to it. For the evaluation measure, we used the standard ROUGE suite of automatic evaluation measures (Lin, 2004). Note that the evaluation conditions of TAC 2010 are different, and thus those results are not directly comparable to ours. For instance, top performing systems in TAC 2010 make use of manually constructed lists of entities known to fit the slots in the provided templates and sample topic statements, which our method automatically learns. We include the leading baseline results from the competition as a point of reference, as it is a well-known and non-trivial one for news articles. This baseline summary consists of the leading sentences from the most recent document in the source text cluster up to the word length limit.

Table 3 shows the summarization results for the three most widely-used settings of ROUGE. All of our models outperform the leading baseline by a large margin, demonstrating the effective of the KL-criterion. In terms of unsupervised performance, all of our models perform similarly. Because the unsupervised method mimics the distributions in the source text at all levels, the method may negate the benefit of learning and simply produce summaries that match the source text in the word distributions, thus being an approximation of KLSUM. Looking at the supervised results, however, the semantic vector models show clear gains in ROUGE, whereas the baseline method does not obtain much benefit from supervision. As in the previous evaluation, the models with contextualized semantic vectors provide the best performance. M&L× performs very well, as in slot induction, but E&P also performs well, unlike in

the previous evaluation. This result reinforces the importance of the contextualization procedure for distributional semantic models.

**Analysis** To better understand what is gained by supervision using in-domain summaries, we analyzed the best performing M&L× model’s output summaries for one document cluster from each domain. For each event state, we calculated the ratio  $\hat{P}_{summ}^E(e)/\hat{P}_{source}^E(e)$ , for the probability of an event state  $e$  as estimated from the training summaries and the the source text respectively. Likewise, we calculated  $\hat{P}_{summ}^S(s)/\hat{P}_{source}^S(s)$  for the slot states. This ratio indicates the change in state’s probability after supervision; the greater the ratio, the more preferred that state becomes after training. We selected the most preferred and dis-preferred event and slot for each document cluster, and took the three most probable lemmata from the associated lemma distribution (Table 4). It seems that supervision is beneficial because it picks out important event heads and arguments in the domain, such as *charge*, *trial*, and *murder* in the TRIALS domain. It also helps the summarizer avoid semantically generic words (*be* or *have*), pronouns, quotatives, and common but irrelevant words (*home*, *city*, *restaurant* in TRIALS).

## 7 Conclusion

We have shown that contextualized distributional semantic vectors can be successfully integrated into a generative probabilistic model for domain modelling, as demonstrated by improvements in slot induction and multi-document summarization. The effectiveness of our model stems from the use of a large domain-general corpus to train the distributional semantic vectors, and the implicit syntactic and word sense information pro-

Domain	Event Heads		Slot Arguments	
	+	-	+	-
ATTACKS	<i>say</i> <sup>2</sup> , <i>cause</i> , <i>doctor</i>	<i>say</i> <sup>2</sup> , <i>be</i> , <i>have</i>	<i>attack</i> , <i>hostage</i> , <i>troops</i>	<i>he</i> , <i>it</i> , <i>they</i>
TRIALS	<i>charge</i> , <i>trial</i> , <i>accuse</i>	<i>say</i> , <i>be</i> , <i>have</i>	<i>prison</i> , <i>murder</i> , <i>charge</i>	<i>home</i> , <i>city</i> , <i>restau- rant</i>
RESOURCES	<i>reduce</i> , <i>increase</i> , <i>university</i>	<i>say</i> , <i>be</i> , <i>have</i>	<i>government</i> , <i>effort</i> , <i>program</i>	<i>he</i> , <i>they</i> , <i>it</i>
DISASTERS	<i>flood</i> , <i>strengthen</i> , <i>engulf</i>	<i>say</i> , <i>be</i> , <i>have</i>	<i>production</i> , <i>statoil</i> , <i>barrel</i>	<i>he</i> , <i>it</i> , <i>they</i>
HEALTH	<i>be</i> , <i>department</i> , <i>have</i>	<i>say</i> , <i>do</i> , <i>make</i>	<i>food</i> , <i>product</i> , <i>meat</i>	<i>she</i> , <i>people</i> , <i>way</i>

Table 4: Analysis of the most probable event heads and arguments in the most preferred (+) and dispreferred (-) events and slots after supervised training.

vided by the contextualization process. Our approach is modular, and allows principled training of the probabilistic model using standard techniques. While we have focused on the overall clustering of entities and the distribution of event and slot topics in this work, we would also like to investigate discourse modelling and content structuring. Finally, our work shows that the application of distributional semantics to NLP tasks need not be confined to lexical disambiguation. We would like to see modern distributional semantic methods incorporated into an even greater variety of applications.

# Extracting bilingual terminologies from comparable corpora

Ahmet Aker, Monica Paramita, Robert Gaizauskas  
University of Sheffield  
ahmet.aker, m.paramita, r.gaizauskas@sheffield.ac.uk

## Abstract

In this paper we present a method for extracting bilingual terminologies from comparable corpora. In our approach we treat bilingual term extraction as a classification problem. For classification we use an SVM binary classifier and training data taken from the EUROVOC thesaurus. We test our approach on a held-out test set from EUROVOC and perform precision, recall and f-measure evaluations for 20 European language pairs. The performance of our classifier reaches the 100% precision level for many language pairs. We also perform manual evaluation on bilingual terms extracted from English-German term-tagged comparable corpora. The results of this manual evaluation showed 60-83% of the term pairs generated are exact translations and over 90% exact or partial translations.

## 1 Introduction

Bilingual terminologies are important for various applications of human language technologies, including cross-language information search and retrieval, statistical machine translation (SMT) in narrow domains and computer-aided assistance to human translators. Automatic construction of bilingual terminology mappings has been investigated in many earlier studies and various methods have been applied to this task. These methods may be distinguished by whether they work on parallel or comparable corpora, by whether they assume monolingual term recognition in source and target languages (what Moore (2003) calls symmetrical approaches) or only in the source (asymmetric approaches), and by the extent to which they rely on linguistic knowledge as opposed to simply statistical techniques.

We focus on techniques for bilingual term extraction from comparable corpora – collections of source-target language document pairs that are not direct translations but are topically related. We

choose to focus on comparable corpora because for many less widely spoken languages and for technical domains where new terminology is constantly being introduced, parallel corpora are simply not available. Techniques that can exploit such corpora to deliver bilingual terminologies are of significant practical interest in these cases.

The rest of the paper is structured as follows. In Section 2 we outline our method. In Section 3 we review related work on bilingual term extraction. Section 4 describes feature extraction for term pair classification. In Section 5 we present the data used in our evaluations and discuss our results. Section 6 concludes the paper.

## 2 Method

The method we present below for bilingual term extraction is a symmetric approach, i.e. it assumes a method exists for monolingual term extraction in both source and target languages. We do not prescribe what a term must be. In particular we do not place any particular syntactic restrictions on what constitutes an allowable term, beyond the requirement that terms must be contiguous sequences of words in both source and target languages.

Our method works by first pairing each term extracted from a source language document  $S$  with each term extracted from a target language document  $T$  aligned with  $S$  in the comparable corpus. We then treat term alignment as a binary classification task, i.e. we extract features for each source-target language potential term pair and decide whether to classify the pair as a term equivalent or not. For classification purposes we use an SVM binary classifier. The training data for the classifier is derived from EUROVOC (Steinberger et al., 2002), a term thesaurus covering the activities of the EU and the European Parliament. We have run our approach on the 21 official EU languages covered by EUROVOC, constructing 20 language pairs with English as the source

language. Considering all these languages allows us to directly compare our method's performance on resource-rich (e.g. German, French, Spanish) and under-resourced languages (e.g. Latvian, Bulgarian, Estonian). We perform two different tests. First, we evaluate the performance of the classifier on a held-out term-pair list from EUROVOC using the standard measures of recall, precision and F-measure. We run this evaluation on all 20 language pairs. Secondly, we test the system's performance on obtaining bilingual terms from comparable corpora. This second test simulates the situation of using the term alignment system in a real world scenario. For this evaluation we collected English-German comparable corpora from Wikipedia, performed monolingual term tagging and ran our tool over the term tagged corpora to extract bilingual terms.

### 3 Related Work

Previous studies have investigated the extraction of bilingual terms from parallel and comparable corpora. For instance, Kupiec (1993) uses statistical techniques and extracts bilingual noun phrases from parallel corpora tagged with terms. Daille et al. (1994), Fan et al. (2009) and Okita et al. (2010) also apply statistical methods to extract terms/phrases from parallel corpora. In addition to statistical methods Daille et al. use word translation information between two words within the extracted terms as a further indicator of the correct alignment. More recently, Bouamor et al. (2012) use vector space models to align terms. The entries in the vectors are co-occurrence statistics between the terms computed over the entire corpus.

Bilingual term alignment methods that work on comparable corpora use essentially three sorts of information: (1) cognate information, typically estimated using some sort of transliteration similarity measure (2) context congruence, a measure of the extent to which the words that the source term co-occurs with have the same sort of distribution and co-occur with words with the same sort distribution as do those words that co-occur with the candidate term and (3) translation of component words in the term and/or in context words, where some limited dictionary exists. For example, in Rapp (1995), Fung and McKeown (1997), Morin et al. (2007), Cao and Li (2002) and Ismail and Manandhar (2010) the context of text units is used to identify term mappings. Transliteration and cognate-based information is exploited in Al-

Onaizan and Knight (2002), Knight and Graehl (1998), Udupa et al. (2008) and Aswani and Gaizauskas (2010).

Very few approaches have treated term alignment as a classification problem suitable for machine learning (ML) techniques. So far as we are aware, only Cao and Li (2002), who treat only base noun phrase (NP) mapping, consider the problem this way. However, it naturally lends itself to being viewed as a classification task, assuming a symmetric approach, since the different information sources mentioned above can be treated as features and each source-target language potential term pairing can be treated as an instance to be fed to a binary classifier which decides whether to align them or not. Our work differs from that of Cao and Li (2002) in several ways. First they consider only terms consisting of noun-noun pairs. Secondly for a given source language term  $\langle N_1, N_2 \rangle$ , target language candidate terms are proposed by composing all translations (given by a bilingual dictionary) of  $N_1$  into the target language with all translations of  $N_2$ . We remove both these restrictions. By considering all terms proposed by monolingual term extractors we consider terms that are syntactically much richer than noun-noun pairs. In addition, the term pairs we align are not constrained by an assumption that their component words must be translations of each other as found in a particular dictionary resource.

### 4 Feature extraction

To align or map source and target terms we use an SVM binary classifier (Joachims, 2002) with a linear kernel and the trade-off between training error and margin parameter  $c = 10$ . Within the classifier we use language dependent and independent features described in the following sections.

#### 4.1 Dictionary based features

The dictionary based features are language dependent and are computed using bilingual dictionaries which are created with GIZA++ (Och and Ney, 2000; Och and Ney, 2003). The DGT-TM parallel data (Steinberger et al., 2012) was input to GIZA++ to obtain the dictionaries. Dictionary entries have the form  $\langle s, t_i, p_i \rangle$ , where  $s$  is a source word,  $t_i$  is the  $i$ -th translation of  $s$  in the dictionary and  $p_i$  is the probability that  $s$  is translated by  $t_i$ , the  $p_i$ 's summing to 1 for each  $s$  in the dictionary. From the dictionaries we removed all entries with  $p_i < 0.05$ . In addition we also removed

every entry from the dictionary where the source word was less than four characters and the target word more than five characters in length and vice versa. This step is performed to try to eliminate translation pairs where a stop word is translated into a non-stop word. After performing these filtering steps we use the dictionaries to extract the following language dependent features:

- ***isFirstWordTranslated*** is a binary feature indicating whether the first word in the source term is a translation of the first word in the target term. To address the issue of compounding, e.g. for languages like German where what is a multi-word term in English may be expressed as a single compound word, we check whether the compound source term has an initial prefix that matches the translation of the first target word, provided that translation is at least 5 character in length.
- ***isLastWordTranslated*** is a binary feature indicating whether the last word in the source term is a translation of the last word in the target term. As with the previous feature in case of compound terms we check whether the source term ends with the translation of the target last word.
- ***percentageOfTranslatedWords*** returns the percentage of words in the source term which have their translations in the target term. To address compound terms we check for each source word translation whether it appears anywhere within the target term.
- ***percentageOfNotTranslatedWords*** returns the percentage of words of the source term which have no translations in the target term.
- ***longestTranslatedUnitInPercentage*** returns the ratio of the number of words within the longest contiguous sequence of source words which has a translation in the target term to the length of the source term, expressed as a percentage. For compound terms we proceed as with ***percentageOfTranslatedWords***.
- ***longestNotTranslatedUnitInPercentage*** returns the percentage of the number of words within the longest sequence of source words which have no translations in the target term.

These six features are direction-dependent and are computed in both directions, reversing which language is taken as the source and which as

the target. We also compute another feature *averagePercentageOfTranslatedWords* which builds the average between the feature values of *percentageOfTranslatedWords* from source to target and target to source. Thus in total we have 13 dictionary based features. Note for non-compound terms if we compare two words for equality we do not perform string match but rather use the Levenshtein Distance (see Section 4.2) between the two words and treat them as equal if the Levenshtein Distance returns  $\geq 0.95$ . This is performed to capture words with morphological differences. We set 0.95 experimentally.

## 4.2 Cognate based features

Dictionaries mostly fail to return translation entries for named entities (NEs) or specialized terminology. Because of this we also use cognate based methods to perform the mapping between source and target words or vice versa. Aker et al. (2012) have applied (1) Longest Common Subsequence Ratio, (2) Longest Common Substring Ratio, (3) Dice Similarity, (4) Needleman-Wunsch Distance and (5) Levenshtein Distance in order to extract parallel phrases from comparable corpora. We adopt these measures within our classifier. Each of them returns a score between 0 and 1.

- **Longest Common Subsequence Ratio (LCSR):** The *longest common subsequence* (LCS) measure measures the longest common non-consecutive sequence of characters between two strings. For instance, the words “dollars” and “dolari” share a sequence of 5 non-consecutive characters in the same ordering. We make use of dynamic programming (Cormen et al., 2001) to implement LCS, so that its computation is efficient and can be applied to a large number of possible term pairs quickly. We normalize relative to the length of the longest term:

$$LCSR(X, Y) = \frac{\text{len}[LCS(X, Y)]}{\max[\text{len}(X), \text{len}(Y)]}$$

where *LCS* is the longest common subsequence between two strings and characters in this subsequence need not be contiguous. The shorthand *len* stands for *length*.

- **Longest Common Substring Ratio (LCSTR):** The *longest common substring* (LCST) measure is similar to the LCS measure, but measures the longest common

*consecutive* string of characters that two strings have in common. I.e. given two terms we need to find the longest character  $n$ -gram the terms share. The formula we use for the LCSTR measure is a ratio as in the previous measure:

$$LCSTR(X, Y) = \frac{\text{len}[LCST(X, Y)]}{\max[\text{len}(X), \text{len}(Y)]}$$

- **Dice Similarity:**

$$dice = \frac{2 * LCST}{\text{len}(X) + \text{len}(Y)}$$

- **Needleman Wunsch Distance (NWD):**

$$NWD = \frac{LCST}{\min[\text{len}(X) + \text{len}(Y)]}$$

- **Levenshtein Distance (LD):** This method computes the minimum number of operations necessary to transform one string into another. The allowable operations are insertion, deletion, and substitution. Compared to the previous methods, which all return scores between 0 and 1, this method returns a score  $s$  that lies between 0 and  $n$ . The number  $n$  represents the maximum number of operations to convert an arbitrarily dissimilar string to a given string. To have a uniform score across all cognate methods we normalize  $s$  so that it lies between 0 and 1, subtracting from 1 to convert it from a distance measure to a similarity measure:

$$LD_{normalized} = 1 - \frac{LD}{\max[\text{len}(X), \text{len}(Y)]}$$

### 4.3 Cognate based features with term matching

The cognate methods assume that the source and target language strings being compared are drawn from the same character set and fail to capture the corresponding terms if this is not the case. For instance, the cognate methods are not directly applicable to the English-Bulgarian and English-Greek language pairs, as both the Bulgarian and Greek alphabets, which are Cyrillic-based, differ from the English Latin-based alphabet. However, the use of distinct alphabets is not the only problem when comparing source and target terms. Although most EU languages use the Latin alphabet, the occurrence of special characters and diacritics, as well spelling and phonetic variations,

are further challenges which are faced by term or entity mapping methods, especially in determining the variants of the same mention of the entity (Snae, 2007; Karimi et al., 2011).<sup>1</sup> We address this problem by mapping a source term to the target language writing system or vice versa. For mapping we use simple character mappings between the writing systems, such as  $\alpha \rightarrow a$ ,  $\phi \rightarrow ph$ , etc., from Greek to English. The rules allow one character on the lefthand side (source language) to map onto one or more characters on the righthand side (target language). We created our rules manually based on sound similarity between source and target language characters. We created mapping rules for 20 EU language pairs using primarily Wikipedia as a resource for describing phonetic mappings to English.

After mapping a term from source to target language we apply the cognate metrics described in 4.2 to the resulting mapped term and the original term in the other language. Since we perform both target to source and source to target mapping, the number of cognate feature scores on the mapped terms is 10 – 5 due to source to target mapping and 5 due to target to source mapping.

### 4.4 Combined features

We also combined dictionary and cognate based features. The combined features are as follows:

- ***isFirstWordCovered*** is a binary feature indicating whether the first word in the source term has a translation (i.e. has a translation entry in the dictionary regardless of the score) or transliteration (i.e. if one of the cognate metric scores is above 0.7<sup>2</sup>) in the target term. The threshold 0.7 for transliteration similarity is set experimentally using the training data. To do this we iteratively ran feature extraction, trained the classifier and recorded precision on the training data using a threshold value chosen from the interval  $[0, 1]$  in steps of 0.1. We selected as final threshold value, the lowest value for which the precision score was the same as when the threshold value was set to 1.
- ***isLastWordCovered*** is similar to the previous feature one but indicates whether the last word in the source term has a translation or

<sup>1</sup>Assuming the terms are correctly spelled, otherwise the misspelling is another problem.

<sup>2</sup>Note that we use the cognate scores obtained on the character mapped terms.

transliteration in the target term. If this is the case, 1 is returned otherwise 0.

- ***percentageOfCoverage*** returns the percentage of source term words which have a translation or transliteration in the target term.
- ***percentageOfNonCoverage*** returns the percentage of source term words which have neither a translation nor transliteration in the target term.
- ***difBetweenCoverageAndNonCoverage*** returns the difference between the last two features.

Like the dictionary based features, these five features are direction-dependent and are computed in both directions – source to target and target to source, resulting in 10 combined features.

In total we have 38 features – 13 features based on dictionary translation as described in Section 4.1, 5 cognate related features as outlined in Section 4.2, 10 cognate related features derived from character mappings over terms as described in Section 4.3 and 10 combined features.

## 5 Experiments

### 5.1 Data Sources

In our experiments we use two different data resources: EUROVOC terms and comparable corpora collected from Wikipedia.

#### 5.1.1 EUROVOC terms

EUROVOC is a term thesaurus covering the activities of the EU and the European Parliament in particular. It contains 6797 term entries in 24 different languages including 22 EU languages and Croatian and Serbian (Steinberger et al., 2002).

#### 5.1.2 Comparable Corpora

We also built comparable corpora in the information technology (IT) and automotive domains by gathering documents from Wikipedia for the English-German language pair. First, we manually chose one seed document in English as a starting point for crawling in each domain<sup>3</sup>. We then identified all articles to which the seed document is linked and added them to the crawling queue. This process is performed recursively for each document in the queue. Since our aim is to build a comparable corpus, we only added English

<sup>3</sup>[http://en.wikipedia.org/wiki/Information\\_technology](http://en.wikipedia.org/wiki/Information_technology) for IT and [http://en.wikipedia.org/wiki/Automotive\\_industry](http://en.wikipedia.org/wiki/Automotive_industry) for automotive domain.

documents which have an inter-language link in Wikipedia to a German document. We set a maximum depth of 3 in the recursion to limit size of the crawling set, i.e. documents are crawled only if they are within 3 clicks of the seed documents. A score is then calculated to represent the importance of each document  $d_i$  in this domain:

$$score_{d_i} = \sum_{j=1}^n \frac{freq_{d_{ij}}}{depth_{d_j}}$$

where  $n$  is the total number of documents in the queue,  $freq_{d_{ij}}$  is 1 if  $d_i$  is linked to  $d_j$ , or 0 otherwise, and  $depth_{d_j}$  is the number of clicks between  $d_j$  and the seed document. After all documents in the queue were assigned a score, we gathered the top 1000 documents and used inter-language link information to extract the corresponding article in the target language.

We pre-processed each Wikipedia article by performing monolingual term tagging using TWSC (Pinnis et al., 2012). TWSC is a term extraction tool which identifies terms ranging from one to four tokens in length. First, it POS-tags each document. For German POS-tagging we use TreeTagger (Schmid, 1995). Next, it uses term grammar rules, in the form of sequences of POS tags or non-stop words, to identify candidate terms. Finally, it filters the candidate terms using various statistical measures, such as pointwise mutual information and TF\*IDF.

### 5.2 Performance test of the classifier

To test the classifier’s performance we evaluated it against a list of positive and negative examples of bilingual term pairs using the measures of precision, recall and  $F$ -measure. We used 21 EU official languages, including English, and paired each non-English language with English, leading to 20 language pairs.<sup>4</sup> In the evaluation we used 600 positive term pairs taken randomly from the EUROVOC term list. We also created around 1.3M negative term pairs by pairing a source term with 200 randomly chosen distinct target terms. We select such a large number to simulate the real application scenario where the classifier will be confronted with a huge number of negative cases

<sup>4</sup>Note that we do not use the Maltese-English language pair, as for this pair we found that 5861 out of 6797 term pairs were identical, i.e. the English and the Maltese terms were the same. Excluding Maltese, the average number of identical terms between a non-English language and English in the EUROVOC data is 37.7 (out of a possible 6797).

Table 1: Wikipedia term pairs processed and judged as positive by the classifier.

	Processed	Positive
DE IT	11597K	3249
DE Automotive	12307K	1772

and a relatively small number of positive pairs. The 600 positive examples contain 200 single term pairs (i.e. single word on both sides), 200 term pairs with a single word on only one side (either source or target) and 200 term pairs with more than one word on each side. For training we took the remaining 6200 positive term pairs from EU-ROVOC and constructed another 6200 term pairs as negative examples, leading to total of 12400 term pairs. To construct the 6200 negative examples we used the 6200 terms on the source side and paired each source term with an incorrect target term. Note that we ensure that in both training and testing the set of negative and positive examples do not overlap. Furthermore, we performed data selection for each language pair separately. This means that the same pairs found in, e.g., English-German are not necessarily the same as in English-Italian. The reason for this is that the translation lengths, in number of words, vary between language pairs. For instance *adult education* is translated into *Erwachsenenbildung* in German and contains just a single word (although compound). The same term is translated into *istruzione degli adulti* in Italian and contains three words. For this reason we carry out the data preparation process separately for each language pair in order to obtain the three term pair sets consisting of term pairs with only a single word on each side, term pairs with a single word on just one side and term pairs with multiple words on both sides.

### 5.3 Manual evaluation

For this evaluation we used the Wikipedia comparable corpora collected for the English-German (EN-DE) language pair. For each pair of Wikipedia articles we used the terms tagged by TWSC and aligned each source term with every target term. This means if both source and target articles contain 100 terms then this leads to 10K term pairs. We extracted features for each pair of terms and ran the classifier to decide whether the pair is positive or negative. Table 1 shows the number of term pairs processed and the count of pairs classified as positive. Table 2 shows five

positive term pairs extracted from the English-German comparable corpora for each of the IT and automotive domains. We manually assessed a subset of the positive examples. We asked human assessors to categorize each term pair into one of the following categories:

1. **Equivalence:** The terms are exact translations/transliterations of each other.
2. **Inclusion:** Not an exact translation/transliteration, but an exact translation/transliteration of one term is entirely contained within the term in the other language, e.g: “F1 car racing” vs “Autorennen (car racing)”.
3. **Overlap:** Not category 1 or 2, but the terms share at least one translated/transliterated word, e.g: “hybrid electric vehicles” vs “hybride bauteile (hybrid components)”.
4. **Unrelated:** No word in either term is a translation/transliteration of a word in the other.

In the evaluation we randomly selected 300 pairs for each domain and showed them to two German native speakers who were fluent in English. We asked the assessors to place each of the term pair into one of the categories 1 to 4.

## 5.4 Results and Discussion

### 5.4.1 Performance test of the classifier

The results of the classifier evaluation are shown in Table 3. The results show that the overall performance of the classifier is very good. In many cases the precision scores reach 100%. The lowest precision score is obtained for Lithuanian (LT) with 67%. For this language we performed an error analysis. In total there are 221 negative examples classified as positive. All these terms are multi-term, i.e. each term pair contains at least two words on each side. For the majority of the misclassified terms – 209 in total – 50% or more of the words on one side are either translations or cognates of words on the other side. Of these, 187 contained 50% or more translation due to cognate words – examples of such cases are *capital increase* – *kapitalo eksportas* or *Arab organisation* – *Arabu lyga* with the cognates *capital* – *kapitalo* and *Arab* – *Arabu* respectively. For the remainder, 50% or more of the words on one side are dictionary translations of words on the other side. In order to understand the reason why the classifier treats such cases as positive we examined the

Table 2: Example positive pairs for English-German.

IT	Automotive
chromatographic technique — chromatographie methode	distribution infrastructure — versorgungsinfrastruktur
electrolytic capacitor — elektrolytkondensatoren	ambient temperature — außenlufttemperatur
natural user interfaces — natürliche benutzerschnittstellen	higher cetane number — erhöhter cetanzahl
anode voltage — anodenspannung	fuel tank — kraftstoffpumpe
digital subscriber loop — digitaler teilnehmeranschluss	hydrogen powered vehicle — wasserstoff fahrzeug

Table 3: Classifier performance results on EUROVOC data (P stands for precision, R for recall and  $F$  for  $F$ -measure). Each language is paired with English. The test set contains 600 positive and 1359400 negative examples.

	ET	HU	NL	DA	SV	DE	LV	FI	PT	SL	FR	IT	LT	SK	CS	RO	PL	ES	EL	BG
P	1	1	.98	1	1	.98	1	1	.7	1	1	1	.67	.81	1	1	1	1	1	1
R	.67	.72	.82	.69	.81	.77	.78	.65	.82	.66	.66	.7	.77	.84	.72	.78	.69	.8	.78	.79
$F$	.80	.83	.89	.81	.89	.86	.87	.78	.75	.79	.79	.82	.71	.91	.83	.87	.81	.88	.87	.88

training data and found 467 positive pairs which had the same characteristics as the negative examples in the testing set classified. We removed these 467 entries from the training set and re-trained the classifier. The results with the new classifier are 99% precision, 68% recall and 80%  $F$  score.

In addition to Lithuanian, two further languages, Portuguese (PT) and Slovak (SK), also had substantially lower precision scores. For these languages we also removed positive entries falling into the same problem categories as the LT ones and trained new classifiers with the filtered training data. The precision results increased substantially for both PT and SK – 95% precision, 76% recall, 84%  $F$  score for PT and 94% precision, 72% recall, 81%  $F$  score for SK. The recall scores are lower than the precision scores, ranging from 65% to 84%. We have investigated the recall problem for FI, which has the lowest recall score at 65%. We observed that all the missing term pairs were not cognates. Thus, the only way these terms could be recognized as positive is if they are found in the GIZA++ dictionaries. However, due to data sparsity in these dictionaries this did not happen in these cases. For these term pairs either the source or target terms were not found in the dictionaries. For instance, for the term pair *offshoring* — *uudelleensijoittautuminen* the GIZA++ dictionary contains the entry *offshoring* but according to the dictionary it is not translated into *uudelleensijoittautuminen*, which is the matching term in EUROVOC.

#### 5.4.2 Manual evaluation

The results of the manual evaluation are shown in Table 4. From the results we can see that both assessors judge above 80% of the IT domain terms as category 1 – the category containing equivalent

Table 4: Results of the EN-DE manual evaluation by two annotators. Numbers reported per category are percentages.

Domain	Ann.	1	2	3	4
IT	P1	81	6	6	7
	P2	83	7	7	3
Automotive	P1	66	12	16	6
	P2	60	15	16	9

term pairs. Only a small proportion of the term pairs are judged as belonging to category 4 (3–7%) – the category containing unrelated term pairs. For the automotive domain the proportion of equivalent term pairs varies between 60 and 66%. For unrelated term pairs this is below 10% for both assessors.

We investigated the inter-annotator agreement. Across the four classes the percentage agreement was 83% for the automotive domain term pairs and 86% for the IT domain term pairs. The kappa statistic,  $\kappa$ , was .69 for the automotive domain pairs and .52 for the IT domain. We also considered two class agreement where we treated term pairs within categories 2 and 3 as belonging to category 4 (i.e. as “incorrect” translations). In this case, for the automotive domain the percentage agreement was 90% and  $\kappa = 0.72$  and for the IT domain percentage agreement was 89% with  $\kappa = 0.55$ . The agreement in the automotive domain is higher than in the IT one although both judges were computer scientists. We analyzed the differences and found that they differ in cases where the German and the English term are both in English. One of the annotators treated such cases as correct translation, whereas the other did not.

We also checked to ensure our technique was not simply rediscovering our dictionaries. Since the GIZA++ dictionaries contain only single word–single word mappings, we examined the

newly aligned term pairs that consisted of one word on both source and target sides. Taking both the IT and automotive domains together, our algorithm proposed 5021 term pairs of which 2751 (55%) were word-word term pairs. 462 of these (i.e. 17% of the word-word term pairs or 9% of the overall set of aligned term pairs) were already in either the EN-DE or DE-EN GIZA++ dictionaries. Thus, of our newly extracted term pairs a relatively small proportion are rediscovered dictionary entries. We also checked our evaluation data to see what proportion of the assessed term pairs were already to be found in the GIZA++ dictionaries. A total of 600 term pairs were put in front of the judges of which 198 (33%) were word-word term pairs. Of these 15 (less than 8% of the word-word pairs and less than 3% of the overall assessed set of assessed term pairs) were word-word pairs already in the dictionaries. We conclude that our evaluation results are not unduly affected by assessing term pairs which were given to the algorithm.

**Error analysis** For both domains we performed an error analysis for the unrelated, i.e. category 4 term pairs. We found that in both domains the main source of errors is due to terms with different meanings but similar spellings such as the following example (1).

- (1) *accelerator* — *decelerator*

For this example the cognate methods, e.g. the Levenshtein similarity measure, returns a score of 0.81. This problem could be addressed in different ways. First, it could be resolved by applying a very high threshold for the cognate methods. Any cognate score below that threshold could be regarded as zero – as we did for the combined features (cf. Section 4.4). However, setting a similarity threshold higher than 0.9 – to filter out cases as in (1) – will cause real cognates with greater variation in the spellings to be missed. This will, in particular, affect languages with a lot of inflection, such as Latvian. Another approach to address this problem would be to take the contextual or distributional properties of the terms into consideration. To achieve this, training data consisting of term pairs along with contextual information is required. However, such training data does not currently exist (i.e. resources like EUROVOC do not contain contextual information) and it would need to be collected as a first step towards applying this approach to the problem.

**Partial Translation** The assessors assigned 6 – 7% of the term pairs in the IT domain and 12 – 16% in the automotive domain to categories 2 and 3. In both categories the term pairs share translations or cognates.

Clearly, if humans such as professional translators are the end users of these terms, then it could be helpful for them to find some translation units within the terms. In category 2 this will be the entire translation of one term in the other such as the following examples.<sup>5</sup>

- (2) *visible graphical interface* — *grafische benutzerschnittstelle*  
 (3) *modern turbocharger systems* — *moderne turbolader*

In example (3) the a translation of the German term is to be found entirely within in the English term but the English term has the additional word *visible*, a translation of which is not found in the German term. In example (4), again the translation of the German term is entirely found in the English term, but as in the previous example, one of the English words – *systems* – in this case, has no match within the German term. In category 3 there are only single word translation overlaps between the terms as shown in the following examples.

- (4) *national standard language* — *niederländischen standardsprache*  
 (5) *thermoplastic material* — *thermoplastische elastomere*

In example (5) *standard language* is translated to *standardsprache* and in example (6) *thermoplastic* to *thermoplastische*. The other words within the terms are not translations of each other.

Another application of the extracted term pairs is to use them to enhance existing parallel corpora to train SMT systems. In this case, including the partially correct terms may introduce noise. This is especially the case for the terms within category 3. However, the usefulness of terms in both these scenarios requires further investigation, which we aim to do in future work.

<sup>5</sup>In our data it is always the case that the target term is entirely translated within the English one and the other way round.

## 6 Conclusion

In this paper we presented an approach to align terms identified by a monolingual term extractor in bilingual comparable corpora using a binary classifier. We trained the classifier using data from the EUROVOC thesaurus. Each candidate term pair was pre-processed to extract various features which are cognate-based or dictionary-based. We measured the performance of our classifier using Information Retrieval (IR) metrics and a manual evaluation. In the IR evaluation we tested the performance of the classifier on a held out test set taken from EUROVOC. We used 20 EU language pairs with English being always the source language. The performance of our classifier in this evaluation reached the 100% precision level for many language pairs. In the manual evaluation we had our algorithm extract pairs of terms from Wikipedia articles – articles forming comparable corpora in the IT and automotive domains – and asked native speakers to categorize a selection of the term pairs into categories reflecting the level of translation of the terms. In the manual evaluation we used the English-German language pair and showed that over 80% of the extracted term pairs were exact translations in the IT domain and over 60% in the automotive domain. For both domains over 90% of the extracted term pairs were either exact or partial translations.

We also performed an error analysis and highlighted problem cases, which we plan to address in future work. Exploring ways to add contextual or distributional features to our term representations is also an avenue for future work, though it clearly significantly complicates the approach, one of whose advantages is its simplicity. Furthermore, we aim to extend the existing dictionaries and possibly our training data with terms extracted from comparable corpora. Finally, we plan to investigate the usefulness of the terms in different application scenarios, including computer assisted translation and machine translation.

## Acknowledgements

The research reported was funded by the TaaS project, European Union Seventh Framework Programme, grant agreement no. 296312. The authors would like to thank the manual annotators for their helpful contributions. We would also like to thank partners at Tilde SIA and at the University of Zagreb for supplying the TWSC term extraction

tool, developed within the EU funded project AC-CURAT.

## Abstract

Expensive feature engineering based on WordNet senses has been shown to be useful for document level sentiment classification. A plausible reason for such a performance improvement is the reduction in data sparsity. However, such a reduction could be achieved with a lesser effort through the means of syntagma based word clustering. In this paper, the problem of data sparsity in sentiment analysis, both monolingual and cross-lingual, is addressed through the means of clustering. Experiments show that cluster based data sparsity reduction leads to performance better than sense based classification for sentiment analysis at document level. Similar idea is applied to Cross Lingual Sentiment Analysis (CLSA), and it is shown that reduction in data sparsity (after translation or bilingual-mapping) produces accuracy higher than Machine Translation based CLSA and sense based CLSA.

## 1 Introduction

Data sparsity is the bane of Natural Language Processing (NLP) (Xue et al., 2005; Minkov et al., 2007). Language units encountered in the test data but absent in the training data severely degrade the performance of an NLP task. NLP applications innovatively handle data sparsity through various means. A special, but very common kind of data sparsity *viz.*, word sparsity, can be addressed in one of the two obvious ways: 1) sparsity reduction through *paradigmatically related* words or 2) sparsity reduction through *syntagmatically related* words.

Paradigmatic analysis of text is the analysis of concepts embedded in the text (Cruse, 1986; Chandler, 2012). WordNet is a byproduct of such an analysis. In WordNet, paradigms are manually generated based on the principles of lexical and semantic relationship among words (Fellbaum, 1998). WordNets are primarily used to address the problem of word sense disambiguation. However, at present there are many NLP applications which use WordNet. One such application is Sentiment Analysis (SA) (Pang and Lee, 2002). Recent research has shown that word sense based semantic features can improve the performance of SA systems (Rentoumi et al., 2009; Tamara et al., 2010; Balamurali et al., 2011) compared to word based features.

Syntagmatic analysis of text concentrates on the surface properties of the text. Compared to paradigmatic property extraction, syntagmatic processing is relatively light weight. One of the obvious syntagmas is *words*, and words are grouped into equivalence classes or clusters, thus reducing the model parameters of a statistical NLP system (Brown et al., 1992). When used as an additional feature with word based language models, it has been shown to improve the system performance *viz.*, machine translation (Uszkoreit and Brants, 2008; Stymne, 2012), speech recognition (Martin et al., 1995; Samuelsson and Reichl, 1999), dependency parsing (Koo et al., 2008; Haffari et al., 2011; Zhang and Nivre, 2011; Tratz and Hovy, 2011) and NER (Miller et al., 2004; Faruqui and Padó, 2010; Turian et al., 2010; Täckström et al., 2012).

In this paper, the focus is on alleviating the data sparsity faced by supervised approaches for SA through the means of cluster based features. As WordNets are essentially word

clusters wherein words with the same meaning are clubbed together, they address the problem of data sparsity at word level. The abstraction and dimensionality reduction thus achieved attributes to the superior performance for SA systems that employs WordNet senses as features. However, WordNets are manually created. Automatic creation of the same is challenging and not much successful because of the linguistic complexity involved. In case of SA, manually creating the features based on WordNet senses is a tedious and an expensive process. Moreover, WordNets are not present for many languages. All these factors make the paradigmatic property based cluster features like WordNet senses a less promising pursuit for SA.

The syntagmatic analysis essentially makes use of distributional similarity and may in many circumstances subsume the paradigmatic analysis. In the current work, this particular insight is used to solve the data sparsity problem in the sentiment analysis by leveraging unlabelled monolingual corpora. Specifically, experiments are performed *to investigate whether features developed from manually crafted clusterings (coming from WordNet) can be replaced by those generated from clustering based on syntagmatic properties.*

Further, *cluster based features are used to address the problem of scarcity of sentiment annotated data in a language.* Popular approaches for Cross-Lingual Sentiment Analysis (CLSA) (Wan, 2009; Duh et al., 2011) depend on Machine Translation (MT) for converting the labeled data from one language to the other (Hiroshi et al., 2004; Banea et al., 2008; Wan, 2009). However, many languages which are truly resource scarce, do not have an MT system or existing MT systems are not ripe to be used for CLSA (Balamurali et al., 2013). To perform CLSA, this study leverages unlabelled parallel corpus to generate the word alignments. These word alignments are then used to link cluster based features to obliterate the language gap for performing SA. No MT systems or bilingual dictionaries are used for this study. Instead, language gap for performing CLSA is bridged using linked cluster or *cross-lingual* clusters (explained in section 4) with the help of unlabelled monolingual corpora. The contributions of this paper are two fold:

1. *Features created from manually built and finer clusters can be replaced by inexpensive cluster based features generated solely from unlabelled corpora.* Experiments performed on four publicly available datasets in three languages *viz.*, *English, Hindi* and *Marathi*<sup>1</sup> suggest that cluster based features can considerably boost the performance of an SA system. Moreover, state of the art result is obtained for one of the publicly available dataset.
2. *An alternative and effective approach for CLSA is demonstrated using clusters as features.* Word clustering is a powerful mechanism to “transfer” a sentiment classifier from one language to another. Thus can be used in truly resource scarce scenarios like that of *English-Marathi* CLSA.

The rest of the paper is organized as follows: section 2 presents related work. Section 3 explains different word cluster based features employed to reduce data sparsity for monolingual SA. In section 4, alternative CLSA approaches based on word clustering are elucidated. Experimental details are explained in section 5. Results and discussions are presented in section 6 and section 7 respectively. Finally, section 8 concludes the paper pointing to some future research possibilities.

## 2 Related Work

The problem of SA at document level is defined as the classification of document into different polarity classes (positive and negative) (Turney, 2002). Both supervised (Benamara et al., 2007; Martineau and Finin, 2009) and unsupervised approaches (Mei et al., 2007; Lin and He, 2009) exist for this task.

Supervised approaches are popular because of their superior classification accuracy (Mullen and Collier, 2004; Pang and Lee, 2008). Feature engineering plays an important role in these systems. Apart from the commonly used bag-of-words features based on unigrams/bigrams/ngrams (Dave et al., 2003; Ng et al., 2006; Martineau and Finin, 2009),

---

<sup>1</sup>Hindi and Marathi belong to the Indo-Aryan subgroup of the Indo-European language family and are two widely spoken Indian languages with a speaker population of 450 million and 72 million respectively.

syntax (Matsumoto et al., 2005; Nakagawa et al., 2010), semantic (Balamurali et al., 2011) and negation (Ikeda et al., 2008) have also been explored for this task. There has been research related to clustering and sentiment analysis. In Rooney et al. (2011), documents are clustered based on the context of each document and sentiment labels are attached at the cluster level. Zhai et al. (2011) attempts to cluster features of a product to perform sentiment analysis on product reviews. In this work, word clusters (syntagmatic and paradigmatic) encoding a mixture of syntactic and semantic information are used for feature engineering.

In situations where labeled data is not present in a language, approaches based on cross-lingual sentiment analysis are used. Most often these methods depend on an intermediary machine translation system (Wan, 2009; Brooke et al., 2009) or a bilingual dictionary (Ghorbel and Jacot, 2011; Lu et al., 2011) to bridge the language gap. Given the subtle and different ways the sentiment can be expressed which itself manifested as a result of cultural diversity amongst different languages, an MT system has to be of a superior quality to capture them.

### 3 Clustering for Sentiment Analysis

The goal of this paper, to remind the reader, is to investigate whether superior word cluster features based on manually crafted and fine grained lexical resource like WordNet can be replaced with the syntagmatic property based word clusters created from unlabelled monolingual corpora.

In this section, different clustering approaches are presented for feature engineering in a monolingual setting.

#### 3.1 Approach 1: Clustering based on WordNet Sense

A synonymous set of words in a WordNet is called a synset. Each synset can be considered as a word cluster comprising of semantically similar words. Balamurali et al. (2011) showed that WordNet synsets can act as good features for document level sentiment classification.

Motivation for their study stems from the fact that different senses of a word can have different polarities. To empirically prove the superiority of sense based features, different variants of a travel review domain corpus were generated

by using automatic/manual sense disambiguation techniques. Thereafter, accuracies of classifiers based on different sense-based and word-based features were compared. The results suggested that WordNet synset based features performed better than word-based features.

In this study, synset identifiers are extracted from manually/automatically sense annotated corpora and used as features for creating sentiment classifiers. The classifier thus build is used as a baseline. Apart from this, another baseline employing word based features are used for a comprehensive comparison.

#### 3.2 Approach 2: Syntagmatic Property based Clustering

For this particular study, a co-occurrence based algorithm is used to create word clusters. As the algorithm is based on co-occurrence, one can extract the classes that have the flavour of syntagmatic grouping, depending on the nature of underlying statistics. Agglomerative clustering algorithm by Brown et al. (1992) is used for this purpose. It is a hard clustering algorithm *i.e.*, each word belongs to one cluster only.

Formally, as mentioned in Brown et al. (1992), let  $C$  be a hard clustering function which maps vocabulary  $V$  to one of the  $K$  clusters. Then, the likelihood ( $L()$ ) of a sequence of word tokens,  $w = [w_j]_{j=1}^m$ , with  $w_j \in V$ , can be factored as,

$$L(w; C) = \prod_{j=1}^m p(w_j | C(w_j)) p(C(w_j) | C(w_{j-1})) \quad (1)$$

Words are assigned to clusters such that the above quantity is maximized. For the purpose of sentiment classification, cluster identifiers representing words in the document are used as features for training.

### 4 Clustering for Cross Lingual Sentiment Analysis

Existing approaches for CLSA depend on an intermediary machine translation system to bridge the language gap (Hiroshi et al., 2004; Banea et al., 2008). Machine translation is very resource intensive. If a language is truly resource scarce, it is mostly unlikely to have an MT system. Given that sentiment analysis is a less resource intensive task compared to machine translation, the use of an MT system is hard to justify for performing

CLSA. As a viable alternative, cluster linkages could be learned from a bilingual parallel corpus and these *linkages* can be used to bridge the language gap for CLSA.

In this section, three approaches using clusters as features for CLSA are compared. The language whose annotated data is used for training is called the source language ( $S$ ), while the language whose documents are to be sentiment classified is referred to as the target language ( $T$ ).

#### 4.1 Approach 1: Projection based on Sense (PS)

In this approach, a Multidict is used to bridge the language gap for SA. A Multidict is an instance of WordNet where the same sense from different languages are linked (Mohanty et al., 2008). An entry in the multidict will have a WordNet sense identifier from  $S$  and the corresponding WordNet sense identifier from  $T$ . The approach of projection based on sense is explained in Algorithm 1. Note that after the *Sense Mark* operation, each document will be represented as a vector of WordNet sense identifiers.

---

##### Algorithm 1 Projection based on sense

---

**Input:** Polarity labeled data in source language ( $S$ ) and data in target language ( $T$ ) to be labeled

**Output:** Classified documents

- 1: Sense mark the polarity labeled data from  $S$
  - 2: Project the sense marked corpora from  $S$  to  $T$  using a Multidict
  - 3: Model the sentiment classifier using the data obtained in step-2
  - 4: Sense mark the unlabelled data from  $T$
  - 5: Test the sentiment classifier on data obtained in step-4 using model obtained in step-3
- 

Sense identifiers are the features for the classifier. For those sense identifiers which do not have a corresponding entry in the Multidict, no projection is performed.

#### 4.2 Approach 2: Direct Cluster Linking (DCL)

Given a parallel bilingual corpus, word clusters in  $S$  can be aligned to clusters in  $T$ . Word alignments are created using parallel corpora. Given two aligned word sequences  $w^S = [w_j^S]_{j=1}^m$  and  $w^T = [w_k^T]_{k=1}^n$ , let  $\alpha^{T|S}$  be a set of scored alignments from the source language to the target

language. Here, an alignment from the  $a_k^{th}$  source word to the  $k^{th}$  target word, with score  $s_{k,a_k} > \epsilon$  is represented as  $(w_k^T, w_{a_k}^S, s_{k,a_k}) \in \alpha^{T|S}$ . To simplify,  $k \in \alpha^{T|S}$  is used to denote those target words  $w_k^T$  that are aligned to some source word  $w_{a_k}^S$ .

The source and the target side clusters are linked using the Equation (2).

$$LC(l) = \underset{t}{\operatorname{argmax}} \sum_{\substack{k \in \alpha^{T|S} \cup \alpha^{S|T} \\ s.t. C^T(w_k^T) = t \\ C^S(w_{a_k}^S) = l}} s_{k,a_k} \quad (2)$$

Here, a target side cluster  $t \in C^T$  is linked to a source side cluster  $l \in C^S$  such that the total alignment score between words in  $l$  and words in  $t$  is maximum.  $C^S$  and  $C^T$  stands for source and target side cluster list respectively.  $LC(l)$  gives the target side cluster  $t$  to which  $l$  is linked.

#### 4.3 Approach 3: Cross-Lingual Clustering (XC)

Direct cluster linking approach suffers from the size of alignment dataset in the form of parallel corpora. The size of the alignment dataset is typically smaller than the monolingual dataset. To circumvent this problem, Täckström et al. (2012) introduced cross-lingual clustering. In cross-lingual clustering, the objective function maximizes the joint likelihood of monolingual and cross-lingual factors. Given a list of words and clusters it belongs to, a clustering algorithm tries to obtain word-cluster association which maximizes the joint likelihood of words and clusters. Whereas in case of cross-lingual clustering, the same clustering can be explained in terms of maximizing the likelihood of monolingual word-cluster pairs of the source, the target and alignments between them.

Formally, as stated in Täckström et al. (2012), Using the model of Uszkoreit and Brants (2008), the likelihood of a sequence of word tokens,  $w = [w_j]_{j=1}^m$ , with  $w_j \in V$ , can be factored as,

$$L(w; C) = \prod_{j=1}^m p(w_j | C(w_j)) p(C(w_j) | w_{j-1}) \quad (3)$$

Note this is different from the likelihood estimation of Brown et al. (1992) (Equation (1)), where  $C(w_j)$  was conditioned on  $C(w_{j-1})$ . This

makes the computation easier as suggested in the original paper. The Equation (3) in a cross lingual setting will be transformed as given below:

$$L^{S,T}(w^S, w^T; \alpha^{T|S}, \alpha^{S|T}, C^S, C^T) = L^S(\dots).L^T(\dots).L^{T|S}(\dots).L^{S|T}(\dots) \quad (4)$$

Here,  $L^{T|S}(\dots)$  and  $L^{S|T}(\dots)$  are factors based on word alignments, which can be represented as:

$$L^{T|S}(w^T; \alpha^{T|S}, C^T, C^S) = \prod_{k \in \alpha^{T|S}} p(w_k^T | C^T(w_k^T)) p(C^T(w_k^T) | C^S(w_{a_k}^S)) \quad (5)$$

Based on the optimization objective in Equation (4), a pseudo algorithm is defined in Algorithm 2. For more information, readers are requested to refer Täckström et al. (2012).

---

**Algorithm 2** Cross-lingual Clustering (XC)

---

**Input:** Source and target language corpus

**Output:** Cross-lingual clusters

- 1: ##  $C^S, C^T$  randomly initialized
  - 2: **for**  $i \leftarrow 1$  to  $N$  **do**
  - 3: Find  $C_*^S \approx \operatorname{argmax}_{C^S} L^S(w^S; C^S)$
  - 4: Project  $C_*^S$  to  $C^T$
  - 5: Find  $C_*^T \approx \operatorname{argmax}_{C^T} L^T(w^T; C^T)$
  - 6: Project  $C_*^T$  to  $C^S$
  - 7: **end for**
- 

An MT based CLSA approach is used as the baseline. Training data from  $S$  is translated to  $T$  and classification model is learned using unigram based features. Thereafter, the classifier is directly tested on data from  $T$ .

## 5 Experimental Setup

Analysis was performed on three languages, *viz.*, *English (En)*, *Hindi (Hi)* and *Marathi (Mar)*. CLSA was performed on two language pairs, *English-Hindi* and *English-Marathi*. For clustering the words, monolingual data of Indian Languages Corpora Initiative (ILCI)<sup>2</sup> was used. It should also be noted that sentiment annotated data was also included in the data used for the word clusterings process. For Brown clustering, an implementation by Liang (2005) was used. Cross-lingual clustering for CLSA

<sup>2</sup><http://sanskrit.jnu.ac.in/ilci/index.jsp>

was implemented as directed in Täckström et al. (2012).

**Monolingual SA:** For experiments in *English*, two polarity datasets were used. The first one (*En-TD*) by Ye et al. (2009) contains user-written reviews on travel destinations. The dataset consists of approximately 600 positive and 591 negative reviews. Reviews were also manually sense annotated using WordNet 2.1. The sense annotation was performed by two annotators with an inter-annotation agreement of 93%. The second dataset (*En-PD*)<sup>3</sup> on product reviews (music instruments) from Amazon by Blitzer et al. (2007) contains 1000 positive and 1000 negative reviews. This dataset was sense annotated using an automatic WSD engine which was trained on tourism domain (Khapra et al., 2010). Experiments using this dataset were done to study the effect of domain on CLSA. For experiments in *Hindi* and *Marathi*, polarity datasets by Balamurali et al. (2012) were used.<sup>4</sup> These are reviews collected from various *Hindi* and *Marathi* blogs and Sunday editorials. *Hindi* dataset consist of 98 positive and 100 negative reviews. Whereas *Marathi* dataset contains 75 positive and 75 negative reviews. Apart from being marked with polarity labels at document level, they are also manually sense annotated using *Hindi* and *Marathi* WordNet respectively.

**CLSA:** The same datasets used in SA are also used for CLSA. Three approaches (as described in section 4) were tested for *English-Hindi* and *English-Marathi* language pairs. To create alignments, *English-Hindi* and *English-Marathi* parallel corpora from ILCI were used. *English-Hindi* parallel corpus contains 45992 sentences and *English-Marathi* parallel corpus contains 47881 sentences. To create alignments, GIZA++<sup>5</sup> was used (Och and Ney, 2003).

As a preprocessing step, all stop words were removed. Stemming was performed on English and Hindi whereas for Marathi data, Morphological Analyzer was used to reduce the words to their respective lemmas.

All experiments were performed using C-SVM

Features	En-TD	En-PD	Hi	Mar
Words	87.02	77.60	77.36	92.28
WordNet Sense (Paradigmatic)	89.13	74.50	<b>85.80</b>	96.88
Clusters (Syntagmatic)	<b>97.45</b>	<b>87.80</b>	83.50 <sup>x</sup>	<b>98.66</b>

Table 1: Classification accuracy for monolingual sentiment analysis. For English, results are reported on two publicly available datasets based on Travel Domain (TD) and Product Domain (PD).

Features	Words	Clust-200	Clust-500	Clust-1000	Clust-1500	Clust-2000	Clust-2500	Clust-3000
En-TD	87.02	97.37	97.45	96.94	96.94	96.52	96.52	96.52
En-PD	77.60	73.20	82.30	84.30	86.35	86.45	87.80	87.40

Table 2: Classification accuracy (in %) versus cluster size (number of clusters to be used).

(linear kernel with parameter optimized over training set using 5 fold cross validation) available as a part of LibSVM package<sup>6</sup>. SVM was used since it is known to perform well for sentiment classification (Pang et al., 2002). Results reported are based on the average of ten-fold cross-validation accuracies. Standard text metrics are used for reporting the experimental results.

## 6 Results

Monolingual classification results are shown in Table<sup>7</sup>1. Table shows accuracies of SA systems developed on feature set based on words, senses and clusters. It must be noted that accuracies reported for cluster based features are with respect to the best accuracy based on different cluster sizes. The improvements in results of cluster features based approach is found to be statistically significant over the word features based approach and sense features based approach at 95% confidence level when tested using a paired t-test (except for *Hindi* cluster features based approach). But in general, their accuracies do not significantly vary after cluster size crosses 1500.

Table 2 shows the classification accuracy variation when cluster size is altered. For, En-TD and En-PD experiments, the cluster size was varied between 200-3000 with an interval of 500 (after a size of 500). In the En-TD experiment, the best accuracy is achieved for cluster size 500, which is lesser than the number of unique-words/unique-senses (6435/6004) present in the data. Similarly, for the En-PD experiment,

the optimal cluster size of 2500 is also lesser than the number of unique-words/unique-senses (30468/4735) present in the data.

To see the effect of training data size variation for different SA approaches in the En-TD experiment, the training data size is varied between 50 to 500. For this, a test set consisting of 100 positive and 100 negative documents is fixed. The training data size is varied by selecting different number of documents from rest of the dataset (~500 negative and ~500 positive) as a training set. For each training data set 10 repeats are performed, *e.g.*, for training data size of 50, 50 negative and 50 positive documents are randomly selected from the training data pool of ~500 negative and ~500 positive. This was repeated 10 times (with replacement). The results of this experiment are presented in Figure 1.

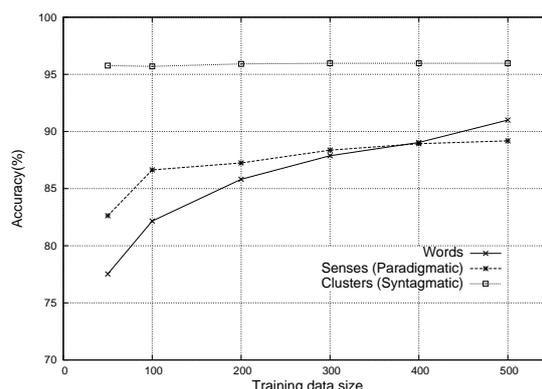

Figure 1: Training data variation on En-TD dataset.

Cross-lingual SA accuracies are presented in Table 3. As in monolingual case, the reported accuracies are for features based on the best cluster size.

<sup>6</sup><http://www.csie.ntu.edu.tw/~cjlin/libsvm>

<sup>7</sup>All results reported here are based on 10-fold except for Marathi (2-fold-5-repeats), as it had comparatively lesser data samples.

Target Language	MT	PS	DCL	XC
<i>T=Hi</i>	63.13	53.80	51.51	<b>66.16</b>
<i>T=Mar</i>	NA	54.00	56.00	<b>60.30</b>

Table 3: Cross-Lingual SA accuracy (%) on *T=Hi* and *T=Mar* with *S=En* for different approaches (MT=Machine Translation, PS=Projection based on Sense, DCL=Direct Cluster Linking, XC=Cross-Lingual Clustering. There is no MT system available for (*S=En, T=Mar*).

## 7 Discussions

In this section, some important observations from the results are discussed.

**1. Syntagmatic analysis may be used in lieu of paradigmatic analysis for SA:** The results suggest that word cluster based features using syntagmatic analysis is comparatively better than cluster (sense) based features using paradigmatic analysis. For two datasets in *English* and for the one in *Marathi* this holds true. For *English*, the gap between classification accuracy based on sense features and cluster features is around 10%. A state-of-art accuracy is obtained for the public dataset on travel domain (*En-TD*).

The difference in accuracy reduces as the language gets morphologically rich. In a morphologically rich language, morphology encompasses syntactical information, limiting the context it can provide for clustering. This can be seen from the classification results on *Marathi*. However for *Hindi*, classifier built on features based on syntagmatic analysis trails the one based on paradigmatic analysis.

Compared to *Marathi*, *Hindi* is a less morphologically rich language, hence, a better result was expected. However, a contrary result was obtained.<sup>8</sup> In *Hindi*, the subject and the object of the sentence are linked using a case marker. Upon error analysis, it was found that there was a lot of irregular compounding based on case markers. Case markers were compounded with the succeeding word. This is a deviation from the real scenario which would have resulted in incorrect clustering leading to an unexpected result. However, the same would not have occurred for a classifier developed on sense based features as it was manually sense tagged.

Clustering induces a reduction in the data sparsity. For example, on *En-PD*, percentage of features present in the test set and not present in the training set to those present in the test set are 34.17%, 11.24%, 0.31% for words, synsets

and cluster based features respectively. The improvement in the performance of classifiers may be attributed to this feature size reduction. However, it must be noted that clustering based on unlabelled corpora is less taxing than manually creating paradigmatic property based clusters like WordNet synsets.

Barring one instance, both cluster based features outperform word based features. The reason for the drop in the accuracy of approach based on sense features for *En-PD* dataset is the domain specific nature of sentiment analysis (Blitzer et al., 2007), which is explained in the next point.

**2. Domain issues are resolved while using cluster based features:** For *En-PD*, the classifier developed using sense features based on paradigmatic analysis performs inferior to word based features. Compared to other datasets used for analysis, this dataset was sense annotated using an automatic WSD engine. This engine was trained on a travel domain corpus and as WSD is also domain specific, the final classification performance suffered. Additionally, as the target domain was on products, the automatic WSD engine employed had an in-domain accuracy of 78%. The sense disambiguation accuracy of the same would have lowered in a cross-domain setting. This might have had a degrading effect on the SA accuracy.

However, it was seen that classifier developed on cluster features based on syntagmatic analysis do not suffer from this. Such clusters obliterate domain related issues. In addition, as more unlabelled data is included for clustering, the classification accuracy improves.<sup>8</sup> Thus, clustering may be employed to tackle other specific domain related issues in SA.

<sup>8</sup>It was observed that adding 0.1 million unlabelled documents, SA accuracy improved by 1%. This was observed in the case of English for which there is abundant unlabelled corpus.

**3. Cluster based features using syntagmatic analysis requires lesser training data:** Cluster based features drastically reduces the dimension of the feature vector. For instance, the size of sense based features for En-TD dataset was  $1/6^{th}$  of the size of word based features. This reduces the perplexity of the classification model. The reduction in the perplexity leads to the reduction of training documents to attain the same classification accuracy without any dimensionality reduction. This is evident from Figure 1 where accuracy of the cluster features based on unlabelled corpora are higher even with lesser training data.

**4. Effect of cluster size:** The cluster size (number of clusters employed) has an implication on the purity of each cluster with respect to the application. The system performance improved upon increasing the cluster size and converged after attaining a certain level of accuracy. In general, it was found that the best classification accuracy was obtained for a cluster size between 1000 and 2500. As evident from Table 2, once the optimal accuracy is obtained, no significant changes were observed by increasing the cluster size.

**5. Clustering based CLSA is effective:** For target language as *Hindi*, CLSA accuracy based on cross-lingual clustering (syntagmatic) outperforms the one based on MT (refer to Table 3). This was true for the constraint clustering approach based on cross-lingual clustering. Whereas, sentiment classifier using sense (PS) or direct cluster linking (DCL) is not very effective. In case of PS approach, the coverage of the mult字典 was a problem. The number of a linkages between sense from *English* to *Hindi* is only around  $1/3^{rd}$  the size of Princeton WordNet (Fellbaum, 1998). Similarly in case of DCL approach, monolingual likelihood is different from the cross-lingual likelihood in terms of the linkages.

**6. A note on CLSA for truly resource scarce languages:** Note that there is no publicly available MT system for *English* to *Marathi*. Moreover, the digital content in *Marathi* language does not have a standard encoding format. This impedes the automatic crawling of the web for corpora creation for SA. Much manual effort has to be put to collect enough corpora for analysis. However, even in these languages, unlabelled corpora is

easy to obtain. *Marathi* was chosen to depict a truly resource scarce SA scenario. Cluster features based classifier comparatively performed well with 60% classification accuracy. An MT based system would have suffered in this case as *Marathi*, as stated earlier, is a morphologically rich language and as compared to English, has a different word ordering. This could degrade the accuracy of the machine translation itself, limiting the performance of an MT based CLSA system. All this is obliterated by the use of a cluster based CLSA approach. Moreover, as more monolingual corpora is added for clustering, the cross lingual cluster linkages could be refined. This can further boost the CLSA accuracy.

## 8 Conclusion and Future Work

This paper explored feasibility of using word cluster based features in lieu of features based on WordNet senses for sentiment analysis to alleviate the problem of data sparsity. Abstractly, the motivation was to see if highly effective features based on paradigmatic property based clustering could be replaced with the inexpensive ones based on syntagmatic property for SA.

The study was performed for both monolingual SA and cross-lingual SA. It was found that cluster features based on syntagmatic analysis are better than the WordNet sense features based on paradigmatic analysis for SA. Investigation revealed that a considerable decrease in the training data could be achieved while using such class based features. Moreover, as syntagma based word clusters are homogenous, it was able to address domain specific nature of SA as well.

For CLSA, clusters linked together using unlabelled parallel corpora do away with the need of translating labelled corpora from one language to another using an intermediary MT system or bilingual dictionary. Such a method outperforms an MT based CLSA approach. Further, this approach was found to be useful in cases where there are no MT systems to perform CLSA and the language of analysis is truly resource scarce. Thus, wider implication of this study is that many widely spoken yet resource scarce languages like *Pashto*, *Sundanese*, *Hausa*, *Gujarati* and *Punjabi* which do not have an MT system could now be analysed for sentiment. The approach presented here for CLSA will still require a parallel corpora. However, the size of the parallel corpora required

for CLSA can considerably be much lesser than the size of the parallel corpora required to train an MT system.

A naive cluster linkage algorithm based on word alignments was used to perform CLSA. As a result, there were many erroneous linkages which lowered the final SA accuracy. Better cluster-linking approaches could be explored to alleviate this problem. There are many applications which use WordNet like IR, IE *etc.* It would be interesting to see if these could be replaced by clusters based on the syntagmatic property.

## Abstract

Supervised training procedures for semantic parsers produce high-quality semantic parsers, but they have difficulty scaling to large databases because of the sheer number of logical constants for which they must see labeled training data. We present a technique for developing semantic parsers for large databases based on a reduction to standard supervised training algorithms, schema matching, and pattern learning. Leveraging techniques from each of these areas, we develop a semantic parser for Freebase that is capable of parsing questions with an F1 that improves by 0.42 over a purely-supervised learning algorithm.

## 1 Introduction

Semantic parsing is the task of translating natural language utterances to a formal meaning representation language (Chen et al., 2010; Liang et al., 2009; Clarke et al., 2010; Liang et al., 2011; Artzi and Zettlemoyer, 2011). There has been recent interest in producing such semantic parsers for large, heterogeneous databases like Freebase (Krishnamurthy and Mitchell, 2012; Cai and Yates, 2013) and Yago2 (Yahya et al., 2012), which has driven the development of semi-supervised and distantly-supervised training methods for semantic parsing. Previous purely-supervised approaches have been limited to smaller domains and databases, such as the GeoQuery database, in part because of the cost of labeling enough samples to cover all of the logical constants involved in a domain.

This paper investigates a reduction of the problem of building a semantic parser to three standard problems in semantics and machine learning: supervised training of a semantic parser, schema matching, and pattern learning. Figure 1 provides a visualization of our system architecture. We apply an existing supervised training algorithm for semantic parsing to a labeled data set. We

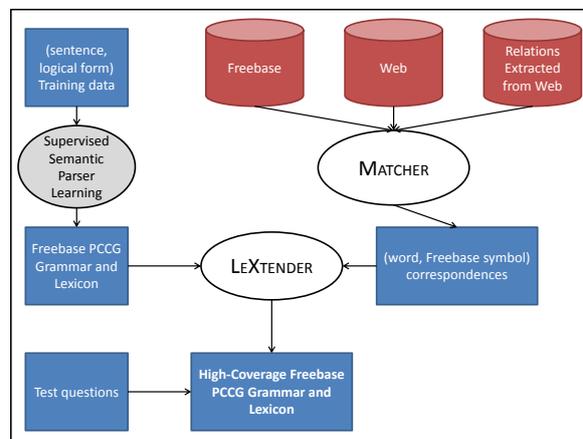

Figure 1: We reduce the task of learning a large-scale semantic parser to a combination of 1) a standard supervised algorithm for learning semantic parsers; 2) our MATCHER algorithm for finding correspondences between words and database symbols; and 3) our LEXTENDER algorithm for integrating (word, database symbol) matches into a semantic parsing lexicon.

apply schema matching techniques to the problem of finding correspondences between English words  $w$  and ontological symbols  $s$ . And we apply pattern learning techniques to incorporate new  $(w, s)$  pairs into the lexicon of the trained semantic parser.

This reduction allows us to apply standard techniques from each problem area, which in combination provide a large improvement over the purely-supervised approaches. On a dataset of 917 questions taken from 81 domains of the Freebase database, a standard learning algorithm for semantic parsing yields a parser with an F1 of 0.21, in large part because of the number of logical symbols that appear during testing but never appear during training. Our techniques can extend this parser to new logical symbols through schema matching, and yield a semantic parser with an F1 of 0.63 on the same task. On a more challenging task where training and test data are divided so that all logical constants in test are never observed dur-

ing training, our approach yields a semantic parser with an F1 of 0.6, whereas the purely supervised approach cannot parse a single test question correctly. These results indicate that it is possible to automatically extend semantic parsers to symbols for which little or no training data has been observed.

The rest of this paper is organized as follows. The next section discusses related work. Section 3 describes our MATCHER algorithm for performing schema matching between a knowledge base and text. Section 4 explains how we use MATCHER’s schema matching to extend a standard semantic parser to logical symbols for which it has seen no labeled training data. Section 5 analyzes the performance of MATCHER and our semantic parser. Section 6 concludes.

## 2 Previous Work

Two existing systems translate between natural language questions and database queries over large-scale databases. Yahya *et al.* (2012) report on a system for translating natural language queries to SPARQL queries over the Yago2 (Hofmann *et al.*, 2013) database. Yago2 consists of information extracted from Wikipedia, WordNet, and other resources using manually-defined extraction patterns. The manual extraction patterns pre-define a link between natural language terms and Yago2 relations. Our techniques automate the process of identifying matches between textual phrases and database relation symbols, in order to scale up to databases with more relations, like Freebase. A more minor difference between Yahya *et al.*’s work and ours is that their system handles SPARQL queries, which do not handle aggregation queries like `argmax` and `count`. We rely on an existing semantic parsing technology to learn the language that will translate into such aggregation queries. On the other hand, their test questions involve more conjunctions and complex semantics than ours. Developing a dataset with more complicated semantics in the queries is part of our ongoing efforts.

Krishnamurthy and Mitchell (2012) also create a semantic parser for Freebase covering 77 of Freebase’s over 2000 relations. Like our work, their technique uses distant supervision to drive training over a collection of sentences gathered from the Web, and they do not require any manually-labeled training data. However, their

technique does require manual specification of rules that construct CCG lexical entries from dependency parses. In comparison, we fully automate the process of constructing CCG lexical entries for the semantic parser by making it a prediction task. We also leverage synonym-matching techniques for comparing relations extracted from text with Freebase relations. Finally, we test our results on a dataset of 917 questions covering over 600 Freebase relations, a more extensive test than the 50 questions used by Krishnamurthy and Mitchell.

Numerous methods exist for comparing two relations based on their sets of tuples. For instance, the DIRT system (Lin and Pantel, 2001) uses the mutual information between the  $(X, Y)$  argument pairs for two binary relations to measure the similarity between them, and clusters relations accordingly. More recent examples of similar techniques include the Resolver system (Yates and Etzioni, 2009) and Poon and Domingos’s USP system (Poon and Domingos, 2009). Our techniques for comparing relations fit into this line of work, but they are novel in their application of these techniques to the task of comparing database relations and relations extracted from text.

Schema matching (Rahm and Bernstein, 2001; Ehrig *et al.*, 2004; Giunchiglia *et al.*, 2005) is a task from the database and knowledge representation community in which systems attempt to identify a “common schema” that covers the relations defined in a set of databases or ontologies, and the mapping between each individual database and the common schema. Owing to the complexity of the general case, researchers have resorted to defining standard similarity metrics between relations and attributes, as well as machine learning algorithms for learning and predicting matches between relations (Doan *et al.*, 2004; Wick *et al.*, 2008b; Wick *et al.*, 2008a; Nottelmann and Straccia, 2007; Berlin and Motro, 2006). These techniques consider only matches between relational databases, whereas we apply these ideas to matches between Freebase and extracted relations. Schema matching in the database sense often considers complex matches between relations (Dhamanka *et al.*, 2004), whereas as our techniques are currently restricted to matches involving one database relation and one relation extracted from text.

### 3 Textual Schema Matching

#### 3.1 Problem Formulation

The textual schema matching task is to identify natural language words and phrases that correspond with each relation and entity in a fixed schema for a relational database. To formalize this task, we first introduce some notation.

A *schema*  $S = (E, R, C, I)$  consists of a set of entities  $E$ , a set of relations  $R$ , a set of categories  $C$ , and a set of instances  $I$ . Categories are one-argument predicates (e.g., `film(e)`), and relations are two- (or more-) argument predicates (e.g., `directed.by(e1, e2)`). Instances are known tuples of entities that make a relation or category true, such as `film(Titanic)` or `directed.by(Titanic, James Cameron)`. For a given  $r \in R$  (or  $c \in C$ ),  $I_S(r)$  indicates the set of known instances of  $r$  in schema  $S$  (and likewise for  $I_S(c)$ ). Examples of such schemas include Freebase (Bollacker et al., 2008) and Yago2 (Hoffart et al., 2013). We say a schema is a *textual* schema if it has been extracted from free text, such as the Nell (Carlson et al., 2010) and ReVerb (Fader et al., 2011) extracted databases.

Given a textual schema  $T$  and a database schema  $D$ , the textual schema matching task is to identify an alignment or *matching*  $M \subset R_T \times R_D$  such that  $(r_T, r_D) \in M$  if and only if  $r_T$  can be used to refer to  $r_D$  in normal language usage. The problem would be greatly simplified if  $M$  were a 1-1 function, but in practice most database relations can be referred to in many ways by natural language users: for instance, `film_actor` can be referenced by the English verbs “played,” “acted,” and “starred,” along with morphological variants of them. In addition, many English verbs can refer to several different relations in Freebase: “make” can refer to `computer_processor_manufacturer` or `distilled_spirits_producer`, among many others. Our MATCHER algorithm for textual schema matching handles this by producing a confidence score for every possible  $(r_T, r_D)$  pair, which downstream applications can then use to reason about the possible alignments.

Even worse than the ambiguities in alignment, some textual relations do not correspond with any database relation exactly, but instead they correspond with a projection of a relation, or a join between multiple relations, or another com-

plex view of a database schema. As a simple example, “actress” corresponds to a subset of the Freebase `film_actor` relation that intersects with the set  $\{x: \text{gender}(x, \text{female})\}$ . MATCHER can only determine that “actress” aligns with `film_actor` or not; it cannot produce an alignment between “actress” and a join of `film_actor` and `gender`. These more complex alignments are an important consideration for future work, but as our experiments will show, quite useful alignments can be produced without handling these more complex cases.

#### 3.2 Identifying candidate matches

MATCHER uses a generate-and-test architecture for determining  $M$ . It uses a Web search engine to issue queries for a database relation  $r_D$  consisting of all the entities in a tuple  $t \in I_D(r_D)$ . 1000 tuples for each  $r_D$  are randomly chosen for issuing queries. The system then retrieves matching snippets from the search engine results. It uses the top 10 results for each search engine query. It then counts the frequency of each word type in the set of retrieved snippets for  $r_D$ . The top 500 non-stopword word types are chosen as candidates for matches with  $r_D$ . We denote the candidate set for  $r_D$  as  $C(r_D)$ .

MATCHER’s threshold of 500 candidates for  $C(r_D)$  results in a maximum possible recall of just less than 0.8 for the alignments in our dataset, but even if we double the threshold to 1000, the recall improves only slightly to 0.82. We therefore settled on 500 as a point with an acceptable upper bound on recall, while also producing an acceptable number of candidate terms for further processing.

#### 3.3 Pattern-based match selection

The candidate pool  $C(r_D)$  of 500 word types is significantly smaller than the set of all textual relations, but it is also extremely noisy. The candidates may include non-relation words, or other frequent but unrelated words. They may also include words that are highly related to  $r_D$ , but not actually corresponding textual relations. For instance, the candidate set for `film_director` in Freebase includes words like “directed,” but also words like “film,” “movie,” “written,” “produced,” and “starring.” We use a series of filters based on synonym-detection techniques to help select the true matching candidates from  $C(r_D)$ .

	Pattern	Condition	Example
1.	“ $r_T$ in $E$ ”	$r_T$ ends with “-ed” and $E$ has type <code>datetime</code> or <code>location</code>	“founded in 1989”
2.	“ $r_T$ by $E$ ”	$r_T$ ends with “-ed”	“invented by Edison”
3.	“ $r_T$ such as $E$ ”	$r_T$ ends with “-s”	“directors such as Tarantino”
4.	“ $E$ is a(n) $r_T$ ”	all cases	“Paul Rudd is an actor”

Table 1: Patterns used by MATCHER as evidence of a match between  $r_D$  and  $r_T$ .  $E$  represents an entity randomly selected from the tuples in  $I_D(r_D)$ .

The first type of evidence we consider for identifying true matches from  $C(r_D)$  consists of pattern-matching. Relation words that express  $r_D$  will often be found in complex grammatical constructions, and often they will be separated from their entity arguments by long-distance dependencies. However, over a large corpus, one would expect that in at least some cases, the relation word will appear in a simple, relatively-unambiguous grammatical construction that connects  $r_T$  with entities from  $r_D$ . For instance, entities  $e$  from the relationship `automotive_designer` appear in the pattern “designed by  $e$ ” more than 100 times as often as the next most-common patterns, “considered by  $e$ ” and “worked by  $e$ .”

MATCHER uses searches over the Web to count the number of instances where a candidate  $r_T$  appears in simple patterns that involve entities from  $r_D$ . Greater counts for these patterns yield greater evidence of a correct match between  $r_D$  and  $r_T$ . Table 1 provides a list of patterns that we consider. For each  $r_D$  and each  $r_T \in C(r_D)$ , MATCHER randomly selects 10 entities from  $r_D$ ’s tuples to include in its pattern queries. Two of the patterns are targeted at past-tense verbs, and the other two patterns at nominal relation words.

MATCHER computes statistics similar to pointwise mutual information (PMI) (Turney, 2001) to measure how related  $r_D$  and  $r_T$  are, for each pattern  $p$ . Let  $c(p, r_D, r_T)$  indicate the sum of all the counts for a particular pattern  $p$ , database relation, and textual relation:

$$f_p(r_T, r_D) = \frac{c(p, r_D, r_T)}{\sum_{r'_D} c(p, r'_D, r_T) * \sum_{r'_T} c(p, r_D, r'_T)}$$

For the sum over all  $r'_D$ , we use all  $r'_D$  in Freebase for which  $r_T$  was extracted as a candidate.

One downside of the pattern-matching evidence is the sheer number of queries it requires. Freebase

currently has over 2,000 relations. For each  $r_D$ , we have up to 500 candidate  $r_T$ , up to 4 patterns, and up to 10 entities per pattern. To cover all of Freebase, MATCHER needs  $2,000 \times 500 \times 4 \times 10 = 40$  million queries, or just over 1.25 years if it issues 1 query per second (we covered approximately one-quarter of Freebase’s relations in our experiments). Using more patterns and more entities per pattern are desirable for accumulating more evidence about candidate matches, but there is a trade-off with the time required to issue the necessary queries.

### 3.4 Comparing database relations with extracted relations

Open Information Extraction (Open IE) systems (Banko et al., 2007) can often provide a large set of extracted tuples for a given  $r_T$ , which MATCHER can then use to make much more comprehensive comparisons with the full tuple set for  $r_D$  than the pattern-matching technique allows.

MATCHER employs a form of PMI to compute the degree of relatedness between  $r_D$  and  $r_T$ . In its simplest form, MATCHER computes:

$$PMI(r_T, r_D) = \frac{|I_D(r_D) \cap I_T(r_T)|}{|I_D(r_D)| \cdot |I_T(r_T)|} \quad (1)$$

While this PMI statistic is already quite useful, we have found that in practice there are many cases where an exact match between tuples in  $I_D(r_D)$  and tuples in  $I_T(r_T)$  is too strict of a criterion. MATCHER uses a variety of approximate matches to compute variations of this statistic. Considered as predictors for the true matches in  $M$ , these variations of the PMI statistic have a lower precision, in that they are more likely to have high values for incorrect matches. However, they also have a higher recall: that is, they will have a high value for correct candidates in  $C(r_D)$  when the strict version of PMI does not. Table 2 lists all the variations used by MATCHER.

Statistics for $(r_T, r_D)$
$s_\kappa(r_T, r_D) = \frac{\sum_{t_D \in I_D(r_D)} \sum_{t_T \in I_T(r_T)} \kappa(t_D, t_T)}{ I_D(r_D)  \cdot  I_T(r_T) }$
$s'_\kappa(r_T, r_D) = \frac{s_\kappa(r_T, r_D)}{\sum_{r'_D} s_\kappa(r'_D, r_T)}$
$s''(r_T, r_D) = \frac{ I_T(r_T) }{ I_D(r_D) }$

Table 2: MATCHER statistics: for each  $\kappa$  function for comparing two tuples (given in Table 3), MATCHER computes the statistics above to compare  $r_D$  and  $r_T$ . The PMI statistic in Equation 1 corresponds to  $s_\kappa$  where  $\kappa$  =strict match over  $\Phi$  =full tuples.

$\kappa(t_1, t_2)$ for comparing tuples $t_1, t_2$
strict match: $\begin{cases} 1, \text{ if } \Phi(t_1) = \Phi'(t_2) \\ 0, \text{ otherwise.} \end{cases}$
type match: $\begin{cases} 1, \text{ if } \forall_k \text{cat}(\Phi(t_1)_k) \\ \quad = \text{cat}(\Phi'(t_2)_k) \\ 0, \text{ otherwise.} \end{cases}$

Table 3: MATCHER’s  $\kappa$  functions for computing whether two tuples are similar. *cat* maps an entity to a category (or type) in the schema. MATCHER has a different  $\kappa$  function for each possible combination of  $\Phi$  and  $\Phi'$  functions, which are given in Table 4.

MATCHER uses an API for the ReVerb Open IE system<sup>1</sup> (Fader et al., 2011) to collect  $I(r_T)$ , for each  $r_T$ . The API for ReVerb allows for relational queries in which some subset of the entity strings, entity categories, and relation string are specified. The API returns all matching triples; types must match exactly, but relation or argument strings in the query will match any relation or argument that contains the query string as a substring. MATCHER queries ReVerb with three different types of queries for each  $r_T$ , specifying the types for both arguments, or just the type of the first argument, or just the second argument. Types for arguments are taken from the types of arguments for a potentially matching  $r_D$  in Freebase. To avoid overwhelming the ReVerb servers, for our experiments we limited MATCHER to queries

<sup>1</sup><http://openie.cs.washington.edu/>

$\Phi(t)$ for tuple $t = (e_1, \dots, e_n)$
$\forall_i e_i$ (projection to one dimension)
$(e_1, \dots, e_n)$ (full tuple)
$\forall_{\sigma(\cdot)} (e_{\sigma(1)}, \dots, e_{\sigma(n)})$ (permutation)

Table 4: MATCHER’s  $\Phi$  functions for projecting or permuting a tuple.  $\sigma$  indicates a permutation of the indices.

for the top 80  $r_T \in C(r_D)$ , when they are ranked according to frequency during the candidate identification process.

### 3.5 Regression models for scoring candidates

Pattern statistics, the ReVerb statistics from Table 2, and the count of  $r_T$  during the candidate identification step all provide evidence for correct matches between  $r_D$  and  $r_T$ . MATCHER uses a regression model to combine these various statistics into a score for  $(r_T, r_D)$ . The regression model is a linear regression with least-squares parameter estimation; we experimented with support vector regression models with non-linear kernels, with no significant improvements in accuracy. Section 5 explains the dataset we use to train this model. Unlike a classifier, MATCHER does not output any single matching  $M$ . However, downstream applications can easily convert MATCHER’s output into a matching  $M$  by, for instance, selecting the top  $K$  candidate  $r_T$  values for each  $r_D$ , or by selecting all  $(r_T, r_D)$  pairs with a score over a chosen threshold. Our experiments analyze MATCHER’s success by comparing its performance across a range of different values for the number of  $r_T$  matches for each  $r_D$ .

## 4 Extending a Semantic Parser Using a Schema Alignment

An alignment between textual relations and database relations has many possible uses: for example, it might be used to allow queries over a database to be answered using additional information stored in an extracted relation store, or it might be used to deduce clusters of synonymous relation words in English. Here, we describe an application in which we build a question-answering system for Freebase by extending a standard learning technique for semantic parsing with schema alignment information.

As a starting point, we used the UBL system

developed by Kwiatkowski *et al.* (2010) to learn a semantic parser based on probabilistic Combinatory Categorical Grammar (PCCG). Source code for UBL is freely available. Its authors found that it achieves results competitive with the state-of-the-art on a variety of standard semantic parsing data sets, including Geo250 English (0.85 F1). Using a fixed CCG grammar and a procedure based on unification in second-order logic, UBL learns a lexicon  $\Lambda$  from the training data which includes entries like:

#### Example Lexical Entries

---

New York City  $\vdash NP : \text{new\_york}$   
 neighborhoods in  $\vdash$   
 $S \setminus NP / NP : \lambda x \lambda y . \text{neighborhoods}(x, y)$

#### Example CCG Grammar Rules

---

$X/Y : f \quad Y : g \Rightarrow X : f(g)$   
 $Y : g \quad X \setminus Y : f \Rightarrow X : f(g)$

Using  $\Lambda$ , UBL selects a logical form  $z$  for a sentence  $S$  by selecting the  $z$  with the most likely parse derivations  $y$ :  $h(S) = \arg \max_z \sum_y p(y, z | x; \theta, \Lambda)$ . The probabilistic model is a log-linear model with features for lexical entries used in the parse, as well as indicator features for relation-argument pairs in the logical form, to capture selectional preferences. Inference (parsing) and parameter estimation are driven by standard dynamic programming algorithms (Clark and Curran, 2007), while lexicon induction is based on a novel search procedure through the space of possible higher-order logic unification operations that yield the desired logical form for a training sentence.

Our Freebase data covers 81 of the 86 core domains in Freebase, and 635 of its over 2000 relations, but we wish to develop a semantic parser that can scale to all of Freebase. UBL gets us part of the way there, by inducing a PCCG grammar, as well as lexical entries for function words that must be handled in all domains. It can also learn lexical entries for relations  $r_D$  that appear in the training data. However, UBL has no way to learn lexical entries for the many valid  $(r_T, r_D)$  pairs that do not appear during training.

We use MATCHER’s learned alignment to extend the semantic parser that we get from UBL by automatically adding in lexical entries for Free-

base relations. Essentially, for each  $(r_T, r_D)$  from MATCHER’s output, we wish to construct a lexical entry that states that  $r_T$ ’s semantics resembles  $\lambda x \lambda y . r_D(x, y)$ . However, this simple process is complicated by the fact that the semantic parser requires two additional types of information for each lexical entry: a syntactic category, and a weight. Furthermore, for many cases the appropriate semantics are significantly more complex than this pattern.

To extend the learned semantic parser to a semantic parser for all of Freebase, we introduce a prediction task, which we call *semantic lexicon extension*: given a matching  $M$  together with scores for each pair in  $M$ , predict the syntactic category  $Syn$ , lambda-calculus semantics  $Sem$ , and weight  $W$  for a full lexical entry for each  $(r_T, r_D) \in M$ . One advantage of the reduction approach to learning a semantic parser is that we can automatically construct training examples for this prediction task from the other components in the reduction. We use the output lexical entries learned by UBL as (potentially noisy) examples of true lexical entries for  $(r_T, r_D)$  pairs where  $r_T$  matches the word in one of UBL’s lexical entries, and  $r_D$  forms part of the semantics in the same lexical entry. For  $(r_T, r_D)$  pairs in  $M$  where  $r_D$  occurs in UBL’s lexical entries, but not paired with  $r_T$ , we create dummy “negative” lexical entries with very low weights, one for each possible syntactic category observed in all lexical entries. Note that in order to train LEXTENDER, we need the output of MATCHER for the relations in UBL’s training data, as well as UBL’s output lexicon from the training data.

Our system for this prediction task, which we call LEXTENDER (for Lexicon eXtender), factors into three components:  $P(Sem | r_D, r_T, score)$ ,  $P(Syn | Sem, r_D, r_T, score)$ , and  $P(W | Syn, Sem, r_D, r_T, score)$ . This factorization is trivial in that it introduces no independence assumptions, but it helps in designing models for the task. We set the event space for random variable  $Sem$  to be the set of all lambda calculus expressions observed in UBL’s output lexicon, modulo the names of specific Freebase relations. For instance, if the lexicon includes two entries whose semantics are  $\lambda x \lambda y . \text{film\_actor}(x, y)$  and  $\lambda x \lambda y . \text{book\_author}(x, y)$ , the event space would include the single expression in which relations `film_actor` and `book_author` were replaced by

a new variable:  $\lambda p \lambda x \lambda y . p(x, y)$ . The final semantics for a lexical entry is then constructed by substituting  $r_D$  for  $p$ , or more formally, by a function application  $Sem(r_D)$ . The event space for  $Syn$  consists of all syntactic categories in UBL’s output lexicon, and  $W$  ranges over  $\mathbf{R}$ .

LEXTENDER’s model for  $Sem$  and  $Syn$  are Naïve Bayes classifiers (NBC), with features for the part-of-speech for  $r_T$  (taken from a POS tagger), the suffix of  $r_T$ , the number of arguments of  $r_D$ , and the argument types of  $r_D$ . For  $Syn$ , we add a feature for the predicted value of  $Sem$ . For  $W$ , we use a linear regression model whose features are the score from MATCHER, the probabilities from the  $Syn$  and  $Sem$  NBC models, and the average weight of all lexical entries in UBL with matching syntax and semantics. Using the predictions from these models, LEXTENDER extends UBL’s learned lexicon with all possible lexical entries with their predicted weights, although typically only a few lexical entries have high enough weight to make a difference during parsing. Pruning entries with low weights could improve the memory and time requirements for parsing, but these were not an issue in our experiments, so we did not investigate this further.

## 5 Experiments

We conducted experiments to test the ability of MATCHER and LEXTENDER to produce a semantic parser for Freebase. We first analyze MATCHER on the task of finding matches between Freebase relations and textual relations. We then compare the performance of the semantic parser learned by UBL with its extension provided by LEXTENDER on a dataset of English questions posed to Freebase.

### 5.1 Experimental Setup

Freebase (Bollacker et al., 2008) is a free, online, user-contributed, relational database (www.freebase.com) covering many different domains of knowledge. The full schema and contents are available for download. The “Freebase Commons” subset of Freebase, which is our focus, consists of 86 domains, an average of 25 relations per domain (total of 2134 relations), and 615,000 known instances per domain (53 million instances total). As a reference point, the GeoQuery database — which is a standard benchmark database for semantic parsing —

### Examples

1. What are the neighborhoods in New York City?  
 $\lambda x . \text{neighborhoods}(\text{new\_york}, x)$
2. How many countries use the rupee?  
 $\text{count}(x) . \text{countries\_used}(\text{rupee}, x)$
3. How many Peabody Award winners are there?  
 $\text{count}(x) . \exists y . \text{award\_honor}(y) \wedge$   
 $\text{award\_winner}(y, x) \wedge$   
 $\text{award}(y, \text{peabody\_award})$

Figure 2: Example questions with their logical forms. The logical forms make use of Freebase symbols as logical constants, as well as a few additional symbols such as `count` and `argmin`, to allow for aggregation queries.

contains a single domain (geography), 8 relations, and 880 total instances.

Our dataset contains 917 questions (on average, 6.3 words per question) and a meaning representation for each question written in a variant of lambda calculus<sup>2</sup>. 81 domains are represented in the data set, and the lambda calculus forms contain 635 distinct Freebase relations. The most common domains, `film` and `business`, each took up no more than 6% of the overall dataset. Several examples are listed in Fig. 2. The questions were provided by two native English speakers. No restrictions were placed on the type of questions they should produce, except that they should produce questions for multiple domains. By inspection, a large majority of the questions appear to be answerable from Freebase, although no instructions were given to restrict questions to this sort. We also created a dataset of alignments from these annotated questions by creating an alignment for each Freebase relation mentioned in the logical form for a question, paired with a manually-selected word from the question.

### 5.2 Alignment Tests

We measured the precision and recall of MATCHER’s output against the manually labeled data. Let  $M$  be the set of  $(r_T, r_D)$  matches produced by the system, and  $G$  the set of matches in the gold-standard manual data. We define

<sup>2</sup>The data is available from the second author’s website.

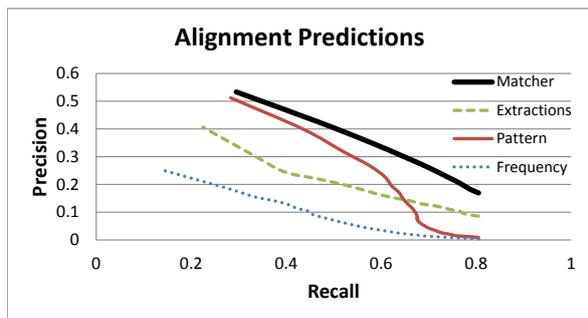

Figure 3: MATCHER’s Pattern features and Extractions features complement one another, so that in combination they outperform either subset on its own, especially at the high-recall end of the curve.

precision and recall as:

$$P = \frac{|M \cap G|}{|M|}, R = \frac{|M \cap G|}{|G|}$$

Figure 3 shows a Precision-Recall (PR) curve for MATCHER and three baselines: a “Frequency” model that ranks candidate matches for  $r_D$  by their frequency during the candidate identification step; a “Pattern” model that uses MATCHER’s linear regression model for ranking, but is restricted to only the pattern-based features; and an “Extractions” model that similarly restricts the ranking model to ReVerb features. We have three folds in our data; the alignments for relation  $r_D$  in one fold are predicted by models trained on the other two folds. Once all of the alignments in all three folds are scored, we generate points on the PR curve by applying a threshold to the model’s ranking, and treating all alignments above the threshold as the set of predicted alignments.

All regression models for learning alignments outperform the Frequency ranking by a wide margin. The Pattern model outperforms the Extractions model at the high-precision, low-recall end of the curve. At the high-recall points, the Pattern model drops quickly in precision. However, the combination of the two kinds of features in MATCHER yields improved precision at all levels of recall.

### 5.3 Semantic Parsing Tests

While our alignment tests can tell us in relative terms how well different models are performing, it is difficult to assess these models in absolute terms, since alignments are not typical applications that people care about in their own right. We

now compare our alignments on a semantic parsing task for Freebase.

In a first semantic parsing experiment, we train UBL, MATCHER, and LEXTENDER on a random sample of 70% of the questions, and test them on the remaining 30%. In a second test, we focus on the hard case where all questions from the test set contain logical constants that have never been seen before during training. We split the data into 3 folds, making sure that no Freebase domain has symbols appearing in questions in more than one fold. We then perform 3-fold cross-validation for all of our supervised models. We varied the number of matches that the alignment model (MATCHER, Pattern, Extractions, or Frequency) could make for each Freebase relation, and measured semantic parsing performance as a function of the number of matches.

Figure 4 shows the F1 scores for these semantic parsers, judged by exact match between the top-scoring logical form from the parser and the manually-produced logical form. Exact-match tests are overly-strict, in the sense that the system may be judged incorrect even when the logical form that is produced is logically equivalent to the correct logical form. However, by inspection such cases appear to be very rare in our data, and the exact-match criterion is often used in other semantic parsing experimental settings.

The semantic parsers produced by MATCHER+LEXTENDER and the other alignment techniques significantly outperform the baseline semantic parser learned by UBL, which achieves an overall F1 of 0.21 on these questions in the 70/30 split of the data, and an F1 of 0 in the cross-domain experiment. Purely-supervised approaches to this data are severely limited, since they have almost no chance of correctly parsing questions that refer to logical symbols that never appeared during training. However, MATCHER and LEXTENDER combine with UBL to produce an effective semantic parser. The best semantic parser we tested, which was produced by UBL, MATCHER, and LEXTENDER with 9 matches per Freebase relation, had a precision of 0.67 and a recall of 0.59 on the 70/30 split experiment.

The difference in alignment performance between MATCHER, Pattern, and Extractions carries over to semantic parsing. MATCHER drops in F1 with more matches as additional matches tend to be low-quality and low-probability, whereas Pat-

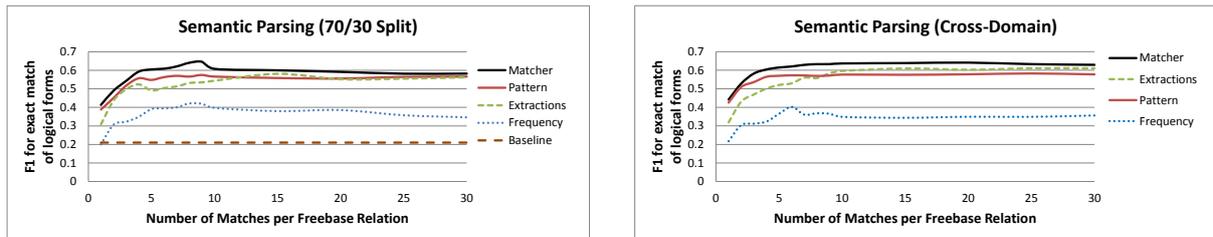

Figure 4: Semantic parsers produced by UBL+MATCHER+LEXTENDER outperform the purely-supervised baseline semantic parser on a random 70/30 split of the data (left) by as much as 0.42 in F1. In the case of this split and in the case of a cross-domain experiment (right), UBL+MATCHER+LEXTENDER outperforms UBL+Pattern+LEXTENDER by as much as 0.06 in F1.

tern and Extractions keep improving as more low-probability alignments are added. Interestingly, the Extractions model begins to overtake the Pattern model in F1 at higher numbers of matches, and all three models trend toward convergence in F1 with increasing numbers of matches. Nevertheless, MATCHER clearly improves over both, and reaches a higher F1 than either Pattern or Extractions using a small number of matches, which corresponds to a smaller lexicon and a leaner model.

To place these results in context, many different semantic parsers for databases like GeoQuery and ATIS (including parsers produced by UBL) have achieved F1 scores of 0.85 and higher. However, in all such tests, the test questions refer to logical constants that also appeared during training, allowing supervised techniques for learning semantic parsers to achieve strong accuracy. As we have argued, Freebase is large enough that is difficult to produce enough labeled training data to cover all of its logical constants. An unsupervised semantic parser for GeoQuery has achieved an F1 score of 0.66 (Goldwasser et al., 2011), impressive in its own right and slightly better than our F1 score. However, this parser was given questions which it knew *a priori* to contain words that refer to the logical constants in the database. Our MATCHER and LEXTENDER systems address a different challenge: how to learn a semantic parser for Freebase given the Web and a set of initial labeled questions.

## 6 Conclusion

Scaling semantic parsing to large databases requires an engineering effort to handle large datasets, but also novel algorithms to extend se-

matic parsing models to testing examples that look significantly different from labeled training data. The MATCHER and LEXTENDER algorithms represent an initial investigation into such techniques, with early results indicating that semantic parsers can handle Freebase questions on a large variety of domains with an F1 of 0.63.

We hope that our techniques and datasets will spur further research into this area. In particular, more research is needed to handle more complex matches between database and textual relations, and to handle more complex natural language queries. As mentioned in section 3.1, words like “actress” cannot be addressed by the current methodology, since MATCHER assumes that a word maps to a single Freebase relation, but the closest Freebase equivalent to the meaning of “actress” involves the two relations `film_actor` and `gender`. Another limitation is that our current methodology focuses on finding matches for nouns and verbs. Other important limitations of the current methodology include:

- the assumption that function words have no domain-specific meaning, which prepositions in particular can violate;
- low accuracy when there are few relevant results among the set of extracted relations;
- and the restriction to a single database (Freebase) for finding answers.

While significant challenges remain, the reduction of large-scale semantic parsing to a combination of schema matching and supervised learning offers a new path toward building high-coverage semantic parsers.

## Abstract

Shift-reduce dependency parsers give comparable accuracies to their chart-based counterparts, yet the best shift-reduce constituent parsers still lag behind the state-of-the-art. One important reason is the existence of unary nodes in phrase structure trees, which leads to different numbers of shift-reduce actions between different outputs for the same input. This turns out to have a large empirical impact on the framework of global training and beam search. We propose a simple yet effective extension to the shift-reduce process, which eliminates size differences between action sequences in beam-search. Our parser gives comparable accuracies to the state-of-the-art chart parsers. With linear run-time complexity, our parser is over an order of magnitude faster than the fastest chart parser.

## 1 Introduction

Transition-based parsers employ a set of shift-reduce actions and perform parsing using a sequence of state transitions. The pioneering models rely on a classifier to make local decisions, and search greedily for a transition sequence to build a parse tree. Greedy, classifier-based parsers have been developed for both dependency grammars (Yamada and Matsumoto, 2003; Nivre et al., 2006) and phrase-structure grammars (Sagae and Lavie, 2005). With linear run-time complexity, they were commonly regarded as a faster but less accurate alternative to graph-based chart parsers (Collins, 1997; Charniak, 2000; McDonald et al., 2005).

Various methods have been proposed to address the disadvantages of greedy local parsing, among which a framework of beam-search and global discriminative training have been shown effective for dependency parsing (Zhang and Clark, 2008; Huang and Sagae, 2010). While beam-search reduces error propagation compared with greedy search, a discriminative model that is globally optimized for whole sequences of transition actions can avoid local score biases (Lafferty et al., 2001). This framework preserves the most important advantage of greedy local parsers, including linear run-time complexity and the freedom to define arbitrary features. With the use of rich non-local features, transition-based dependency parsers achieve state-of-the-art accuracies that are comparable to the best-graph-based parsers (Zhang and Nivre, 2011; Bohnet and Nivre, 2012). In addition, processing tens of sentences per second (Zhang and Nivre, 2011), these transition-based parsers can be a favorable choice for dependency parsing.

The above global-learning and beam-search framework can be applied to transition-based phrase-structure (constituent) parsing also (Zhang and Clark, 2009), maintaining all the aforementioned benefits. However, the effects were not as significant as for transition-based dependency parsing. The best reported accuracies of transition-based constituent parsers still lag behind the state-of-the-art (Sagae and Lavie, 2006; Zhang and Clark, 2009). One difference between phrase-structure parsing and dependency parsing is that for the former, parse trees with different numbers of unary rules require different numbers of actions to build. Hence the scoring model needs to disambiguate between transitions sequences with different sizes. For the same sentence, the largest output can take twice as many as actions to build as the

smallest one. This turns out to have a significant empirical impact on parsing with beam-search.

We propose an extension to the shift-reduce process to address this problem, which gives significant improvements to the parsing accuracies. Our method is conceptually simple, requiring only one additional transition action to eliminate size differences between different candidate outputs. On standard evaluations using both the Penn Treebank and the Penn Chinese Treebank, our parser gave higher accuracies than the Berkeley parser (Petrov and Klein, 2007), a state-of-the-art chart parser. In addition, our parser runs with over 89 sentences per second, which is 14 times faster than the Berkeley parser, and is the fastest that we are aware of for phrase-structure parsing. An open source release of our parser (version 0.6) is freely available on the Web.<sup>1</sup>

In addition to the above contributions, we apply a variety of semi-supervised learning techniques to our transition-based parser. These techniques have been shown useful to improve chart-based parsing (Koo et al., 2008; Chen et al., 2012), but little work has been done for transition-based parsers. We therefore fill a gap in the literature by reporting empirical results using these methods. Experimental results show that semi-supervised methods give a further improvement of 0.9% in F-score on the English data and 2.4% on the Chinese data. Our Chinese results are the best that we are aware of on the standard CTB data.

## 2 Baseline parser

We adopt the parser of Zhang and Clark (2009) for our baseline, which is based on the shift-reduce process of Sagae and Lavie (2005), and employs global perceptron training and beam search.

### 2.1 Vanilla Shift-Reduce

Shift-reduce parsing is based on a left-to-right scan of the input sentence. At each step, a transition action is applied to consume an input word or construct a new phrase-structure. A stack is used to maintain partially constructed phrase-structures, while the input words are stored in a buffer. The set of transition actions are

- *SHIFT*: pop the front word from the buffer, and push it onto the stack.

<sup>1</sup><http://sourceforge.net/projects/zpar/>

Axioms	$[\phi, 0, false, 0]$
Goal	$[S, n, true, C]$
Inference Rules:	
<i>SHIFT</i>	$\frac{[S, i, false, c]}{[S w, i + 1, false, c + c_s]}$
<i>REDUCE-L/R-X</i>	$\frac{[S s_1 s_0, i, false, c]}{[S X, i, false, c + c_r]}$
<i>UNARY-X</i>	$\frac{[S s_0, i, false, c]}{[S X, i, false, c + c_u]}$
<i>FINISH</i>	$\frac{[S, n, false, c]}{[S, n, true, c + c_f]}$

Figure 1: Deduction system of the baseline shift-reduce parsing process.

- *REDUCE-L/R-X*: pop the top two constituents off the stack, combine them into a new constituent with label X, and push the new constituent onto the stack.
- *UNARY-X*: pop the top constituent off the stack, raise it to a new constituent with label X, and push the new constituent onto the stack.
- *FINISH*: pop the root node off the stack and ends parsing.

The deduction system for the process is shown in Figure 1, where the item is formed as  $\langle stack, buffer\ front\ index, completion\ mark, score \rangle$ , and  $c_s$ ,  $c_r$ , and  $c_u$  represent the incremental score of the *SHIFT*, *REDUCE*, and *UNARY* parsing steps, respectively; these scores are calculated according to the context features of the parser state item.  $n$  is the number of words in the input.

### 2.2 Global Discriminative Training and Beam-Search

For a given input sentence, the initial state has an empty stack and a buffer that contains all the input words. An agenda is used to keep the  $k$  best state items at each step. At initialization, the agenda contains only the initial state. At each step, every state item in the agenda is popped and expanded by applying a valid transition action, and the top  $k$  from the newly constructed state items are put back onto the agenda. The process repeats until the agenda is empty, and the best completed state item (recorded as *candidate output*) is taken for

Table 1: A summary of baseline feature templates, where  $s_i$  represents the  $i_{th}$  item on the stack  $S$  and  $q_i$  denotes the  $i_{th}$  item in the queue  $Q$ .  $w$  refers to the head lexicon,  $t$  refers to the head POS, and  $c$  refers to the constituent label.

the output.

The score of a state item is the total score of the transition actions that have been applied to build the item:

$$C(\alpha) = \sum_{i=1}^N \Phi(a_i) \cdot \vec{\theta}$$

Here  $\Phi(a_i)$  represents the feature vector for the  $i_{th}$  action  $a_i$  in state item  $\alpha$ . It is computed by applying the feature templates in Table 1 to the context of  $\alpha$ .  $N$  is the total number of actions in  $\alpha$ .

The model parameter  $\vec{\theta}$  is trained with the averaged perceptron algorithm, applied to state items (sequence of actions) globally. We apply the early update strategy (Collins and Roark, 2004), stopping parsing for parameter updates when the gold-standard state item falls off the agenda.

### 2.3 Baseline Features

Our baseline features are adopted from Zhang and Clark (2009), and are shown in Table 1 Here  $s_i$  represents the  $i_{th}$  item on the top of the stack  $S$  and  $q_i$  denotes the  $i_{th}$  item in the front end of the queue  $Q$ . The symbol  $w$  denotes the lexical head of an item; the symbol  $c$  denotes the constituent label of an item; the symbol  $t$  is the POS of a lexical head. These features are adapted from Zhang and Clark (2009). We remove Chinese specific features and make the baseline parser language-independent.

## 3 Improved hypotheses comparison

Unlike dependency parsing, constituent parse trees for the same sentence can have different numbers of nodes, mainly due to the existence of unary nodes. As a result, completed state

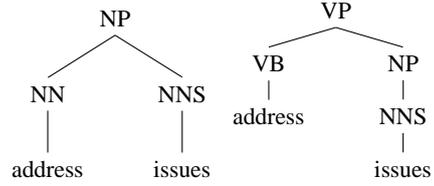

Figure 2: Example parse trees of the same sentence with different numbers of actions.

items for the same sentence can have different numbers of unary actions. Take the phrase “address issues” for example, two possible parses are shown in Figure 2 (a) and (b), respectively. The first parse corresponds to the action sequence [SHIFT, SHIFT, REDUCE-R-NP, FINISH], while the second parse corresponds to the action sequence [SHIFT, SHIFT, UNARY-NP, REDUCE-L-VP, FINISH], which consists of one more action than the first case. In practice, variances between state items can be much larger than the chosen example. In the extreme case where a state item does not contain any unary action, the number of actions is  $2n$ , where  $n$  is the number of words in the sentence. On the other hand, if the maximum number of consequent unary actions is 2 (Sagae and Lavie, 2005; Zhang and Clark, 2009), then the maximum number of actions a state item can have is  $4n$ .

The significant variance in the number of actions  $N$  can have an impact on the linear separability of state items, for which the feature vectors are  $\sum_{i=1}^N \Phi(a_i)$ . This turns out to have a significant empirical influence on perceptron training with early-update, where the training of the model interacts with search (Daume III, 2006).

One way of improving the comparability of state items is to reduce the differences in their sizes, and we use a *padding* method to achieve this. The idea is to extend the set of actions by adding an *IDLE* action, so that completed state items can be further expanded using the *IDLE* action. The action does not change the state itself, but simply adds to the number of actions in the sequence. A feature vector is extracted for the *IDLE* action according to the final state context, in the same way as other actions. Using the *IDLE* action, the transition sequence for the two parses in Figure 2 can be [SHIFT, SHIFT, REDUCE-NP, FINISH, IDLE] and [SHIFT, SHIFT, UNARY-NP, REDUCE-L-VP, FINISH], respectively. Their

Axioms	$[\phi, 0, \text{false}, 0, 0]$
Goal	$[S, n, \text{true}, m : 2n \leq m \leq 4n, C]$
	Inference Rules:
<i>SHIFT</i>	$\frac{[S, i, \text{false}, k, c]}{[S w, i + 1, \text{false}, k + 1, c + c_s]}$
<i>REDUCE-L/R-X</i>	$\frac{[S s_1 s_0, i, \text{false}, k, c]}{[S X, i, \text{false}, k + 1, c + c_r]}$
<i>UNARY-X</i>	$\frac{[S s_0, i, \text{false}, k, c]}{[S X, i, \text{false}, k + 1, c + c_u]}$
<i>FINISH</i>	$\frac{[S, n, \text{false}, k, c]}{[S, n, \text{true}, k + 1, c + c_f]}$
<i>IDLE</i>	$\frac{[S, n, \text{true}, k, c]}{[S, n, \text{true}, k + 1, c + c_i]}$

Figure 3: Deductive system of the extended transition system.

corresponding feature vectors have about the same sizes, and are more linearly separable. Note that there can be more than one action that are padded to a sequence of actions, and the number of IDLE actions depends on the size difference between the current action sequence and the largest action sequence without IDLE actions.

Given this extension, the deduction system is shown in Figure 3. We add the number of actions  $k$  to an item. The initial item (Axioms) has  $k = 0$ , while the goal item has  $2n \leq k \leq 4n$ . Given this process, beam-search decoding can be made simpler than that of Zhang and Clark (2009). While they used a *candidate output* to record the best completed state item, and finish decoding when the agenda contains no more items, we can simply finish decoding when all items in the agenda are completed, and output the best state item in the agenda. With this new transition process, we experimented with several extended features, and found that the templates in Table 2 are useful to improve the accuracies further. Here  $s_i ll$  denotes the left child of  $s_i$ 's left child. Other notations can be explained in a similar way.

#### 4 Semi-supervised Parsing with Large Data

This section discusses how to extract information from unlabeled data or auto-parsed data to further improve shift-reduce parsing accuracies. We consider three types of information, including

$s_0 llwc, s_0 lrwc, s_0 luwc$
$s_0 rlwc, s_0 rrwc, s_0 ruwc$
$s_0 ulwc, s_0 urwc, s_0 uuwc$
$s_1 llwc, s_1 lrwc, s_1 luwc$
$s_1 rlwc, s_1 rrwc, s_1 ruwc$

Table 2: New features for the extended parser.

paradigmatic relations, dependency relations, and structural relations. These relations are captured by word clustering, lexical dependencies, and a dependency language model, respectively. Based on the information, we propose a set of novel features specifically designed for shift-reduce constituent parsing.

#### 4.1 Paradigmatic Relations: Word Clustering

Word clusters are regarded as lexical intermediaries for dependency parsing (Koo et al., 2008) and POS tagging (Sun and Uszkoreit, 2012). We employ the Brown clustering algorithm (Liang, 2005) on unannotated data (word segmentation is performed if necessary). In the initial state of clustering, each word in the input corpus is regarded as a cluster, then the algorithm repeatedly merges pairs of clusters that cause the least decrease in the likelihood of the input corpus. The clustering results are a binary tree with words appearing as leaves. Each cluster is represented as a bit-string from the root to the tree node that represents the cluster. We define a function  $CLU(w)$  to return the cluster ID (a bit string) of an input word  $w$ .

#### 4.2 Dependency Relations: Lexical Dependencies

Lexical dependencies represent linguistic relations between words: whether a word modifies another word. The idea of exploiting lexical dependency information from auto-parsed data has been explored before for dependency parsing (Chen et al., 2009) and constituent parsing (Zhu et al., 2012).

To extract lexical dependencies, we first run the baseline parser on unlabeled data. To simplify the extraction process, we can convert auto-parsed constituency trees into dependency trees by using Penn2Malt.<sup>2</sup> From the dependency trees, we extract bigram lexical dependencies  $\langle w_1, w_2, L/R \rangle$  where the symbol  $L$  ( $R$ ) means that  $w_1$  ( $w_2$ ) is the head of  $w_2$  ( $w_1$ ). We also extract trigram lexical

<sup>2</sup><http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html>

dependencies  $\langle w_1, w_2, w_3, L/R \rangle$ , where  $L$  means that  $w_1$  is the head of  $w_2$  and  $w_3$ , meanwhile  $w_2$  and  $w_3$  are required to be siblings.

Following the strategy of Chen et al. (2009), we assign categories to bigram and trigram items **separately** according to their frequency counts. Specifically, top-10% most frequent items are assigned to the category of *High Frequency (HF)*; otherwise if an item is among top 20%, we assign it to the category of *Middle Frequency (MF)*; otherwise the category of *Low Frequency (LF)*. Hereafter, we refer to the bigram and trigram lexical dependency lists as *BLD* and *TLD*, respectively.

### 4.3 Structural Relations: Dependency Language Model

The dependency language model is proposed by Shen et al. (2008) and is used as additional information for graph-based dependency parsing in Chen et al. (2012). Formally, given a dependency tree  $y$  of an input sentence  $x$ , we can denote by  $H(y)$  the set of words that have at least one dependent. For each  $x_h \in H(y)$ , we have a corresponding dependency structure  $D_h = (x_{Lk}, \dots, x_{L1}, x_h, x_{R1}, \dots, x_{Rm})$ . The probability  $P(D_h)$  is defined to be

$$P(D_h) = P_L(D_h) \times P_R(D_h)$$

where  $P_L(D_h)$  can be in turn defined as:

$$\begin{aligned} P_L(D_h) \approx & P(x_{L1}|x_h) \\ & \times P(x_{L2}|x_{L1}, x_h) \\ & \times \dots \\ & \times P(x_{Lk}|x_{Lk-1}, \dots, x_{Lk-N+1}, x_h) \end{aligned}$$

$P_R(D_h)$  can be defined in a similar way.

We build dependency language models on auto-parsed data. Again, we convert constituency trees into dependency trees for the purpose of simplicity. From the dependency trees, we build a bigram and a trigram language model, which are denoted by BLM and TLM, respectively. The following are the templates of the records of the dependency language models.

(1)	$\langle x_{Li}, x_h, P(x_{Li} x_h) \rangle$
(2)	$\langle x_{Ri}, x_h, P(x_{Ri} x_h) \rangle$
(3)	$\langle x_{Li}, x_{Li-1}, x_h, P(x_{Li} x_{Li-1}, x_h) \rangle$
(4)	$\langle x_{Ri}, x_{Ri-1}, x_h, P(x_{Ri} x_{Ri-1}, x_h) \rangle$

Here the templates (1) and (2) belong to BLM and the templates (3) and (4) belong to TLM. To

	Stat	Train	Dev	Test	Unlabeled
EN	# sent	39.8k	1.7k	2.4k	3,139.1k
	# word	950.0k	40.1k	56.7k	76,041.4k
CH	# sent	18.1k	350	348	11,810.7k
	# word	493.8k	8.0k	6.8k	269,057.2k

Table 4: Statistics on sentence and word numbers of the experimental data.

use the dependency language models, we employ a map function  $\Phi(r)$  to assign a category to each record  $r$  according to its probability, as in Chen et al. (2012). The following is the map function.

$$\Phi(r) = \begin{cases} HP & \text{if } P(r) \in \text{top-10\%} \\ MP & \text{else if } P(r) \in \text{top-30\%} \\ LP & \text{otherwise} \end{cases}$$

### 4.4 Semi-supervised Features

We design a set of features based on the information extracted from auto-parsed data or unannotated data. The features are summarized in Table 3. Here *CLU* returns a cluster ID for a word. The functions  $BLD_{l/r}(\cdot)$ ,  $TLD_{l/r}(\cdot)$ ,  $BLM_{l/r}(\cdot)$ , and  $TLM_{l/r}(\cdot)$  check whether a given word combination can be found in the corresponding lists. For example,  $BLD_l(s_1w, s_0w)$  returns a category tag (*HF*, *MF*, or *LF*) if  $\langle s_1w, s_0w, L \rangle$  exists in the list BLD, else it returns *NONE*.

## 5 Experiments

### 5.1 Set-up

Labeled English data employed in this paper were derived from the Wall Street Journal (WSJ) corpus of the Penn Treebank (Marcus et al., 1993). We used sections 2-21 as labeled training data, section 24 for system development, and section 23 for final performance evaluation. For labeled Chinese data, we used the version 5.1 of the Penn Chinese Treebank (CTB) (Xue et al., 2005). Articles 001-270 and 440-1151 were used for training, articles 301-325 were used as development data, and articles 271-300 were used for evaluation.

For both English and Chinese data, we used ten-fold jackknifing (Collins, 2000) to automatically assign POS tags to the training data. We found that this simple technique could achieve an improvement of 0.4% on English and an improvement of 2.0% on Chinese. For English POS tagging, we adopted SVMTool,<sup>3</sup> and for Chinese POS tagging

we employed the Stanford POS tagger.<sup>4</sup>

We took the WSJ articles from the TIPSTER corpus (LDC93T3A) as unlabeled English data. In addition, we removed from the unlabeled English data the sentences that appear in the WSJ corpus of the Penn Treebank. For unlabeled Chinese data, we used Chinese Gigaword (LDC2003T09), on which we conducted Chinese word segmentation by using a CRF-based segmenter. Table 4 summarizes data statistics on sentence and word numbers of the data sets listed above.

We used *EVALB* to evaluate parser performances, including labeled precision (LP), labeled recall (LR), and bracketing F1.<sup>5</sup> For significance tests, we employed the randomized permutation-based tool provided by Daniel Bikel.<sup>6</sup>

In both training and decoding, we set the beam size to 16, which achieves a good tradeoff between efficiency and accuracy. The optimal iteration number of perceptron learning is determined

on the development sets. For word clustering, we set the cluster number to 50 for both the English and Chinese experiments.

## 5.2 Results on Development Sets

Table 5 reports the results of the extended parser (baseline + padding + supervised features) on the English and Chinese development sets. We integrated the padding method into the baseline parser, based on which we further incorporated the supervised features in Table 2. From the results we find that the padding method improves the parser accuracies by 0.5% and 0.4% on English and Chinese, respectively. Incorporating the supervised features in Table 2 gives further improvements of 0.2% on English and 0.1% on Chinese.

Based on the extended parser, we experimented different types of semi-supervised features by adding the features incrementally. The results are shown in Table 6. By comparing the results in Table 5 and the results in Table 6 we can see that the semi-supervised features achieve an overall improvement of 1.0% on the English data and an im-

provement of 1.5% on the Chinese data.

### 5.3 Final Results

Here we report the final results on the English and Chinese test sets. We compared the final results with a large body of related work. We grouped the parsers into three categories: single parsers (SI), discriminative reranking parsers (RE), and semi-supervised parsers (SE). Table 7 shows the comparative results on the English test set and Table 8 reports the comparison on the Chinese test set.

From the results we can see that our extended parser (baseline + padding + supervised features) outperforms the Berkeley parser by 0.3% on English, and is comparable with the Berkeley parser on Chinese (-0.1% less). Here *+padding* means the padding technique and the features in Table 2. After integrating semi-supervised features, the parsing accuracy on English is improved to 91.3%. We note that the performance is on the same level

Table 9: Comparison of running times on the English test set, where the time for loading models is excluded. \* The results of SVM-based shift-reduce parsing with greedy search. <sup>†</sup> The results of MaxEnt-based shift-reduce parser with best-first search. <sup>‡</sup> Times reported by authors running on different hardware.

as the performance of self-trained parsers, except for McClosky et al. (2006), which is based on the combination of reranking and self-training. On Chinese, the final parsing accuracy is 85.6%. To our knowledge, this is by far the best reported performance on this data set.

The padding technique, supervised features, and semi-supervised features achieve an overall improvement of 1.4% over the baseline on English, which is significant on the level of  $p < 10^{-5}$ . The overall improvement on Chinese is 3.0%, which is also significant on the level of  $p < 10^{-5}$ .

### 5.4 Comparison of Running Time

We also compared the running times of our parsers with the related single parsers. We ran timing tests on an Intel 2.3GHz processor with 8GB memory. The comparison is shown in Table 9. From the table, we can see that incorporating semi-supervised features decreases parsing speed, but the semi-supervised parser still has the advantage of efficiency over other parsers. Specifically, the semi-supervised parser is 7 times faster than the Berkeley parser. Note that Sagae & Lavie (2005) and Sagae & Lavie (2006) are also shift-reduce parsers, and their running times were evaluated on different hardwares. In practice, the running times of the shift-reduce parsers should be much shorter than the reported times in the table.

### 5.5 Error Analysis

We conducted error analysis for the three systems: the baseline parser, the extended parser with

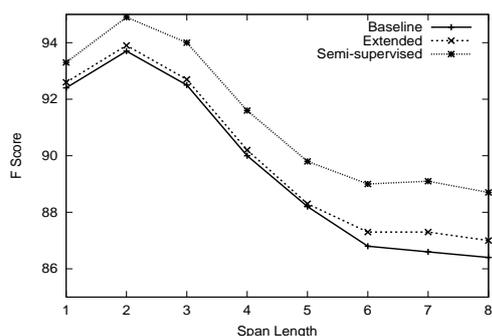

Figure 5: Comparison of parsing accuracies of the baseline, extended parser, and semi-supervised parsers on spans of different lengths.

the padding technique, and the semi-supervised parser, focusing on the English test set. The analysis was performed in four dimensions: parsing accuracies on different phrase types, on constituents of different span lengths, on different sentence lengths, and on sentences with different numbers of unknown words.

### 5.5.1 Different Phrase Types

Table 10 shows the parsing accuracies of the baseline, extended parser, and semi-supervised parser on different phrase types. Here we only consider the nine most frequent phrase types in the English test set. In the table, the phrase types are ordered from left to right in the descending order of their frequencies. We also show the improvements of the semi-supervised parser over the baseline parser (the last row in the table). As the results show, the extended parser achieves improvements on most of the phrase types with two exceptions: Preposition Phrase (PP) and Quantifier Phrase (QP). Semi-supervised features further improve parsing accuracies over the extended parser (QP is an exception). From the last row, we can see that improvements of the semi-supervised parser over the baseline on VP, S, SBAR, ADVP, and ADJP are above the average improvement (1.4%).

### 5.5.2 Different Span Lengths

Figure 5 shows a comparison of the three parsers on spans of different lengths. Here we consider span lengths up to 8. As the results show, both the padding extension and semi-supervised features are more helpful on relatively large spans: the performance gaps between the three parsers are enlarged with increasing span lengths.

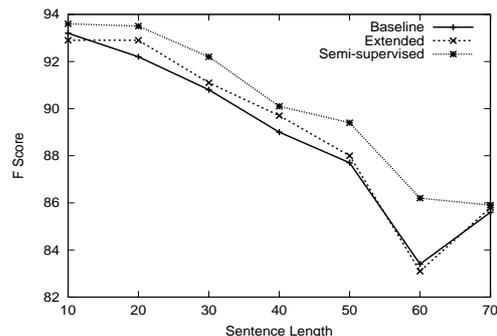

Figure 6: Comparison of parsing accuracies of the baseline, extended parser, and semi-supervised parser on sentences of different lengths.

### 5.5.3 Different Sentence Lengths

Figure 6 shows a comparison of parsing accuracies of the three parsers on sentences of different lengths. Each number on the horizontal axis represents the sentences whose lengths are between the number and its previous number. For example, the number 30 refers to the sentences whose lengths are between 20 and 30. From the results we can see that semi-supervised features improve parsing accuracy on both short and long sentences. The points at 70 are exceptions. In fact, sentences with lengths between 60 and 70 have only 8 instances, and the statistics on such a small number of sentences are not reliable.

### 5.5.4 Different Numbers of Unknown Words

Figure 4 shows a comparison of parsing accuracies of the baseline, extended parser, and semi-supervised parser on sentences with different numbers of unknown words. As the results show, the padding method is not very helpful on sentences with large numbers of unknown words, while semi-supervised features help significantly on this aspect. This conforms to the intuition that semi-supervised methods reduce data sparseness and improve the performance on unknown words.

## 6 Conclusion

In this paper, we addressed the problem of different action-sequence lengths for shift-reduce phrase-structure parsing, and designed a set of novel non-local features to further improve parsing. The resulting supervised parser outperforms the Berkeley parser, a state-of-the-art chart parser, in both accuracies and speeds. In addition, we incorporated a set of semi-supervised features. The

System	NP	VP	S	PP	SBAR	ADVP	ADJP	WHNP	QP
Baseline	91.9	90.1	89.8	88.1	85.7	84.6	72.1	94.8	89.3
Extended	92.1	90.7	90.2	87.9	86.6	84.5	73.6	95.5	88.6
Semi-supervised	93.2	92.0	91.5	89.3	88.2	86.8	75.1	95.7	89.1
Improvements	+1.3	+1.9	+1.7	+1.2	+2.5	+2.2	+3.0	+0.9	-0.2

# Nonconvex Global Optimization for Latent-Variable Models\*

Matthew R. Gormley     Jason Eisner  
Department of Computer Science  
Johns Hopkins University, Baltimore, MD  
{mrg, jason}@cs.jhu.edu

## Abstract

Many models in NLP involve latent variables, such as unknown parses, tags, or alignments. Finding the optimal model parameters is then usually a difficult nonconvex optimization problem. The usual practice is to settle for *local* optimization methods such as EM or gradient ascent.

We explore how one might instead search for a *global* optimum in parameter space, using branch-and-bound. Our method would eventually find the global maximum (up to a user-specified  $\epsilon$ ) if run for long enough, but at any point can return a suboptimal solution together with an upper bound on the global maximum.

As an illustrative case, we study a generative model for dependency parsing. We search for the maximum-likelihood model parameters and corpus parse, subject to posterior constraints. We show how to formulate this as a mixed integer quadratic programming problem with nonlinear constraints. We use the Reformulation Linearization Technique to produce convex relaxations during branch-and-bound. Although these techniques do not yet provide a practical solution to our instance of this NP-hard problem, they sometimes find better solutions than Viterbi EM with random restarts, in the same time.

## 1 Introduction

Rich models with latent linguistic variables are popular in computational linguistics, but in general it is not known how to find their optimal parameters. In this paper, we present some “new” attacks for this common optimization setting, drawn from the mathematical programming toolbox.

We focus on the well-studied but unsolved task of unsupervised dependency parsing (i.e., depen-

\*This research was partially funded by the JHU Human Language Technology Center of Excellence.

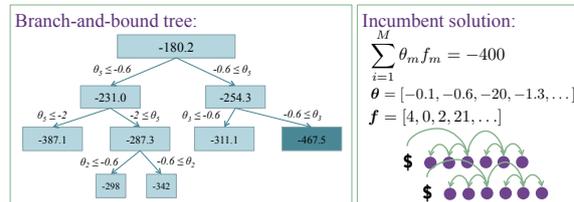

Figure 1: Each node contains a local upper bound for its subspace, computed by a relaxation. The node branches on a single model parameter  $\theta_m$  to partition its subspace. The lower bound, -400, is given by the best solution seen so far, the incumbent. The upper bound, -298, is the min of all remaining leaf nodes. The node with a local bound of -467.5 can be pruned because no solution within its subspace could be better than the incumbent.

dency grammar induction). This may be a particularly hard case, but its structure is typical. Many parameter estimation techniques have been attempted, including expectation-maximization (EM) (Klein and Manning, 2004; Spitzkovsky et al., 2010a), contrastive estimation (Smith and Eisner, 2006; Smith, 2006), Viterbi EM (Spitzkovsky et al., 2010b), and variational EM (Naseem et al., 2010; Cohen et al., 2009; Cohen and Smith, 2009). These are all *local search* techniques, which improve the parameters by hill-climbing.

The problem with local search is that it gets stuck in local optima. This is evident for grammar induction. An algorithm such as EM will find numerous different solutions when randomly initialized to different points (Charniak, 1993; Smith, 2006). A variety of ways to find better local optima have been explored, including heuristic initialization of the model parameters (Spitzkovsky et al., 2010a), random restarts (Smith, 2006), and annealing (Smith and Eisner, 2006; Smith, 2006). Others have achieved accuracy improvements by enforcing linguistically motivated *posterior constraints* on the parameters (Gillenwater et al., 2010; Naseem et al., 2010), such as requiring most sentences to have verbs or encouraging nouns to be children of verbs or prepositions.

We introduce a method that performs *global*

*search* with certificates of  $\epsilon$ -optimality for both the corpus parse and the model parameters. Our search objective is log-likelihood. We can also impose posterior constraints on the latent structure.

As we show, maximizing the joint log-likelihood of the parses and the parameters can be formulated as a mathematical program (MP) with a nonconvex quadratic objective and with integer linear and nonlinear constraints. Note that this objective is that of hard (Viterbi) EM—we do not marginalize over the parses as in classical EM.<sup>1</sup>

To globally optimize the objective function, we employ a branch-and-bound algorithm that searches the continuous space of the model parameters by branching on individual parameters (see Figure 1). Thus, our branch-and-bound tree serves to recursively subdivide the global parameter hypercube. Each node represents a search problem over one of the resulting boxes (i.e., orthotopes).

The crucial step is to prune nodes high in the tree by determining that their boxes *cannot* contain the global maximum. We compute an upper bound at each node by solving a relaxed maximization problem tailored to its box. If this upper bound is worse than our current best solution, we can prune the node. If not, we split the box again via another branching decision and retry on the two halves.

At each node, our relaxation derives a linear programming problem (LP) that can be efficiently solved by the dual simplex method. First, we linearly relax the constraints that grammar rule probabilities sum to 1—these constraints are nonlinear in our parameters, which are *log*-probabilities. Second, we linearize the quadratic objective by applying the Reformulation Linearization Technique (RLT) (Sherali and Adams, 1990), a method of forming tight linear relaxations of various types of MPs: the *reformulation* step multiplies together pairs of the original linear constraints to generate new quadratic constraints, and then the *linearization* step replaces quadratic terms in the new constraints with auxiliary variables.

Finally, if the node is not pruned, we search for a better incumbent solution under that node by projecting the solution of the RLT relaxation back onto the feasible region. In the relaxation, the model parameters might sum to slightly more than

<sup>1</sup>This objective might not be a great sacrifice: Spitzkovsky et al. (2010b) present evidence that hard EM can outperform soft EM for grammar induction in a hill-climbing setting. We use it because it is a quadratic objective. However, maximizing it remains NP-hard (Cohen and Smith, 2010).

one and the parses can consist of fractional dependency edges. We project in order to compute the true objective and compare with other solutions.

Our results demonstrate that our method can obtain higher likelihoods than Viterbi EM with random restarts. Furthermore, we show how posterior constraints inspired by Gillenwater et al. (2010) and Naseem et al. (2010) can easily be applied in our framework to obtain competitive accuracies using a simple model, the Dependency Model with Valence (Klein and Manning, 2004). We also obtain an  $\epsilon$ -optimal solution on a toy dataset.

We caution that the linear relaxations are very loose on larger boxes. Since we have many dimensions, the binary branch-and-bound tree may have to grow quite deep before the boxes become small enough to prune. This is why nonconvex quadratic optimization by LP-based branch-and-bound usually fails with more than 80 variables (Burer and Vandembussche, 2009). Even our smallest (toy) problems have hundreds of variables, so our experimental results mainly just illuminate the method’s behavior. Nonetheless, we offer the method as a new tool which, just as for local search, might be combined with other forms of problem-specific guidance to produce more practical results.

## 2 The Constrained Optimization Task

We begin by describing how for our typical model, the Viterbi EM objective can be formulated as a **mixed integer quadratic programming** (MIQP) problem with **nonlinear constraints** (Figure 2).

Other locally normalized log-linear generative models (Berg-Kirkpatrick et al., 2010) would have a similar formulation. In such models, the log-likelihood objective is simply a linear function of the feature counts. However, the objective becomes **quadratic** in unsupervised learning, because the feature counts are themselves unknown variables to be optimized. The feature counts are constrained to be derived from the latent variables (e.g., parses), which are unknown discrete structures that must be encoded with **integer** variables. The **nonlinear** constraints ensure that the model parameters are true log-probabilities.

Concretely, (1) specifies the Viterbi EM objective: the total log-probability of the *best* parse trees under the parameters  $\theta$ , given by a sum of log-probabilities  $\theta_m$  of the individual steps needed to generate the tree, as encoded by the features  $f_m$ . The (nonlinear) sum-to-one constraints on the

Variables:

$\theta_m$	Log-probability for feature $m$
$f_m$	Corpus-wide feature count for $m$
$e_{sij}$	Indicator of an arc from $i$ to $j$ in tree $s$

Indices and constants:

$m$	Feature / model parameter index
$s$	Sentence index
$c$	Conditional distribution index
$M$	Number of model parameters
$C$	Number of conditional distributions
$\mathcal{M}_c$	$c^{\text{th}}$ Set of feature indices that sum to 1.0
$S$	Number of sentences
$N_s$	Number of words in the $s^{\text{th}}$ sentence

Objective and constraints:

$\max \sum_m \theta_m f_m$	(1)
s.t. $\sum_{m \in \mathcal{M}_c} \exp(\theta_m) = 1, \forall c$	(2)
$A \begin{bmatrix} \mathbf{f} \\ \mathbf{e} \end{bmatrix} \leq b$	(Model constraints) (3)
$\theta_m \leq 0, f_m, e_{sij} \in \mathbb{Z}, \forall m, s, i, j$	(4)

Figure 2: Viterbi EM as a mathematical program

probabilities are in (2). The linear constraints in (3) will ensure that the arc variables for each sentence  $e_s$  encode a valid latent dependency tree, and that the  $\mathbf{f}$  variables count up the features of these trees. The final constraints (4) simply specify the range of possible values for the model parameters and their integer count variables.

Our experiments use the dependency model with valence (DMV) (Klein and Manning, 2004). This generative model defines a joint distribution over the sentences and their dependency trees.

We encode the DMV using integer linear constraints on the arc variables  $e$  and feature counts  $\mathbf{f}$ . These will constitute the model constraints in (3). The constraints must declaratively specify that the arcs form a valid dependency tree and that the resulting feature values are as defined by the DMV.

**Tree Constraints** To ensure that our arc variables,  $e_s$ , form a dependency tree, we employ the same single-commodity flow constraints of Magnanti and Wolsey (1994) as adapted by Martins et al. (2009) for parsing. We also use the projectivity constraints of Martins et al. (2009).

The single-commodity flow constraints simultaneously enforce that each node has exactly one parent, the special root node (position 0) has no in-

coming arcs, and the arcs form a connected graph.

For each sentence,  $s$ , the variable  $\phi_{sij}$  indicates the amount of flow traversing the arc from  $i$  to  $j$  in sentence  $s$ . The constraints below specify that the root node emits  $N_s$  units of flow (5), that one unit of flow is consumed by each each node (6), that the flow is zero on each disabled arc (7), and that the arcs are binary variables (8).

**Single-commodity flow** (Magnanti & Wolsey, 1994)

$$\sum_{j=1}^{N_s} \phi_{s0j} = N_s, \forall j \quad (5)$$

$$\sum_{i=0}^{N_s} \phi_{sij} - \sum_{k=1}^{N_s} \phi_{sjk} = 1, \forall j \quad (6)$$

$$\phi_{sij} \leq N_s e_{sij}, \forall i, j \quad (7)$$

$$e_{sij} \in \{0, 1\}, \forall i, j \quad (8)$$

Projectivity is enforced by adding a constraint (9) for each arc ensuring that no edges will cross that arc if it is enabled.  $\mathcal{X}_{ij}$  is the set of arcs  $(k, l)$  that cross the arc  $(i, j)$ .

**Projectivity** (Martins et al., 2009)

$$\sum_{(k,l) \in \mathcal{X}_{ij}} e_{skl} \leq N_s (1 - e_{sij}), \forall s, i, j \quad (9)$$

**DMV Feature Counts** The DMV generates a dependency tree recursively as follows. First the head word of the sentence is generated,  $t \sim \text{Discrete}(\boldsymbol{\theta}_{\text{root}})$ , where  $\boldsymbol{\theta}_{\text{root}}$  is a subvector of  $\boldsymbol{\theta}$ . To generate its children on the **left** side, we flip a coin to decide whether an adjacent child is generated,  $d \sim \text{Bernoulli}(\boldsymbol{\theta}_{\text{dec.L},0,t})$ . If the coin flip  $d$  comes up `continue`, we sample the word of that child as  $t' \sim \text{Discrete}(\boldsymbol{\theta}_{\text{child.L},t})$ . We continue generating non-adjacent children in this way, using coin weights  $\boldsymbol{\theta}_{\text{dec.L},\geq 1,t}$  until the coin comes up `stop`. We repeat this procedure to generate children on the **right** side, using the model parameters  $\boldsymbol{\theta}_{\text{dec.R},0,t}$ ,  $\boldsymbol{\theta}_{\text{child.R},t}$ , and  $\boldsymbol{\theta}_{\text{dec.R},\geq 1,t}$ . For each new child, we apply this process recursively to generate its descendants.

The feature count variables for the DMV are encoded in our MP as various sums over the edge variables. We begin with the **root/child feature counts**. The constraint (10) defines the feature count for model parameter  $\theta_{\text{root},t}$  as the number of all enabled arcs connecting the root node to a word of type  $t$ , summing over all sentences  $s$ . The constraint in (11) similarly defines  $f_{\text{child.L},t,t'}$  to be the number of enabled arcs connecting a parent of

type  $t$  to a left child of type  $t'$ .  $\mathcal{W}_{st}$  is the index set of tokens in sentences  $s$  with word type  $t$ .

DMV root/child feature counts	
$f_{\text{root},t} = \sum_{s=1}^{N_s} \sum_{j \in \mathcal{W}_{st}} e_{s0j}, \forall t$	(10)
$f_{\text{child.L},t,t'} = \sum_{s=1}^{N_s} \sum_{j < i} \delta \left[ \begin{smallmatrix} i \in \mathcal{W}_{st} \\ j \in \mathcal{W}_{st'} \end{smallmatrix} \right] e_{sij}, \forall t, t'$	(11)

The **decision feature counts** require the addition of an auxiliary count variables  $f_m^{(si)} \in \mathcal{Z}$  indicating how many times decision feature  $m$  fired at some position in the corpus  $s, i$ . We then need only add a constraint that the corpus wide feature count is the sum of these token-level feature counts  $f_m = \sum_{s=1}^S \sum_{i=1}^{N_s} f_m^{(si)}, \forall m$ .

Below we define these auxiliary variables for  $1 \leq s \leq S$  and  $1 \leq i \leq N_s$ . The helper variable  $n_{s,i,l}$  counts the number of enabled arcs to the left of token  $i$  in sentence  $s$ . Let  $t$  denote the word type of token  $i$  in sentence  $s$ . Constraints (11) - (16) are defined analogously for the *right side* feature counts.

DMV decision feature counts	
$n_{s,i,l} = \sum_{j=1}^{i-1} e_{sij}$	(12)
$n_{s,i,l}/N_s \leq f_{\text{dec.L},0,t,\text{cont}}^{(s,i)} \leq 1$	(13)
$f_{\text{dec.L},0,t,\text{stop}}^{(s,i)} = 1 - f_{\text{dec.L},0,t,\text{cont}}^{(s,i)}$	(14)
$f_{\text{dec.L},\geq 1,t,\text{stop}}^{(s,i)} = f_{\text{dec.L},0,t,\text{cont}}^{(s,i)}$	(15)
$f_{\text{dec.L},\geq 1,t,\text{cont}}^{(s,i)} = n_{s,i,l} - f_{\text{dec.L},0,t,\text{cont}}^{(s,i)}$	(16)

### 3 A Branch-and-Bound Algorithm

The mixed integer quadratic program with nonlinear constraints, given in the previous section, maximizes the nonconvex Viterbi EM objective and is NP-hard to solve (Cohen and Smith, 2010). The standard approach to optimizing this program is local search by the hard (Viterbi) EM algorithm. Yet local search can only provide a lower (pessimistic) bound on the global maximum.

We propose a branch-and-bound algorithm, which will iteratively tighten both pessimistic and optimistic bounds on the optimal solution. This algorithm may be halted at any time, to obtain the best current solution and a bound on how much better the global optimum could be.

A *feasible solution* is an assignment to all

the variables—both model parameters and corpus parse—that satisfies all constraints. Our branch-and-bound algorithm maintains an *incumbent solution*: the best known feasible solution according to the objective function. This is updated as better feasible solutions are found.

Our algorithm implicitly defines a search tree in which each node corresponds to a region of model parameter space. Our search procedure begins with only the root node, which represents the full model parameter space. At each node we perform three steps: bounding, projecting, and branching.

In the **bounding** step, we solve a relaxation of the original problem to provide an upper bound on the objective achievable within that node’s subregion. A node is pruned when  $L_{\text{global}} + \epsilon |L_{\text{global}}| \geq U_{\text{local}}$ , where  $L_{\text{global}}$  is the incumbent score,  $U_{\text{local}}$  is the upper bound for the node, and  $\epsilon > 0$ . This ensures that its entire subregion will not yield a  $\epsilon$ -better solution than the current incumbent.

The overall optimistic bound is given by the worst optimistic bound of all current leaf nodes.

The **projecting** step, if the node is not pruned, projects the solution of the relaxation back to the feasible region, replacing the current incumbent if this projection provides a better lower bound.

In the **branching** step, we choose a variable  $\theta_m$  on which to divide. Each of the child nodes receives a lower  $\theta_m^{\min}$  and upper  $\theta_m^{\max}$  bound for  $\theta_m$ . The child subspaces partition the parent subspace.

The search tree is defined by a variable ordering and the splitting procedure. We do binary branching on the variable  $\theta_m$  with the highest regret, defined as  $z_m - \theta_m f_m$ , where  $z_m$  is the auxiliary objective variable we will introduce in § 4.2. Since  $\theta_m$  is a log-probability, we split its current range at the midpoint in probability space,  $\log((\exp \theta_m^{\min} + \exp \theta_m^{\max})/2)$ .

We perform best-first search, ordering the nodes by the the optimistic bound of their parent. We also use the LP-guided rule (Martin, 2000; Achterberg, 2007, section 6.1) to perform depth-first plunges in search of better incumbents.

### 4 Relaxations

The relaxation in the bounding step computes an optimistic bound for a subspace of the model parameters. This upper bound would ideally be not much greater than the true maximum achievable on that region, but looser upper bounds are generally faster to compute.

We present successive relaxations to the original nonconvex mixed integer quadratic program with nonlinear constraints from (1)–(4). First, we show how the nonlinear sum-to-one constraints can be relaxed into linear constraints and tightened. Second, we apply a classic approach to bound the nonconvex quadratic objective by a linear concave envelope. Finally, we present our full relaxation based on the Reformulation Linearization Technique (RLT) (Sherali and Adams, 1990). We solve these LPs by the dual simplex algorithm.

#### 4.1 Relaxing the sum-to-one constraint

In this section, we use cutting planes to create a linear relaxation for the sum-to-one constraint (2). When relaxing a constraint, we must ensure that any assignment of the variables that was feasible (i.e. respected the constraints) in the original problem must also be feasible in the relaxation. In most cases, the relaxation is not perfectly tight and so will have an enlarged space of feasible solutions.

We begin by weakening constraint (2) to

$$\sum_{m \in \mathcal{M}_c} \exp(\theta_m) \leq 1 \quad (17)$$

The optimal solution under (17) still satisfies the original equality constraint (2) because of the maximization. We now relax (17) by approximating the surface  $z = \sum_{m \in \mathcal{M}_c} \exp(\theta_m)$  by the max of  $N$  lower-bounding linear functions on  $\mathbb{R}^{|\mathcal{M}_c|}$ . Instead of requiring  $z \leq 1$ , we only require each of these lower bounds to be  $\leq 1$ , slightly enlarging the feasible space into a convex polytope. Figure 3a shows the feasible region constructed from  $N=3$  linear functions on two log-probabilities  $\theta_1, \theta_2$ .

Formally, for each  $c$ , we define the  $i^{\text{th}}$  linear lower bound ( $i = 1, \dots, N$ ) to be the tangent hyperplane at some point  $\hat{\theta}_c^{(i)} = [\hat{\theta}_{c,1}^{(i)}, \dots, \hat{\theta}_{c,|\mathcal{M}_c|}^{(i)}] \in \mathbb{R}^{|\mathcal{M}_c|}$ , where each coordinate is a log-probability  $\hat{\theta}_{c,m}^{(i)} < 0$ . We require each of these linear functions to be  $\leq 1$ :

**Sum-to-one Relaxation**

$$\sum_{m \in \mathcal{M}_c} \left( \theta_m + 1 - \hat{\theta}_{c,m}^{(i)} \right) \exp \left( \hat{\theta}_{c,m}^{(i)} \right) \leq 1, \forall i, \forall c \quad (18)$$

#### 4.2 “Relaxing” the objective

Our true maximization objective  $\sum_m \theta_m f_m$  in (1) is a sum of quadratic terms. If the parameters  $\theta$

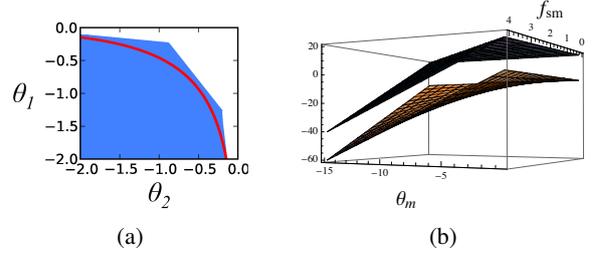

Figure 3: In (a), the area under the curve corresponds to those points  $(\theta_1, \theta_2)$  that satisfy (17) ( $z \leq 1$ ), with equality (2) achieved along the curve ( $z = 1$ ). The shaded area shows the enlarged feasible region under the linear relaxation. In (b), the curved lower surface represents a single product term in the objective. The piecewise-linear upper surface is its concave envelope (raised by 20 for illustration; in reality they touch).

were fixed, the objective would become linear in the latent features. Although the parameters are *not* fixed, the branch-and-bound algorithm does box them into a small region, where the quadratic objective is “more linear.”

Since it is easy to maximize a concave function, we will maximize the *concave envelope*—the concave function that most tightly upper-bounds our objective over the region. This turns out to be *piecewise linear* and can be maximized with an LP solver. Smaller regions yield tighter bounds.

Each node of the branch-and-bound tree specifies a region via bounds constraints  $\theta_m^{\min} < \theta_m < \theta_m^{\max}, \forall m$ . In addition, we have known bounds  $f_m^{\min} \leq f_m \leq f_m^{\max}, \forall m$  for the count variables.

McCormick (1976) described the concave envelope for a *single* quadratic term subject to bounds constraints (Figure 3b). In our case:

$$\theta_m f_m \leq \min \left[ f_m^{\max} \theta_m + \theta_m^{\min} f_m - \theta_m^{\min} f_m^{\max}, \right. \\ \left. f_m^{\min} \theta_m + \theta_m^{\max} f_m - \theta_m^{\max} f_m^{\min} \right]$$

We replace our objective  $\sum_m \theta_m f_m$  with  $\sum_m z_m$ , where we would like to constrain each auxiliary variable  $z_m$  to be  $= \theta_m f_m$  or (equivalently)  $\leq \theta_m f_m$ , but instead settle for making it  $\leq$  the concave envelope—a linear programming problem:

**Concave Envelope Objective**

$$\max \sum_m z_m \quad (19)$$

s.t.  $z_m \leq f_m^{\max} \theta_m + \theta_m^{\min} f_m - \theta_m^{\min} f_m^{\max}$  (20)

$z_m \leq f_m^{\min} \theta_m + \theta_m^{\max} f_m - \theta_m^{\max} f_m^{\min}$  (21)

### 4.3 Reformulation Linearization Technique

The *Reformulation Linearization Technique* (RLT)<sup>2</sup> (Sherali and Adams, 1990) is a method of forming tighter relaxations of various types of MPs. The basic method reformulates the problem by adding products of existing constraints. The quadratic terms in the objective and in these new constraints are redefined as auxiliary variables, thereby linearizing the program.

In this section, we will show how the RLT can be applied to our grammar induction problem and contrast it with the concave envelope relaxation presented in section 4.2.

Consider the original MP in equations (1) - (4), with the nonlinear sum-to-one constraints in (2) replaced by our linear constraints proposed in (18). If we remove the integer constraints in (4), the result is a quadratic program with *purely linear constraints*. Such problems have the form

$$\max x^T Qx \quad (22)$$

$$\text{s.t. } Ax \leq b \quad (23)$$

$$-\infty < L_i \leq x_i \leq U_i < \infty, \forall i \quad (24)$$

where the variables are  $x \in \mathbb{R}^n$ ,  $A$  is an  $m \times n$  matrix, and  $b \in \mathbb{R}^m$ , and  $Q$  is an  $n \times n$  indefinite<sup>3</sup> matrix. Without loss of generality we assume  $Q$  is symmetric. The application of the RLT here was first considered by Sherali and Tuncbilek (1995).

For convenience of presentation, we represent both the linear inequality constraints and the bounds constraints, under a different parameterization using the matrix  $G$  and vector  $g$ .

$$\begin{bmatrix} (b_i - A_i x) \geq 0, & 1 \leq i \leq m \\ (U_k - x_k) \geq 0, & 1 \leq k \leq n \\ (-L_k + x_k) \geq 0, & 1 \leq k \leq n \end{bmatrix} \equiv \begin{bmatrix} (g_i - G_i x) \geq 0, \\ 1 \leq i \leq m + 2n \end{bmatrix}$$

The *reformulation* step forms all possible products of these linear constraints and then adds them to the original quadratic program.

$$(g_i - G_i x)(g_j - G_j x) \geq 0, \forall 1 \leq i \leq j \leq m + 2n$$

In the *linearization* step, we replace all quadratic terms in the quadratic objective and new quadratic constraints with auxiliary variables:

$$w_{ij} \equiv x_i x_j, \forall 1 \leq i \leq j \leq n$$

<sup>2</sup>The key idea underlying the RLT was originally introduced in Adams and Sherali (1986) for 0-1 quadratic programming. It has since been extended to various other settings; see Sherali and Liberti (2008) for a complete survey.

<sup>3</sup>In the general case, that  $Q$  is indefinite causes this program to be nonconvex, making this problem NP-hard to solve (Vavasis, 1991; Pardalos, 1991).

This yields the following RLT relaxation:

**RLT Relaxation**

$$\max \sum_{1 \leq i \leq j \leq n} Q_{ij} w_{ij} \quad (25)$$

$$\text{s.t. } g_i g_j - \sum_{k=1}^n g_j G_{ik} x_k - \sum_{k=1}^n g_i G_{jk} x_k$$

$$+ \sum_{k=1}^n \sum_{l=1}^n G_{ik} G_{jl} w_{kl} \geq 0,$$

$$\forall 1 \leq i \leq j \leq m + 2n \quad (26)$$

Notice above that we have omitted the original inequality constraints (23) and bounds (24), because they are fully enforced by the new RLT constraints (26) from the reformulation step (Sherali and Tuncbilek, 1995). In our experiments, we keep the original constraints and instead explore subsets of the RLT constraints.

If the original QP contains equality constraints of the form  $G_e x = g_e$ , then we can form constraints by multiplying this one by each variable  $x_i$ . This gives us the following new set of constraints, for each equality constraint  $e$ :  $g_e x_i + \sum_{j=1}^n -G_{ej} w_{ij} = 0, \forall 1 \leq i \leq n$ .

**Theoretical Properties** The new constraints in eq. (26) will impose the concave envelope constraints (20)–(21) (Anstreicher, 2009).

The constraints presented above are considered to be *first-level* constraints corresponding to the first-level variables  $w_{ij}$ . However, the same technique can be applied repeatedly to produce polynomial constraints of higher degree. These higher level constraints/variables have been shown to provide increasingly tighter relaxations (Sherali and Adams, 1990) at the cost of a large number of variables and constraints. In the case where  $x \in \{0, 1\}^n$  the degree- $n$  RLT constraints will restrict to the convex hull of the feasible solutions (Sherali and Adams, 1990).

This is in direct contrast to the concave envelope relaxation presented in section 4.2 which relaxes to the convex hull of each quadratic term independently. This demonstrates the key intuition of the RLT relaxation: The products of constraints are implied (and unnecessary) in the original variable space. Yet when we project to a higher-dimensional space by including the auxiliary variables, the linearized constraints cut off portions of the feasible region given by only the concave envelope relaxation in eqs. (20)–(21).

#### 4.4 Adding Posterior Constraints

It is a simple extension to impose posterior constraints within our framework. Here we emphasize constraints that are analogous to the universal linguistic constraints from Naseem et al. (2010). Since we optimize the Viterbi EM objective, we directly constrain the counts in the single corpus parse rather than expected counts from a distribution over parses. Let  $\mathcal{E}$  be the index set of model parameters corresponding to edge types from Table 1 of Naseem et al. (2010), and  $N_s$  be the number of words in the  $s$ th sentence. We impose the constraint that 75% of edges come from  $\mathcal{E}$ :  $\sum_{m \in \mathcal{E}} f_m \geq 0.75 \left( \sum_{s=1}^S N_s \right)$ .

#### 5 Projections

A pessimistic bound, from the projecting step, will correspond to a feasible but not necessarily optimal solution to the original problem. We propose several methods for obtaining pessimistic bounds during the branch-and-bound search, by projecting and improving the solutions found by the relaxation. A solution to the relaxation may be infeasible in the original problem for two reasons: the model parameters might not sum to one, and/or the parse may contain fractional edges.

**Model Parameters** For each set of model parameters  $\mathcal{M}_c$  that should sum-to-one, we project the model parameters onto the  $\mathcal{M}_c - 1$  simplex by one of two methods: (1) normalize the infeasible parameters or (2) find the point on the simplex that has minimum Euclidean distance to the infeasible parameters using the algorithm of Chen and Ye (2011). For both methods, we can optionally apply add- $\lambda$  smoothing before projecting.

**Parses** Since we are interested in projecting the fractional parse onto the space of projective spanning trees, we can simply employ a dynamic programming parsing algorithm (Eisner and Satta, 1999) where the weight of each edge is given as the fraction of the edge variable.

Only one of these projection techniques is needed. We then either use *parsing* to fill in the optimal parse trees given the projected model parameters, or use *supervised parameter estimation* to fill in the optimal model parameters given the projected parses. These correspond to the Viterbi E step and M step, respectively. We can locally

improve the projected solution by continuing with a few additional iterations of Viterbi EM.

Related models could use very similar projection techniques. Given a relaxed joint solution to the parameters and the latent variables, one must be able to project it to a nearby feasible one, by projecting either the fractional parameters or the fractional latent variables into the feasible space and then solving exactly for the other.

#### 6 Related Work

The goal of this work was to better understand and address the non-convexity of maximum-likelihood training with latent variables, especially parses.

Gimpel and Smith (2012) proposed a concave model for unsupervised dependency parsing using IBM Model 1. This model did not include a tree constraint, but instead initialized EM on the DMV. By contrast, our approach incorporates the tree constraints directly into our convex relaxation and embeds the relaxation in a branch-and-bound algorithm capable of solving the original DMV maximum-likelihood estimation problem.

Spectral learning constitutes a wholly different family of consistent estimators, which achieve efficiency because they sidestep maximizing the nonconvex likelihood function. Hsu et al. (2009) introduced a spectral learner for a large class of HMMs. For supervised parsing, spectral learning has been used to learn latent variable PCFGs (Cohen et al., 2012) and hidden-state dependency grammars (Luque et al., 2012). Alas, there are not yet any spectral learning methods that recover latent tree *structure*, as in grammar induction.

Several integer linear programming (ILP) formulations of dependency parsing (Riedel and Clarke, 2006; Martins et al., 2009; Riedel et al., 2012) inspired our definition of grammar induction as a MP. Recent work uses branch-and-bound for decoding with non-local features (Qian and Liu, 2013). These differ from our work by treating the model parameters as constants, thereby yielding a linear objective.

For semi-supervised dependency parsing, Wang et al. (2008) used a convex objective, combining unsupervised least squares loss and a supervised large margin loss. This does not apply to our unsupervised setting. Branch-and-bound has also been applied to semi-supervised SVM training, a nonconvex search problem (Chapelle et al., 2007), with a relaxation derived from the dual.

## 7 Experiments

We first analyze the behavior of our method on a toy synthetic dataset. Next, we compare various parameter settings for branch-and-bound by estimating the total solution time. Finally, we compare our search method to Viterbi EM on a small subset of the Penn Treebank.

All our experiments use the DMV for unsupervised dependency parsing of part-of-speech (POS) tag sequences. For Viterbi EM we initialize the parameters of the model uniformly, breaking parser ties randomly in the first E-step (Spitkovsky et al., 2010b). This initializer is state-of-the-art for Viterbi EM. We also apply add-one smoothing during each M-step. We use random restarts, and select the model with the highest likelihood.

We add posterior constraints to Viterbi EM’s E-step. First, we run a relaxed linear programming (LP) parser, then project the (possibly fractional) parses back to the feasible region. If the resulting parse does not respect the posterior constraints, we discard it. The posterior constraint in the LP parser is tighter<sup>4</sup> than the one used in the true optimization problem, so the projections tends to be feasible under the true (looser) posterior constraints. In our experiments, all but one projection respected the constraints. We solve all LPs with CPLEX.

### 7.1 Synthetic Data

For our toy example, we generate sentences from a synthetic DMV over three POS tags (Verb, Noun, Adjective) with parameters chosen to favor short sentences with English word order.

In Figure 4 we show that the quality of the root relaxation increases as we approach the full set of RLT constraints. That the number of possible RLT constraints increases quadratically with the length of the corpus poses a serious challenge. For just 20 sentences from this synthetic model, the RLT generates 4,056,498 constraints.

For a single run of branch-and-bound, Figure 5 shows the global upper and lower bounds over time.<sup>5</sup> We consider five relaxations, each using only a subset of the RLT constraints. *Max.0k* uses only the concave envelope (20)-(21). *Max.1k* uses the concave envelope and also randomly samples 1,000 other RLT constraints, and so on for *Max.10k* and *Max.100k*. *Obj.Filter* includes all

<sup>4</sup>80% of edges must come from  $\mathcal{E}$  as opposed to 75%.

<sup>5</sup>The initial incumbent solution for branch-and-bound is obtained by running Viterbi EM with 10 random restarts.

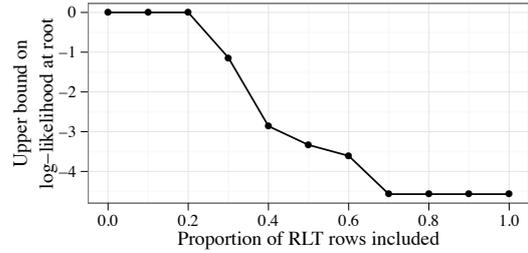

Figure 4: The bound quality at the root improves as the proportion of RLT constraints increases, on 5 synthetic sentences. A random subset of 70% of the 320,126 possible RLT constraints matches the relaxation quality of the full set. This bound is very tight: the relaxations in Figure 5 solve hundreds of nodes before such a bound is achieved.

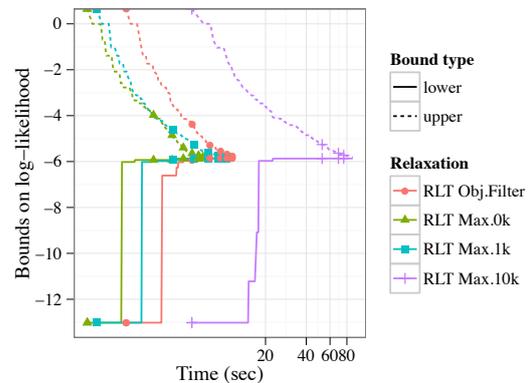

Figure 5: The global upper and lower bounds improve over time for branch-and-bound using different subsets of RLT constraints on 5 synthetic sentences. Each solves the problem to  $\epsilon$ -optimality for  $\epsilon = 0.01$ . A point marks every 200 nodes processed. (The time axis is log-scaled.)

constraints with a nonzero coefficient for one of the RLT variables  $z_m$  from the linearized objective. The rightmost lines correspond to *RLT Max.10k*: despite providing the tightest (local) bound at each node, it processed only 110 nodes in the time it took *RLT Max.1k* to process 1164. *RLT Max.0k* achieves the best balance of tight bounds and speed per node.

### 7.2 Comparing branch-and-bound strategies

It is prohibitively expensive to repeatedly run our algorithm to completion with a variety of parameter settings. Instead, we estimate the size of the branch-and-bound tree and the solution time using a high-variance estimate that is effective for comparisons (Lobjois and Lemaître, 1998).

Given a fixed set of parameters for our algorithm and an  $\epsilon$ -optimality stopping criterion, we

<i>RLT Relaxation</i>	<i>Avg. ms per node</i>	<i># Samples</i>	<i>Est. # Nodes</i>	<i>Est. # Hours</i>
Obj.Filter	63	10000	3.2E+08	4.6E+09
Max.0k	6	10000	1.7E+10	7.8E+10
Max.1k	15	10000	3.5E+08	4.2E+09
Max.10k	161	10000	1.3E+09	3.4E+10
Max.100k	232259	5	1.7E+09	9.7E+13

Table 1: Branch-and-bound node count and completion time estimates. Each standard deviation was close in magnitude to the estimate itself. We ran for 8 hours, stopping at 10,000 samples on 8 synthetic sentences.

can view the branch-and-bound tree  $T$  as fixed and finite in size. We wish to estimate some cost associated with the tree  $C(T) = \sum_{\alpha \in \text{nodes}(T)} f(\alpha)$ . Letting  $f(\alpha) = 1$  estimates the number of nodes; if  $f(\alpha)$  is the time to solve a node, then we estimate the total solution time using the Monte Carlo method of Knuth (1975). Table 1 gives these estimates, for the same five RLT relaxations. *Obj.Filter* yields the smallest estimated tree size.

### 7.3 Real Data

In this section, we compare our global search method to Viterbi EM with random restarts each with or without posterior constraints. We use 200 sentences of no more than 10 tokens from the WSJ portion of the Penn Treebank. We reduce the treebank’s gold part-of-speech (POS) tags to a universal set of 12 tags (Petrov et al., 2012) plus a tag for auxiliaries, ignoring punctuation. Each search method is run for 8 hours. We obtain the initial incumbent solution for branch-and-bound by running Viterbi EM for 45 minutes. The average time to solve a node’s relaxation ranges from 3 seconds for *RLT Max.0k* to 42 seconds for *RLT Max.100k*.

Figure 6a shows the log-likelihood of the incumbent solution over time. In our global search method, like Viterbi EM, the posterior constraints lead to lower log-likelihoods. *RLT Max.0k* finds the highest log-likelihood solution.

Figure 6b compares the *unlabeled directed dependency accuracy* of the incumbent solution. In both global and local search, the posterior constraints lead to higher accuracies. Viterbi EM with posterior constraints demonstrates the oscillation of incumbent accuracy: starting at 58.02% accuracy, it finds several high accuracy solutions early on (61.02%), but quickly abandons them to increase likelihood, yielding a final accuracy of 60.65%. *RLT Max.0k* with posterior constraints obtains the highest overall accuracy of 61.09% at

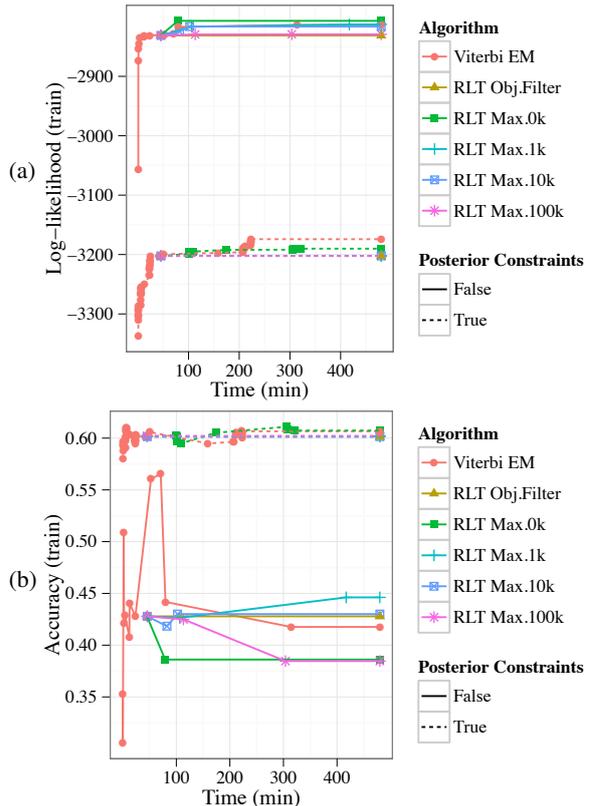

Figure 6: Likelihood (a) and accuracy (b) of incumbent solution so far, on a small real dataset.

306 min and the highest final accuracy 60.73%.

## 8 Discussion

In principle, our branch-and-bound method can approach  $\epsilon$ -optimal solutions to Viterbi training of locally normalized generative models, including the NP-hard case of grammar induction with the DMV. The method can also be used with posterior constraints or a regularized objective.

Future work includes algorithmic improvements for solving the relaxation and the development of tighter relaxations. The Dantzig-Wolfe decomposition (Dantzig and Wolfe, 1960) or Lagrangian Relaxation (Held and Karp, 1970) might satisfy both of these goals by pushing the integer tree constraints into a subproblem solved by a dynamic programming parser. Recent work on semidefinite relaxations (Anstreicher, 2009) suggests they may provide tighter bounds at the expense of greater computation time.

Perhaps even more important than tightening the bounds at each node are search heuristics (e.g., surface cues) and priors (e.g., universal grammar) that guide our global search by deciding *which* node to expand next (Chomsky and Lasnik, 1993).
